Treatment for generalized anxiety disorder is likely to be long term. Methods employed may include medication, psychotherapy, or a combination of both. The common medications used for this disorder include the antianxiety medications such as Ativan, Cymbalta, and Xanax. The psychotherapies used for this disorder are numerous, but the most common is cognitive behavior therapy. The focus of this therapy in generalized anxiety disorder is changing the beliefs and behaviors of the individual. For example, if an individual maintains an exaggerated fear about his or her children's safety (belief), the therapist might help the individual challenge his or her thoughts with facts or alternative explanations. Also, if the same individual constantly checks on his or her children (behavior), he or she might be instructed to replace this act with an alternative that is not related to directly investigating children's whereabouts. An additional activity employed in the treatment of this disorder is vigorous exercise. Although the specific reasons why exercise is effective in diminishing symptoms are not completely clear, certain neurotransmitters (chemical messengers) that are part of the brain's reward system are released. This chemical activity is often experienced by the individual as a sense of well-being and relaxation. This experience is commonly referred to as the "runners high."

Genito-Pelvic Pain/Penetration Disorder

Genito-pelvic pain/penetration disorder is a mental disorder characterized by fear, pain, or difficulty with sexual intercourse. Previously it was referred to as dyspareunia and vaginismus.

Definitions

- **Cognitive behavior therapy** is a type of psychotherapy that focuses on maladaptive (problematic) behaviors, emotions, and thoughts. It is also called CBT.
- **Dyspareunia** is the experience of genital pain during sexual intercourse.
- **Exposure** is a cognitive behavior therapy intervention (method) in which a client is exposed to a feared object or situation. It is also referred to as flooding.
- **Pelvic floor muscle training** involves a series of exercises designed to strengthen the muscles of the pelvic floor. These exercises are used to treat problems with urine leakage, bowel control, and pelvic pain.
- **Sexual dysfunctions disorders** are a group of mental disorders characterized by significant difficulty in responding sexually or experiencing sexual pleasure. They include delayed ejaculation, female organismic disorder, and genito-pelvic pain/penetration disorder.
- **Systematic desensitization** is a form of cognitive behavior therapy that gradually exposes individuals to their phobia (fear) while remaining calm and relaxed.
- **Vaginismus** is the inability to allow vaginal penetration because of anxiety and fear of pain that results in vaginal spasm.

Description and Diagnosis

Genito-pelvic pain/penetration disorder is one of the sexual dysfunctions disorders. It is characterized by recurrent or persistent fear, pain, or difficulty with vaginal penetration during intercourse. Pain with sexual activity is a common experience for many women. Approximately 15% of women in North America report ongoing pain during sexual intercourse (American Psychiatric Association, 2013). Women who experience pain rather than pleasure when attempting intercourse may avoid sexual activity as a way to avoid pain and manage anxiety. A link among pain, fear, and muscular tension during intercourse occurs. As with other phobias (fears), an aversion to and avoidance of physical pain results. In time, this becomes an anxiety/aversion pattern. Women may also develop other sexual dysfunctions such as reduced sexual interest or arousal as a way to avoid pain.

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, women can be diagnosed with this disorder if they exhibit difficulties with vaginal penetration during intercourse for at least six months. They may experience difficulty with penetration during intercourse. They may experience pain during vaginal intercourse or penetration attempts. They may experience fear and anxiety in anticipation of penetration. Or, they may experience tightening of the pelvic floor muscles while attempting intercourse. This diagnosis cannot be made if the symptoms can better be explained by a nonsexual mental disorder. Nor can they be a consequence of severe relationship or other stressors. Women can experience these symptoms lifelong, or they can be acquired over time (American Psychiatric Association, 2013).

The cause of this disorder is not well understood. It is often unclear whether biological, psychological, or social factors are the initial contributor to physical pain during penetration. However, once genital pain is experienced, all three factors may continue to reinforce pain avoidance. Other contributing factors to this disorder include partner factors, relationship factors, and individual factors such as poor body image, a history of sexual or emotional abuse, cultural and religious factors, and medical factors. These factors help the clinician understand the possible cause for the disorder as well as the maintenance of symptoms. If the cause of the disorder is primarily due to a physical condition of the sex organs, then the clinician would work with the individual to seek treatment from a medical professional who

treats this disorder. If the cause is more psychological in nature, the clinician would begin to explore the purpose of the symptom that perpetuates it. Finally, social or external factors should also be taken into account.

Treatment

Treatment for this disorder usually includes medical and psychological interventions. Prior to any psychological treatment for this disorder, the woman should be examined by a medical professional to rule out medical conditions that might contribute to sexual pain. Such medical conditions are then treated. If sexual symptoms remain, psychological treatment commences. However, because emotional and physiological components both reinforce the pain-fear-tension cycle, this disorder is best treated with a team approach, involving medical, physical therapy, and mental health professionals. Physical therapy focuses on pelvic floor muscle training. It teaches exercises that can be practiced at home. Cognitive behavior therapy (CBT) is used to reduce fear, anxiety, and pain. CBT emphasizes systematic desensitization and exposure techniques.

If trauma issues are involved, it would also be addressed or referred to for specialized treatment.

Genograms

Genograms are a detailed representation of a client's family tree, focusing especially on how individuals communicate and interact with one another, including psychological factors that affect relationships.

Description

Most individuals are influenced by the interactions with their families, and often patterns emerge and even repeat over several generations. Genograms offer a clinician a visual representation of a client's family tree, which shows even the most complex interpersonal relationships between family members using codes and symbols. The genogram often reveals patterns, events, and information that assist the therapist in clinically assessing an individual or family. The genogram is used for gathering information for diagnostic assessment of psychological issues and also as an intervention. Widely used by many family therapists, this counseling tool can be used to show a variety of information about a client's relationships, family, medical, social, and even developmental history.

Development

Although Murray Bowen (1913–1990) was the first to use genograms for family therapy, Monica McGoldrick and Randy Gerson popularized genograms in 1985 with the publication of their book *Genograms in Family Assessment*. Since then, the use of genograms has expanded to be used in the medical, education, social work, and genetic research fields.

Genograms offer far more than what is normally found in a family tree, such as date of birth, gender, and date of death. Other information in a genogram often includes major life events, behavior, occupation, education, illness, and interpersonal relationships, as well as information on mental health disorders such as drug addiction or depression. According to McGoldrick and Gerson, genograms offer a therapeutic tool for better understanding and individual and his or her family system, as well as a counseling intervention in and of itself.

An experienced clinician asks questions that are part of his or her overall assessment and a therapeutic intervention in terms of reframing the views of the client's family dynamics and interpersonal relationships. The development of genograms is commonly

associated with Bowen family systems therapy and is considered a useful means of collecting family information. On average, a genogram takes about 15 to 30 minutes to complete. Computer software programs are now available to help create genograms.

Geodon (Ziprasidone)

Geodon is a prescribed antipsychotic mediation used to treat schizophrenia and mania. Its generic name is ziprasidone.

Definitions

- **Antipsychotic medications** are prescription drugs used to treat psychotic disorders. They are sometimes referred to as antipsychotics or neuroleptics.
- **Delusions** are fixed false beliefs that persist despite contrary evidence. Delusions are distinct from culturally or religiously based beliefs that may be seen as untrue by outsiders.
- **Food and Drug Administration** is the federal agency responsible for monitoring safety standards for food and prescription medications.
- **Mania** is an elevated or irritable mood as well as mental and physical hyperactivity, and disorganized behavior. It is characteristic of the manic phase of bipolar disorder.
- **Schizophrenia** is a mental disorder in which it is difficult to distinguish real from unreal experiences. Symptoms include hallucinations, delusions, thought and communication disturbances, and withdrawal from others.

Description

Geodon is in a class of antipsychotic medications known as second-generation or atypical antipsychotics. It is primarily used to treat schizophrenia. Geodon is also used to treat acute manic and mixed episodes associated with bipolar disorder. It can be combined with lithium or Depakote in the maintenance and treatment of bipolar disorder. As one of the newer antipsychotics, Geodon is less likely to cause significant adverse side effects than the first-generation or typical antipsychotic medications. Geodon is not approved by the FDA for treating older adults with dementia-related psychosis.

Precautions and Side Effects

Geodon should not be taken by those with a history of irregular heart rhythms, congestive heart failure, or a recent heart attack. It can also lower blood pressure to dangerously low levels. Individuals with a history of seizures should use Geodon cautiously and with close medical supervision, as it may increase the risk of seizures. Geodon may also increase body temperatures to dangerously high levels so that those who exercise strenuously, are exposed to extreme heat, take anticholinergic medications (including common antidepressants), or are prone to dehydration should use the drug cautiously. Those with an increased risk of developing pneumonia should be carefully monitored while taking Geodon. Because there is a high incidence of suicide in those with psychotic illnesses, people using Geodon should be observed carefully for signs of suicidal behavior. Women who are pregnant or breast-feeding should not take Geodon, as it can harm the fetus. Some newborns of mothers who were on Geodon during pregnancy exhibited withdrawal symptoms, including respiratory problems and tremor.

The most common side effects of Geodon are rash, drowsiness, involuntary twitching, nausea, constipation, indigestion, and dizziness due to low blood

pressure. Less common side effects include rapid heartbeat, low blood pressure, agitation, tremor, confusion, amnesia, dry mouth, increased salivation, joint pains, and abnormal vision. Many of these side effects start to appear at higher dosages.

Geodon interacts with several medications. Drugs that cause drowsiness, such as antidepressants, antihistamines, some pain relievers, and alcohol, may increase the sedative effects of Geodon. Individuals taking Ambien concurrently with Geodon should be monitored for central nervous system effects such as respiratory depression and should avoid activities that require mental alertness and motor coordination. Medications, such as Tegretol used to treat seizures and bipolar disorder, that increase liver metabolism may cause Geodon to be less effective. Geodon may also decrease the effects of drugs used to treat Parkinson's disease, such as levodopa.

Gerontological Counseling

Gerontological counseling is a psychological method for working with older clients who face the emotional and mental health challenges associated with aging.

Description

The fastest-growing segment of the U.S. population is older adults. Although two-thirds of clinicians work with those 65 years and older, only one-third of these clinicians have received any graduate training in gerontological counseling, and even fewer worked with older adults in an internship or practicum setting. Gerontological counselors working with elderly clients face the emotional and mental health challenges associated with aging. It can be difficult to treat older adults, because they may have multiple psychological or physical issues, and often face social issues as well.

Development

Gerontological counseling gained attention after the passage of the Older Americans Act of 1965, and Medicare and Medicaid in 1966. At this time, social work also became a significant part of the health-care system. In the 1970s and 1980s, the struggle was to balance proper care for the elderly with proper diagnosis. Initially the focus on elder health care led to longer hospital stays; then there was a push for shorter hospital stays and collaborative care among practitioners.

There are many negative stereotypes about aging and the elderly held by society, and by older adults themselves. It's not unusual for the elderly to feel that therapy will be of no use to them. Unfortunately, many mental health professionals also feel the same way and are not interested in working with the elderly. Counselors in training indicate they have little interest in specializing in gerontological counseling. They are likely to see depression in the elderly as normal, while it's abnormal and more severe in younger adults, even when the two groups have identical symptoms. Professionals often think that there is little hope for improvement of symptoms and that older adults are unwilling or unable to change, though evidence shows the elderly are more open to change than middle-aged people.

Clinicians are generally of the opinion that psychotherapy is less appropriate for older adults. This can be a breach of patient rights, since stereotyping by mental health professionals limits access to mental health services by older adults and goes against the guidelines of professional organizations.

Though it has been found that up to 40% of older adults suffer from at least one mental disorder, only a fraction seek help. Treatment is important for the

elderly, since therapy can help relieve pain from physical problems, as well as mental issues.

A common mental issue among older adults is substance abuse of alcohol, prescriptions, and opioids. It can be a problem, since the elderly receive 35% of all U.S. prescriptions, yet account for only 13% of the population. Older patients don't often seek help for addiction, and families and physicians attribute symptoms to age.

Health-care providers also tend to contribute to the problem with overprescribing medications, prescribing for excessive periods of time, or failing to ask about a history of substance abuse.

After a diagnosis of addiction, older adults should be watched for related disorders, such as liver disease, malnutrition, withdrawal, depression, and dementia. Like other counseling, treatment outcomes for addiction in the elderly are good. Generally, therapy for addiction is more successful for older than for younger people.

Another important focus of mental health care for the elderly is sexuality. Therapists must address all of their client's needs, including sexuality, during their counseling sessions and not dismiss them due to the client's age and mental or physical state.

Counselors can help their older clients by encouraging them to discuss their sexuality. They can offer suggestions for physical limitations to intimacy and help the patient decide how and when to have sexual activity. They should be comfortable talking about sexuality with older adults and must take into account the client's cultural background so as to make appropriate suggestions.

Assisted living is the fastest-growing area of long-term care for older adults today and presents its own issues. Social workers are an important feature of assistant living and provide mental health counseling, help address dementia care, help elders and their families sort out the appropriate long-term care settings, and provide mental health services for residents in assisted living.

Current Status

There is a need for end-of-life mental health care for the elderly. Studies on aging must be focused on improving geriatric practice and policy. Currently there is a disparity between therapists' beliefs about the elderly and what is factual. The elderly need the same access to mental health care as younger clients. To combat age bias among therapists, more professional training is needed on how to address the unique needs of older adults.

Gestalt Psychotherapy

Gestalt psychotherapy is an existential, experiential, and insight-oriented form of counseling.

Description

Gestalt therapy focuses on the present moment in therapy and what is taking place between the therapist and client. Great attention is given to the client's awareness and understanding of his or her perceptions, feelings, and behaviors, both verbal and nonverbal, in the here and now as they interact with the therapist. As clients

become increasingly aware of their reality, change automatically occurs.

Development

Gestalt psychotherapy was founded by husband and wife, Fritz and Laura Perls in the 1940s. Fritz Perls (1893–1970) was a controversial figure known as much for his showmanship as for his dramatic, confrontational, and hostile style. During the development of Gestalt therapy, many of Fritz's students emulated his confrontational style, which remains one of the most significant criticisms of the method. Laura Perls (1905–1990) also made significant contributions to Gestalt therapy and took a much more supportive and relational approach to the method. She is credited with correcting many of the excesses exhibited by Fritz.

Current Status

The word "gestalt" is defined as something made of many parts that are more than the combination of those parts. In other words, people are more than the sum of their parts. Gestalt therapy is "phenomenological," meaning that it focuses on the client's experiences and perceptions in discovering and understanding the meaning of events rather than the counselor interpreting or imposing the meaning on the client. Gestalt psychotherapy is also considered an existential therapy and is grounded in the belief that people are constantly remaking, rediscovering, and becoming themselves. Gestalt therapy is experiential, meaning that it is a type of therapy that utilizes talking, role-playing, and other activities in order to discover the hidden or subconscious issues related to client problems.

Gestalt psychotherapy places emphasis on the here and now. The focus of treatment is on what is happening at the present moment between the therapist and the client. The "now" is influenced by unexpressed and unresolved painful past experiences referred to as "unfinished business." Assisting clients in becoming fully aware in the here and now as they interact with the therapist is a primary goal of gestalt psychotherapy. As clients gain awareness, change automatically occurs. Through awareness clients are able to integrate their way of thinking, feeling, and behaving in ways that make sense to them and which results in greater sense of wholeness.

The therapist's own attitudes and behaviors have a deep impact on the therapeutic process. Developing an authentic relationship with the client is essential, and therapists must be highly knowledgeable and skilled in the concepts and methods of gestalt psychotherapy. "Experiments" are foundational to the gestalt process and are designed to provide new emotional experiences and insights into a client's thinking, feeling, and behaving in the here and now. Gestalt psychotherapy uses a wide range of experiments, which may include role-play, guided fantasy, and acting out past events rather than just talking about them. An example is the "empty chair" technique in which clients are instructed to speak to an actual empty chair while imagining the person who they were hurt by is sitting in the chair. Experiments are developed during client–therapist interaction, and therapists are often very creative as they invent experiments to enhance their client's awareness and promote change.

Gestalt psychotherapy is an insight-oriented approach to helping that focuses on the client's experiences in the here and now to promote personal responsibility and growth through awareness.

Gifted Students

Gifted students are children who are acknowledged for a special talent, skill, or intelligence.

Definitions

- **Gifted** is an adjective that indicates the persons described have talent or natural ability greater than the expected norm or average.
- **Intelligence** is the capacity a person has to learn and understand information and solve problems.
- **Intelligence quotient** is a measure of intellect to determine a person's level of cognitive ability.

Description

Gifted students are recognized for their ability to think or create at levels more advanced than their peers. It is important to note that even the National Association for Gifted Children admits that there is no universally accepted definition of giftedness. For example, gifted does not simply mean intelligence although that can be one important factor in the recognition of giftedness. "Talented" is another operative term used to describe gifted students in different areas. This includes children who are creative, artistic, and excel interpersonally.

A child is designated as a gifted student after he or she completes a psychological evaluation with the result of a high intelligence quotient (IQ). It has been estimated that about 3 million elementary, middle, and high school students in the country would be considered eligible for gifted and talented programs. An even smaller percentage would be classified as highly gifted. Obviously there are not enough programs to accommodate the number of gifted students nor is the effectiveness of the existing programs clearly measurable. Although there are national directives for special education, the provision of educational programs is the responsibility of states and local communities. There is a challenge for educational systems to provide services that will help gifted and talented children. That challenge is to develop their skills and capabilities and not have their gifts lost in a system which often focuses on academic achievement.

Current Status and Impact (Psychological Influence)

Despite having services and programs in place, there is little convincing evidence that links student achievement to the results of programs for gifted students. In fact, students who are admitted to gifted programs at the lower end of testing may actually end up doing worse on testing and grade results. This could mean that being segregated with even better-performing students seems to sometimes have a negative effect on their efforts. It is also difficult to evaluate the effects of environment, culture, and family factors, which are outside the school environment.

Teachers and counselors are aware that children have a broad range of needs that are not only based on academics. This can be true for gifted students as well who may often be poor performers in the classroom for reasons such as a deficit of social skills.

Professionals working with gifted students need to be careful to analyze and judge each child's situation individually. There is also a need to balance the academic with the social aspects of education. Isolating the gifted can have negative social effects on students if educators are not aware of the dangers. Educators, parents, and counselors need to be ready to help not just with intellectual but with social and emotional supports as well.

Gifts Differing: Understanding Personality Types (Book)

Gifts Differing: *Understanding Personality Types* is a book about personality based on how individuals view the world and make decisions. It was written by Isabel Briggs Myers and first published in 1980.

Definitions

- **Couples therapy** is a type of psychotherapy that focuses on resolving conflicts and improving couple's relationships. It is also called marriage counseling and marital therapy.
- **Myers–Briggs Type Indicator** is a personality test for evaluating preferences in how individuals perceive (view) the world and make decisions.
- **Personality** is the enduring pattern of perceiving, feeling, relating, and thinking about one's environment and oneself.
- **Psychotherapy** is a psychological method for achieving desired changes in thinking, feeling, and behavior. It is also called therapy and therapeutic counseling.

Description

Isabel Briggs Myers (1897–1980) and her mother, Katherine Cook Briggs (1875–1968), developed a system to classify personality types. This was largely based on the work of Carl Jung (1875–1961). Briggs Myers was not trained as a psychologist, but she learned about personality assessment by evaluating employees at a local bank. She developed her first test in 1944, called the Myers–Briggs Type Indicator (MBTI). It was formally published in 1957. The MBTI was initially tested on students and is now a very popular test used by millions. It is commonly used to assess an individual's fit in a specific job. It can also be used in individual psychotherapy and couples therapy. In her book *Gifts Differing: Understanding Personality Type*, Briggs Myers outlines the theory behind the test.

According to this theory, there are four different personality types or "preferences" across two different dimensions. The first dimension relates to how individuals perceive the outside world. Some rely on their five senses, such as touch and vision. These are called *sensing* (*S*) types. Others look to their internal reactions, or "gut feelings." These are *intuitive* (*N*) types, relying on intuition. The second dimension of personality relates to how individuals make judgments and decisions. *Thinking* (*T*) types prefer impersonal logical analysis, while *feeling* (*F*) types consider what something means to them. An individual's tendencies in these different areas result in his or her personality preference. The four preferences are *ST* (Sensing plus Thinking), *SF* (Sensing plus Feeling), *NF* (Intuition plus Feeling), and *NT* (Intuition plus Thinking). These preferences explain an individual's behavior in relationships, work, and other areas. For example, *ST* (Sensing plus Thinking) individuals focus on facts that can be verified by their senses. They are successful in jobs that require impersonal analysis, such as accounting, and are not focused on others. On the other hand, *NF* (Intuition plus Feeling) individuals are considered to be friendly and enjoy work that involves communication such as teaching. Another component of Briggs Myers's personality types is introversion and extraversion. Introverts prefer to develop their ideas gradually and need to have time alone. Extroverts move quickly and enjoy being around others. The final part of personality relates to individuals' preferred extraverted function. This may either be *judging* (*J*), for those who want matters settled, or *perceiving* (*P*), for those who like to explore new possibilities.

All of these components come together to form an individual's four-letter personality type. For example, an ESFJ represents an *extravert* who has a preference for *sensing* and *feeling*, with *judging* as the preferred extraverted function. The MBTI test consists of "yes" or "no" questions intended to identify an individual's personality type. Items include statements such as "you are almost never late for appointments" and "you enjoy having a wide circle of acquaintances." Some have criticized Briggs Myers's theory because she did not have formal education in psychology. Others have suggested that her categories were not based on research and misrepresented the work of Carl Jung. Nevertheless, the MBTI continued to be a popular assessment tool.

Ginkgo Biloba

Ginkgo biloba is an herbal remedy used for many medical conditions, including memory problems and dementia. It is commonly called ginkgo.

Definitions

- **The National Center for Complementary and Alternative Medicine** is part of the National Institutes of Health. Formerly called the Office of Alternative Medicine, it scientifically investigates complementary and alternative medicine healing practices, and disseminates authoritative information to professionals and the public.
- **Traditional Chinese medicine** is an ancient but still practiced form of healing based on harmony and balance. It emphasizes diet and prevention and uses acupuncture and herbal remedies to stimulate the body's own natural curative powers and reestablish balance.

Description

Ginkgo biloba is an herbal supplement made from the leaves of the tree Ginkgo biloba. It has been used in traditional Chinese medicine for nearly 5,000 years to treat memory loss and mood, nerve, circulatory, and many other health problems. When combined with ginseng, ginkgo can boost memory, improve the quality of life, and increase well-being. Ginkgo is often used for memory disorders, including Alzheimer's disease. It is also used for conditions that seem to be due to reduced blood flow in the brain, especially in older adults. These conditions include headache, ringing in the ears, vertigo, difficulty concentrating, and hearing disorders. Ginkgo is a top-selling herbal remedy in the United States as well as in Europe.

The effectiveness of ginkgo in relieving pain caused by clogged arteries in the leg, in treating Alzheimer's disease, and in improving blood flow to the brain has already been evaluated in well-designed studies and is generally accepted by practitioners of conventional medicine. The National Center for Complementary and Alternative Medicine is sponsoring clinical trials to determine safety and effectiveness of ginkgo as a treatment for more than a dozen other medical conditions. Information on these clinical trials can be found at http://www.clinicaltrials.gov.

Precautions and Side Effects

Ginkgo biloba is not recommended during pregnancy and breast-feeding, due to lack of reliable medical information. People who are preparing for dental or surgical procedures should stop taking ginkgo at least two days before their operation because of the risk of increased bleeding.

Ginkgo is generally safe and causes few side effects when taken at recommended doses for up to six months. The most common mild side effects are headache, dizziness, nausea, diarrhea, restlessness, racing heart, and allergic skin reactions. Serious side effects of ginkgo are rare. These include increased bleeding and the skin blisters and sloughs off (Stevens-Johnson syndrome).

Because ginkgo has blood-thinning properties, it can increase the blood-thinning and anticoagulant effects of medications such as Coumadin, Plavix, aspirin, Advil, or Motrin. Individuals taking these drugs should not begin taking ginkgo without talking to their doctor.

Ginseng

Ginseng is an herbal remedy that is used to increase energy, reduce stress, and treat a number of medical conditions.

Definitions

- **Polysaccharides** are complex carbohydrates (nutrients) like starch or cellulose that are made up of sugar molecules that are linked together.
- **Traditional Chinese medicine** is an ancient but still practiced form of healing based on harmony and balance. It emphasizes diet and prevention and uses acupuncture and herbal to stimulate the body's own natural curative powers and reestablish balance.

Description

There are two main types of ginseng: Asian (Panax ginseng) and American ginseng (Panax quinquefolius). Other herbs are called ginseng, such as Siberian ginseng, but they do not contain the active ingredient of ginsenosides. Ginsenosides are chemical substances in the body that may increase insulin levels and lower blood sugar. Other active ingredients in ginseng are polysaccharides that can increase immunity.

For over 2,000 years Ginseng has been used in traditional Chinese medicine to increase energy, reduce stress, promote recovery from illness and injury, and improve mental and physical performance. It has also been used to treat various medical conditions, including infections, gastrointestinal disorders, circulatory problems, cancer, diabetes, and migraine headache. While many of these traditional uses of ginseng have yet to be scientifically verified, some have. For example, some research has found that Asian ginseng can boost the immune system, especially when taken with a vaccine, or by older adults recovering from an infection or other illness. Other research has shown that ginseng may lower blood sugar levels, which could benefit those with type 2 diabetes. Ginseng may also improve concentration and learning ability. In some research on mental performance, ginseng has been combined with ginkgo biloba. There has been less research on the use of ginseng to treat cancer, heart disease, fatigue, erectile dysfunction, high blood pressure, or menopausal symptoms. The National Center for Complementary and Alternative Medicine has reviewed such studies and concluded that ginseng merits further investigation. It has begun sponsoring clinical trials to determine safety and effectiveness of ginseng. Information on these clinical trials can be found at http://www.clinicaltrials.gov.

Precautions and Side Effects

Because ginseng may affect blood sugar levels, those taking diabetes medications should not use ginseng without first talking to their physician. Because caffeine can increase ginseng's stimulant effects, it may be necessary to cut back on coffee and other sources of caffeine. Because there is little evidence of its safety, ginseng is not recommended for women who are pregnant or are breast-feeding. Similarly, it is not recommended for children.

Generally, the side effects of ginseng are generally mild. These include nervousness and difficulty falling or staying asleep, nausea, diarrhea, and rash. Long-term use or high doses of ginseng has been reported to cause headaches, dizziness, stomach upset, breast tenderness, and menstrual changes. Such side effects can be avoided by taking ginseng for a few weeks but less than three months and then stopping it. After a short break, ginseng can be restarted.

Because ginseng has blood-thinning properties, it can increase the blood-thinning and anticoagulant effects of medications such as Coumadin, Plavix, aspirin, Advil, or Motrin. Individuals taking these drugs should not begin taking ginseng without first talking to their doctor.

Glasser, William (1925–2013)

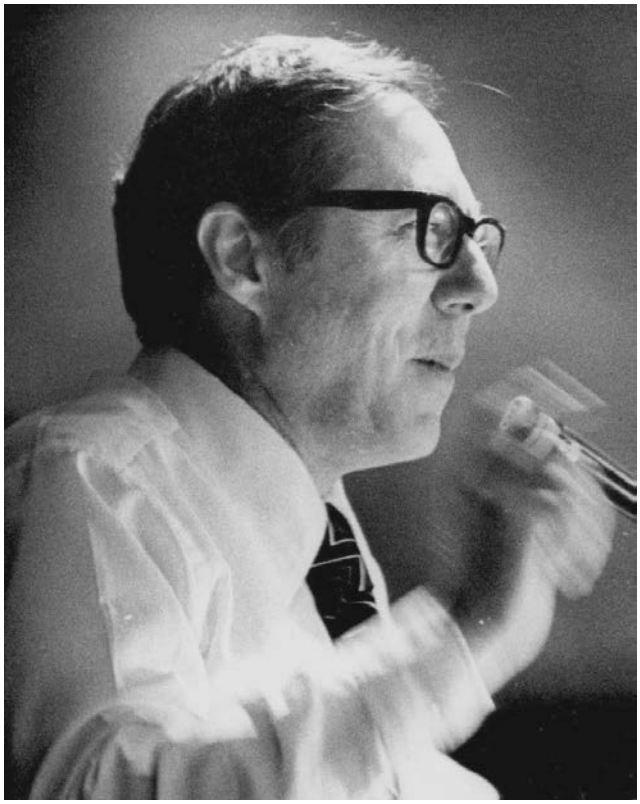
American psychiatrist and theorist William Glasser is known for his work in developing both a therapeutic approach, reality therapy, and a theoretical basis for that approach, termed choice theory, both of which emphasize personal choice and responsibility in explaining mental health and happiness. Glasser's ideas have been applied in the fields of education, management, and marriage and family therapy.

Description

William Glasser was born on May 11, 1925, in Cleveland, Ohio, to Ben and Betty Glasser. He graduated from Cleveland Heights High School in 1942 and went on to pursue a degree in applied sciences from Case Western Reserve University. After graduating, he worked for Lubrizol at Case as a chemical engineer but soon realized that this was not what he wanted to do long term. In 1946, he enrolled in Western Reserve University's psychology program, but was then drafted into the army. After completing basic training, Glasser was sent to Dugway Proving Ground in Utah where his duty was to test German poisonous gases. In 1953, he returned to school to finish his MD in psychiatry. He went on to complete his residence training in Los Angeles, California, at UCLA and the Veteran's Administration Center between 1956 and 1957. Glasser worked under psychiatrist, Dr. G.L. Harrington at the Veteran's Center, whom he credits as his mentor.

Glasser maintained a private practice for 30 years, from 1956 to 1985. It was during this time that he formed his own theory about how to approach mental illness, which he coined "reality therapy." This approach was in complete contrast to the popular "medical model" of the time that emphasized diagnoses and the use of prescription drugs. Glasser posited rather that people were responsible for their own choices and those that had difficulty in connecting and forming positive relationships with others eventually led to their unhappiness and mental instability. He believed that a person has the power to transform his or her life simply by making different choices. Choice theory, first termed "control theory," explains human behavior by stating that all humans choose to behave in ways that satisfy five basic needs, the most important being love and belonging. The tenets of this theory have been applied across several areas of study, including education, business, and relationships. Its goal is to increase connectedness to prevent human problems. Thus, Glasser is credited with making mental wellness a public health concern.

William Glasser's approach to counseling is referred to as "reality therapy," which he coined in 1965 in his book *Reality Therapy: A New Approach to Psychiatry*. Practitioners who work from this model must have a deep understanding and acceptance of control, or choice theory. Glasser believed that mental illness was caused by faulty choices and a person's unwillingness to accept responsibility for his or her actions. Brain malfunction was a true diagnosis only if it could be confirmed by a pathologist. Reality therapy's foundation is grounded in the belief that all people need to feel connected and cared for in order to protect them from life's woes. A reality therapy counselor will emphasize the present, avoid discussing symptoms or complaints, urge the client to focus on what he or she can do directly to change his or her feelings and physiology, refrain from criticism or blame, remain nonjudgmental, help the client to avoid making excuses, and assist in developing a realistic and workable plan toward positive change. In 1967, Glasser founded The Institute for Reality Therapy in Tempe, Arizona. In 1994, he changed it to The Institute for Control Theory, Reality Therapy, and Quality Management and then to The William Glasser Institute in 1996. Branches can now be found throughout the United States as well as internationally.



William Glasser's approach to counseling is referred to as "reality therapy"—a term he coined in his 1965 book *Reality Therapy: A New Approach to Psychiatry*. (Ernie Leyba/The Denver Post via Getty Images)

Some of the basic principles of Glasser's theory were influenced by scientist William T. Powers's writings on perceptual control theory (PCT). PCT states that humans behave in direct response to what they perceive in their environments. The range of actions one takes in a given situation depends on the possibilities one perceives in that situation. If one perceives that the possibilities are limited, then one acts in a confined manner or may not even act at all. Glasser's first called his theory "control theory" during the 1970s but later changed the name to "choice theory" in the late 1990s, so as not to confuse it with PCT. Choice theory has three main principles: (1) all humans do is behave, (2) almost all behavior is chosen, and (3) humans are driven by their genes to satisfy five basic needs: survival, love and belonging, power, freedom, and fun. The most important of these is love and belonging, as connectedness to others is a requisite in preventing problems such as mental illness, crime, abuse, and school failure. People are believed to be in control of their own lives; therefore, personal choice, responsibility, and ownership lead to transformation. Glasser's key book on the topic *Choice Theory: A New Psychology of Personal Freedom* was published in 1998.

Glasser's teachings have been applied in other areas, including education, business, substance abuse, and marriage and family therapy. He has worked with countless schools and businesses incorporating reality therapy and choice theory principles. A management style he termed "lead management" fosters an environment of non-coercion where members are trusted, respected, and valued, and strive to produce high-quality work. Several books were written applying this approach in schools, including Glasser's own popular work *The Quality School: Managing Students without Coercion* (1990). Glasser defined "quality schools" as those that apply the principles of reality therapy and choice theory, whereby the members respect one another, are responsible for the choices they make, and are held to high expectations.

In 2007, he coauthored *Eight Lessons for a Happier Marriage* with his wife Carleen, to help couples improve their relationship.

Impact (Psychological Influence)

William Glasser has had many profound accomplishments. He's been listed in *Who's Who in America* since the 1970s. In 1990, he was awarded an honorary degree of Doctor of Humane Letters, Honoris Causa, from the University of San Francisco. He was presented with the ACA Professional Development Award in 2003 and with the A Legend in Counseling Award in 2004. In 2005, he received the designation of Master Therapist from the American Psychotherapy Association and the Lifetime Achievement Award from the International Center for the Study of Psychiatry and Psychology. In July 2010, the William Glasser Association International was established to coordinate the institute's activities worldwide. Active organizations are located in the United States, Canada, the United Kingdom, Europe, Asia, Australia, New Zealand, and Central and South America. William Glasser died in his home in Los Angeles, California, on August 23, 2013, due to respiratory failure as a complication of

pneumonia. Glasser's work continues to impact several fields of study.

Going Postal

"Going postal" is a slang term for becoming suddenly and uncontrollably angry to the point of violence. The term originated from a series of shootings involving U.S. postal employees.

Description

The term originated from a series of shootings involving current or former United States Postal Services (USPS) employees who shot and killed managers, coworkers, police, and the general public. The first reported shooting occurred on August 19, 1983, when Perry Smith charged into a Johnston, South Carolina, post office with a 12-gauge shotgun killing the postmaster and wounding two other employees. Three years later, Patrick Sherrill entered an Edmond, Oklahoma, postal facility and fatally shot 14 employees and wounded another 6, before killing himself. In 1989 John Merlin Taylor killed his wife, then two colleagues, and himself at Orange Glen post office in Escondido, California. Two years later, Joseph M. Harris killed his ex-supervisor and her boyfriend at their home in Wayne, New Jersey. He then shot two former colleagues at a Ridgewood, New Jersey, post office where they all previously worked together. Harris was subsequently convicted of murder and died on death row in 1996. In Royal Oak, Michigan, Thomas McIlvane killed four and wounded five, before killing himself in 1991. Then in 1993 Larry Jasion killed one, wounded three, and then killed himself at a post office garage in Dearborn, Michigan. At a Miami Beach, Florida post office, Jesus Antonio Tamayo shot his ex-wife and a friend as they were waiting in line, and then killed himself on September 2, 1997. A few months later, Anthony Deculit killed a coworker and wounded a supervisor and another coworker before killing himself at a postal facility in Milwaukee, Wisconsin. On January 30, 2006, the deadliest workplace shooting in the United States by a female occurred. Jennifer San Marco killed six employees and then herself at a Goleta, California, postal facility.

Impact (Psychological Influence)

These shootings occurred in the context of significant changes in the USPS to increase productivity. For many postal employees, the pressure of increasing demands from management became unbearable. Patrick Henry Sherrill well illustrates the enormity of the pressure on postal employees during that era. On August 19, 1986, two supervisors at an Edmond, Oklahoma, postal facility verbally abused Sherrill in an effort to further increase his productivity. Sherrill, who had excellent annual performance reviews, was then threatened with termination if his productivity did not increase appreciably. He subsequently attempted to transfer to a maintenance job. After learning that such a transfer was doubtful, he went home, got a gun, and returned and responded to his supervisors' demands with fatal gun fire. The explanation offered by the USPS and promulgated by the media was that problems in the USPS were undeniably problems with disgruntled postal workers, mostly by Vietnam vets who went to work for the postal service after military discharge. Unfortunately, it did not address the issue of mobbing, which involves abuse of employees in an organization which does not hold the abusers accountable for their actions.

Going Viral

"Going viral" is a term that refers to the overnight spread of information, through electronic means such as e-mail, Twitter, Facebook, and YouTube, making the information instantaneously popular.

Description

The cultural phrase "going viral" refers to information being spread through electronic media in a very short amount of time. The rate at which this information reaches others drastically increases the phenomenon's popularity. Various electronic means contribute to items "going viral" such as Twitter, YouTube, Instagram, Facebook, and e-mail. The "going viral" phenomenon follows the same concept as that of a computer virus. Once one person receives the virus (idea) from a source, he or she passes it along to another person, and so on and so on, until the information has fanned out to thousands or even millions of people in a relatively short span of time.

Most information goes viral because people choose to forward it, or pass it along, to friends, family members, and coworkers. Whether this information comes in the form of e-mail content, an image, a video, a blog article, a photo, a song, or a link, what makes it viral is that it has been passed on to many other people. Political content, celebrity news, jokes, and home videos are examples of topics that may go viral. It is not necessarily the information that is the critical factor but the passing along of the information by the person forwarding it or posting it on his or her online status. Viral information is an interesting occurrence because it is not determined by the creator but by the viewer or consumer.

The basis of the "going viral" dynamic has been present in various aspects of human behavior for centuries. Basically, human beings have used dialogue to forward information for some time. Topics and ideas that reach others "through word of mouth" can be likened to this process. The field of marketing has long capitalized on this type of phenomenon in order to popularize companies and their products. Viral information relies on some sort of hook in order for the information to catch on; however, one can never be certain what that hook may be or how to create it.

Impact (Psychological Influence)

Technological advances and the rise in popularity of certain forms of media like social networking sites, e-mail, Twitter, and Instagram have drastically increased the potential of information "going viral." In 2012, the video by Invisible Children named Kony became the most viral video in history, with over 34,000,000 views on the first day of its upload on March 5, 2012. As of April 1, 2013, it had been viewed more than 97,000,000 times.

Gottman, John (1942–)

John Gottman is a clinical psychologist and founder of the Gottman Institute who is best known for his research into marriage, couple, and family functioning.

Description

John Gottman is best known for his research into marriage and couples relationships and has published his

findings in over 200 peer-reviewed articles and authored over 40 books. Gottman and his wife, Julie Schwartz Gottman, PhD, lead the Relationship Research Institute, a nonprofit research institute. They also cofounded and run The Gottman Institute, a for-profit training center for family and marital therapists in the Gottman Method Couples Therapy.

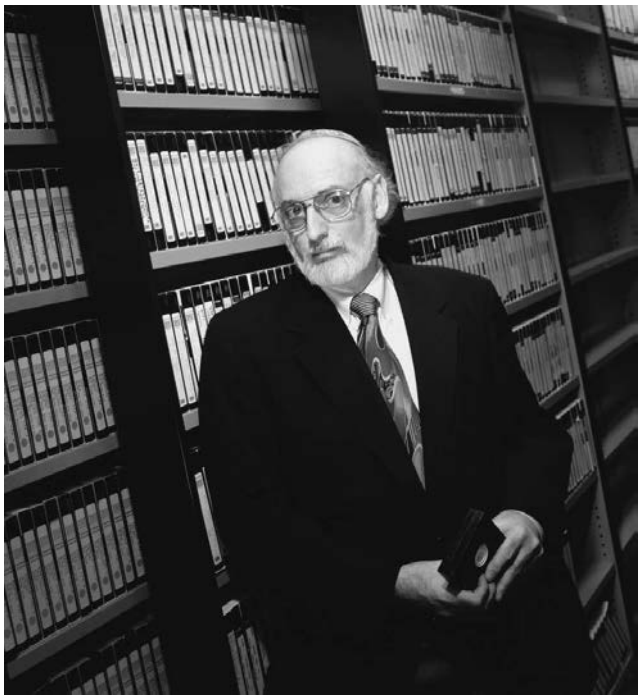
John Gottman was born on April 26, 1942, in the Dominican Republic to Jewish parents. He received a mathematics-physics undergraduate degree from Fairleigh Dickinson University in New Jersey in 1962. Gottman went on to earn two master's degrees: a master's in science in mathematics-psychology from Massachusetts Institute of Technology in 1964 and a master's in arts in clinical psychology-mathematics from the University of Wisconsin in 1967. Gottman received his PhD in clinical psychology in 1971 from UW in 1971.

Gottman taught at Indiana University for 5 years (1972–1976) and then at the University of Illinois for 10 years (1976–1986). From 1986 to 2002 Gottman was professor of psychology at the University of Washington where he remains as emeritus professor of psychology. He is currently the executive director of the Relationship Research Institute in Seattle, Washington.

Gottman launched his career in marital and family research with a 1969 peer-reviewed article on marital interaction and parenting. In 1986 Gottman set up the Family Research Lab, a furnished apartment overlooking a lake where he could videotape couples having discussions. Affectionately known as the "Love Lab," it was the first scientific observations of couple's interactions as they attempted to resolve conflicts. Since that time Gottman has become well known for his research on predicting divorce and has completed several studies that explored what predicts marital stability and divorce. In a 1992 study he was able to predict with 93.6% accuracy which couples would divorce. Building on that study Gottman conducted and published additional research findings on predicting divorce and marital stability. An example of how Gottman studied couples is his 1999 study. Using newlyweds who were married less than six months, Gottman videotaped couples discussing an ongoing marital conflict. Gottman coded the couple's interactions, facial expressions, vocal tone, speech content, positive and negative affect, physiological data, and self-ratings by each partner. Gottman was able to predict marital outcome over a six-year period.

Gottman's consistently high prediction rate suggests that the type of interaction and pattern of behavior can make couples vulnerable to divorce. One such pattern that Gottman observed he named "Four Horsemen of the Apocalypse." The four horsemen are criticism, contempt, defensiveness, and stonewalling, which predict the end of a relationship. Based on his research observations of couple's interactions and behavior patterns, Gottman published *The Seven Principles for Making Marriage Work* in 1999. The book is the culmination of what Gottman has learned about what makes marriages work and what makes them fail. The book also serves as the foundation for training lay people in conducting couples groups through the Gottman Institute.

Founded by John and Julie Gottman, the Gottman Institute serves two purposes. It provides direct services to couples and provides state-of-the-art training



John Gottman is a clinical psychologist and founder of the Gottman Institute. He is best known for his research into marriage, couple, and family functioning. (Andrew Brusso/Corbis)

to mental health professionals in the application of 30 plus years of marriage research. The Gottman Institute offers a wide variety of workshops and training for couples and professionals. In addition, licensed mental health practitioners are able to become Certified Gottman Therapist.

Impact (Psychological Influence)

John Gottman has received numerous awards in recognition of his research and work with couples. He has received four national Institute of Mental Health Research Scientist Awards; the American Association for Marriage and Family Therapy Distinguished Research Award; and the American Psychological Associating Presidential Citation for Outstanding Lifetime Research Contributions.

Grief

"Grief" is a term that refers to a person's emotional response or reaction to the loss of someone or something that was close to them.

Definitions

- **Anticipatory grief** is the type of grief associated with situations where the loss of a loved one is impending as with a terminal illness.
- **Bereavement** is a term that refers to the state of loss.
- **Complicated grief** describes when an individual does not cope well with a loss and it begins to impact his or her life in physically, emotionally, socially, and psychologically unhealthy ways, or at a level that is not considered normal in that culture and/or society.
- **Five Stages of Grief** is a popular theory used to describe the grieving process as outlined by Kübler-Ross; five stages are denial, anger, bargaining, depression, and acceptance.
- **Grieving process** describes steps or stages one goes through when experiencing or attempting to cope with a loss or tragedy.

Description

Grief is the emotion that describes how a person responds to loss. It is often used interchangeably with the term "bereavement" which defines the state of loss, while grief defines an individual's reaction to the state of loss. Loss can be related to things that are tangible, or can be measured, such as the death of a loved one or the loss of income, or intangible (abstract) such as the loss of one's youthfulness or sense of independence. People dealing with life-threatening diseases or family members witnessing a loved one's journey through a terminal illness may experience what is referred to as anticipatory grief. With this type of grief, the patient or loved one is preoccupied by thoughts and feelings surrounding the impending death. Grief is multifaceted, encompassing not only emotional reactions but also physical, cognitive, behavioral, social, and physiological components. Grief is distinct to each individual and each circumstance; no two people experience grief in the same way or in the same period of time. Multicultural differences can also impact how a person grieves. Some common ways people express grief include crying, angry outbursts, and talking about the

loss. Experiencing and expressing grief is natural and healthy; however, individuals may also struggle to deal with grief in effective ways. Children, in particular, may need assistance in working through loss situations. In these cases, a mental health professional or health-care provider should be consulted.

When one experiences a loss, one enters into what is known as "the grieving process." There are varying steps and terms used to describe this process depending on the theory. The most well known is the Kübler-Ross model, or Five Stages Theory. This model was developed by Elisabeth Kübler-Ross and outlined in her 1969 book *On Death and Dying*. The theory lists five distinct stages that people experience during a loss or tragedy: denial, anger, bargaining, depression, and acceptance. These stages are not linear and not every person experiences every stage. A later model, developed by psychologist George Bonanno, contradicts the Five Stages Theory based on evidence that the majority of people do not grieve. Rather, Bonanno's research suggested that most people are resilient when faced with loss or tragedy. His model refers to the Four Trajectories of Grief: resilience, recovery, chronic dysfunction, and delayed grief/trauma. Psychiatrist Mardi Horowitz also developed stages of loss, including outcry, denial and intrusion, working through, and completion. Like Kübler-Ross's model, these stages are not linear, and each individual does not necessarily experience every stage. Researcher and clinical psychologist Therese Rando came up with yet another model for the stages of grief. Her six Rs theory describes the way people respond to grief: recognize, react, recollect and reexperience, relinquish, readjust, and reflect. A similar approach was taken by psychologist J. W. Worden, outlining the four tasks of grief. They are (1) to accept the reality of the loss, (2) to work through the pain of grief, (3) to adjust to an environment in which the deceased is missing, and (4) to emotionally relocate the deceased and move on with life. Regardless of the model of theory that one subscribes to, the primary goal of a natural and healthy grieving process is acceptance.

Current Status and Impact (Psychological Influence)

Currently, the *Diagnostic and Statistical Manual* (DSM) does not specifically define grief or bereavement as a disorder, though other formal diagnoses may be associated with these experiences, including major depressive disorder, post-traumatic stress disorder, and generalized anxiety disorder. Prolonged grief disorder, previously referred to as complicated grief, has been proposed for inclusion in the DSM, though critics argue that this would pathologize a natural process. Though most people are able to cope effectively with grief a small percentage, approximately 10%–15% experience severe reactions, including those that affect their relationships, work, and health. Seeking the assistance of a psychologist, psychiatrist, or other mental health professional is recommended in these instances.

Grief Counseling

Grief counseling is a type of specialized counseling service directed toward persons experiencing grief-related issues.

Definition

- **Grief therapy** is a therapy used to address those suffering with bereavement issues, which involves the use of psychotherapeutic techniques and/or psychotropic medications; it is distinguished from grief counseling in that it may be required for individuals displaying complicated grief, a level of grief considered outside of the cultural or societal norm.

Description

Grief counseling is a supplemental support service offered to people dealing with loss or bereavement issues. It focuses on assisting the client in coping through the grieving process. Psychologists, counselors, social workers, therapists, and other mental health professionals are schooled in providing this type of counseling. One may also receive further specialization, training, or certification in this area. Grief counseling can be offered on an individual basis or in a group setting.

Those dealing with the normal grieving process may find grief counseling beneficial. Most people who have experienced loss are encouraged to seek grief counseling as it is considered a healthy coping strategy for expressing one's thoughts and feelings. Counseling for grief differs from grief therapy in that the latter may be recommended for those who are grieving in unhealthy ways and/or are doing so for an extended period of time. Therapy is considered a more focused, intensive, and necessary form of treatment to prevent further possible consequences. It employs the use of psychotherapeutic techniques and/or possibly the assistance of psychotropic medications in order to assist the individual in dealing with his or her loss. Situations requiring grief therapy typically involve people who are suffering from what is referred to as complicated grief, that is, displaying levels of grief that are considered outside of societal or cultural norms. The goal of both grief counseling and therapy is acceptance and resolution of the client's feelings related to his or her loss.

Development

Grief counseling, though always a part of general counseling practice, began in the early 1940s with research conducted by psychiatrist Erich Lindemann on what he described as "normal grief." His article "The Symptomatology of Management of Acute Grief" was the first scholarly paper written that addressed grief counseling as a practice. A peak in interest then came during the late 1960s and early 1970s. Much of this was due to the work of Elisabeth Kübler-Ross and her seminal book *On Death and Dying* (1969), which examined how the medical community deals with the terminally ill. She also outlined five distinct stages experienced by the bereaved: denial, anger, bargaining, depression, and acceptance. Attachment theory, developed by psychoanalyst John Bowlby, also occurred around this time and contributed to a deeper understanding of bereavement. Bowlby suggested that grief was an adaptive process influenced by both past and present losses and environmental factors. Later in the 1970s, psychiatrist Colin Murray Parke expanded bereavement research focusing more on traumatic loss and complicated grief. In the 1996 book *Continuing Bonds*, Klass, Silverman, and Nickman discussed grief as an ongoing process rather than a completion of stages whereby healing can be fostered by holding onto bonds with the lost. Grief counseling practices in the 21st century require that practitioners have a multicultural understanding of grief responses.

Current Status

Modern grief counseling theory incorporates some aspects of the foundational theories; however, most counselors today oppose the idea that the grieving process is confined to phases and that one must successfully complete one or all of these in order to successfully resolve or effectively accept one's loss. The Oscillation Model is one such theory that indicates that individuals continually learn new ways to adapt to their different life. Furthermore, current research offers that it is not necessary for an individual to let go of his or her loved one in order to heal. Findings suggest both holding onto attachments and simultaneously letting go of the loss. Psychologist and researcher Robert Neimeyer recommends that grief counseling practice shift away from private and sequential models and more toward personalized/individualized care.

Group Counseling

Group counseling is a form of therapy that is used to help two or more participants resolve both typical and challenging problems in life. It is sometimes referred to as group therapy or group work.

Description

Group counseling is therapy that involves two or more people and a counselor who work together to achieve mutually agreed-upon goals. Ideally, groups consist of generally about 3 to 4 members for children or adolescent groups and as many as 8 to 12 members for adults. The size of the group is important as when the group becomes too large, it can hinder group interaction and the feeling of safety that is necessary for open and honest communication within the group. The groups typically meet weekly for as much as 6 to 16 weeks.

Group counseling provides an opportunity for deeper insight and understanding by providing an opportunity to help heal, provide support, and offer encouragement from other members. Groups are formed for common life problems that focus on interpersonal processes. The group leader sets the tone with being genuine and warm to encourage members to do the same as the higher degree of empathy and understanding present the better opportunity for growth for each member.

The purpose of group counseling is to guide members toward self-exploration and awareness. The goals of group counseling include helping the members to develop positive outlooks and improve interpersonal skills through interaction with other group members. The process is used to help facilitate the change process through feedback and support from other group members. The group allows for a safe environment to begin these skills so they can be used and applied in everyday life.

Development

Working in groups is a natural process and those in the helping professions, including counseling, have worked with people in group formats since the early 1900s. Group work in its larger context is typically broken down into different types of groups: task/work, psychoeducational, counseling, and psychotherapy groups. Each type has a distinct purpose for its members. It is often said in the field of counseling that "there's a group for that" as group counseling has grown dramatically offering various different types of groups for different needs.

Current Status

With the growth and increasing commonality of groups, the presence of the Association for Specialists in Group Work provides a wealth of information. This organization provides information not only about groups but also about the proper training to lead groups. The Association for Specialists in Group Work recommends that group leaders be adequately trained and have knowledge in the areas of human development as well as identification and treatment of common problems of living.

Group Homes

A group home is a residence for persons requiring care or supervision, such as troubled youth, the developmentally disabled, the elderly, or those suffering from addiction.

Description

Group homes are generally private residences that house children or adults with either mental or physical disabilities. For some residents, living independently is not an option as they require assistance to complete daily tasks. Group homes are also common for children or adolescents with behavioral problems, such as those who are dangerous to themselves or others. Thus, group homes are generally supervised to varying degrees based on the type of population being housed and their respective needs.

Group homes are common for children in foster care, runaway teens, at-risk youth, and the developmentally disabled. Group homes for adolescents are generally temporary or short-term placements, whereas with adults they tend to function as long-term placements although some adults build the skills necessary to move into independent living situations. In the early and mid-20th century, these functions were handled by asylums, orphanages, and other institutions.

Most group homes are single family homes adapted to the needs of the residents. Oftentimes, group homes are located in residential neighborhoods with no distinction from other homes in the community. Residents in group homes often have either chronic mental health disorders or physical disabilities. Each home has a team of workers who are present for around-the-clock care and supervision. The majority of group homes that house children are often temporary placements until a foster family becomes available. However, group homes for adolescents are also utilized for at-risk youth who require higher levels of care.

A primary goal of group homes is to build independence and self-care skills. Adult residents are among the most severely disabled. Group home staff provide transportation, meals, medication, and recreational activities. Group homes also often provide mental health services. Children who are psychotic, suicidal, or extremely aggressive are considered to be poor candidates for group homes; however, there has been a trend to use group homes as a short-term care option for adolescents with varying emotional and behavioral problems.

Development

Group homes were a response to the closing of institutions, asylums, and orphanages in the 1960s and 1970s. The first known use of the term "group home" was in 1967. Psychiatric hospitals were closing and those hospital patients needed places to go. A group home provided care for the individuals while allowing for adjustment into community. This functioned as a less-restrictive environment and was intended to reflect typical daily life.

Group homes are often funded by grant programs or through state and federal funds. Many are run by nonprofit organizations. They are considered positive alternative to institutionalization. Group homes within neighborhoods often receive opposition from those living in the residential area. The common reaction of residents to the news of a group home opening is "Not in my backyard," which spawned the acronym NIMBY. There are often protests, with residents concerned about safety, security, and declining property values. Social workers and case managers are constantly looking for ways to improve the relations between neighborhoods and the group homes.

Current Status

Research over the past 25 years has indicated that individuals in group homes have demonstrated increases in level of independence and function. Current research is also looking to determine best outcomes for children in residential group homes versus therapeutic foster

care. There is also a current debate about the short-term and long-term effects of living in group homes for adolescents.

Group Therapy

Group therapy involves one or more therapists meeting with several clients at one time, and it is widely used for a variety of psychiatric problems.

Description

Group therapy can be an important part of a client's treatment, depending on his or her diagnosis. Some patients may require a combination of group and individual therapy to improve. Patients with more serious mental health issues generally do best with several treatment formats.

It's common for patients to begin their treatment with individual therapy, and many patients prefer it. The idea of opening up to strangers can be uncomfortable. Newcomers to therapy may feel vulnerable and are often not at ease with the idea of sharing in a group. These patients can benefit from a two-step approach, whereby they start with individual sessions with a therapist and then move into group therapy.

Development

Treating patients in small groups has unique advantages. Groups may help participants to feel that they are not alone in their situation, because they spend time with others who are experiencing the same or similar issues. Groups also help participants gain the skills to relate to others. Group therapy can also have its challenges, however. It's possible to experience conflict among the members in a group. There also may be issues with the group dynamic. Some members may talk too much, while others talk too little. Subgroups may form, which can interfere with the dynamic of the larger group.

In a group therapy setting, it's important for the therapist to provide structure and boundaries while maintaining a safe space for the participants in the group. This allows members to feel comfortable about opening up. Therapists also should encourage members to form new attachments within the group.

Certain disorders respond well to group therapy. Group therapy has been responsible for breakthroughs with many patients, especially those with relational disorders. It is one of the best arenas for patients to learn how to relate to other people. One example is relational disorders, or dysfunctional patterns in dealing with others. Relational disorders are best treated in the same environments where they were created. Group therapy allows patients to reenact situations that cause them problems and work through them.

Group therapy allows for cohesion, where the group members stick together and are able to relate to each other. Cohesion can also refer to the relationship quality and structure of the group. In groups, members experience three types of relationships: member to member, member to group, and member to leader. Cohesion is unique to group therapy and is therapeutic to the participants.

The more cohesive the group, the more likely the members are to experience improvement. Member interaction leads to higher group cohesion. Because of this, it's important for group leaders to encourage interaction during sessions. Studies also show that groups lasting more than 12 sessions, with 5 to 9 members, have the highest cohesion rates and the best outcomes. Cohesion is especially important with younger group members. Young people have more positive outcomes from group therapy in a cohesive group, no matter what the setting or diagnostic classification.

Clients who have been abused, substance abusers, and those who have suffered traumatic events usually

achieve positive results in group therapy. Homeless patients tend to be diagnostically diverse, yet the group setting can still be effective. Those who suffer from PTSD, have been the victims of violence or abuse, and have a need for effective psychiatric treatment can benefit from including group therapy in their treatment. Shelters that provide on-site group therapy for homeless women give them a supportive environment, confidentiality, and a chance to connect, while helping women define boundaries and limit aggressive behavior.

The group therapy setting helps individuals to see themselves as others do, find their strengths, and empathize, which in turn help their ability to build relationships. Patients sharing in a safe environment can increase their sense of belonging and begin healing.

The gender makeup of a group matters to the dynamic. When a group is all female, the participants tend to set up a flexible order of speaking, express emotions, talk about personal experiences/problems, and learn from each other. Women are likely to create a nurturing environment and offer support and equality. However, in mixed groups, men can sometimes dominate the speaking and interrupt other participants.

It's important in any session that the group leader be seen as a member. If the leader does not share similar experiences, which is often the case, he or she must be able to draw upon his or her own experiences and relate them to what the group is going through. Otherwise, the group members may not open up in the session.

Current Status

Whether used as a standalone treatment or combined with other therapies, group therapy can help patients achieve maximum results. It is a valuable tool for treating patients for a variety of conditions. Group therapy offers a solid track record for patient improvement, especially when combined with a complementary treatment, such as individual therapy. It is used extensively within public mental health agencies. While it is an effective form of treatment, in most areas there are not enough therapists trained in group therapy.

Guidance Counselor

Guidance counselors, now referred to as professional school counselors or school counselors, are counseling professionals who provide direct and indirect support services to students in educational settings.

Definition

- **Professional school counselors** are counseling practitioners employed in various educational settings who collaborate with parents and teachers to help students develop across academic, social, and career domains.

Description

Guidance counselors are practitioners who work in educational settings to provide a range of support services to students, parents, and teachers as a supplement to the regular school curriculum. They hold a minimum of a master's degree in school guidance and counseling and are either certified or licensed, depending on the state where they practice. These professional educators are employed in elementary, middle, and high school settings but may also work in district supervisory positions. There has been a recent shift in the school counseling field from use of the former term "guidance counselor" to "school counselor," "certified school counselor," or "professional school counselor." This change has been made in an attempt to increase awareness about the role of a school counselor and the appropriate tasks he or she should engage in on a daily basis.

Professional school counselors are qualified to design, implement, and evaluate comprehensive guidance programs focused on the needs of all students in areas related to their academic, personal/social, and career development. Daily tasks include both direct and indirect services. Direct services describe in-person interactions between the school counselor and students and include school counseling core curriculum, individual student planning, and responsive services such as individual or small group counseling, or responding to crisis. Indirect services are provided on behalf of the student to parents, teachers, other educators, and community organizations in an effort to promote positive relationships and provide additional assistance.

Guidance and counseling began with vocational/career guidance back in the 1950s after the launch of Sputnik, the Russian Space Station. This event spurred concern about students being prepared to compete with other nations in the fields of math and science. Soon after, the U.S. government passed the Elementary and Secondary Education Act, requiring funds to be set aside for guidance services in schools. At this time the term "career counselor" or "vocational counselor" best described the role of guidance counselors in schools, with limited time allotted to addressing student's personal and social needs.

The American School Counselor Association (ASCA), founded in 1952, is an international nonprofit organization that was developed specifically to meet the needs of professional school counselors. Its mission is to represent school counselors and to promote professionalism and ethical practices in the field. Regional, state, and local divisions of this organization have been established to support these professionals in providing services to all students in grades K-12. School counselors uphold the standards outlined in the ASCA National Model as well as in other related professional counseling associations.

Impact

Current concern in the field surrounds the lack of professional school counselors in schools and the duties with which they are required to perform which are oftentimes not reflective of their education and skill set. ASCA recommends a ratio of 1 school counselor for every 250 students; however, most schools have student numbers that greatly exceed this, while other schools may not have a certified school counselor on staff at all. As ASCA states, school counselors are called to provide comprehensive developmental guidance programs that address the personal/social, academic, and career needs of all students. Programs should also be current, culturally relevant, and preventative in nature, and promote and enhance student success. Accountability is another concern as professional school counselors are required to demonstrate the effectiveness of their services. Ongoing debate continues over how to document, evaluate, and reward professional educators that have a positive impact on student outcomes.

Guide to Rational Living, A (Book)

With more than 1.5 million copies sold, *A Guide to Rational Living*, written by legendary psychologist Dr. Albert Ellis and coauthored by Dr. Robert A. Harper, continues to be near the top of the self-help best-seller lists. Ellis's ideas have withstood the test of time, considering his book is still in print and in demand even though it was first published more than five decades ago in 1961.

Author Albert Ellis, PhD (1913–2007), was the creator of rational emotive behavior therapy (REBT) and is widely considered one of the most influential psychologists of all time. A 1982 survey placed him as the second-most influential psychologist of his time—ahead of Sigmund Freud and directly behind Carl Rogers. He is credited with thousands of speeches and workshops, more than 150 audio tapes, and writing more than 800 articles and 75 books, including several best sellers, such as *A Guide to Rational Living*, making him among the most prolific psychologists of his time.

Ellis shares his beliefs in the book as he writes that people can change their emotions and also their behaviors by simply confronting their irrational thoughts with facts and reason. This book was not written for therapists but for the average person to help understand how his or her emotions and irrational thoughts can lead to anxiety and depression. The authors state that emotions are often a result of reacting to other people. This, they say, creates emotion that is a three-way combination of physiological, psychological, and social reactions that are all occurring at the same time. Ellis and Harper explain how REBT helps an individual discriminate between rational and irrational thoughts, thereby helping him or her actually get better instead of just feeling better.

A Guide to Rational Living was Ellis's first book to outline his theory of REBT. This book offers an introduction to the theoretical foundations of REBT, which is based on the concept that our thoughts lead to emotions, which in turn influence our behaviors. Thus, since what we are feeling is based on what we are thinking, Ellis firmly believed that people can change emotions and behaviors by simply challenging irrational thoughts and confronting them with rational thought and reason.

The book breaks down what Ellis believes to be are the top 10 irrational thoughts and ideas that lead to most people experiencing negative emotions. This classic self-help manual lists these common irrational ideas, as well as walking the reader through the disputing irrational beliefs activity. For example, Ellis and Harper explain that we don't get upset, we "do" upset. Through unhealthy and self-defeating thoughts and emotions, we cause an emotional disturbance. The authors offer effective techniques to correct these faulty ways of thinking, which are divided into cognitive, emotive, and behavior categories.

Ellis credits Alfred Adler, Karen Horney, and Erich Fromm as being among his biggest influences. He is given full credit by Aaron T. Beck, considered to be the "father" of cognitive behavior therapy. Thus, many place Ellis as the "grandfather" of CBT. The ripple effect from Ellis is quite strong and includes those that Beck influenced, such as David D. Burns, MD, who wrote the best seller *Feeling Good: The New Mood Therapy*, a self-help guide that has sold more than 4 million copies and arguably can be traced back to Ellis's writings in *A Guide to Rational Living*.

Guided Imagery

Guided imagery is a therapeutic technique that guides the imagination in a focused direction.

Description

Imagine that you are walking along a trail through a beautiful mountain valley on a perfect spring day. There is a creek on your right, rolling hills on your left, and a pond just a little further ahead. You feel the warmth of the sunlight filtered through tall pines, hear the gentle sounds of rippling water and singing birds, smell the fragrance of the forest pines, and up ahead see a pair of ducks paddling on the surface of the pond. Take a moment and explore this setting. What else do you see, hear, smell, and feel? Are you filled with a sense of peace and well-being in this perfect place? This is an example of an exercise in guided imagery, which involves the generation of mental and perceptual experiences in the absence of external stimuli.

Guided imagery (GI) is a powerful therapeutic technique used to focus and direct a person's imagination in order to bring about positive change. GI involves multiple senses using only the imagination. In the preceding example you most likely generated visual images (mountain valley, rolling hills, pine forest, creek, pond, ducks), auditory sensation (rippling water, singing birds), tactile sensation (warmth of the sun), olfactory sensation (smell of the pines), and emotional sensation (peace and well-being). GI frequently includes the use of metaphor and storytelling.

Guided imagery is used in a wide variety of settings and is utilized in many professions, including the medical and mental health fields. In health psychology GI has been found to decrease presurgical anxiety and decrease need of pain medications in postsurgical recovery. GI has been found to lower blood pressure, decrease muscle tension, and maximize treatment benefits across a wide range of medical conditions. In sports psychology GI is used to increase athletic performance by visualizing a perfect performance. For instance, a field and track sprint runner having difficulties in making a quick start states he gets distracted because all he can think about is getting his feet comfortable in the starting blocks. The therapist suggests that he focus on the image of a powerful drag racing car coming to the starting line, engine revving, with flames shooting out of the exhaust. The therapist helps the client hear the sounds, feel the power, and visualize how the tires grip the surface, how the front lifts up under the powerful acceleration, and how quickly the car accelerates and wins the race. Focusing on the image of a drag car race keeps the runner's mind clear of anything other than a fast and powerful start.

Guided imagery is used in most models of psychotherapy, and there is a wide body of evidence that GI is effective in promoting positive change. GI uses the imagination to explore events in the past, difficulties in the present, goals for the future, and the emotions related to these. GI has been utilized in reducing anxiety and stress; trauma recovery, resolving conflicts; overcoming depression; and treating eating disorders. In psychotherapy GI experiences can be fully guided, as in the earlier examples, or partially guided as when a therapist would ask "Imagine the most likely response, describe what you see, hear and feel."

Guided imagery is used to explore emotional themes, gain self-insight, and process relationship issues. One of the primary goals of GI is to assist clients in developing and engaging in their own images that promote growth, health, and emotional development. For instance, a therapist asks a student who is anxious and afraid to attend a new school to think of an animal and describe the scene that would symbolize the experience. The child describes a puppy that is surrounded by big barking dogs. The therapist could use this scene to explore issues of social anxiety, inadequacy, fear, and low self esteem. Using guided imagery the therapist could help the student develop a more positive self-image by exploring the benefits of being part of the pack and barking with the big dogs. The therapist could guide the story of a fearful puppy maturing into a happy part of the pack. GI often generates metaphors that can assist clients in developing helpful new beliefs, solutions, and attitudes.

Guided imagery is a flexible therapeutic technique utilized in most forms of psychotherapy. GI has been studied extensively as a therapeutic tool and is frequently utilized in reducing stress, seeing new possibilities, gaining insight, and moving toward a more positive future.

H

Haldol (Haloperidol)

Haldol is a prescribed medication used to treat psychotic disorders and other conditions. Its generic name is haloperidol.

Definitions

- **Antipsychotic medications** are prescription drugs used to treat psychotic disorders. They are sometimes referred to as antipsychotics or neuroleptics.
- **Dementia** is a group of symptoms, including loss of memory, judgment, language, and other intellectual (mental) function caused by the death of neurons (nerve cells) in the brain.
- **Extrapyramidal symptoms** are a group of side effects associated with antipsychotic medication use that are characterized by involuntary muscle movements, including rigidity, contraction, and tremor. It is also called EPS.
- **Psychotic disorder** is a severe mental disorder in which an individual loses touch with reality. Symptoms can include hallucinations (hearing or seeing things that are not there), delusions (fixed false beliefs that persist despite contrary evidence), and disordered thinking.
- **Tics** are involuntary, compulsive, repetitive, and stereotyped movements or vocalizations. While they are experienced as irresistible, they can be temporarily suppressed.
- **Tourette's syndrome** is a neurological disorder characterized by recurrent involuntary movements and vocal tics such as grunts, barks, or words, including obscenities.

Description

Haldol is one of the antipsychotic medications used for treating acute and chronic symptoms of psychotic disorders. It is also used to treating symptoms of dementia like agitation. In children, it has been used to manage severe behavior problems like combativeness and extreme outbursts that occur without immediate provocation. Haldol is also effective in controlling tics and inappropriate vocalizations associated with Tourette's syndrome in children and adults. It is believed that Haldol controls symptoms by blocking or lessening the effects of dopamine, a chemical messenger, in the brain.

Precautions and Side Effects

Because Haldol can cause low blood pressure, heart arrhythmias, and seizures, those with heart and blood pressure problems should be carefully monitored while taking this medication. Women who are pregnant or breast-feeding should consult with their doctor before taking Haldol. Haldol may cause extrapyramidal symptoms and signs of withdrawal in newborns, especially if the drug was taken during the last trimester of the mother's pregnancy. Signs of withdrawal include increased agitation, respiratory problems, and trouble feeding. Haldol may increase the action of central nervous system depressants such as anesthetics, alcohol, and some pain medications and sleeping pills.

Common side effects include dry mouth, lethargy, and restlessness. Other side effects include muscle stiffness or cramping, restlessness, tremors, and

weight gain. These are more likely to occur when Haldol is given in high doses and also with prolonged use. A more serious side effect is tardive dyskinesia, which involves involuntary movements of the tongue, jaw, mouth, face, or other groups of skeletal muscles. Haldol use can also result in the development of Parkinson-like symptoms. These include a taut or mask-like expression on the face, drooling, tremors, pill-rolling motions in the hands, a shuffling gait, and jerky movements when the hand muscle is passively stretched. The simultaneous use of Haldol and lithium, which was a common treatment for bipolar disorder, should be avoided.

Haley, Jay (1923–2007)

Jay Haley was a pioneer who changed the approach to individual and family therapy. Devoted to understanding human communication, Jay Haley used his background to hone his theories and put forth the idea that therapists were problem solvers who should guide their patients toward a solution. He felt therapists should take control of sessions and influence their patients. One of the architects of strategic therapy, he was influential in promoting the concept of therapists acknowledging their ability to influence the behavior of their patients.

Description

Haley graduated with a BA degree from UCLA in 1948 and in 1951 earned a BS in Library Science from the University of California at Berkeley. He studied communications at Stanford University and received an MA degree in 1953. In 1952, Haley joined anthropologist Gregory Bateson to consult on his "double bind" research. "Double bind" refers to a situation where a person receives two conflicting messages, and responding to either means failing the other.

The goal of the double bind project was to find a causal link between schizophrenia and family communication, instead of biology. Haley studied many different forms of communication while working on the project. However, the double bind theory was controversial and was never widely accepted. Haley worked with Bateson and his team, including John Weakland, Don Jackson, and William Fry, for a decade. During this time, he also worked with hypnotist Milton Erickson, who was a great influence on Haley.

Development

In 1959, Haley went to the newly formed Mental Research Institute in Palo Alto, California, as the director of research, and studied how families with schizophrenic members were different than families without. In 1967, Haley went to work with Salvador Minuchin at the Philadelphia Child Guidance Clinic and taught many of the best-known family therapists. Early in his career, Haley challenged the prevailing idea that psychotherapy meant long-term treatment. He was not afraid to challenge long-standing beliefs and traditions, and was a proponent of brief therapy. A major part of Haley's approach was that he was less concerned with the diagnosis of a patient and more concerned with solving the patient's her problems and getting him or her off medication so he or she could live a normal life. As one of the first to champion strategic therapy, Haley put forward the idea that therapists should be held accountable for their treatment and that they should look for solutions, not just listen. An effective therapist has a treatment goal in mind and works toward it. He pointed out that transition points in patients' lives led to their psychological problems and that their issues weren't just related to their personality. Haley believed that the patient's family was also part of the problem and should be part of the treatment.

Haley also was an early promoter of supervising therapy sessions behind a one-way mirror, as well as recording sessions to analyze later. This was a new approach at the time and came out of his experience with Bateson. This practice is now common in family therapy. Dedicated to teaching others, Haley was the first to document how to perform an initial patient interview in his book *Problem Solving Therapy*. Later in his career, he made training films for therapists with his wife Dr. Madeleine Richeport-Haley. He trained many in psychotherapy and preferred research and teaching over private practice.

Impact (Psychological Influence)

Haley wrote 20 books during his career, many aimed at taking the mystery out of the practice of therapy. Some of his most well-known titles include *Strategies of Psychotherapy* (1963), *Uncommon Therapy* (1973), *Problem Solving Therapy* (1976), *Leaving Home* (1980), and *Learning and Teaching Therapy* (1996). He also wrote many influential papers throughout his career.

In 1962, Haley cofounded the *Family Process Journal* with Nathan Ackerman and Don Jackson. This for-profit journal had no ties to universities or professional organizations but was devoted to the science and treatment of family behavior. Haley was the first editor of the journal and remained in that position for a decade.

Haley founded the Family Therapy Institute of Washington, D.C., with his second wife Chloe Madanes in 1974. There he taught and studied family therapy until 1994, when he moved back to California for the remainder of his career. In 1985, he was awarded the first Lifetime Achievement Award of the Milton Erickson Foundation. Today, Haley is remembered for his advances in strategic therapy and for training generations of therapists.

Hallucinations

Hallucinations are false or distorted sensory perceptions that appear to be real perceptions that are generated by the mind rather than by an external stimuli.

Definitions

- **Antipsychotic medications** are prescription medications used to treat psychotic disorders, including schizophrenia, schizoaffective disorder, and delusional disorder.
- **Cognitive behavior therapy** is a type of psychotherapy that focuses on maladaptive (problematic) behaviors, emotions, and thoughts. It is also called CBT.
- **Delusions** are fixed, false beliefs that persist despite contrary evidence.
- **Hypnagogic hallucinations** are false perceptions that occur as individuals are falling asleep.
- **Hypnopompic hallucinations** are false perceptions that occur as individuals are awakening.
- **Illusions** are a misperception or false interpretation of an actual sensory image or impression.
- **Paranoia** is an unfounded or exaggerated distrust or suspiciousness of others.
- **Psychosis (psychotic disorder)** is a mental disorder characterized by a loss of touch with reality and psychotic features.
- **Schizophrenia** is a chronic mental disorder that affects behavior, thinking, and emotion, which make distinguishing between real and unreal experiences difficult. Symptoms

include hallucinations, delusions, thought and communication disturbances, and withdrawal from others.

Description

A hallucination is a sensory perception that occurs without the external stimulation of one of the senses (American Psychiatric Association, 2013). Hallucinations can affect any of the senses, although specific medical conditions and mental disorders are associated with specific types of hallucinations. Since they are commonly confused, care must be taken to distinguish hallucinations from illusions and delusions. Hallucinations are false perceptions without sensory stimulation. For example, widows will report "seeing" their dead spouse. In contrast, illusions are false interpretations of real sensory experiences. For example, drivers may report seeing what looks like a pool of water on a road when it is really a mirage caused by the reflection of light passing through layers of different air densities. On the other hand, delusions are false beliefs that persist without any basis in reality. For example, an individual may continue to insist that he or she is a war hero despite evidence that he or she is not old enough for military services. The term "hallucination" is not used for false perceptions that occur during dreaming or falling asleep (hypnogogic) or awakening (hypnopompic). These hallucinatory experiences are short lived and often occur without a mental disorder (American Psychiatric Association, 2013).

Among the most common hallucinations are the following.

Auditory hallucinations. Individuals with this type of hallucination hear sounds or voices that are not there. For example, individuals may hear voices talking about their behavior. The voices may also order them to act or behave in ways that they would not do on their own. These are the most common types of hallucination in schizophrenia.

Visual hallucinations. Individuals with this type of hallucination see other individuals or objects that do not exist. They may be unfocused images such as flashes of light. These images may appear to be distorted or strange, or frightening. These are the second most common type of hallucination in schizophrenia.

Tactile hallucinations. Individuals with this type of hallucination feel or sense something that is not there. It usually involves the sense of being touched or of something under their skin. For example, individuals may feel that invisible fingers are touching them even when no one else is close to them. It may be the sense the bugs are crawling under their skin. Or, it may be the sense that of electricity moving through their body.

Olfactory hallucinations. Individuals with this type of hallucination will smell odors that no one else does. For example, individuals may smell unpleasant odor such as decaying fish or burning rubber. Or, they may believe that the odor is coming from them. These are the least common types of hallucination in schizophrenia.

The causes of hallucinations are not well understood. However, they can be associated with certain mental disorders and medical conditions. Schizophrenia and other psychotic disorders may be the most common cause of hallucinations. Brain tumors, Parkinson's disease, inflections, stroke, and dementia are medical conditions associated with hallucinations. Substance abuse and medication side effects are common causes. Lifestyle factors such as sleep deprivation and severe fatigue are also associated with hallucinations.

Treatment

Hallucinations are treated with regard to the underlying cause. Such causes may be a medical condition, mental disorder, medication side effect, substance, or lifestyle factors. Accordingly, treatment may involve medical treatment, antipsychotic medications, cognitive behavior therapy, or substance abuse treatment for drug dependence.

Hallucinogen-Related Disorders

Hallucinogen-related disorders are mental disorders characterized by the use of mind-altering drugs that cause auditory and visual hallucinations.

Definitions

- **Addiction** is a chronic disease of the brain, which involves compulsive and uncontrolled pursuit of reward or relief with substance use or other compulsive behaviors.
- **Auditory and visual hallucinations** are severely distorted perceptions of what is real.
- **Cognitive behavior therapy** is a type of psychotherapy that focuses on maladaptive (problematic) behaviors, emotions, and thoughts. It is also called CBT.
- **Dissociative drugs** are substances that severely distort vision and hearing and produce a feeling of floating or feeling removed from reality. Examples are PCP, ketamine, and DXM.
- **DSM** is the abbreviation for the *Diagnostic and Statistical Manual of Mental Disorders*, which is the handbook mental health professionals use to diagnose mental disorders. The current edition is DSM-5.
- **Psychedelics drugs** are psychoactive substances that profoundly distort thoughts and perceptions. Examples include LSD ("acid"), mescaline, and MDMA ("ecstasy").
- **Psychotherapy** is a psychological method for achieving desired changes in thinking, feeling, and behavior. It is also called therapy and therapeutic counseling.
- **Substance-related and addictive disorders** are a group of DSM-5 mental disorders characterized by maladaptive thoughts, excessive and repetitive behaviors, and physical symptoms. It includes alcohol intoxication, cannabis use disorder, and hallucinogen disorders.
- **Twelve-Step Group** is a self-help group whose members attempt recovery from various addictions based on a plan called the Twelve Steps. Twelve-Step Groups can focus on specific addictions such as Alcoholics Anonymous and Narcotics Anonymous (NA).

Description and Diagnosis

Hallucinogen-related disorders are in the class of DSM-5 substance-related and addictive disorders. They are unique among the substance-related disorders because they cause auditory and visual hallucinations. Hallucinogens come from plants and mushrooms or can be made synthetically. They are categorized into classic hallucinogens (psychedelic drugs) or dissociative drugs (PCP). Both categories produce serious effects. These include disorientation, numbness, dizziness, vomiting, auditory and visual hallucinations, and increase in blood pressure and heart rate. Dissociative drugs increase the feelings of detachment from reality or of detachment from one's own body. In severe cases, hallucinogens may cause seizures, muscles spasms, violent behavior, and amnesia. They alter chemical actions in the brain to produce feelings of euphoria.

The occurrence of this disorder is much lower than that of other substance use disorders. Around 1 out of 200 individuals between the ages of 12 and 17 have this disorder. More females than males are diagnosed in this age group. Out of 1,000 individuals 18 years old and older, 1 is diagnosed with hallucinogen-related disorder. More males than females are diagnosed in this age group. The rate of occurrence is highest among individuals under the age of 30 and virtually zero for individuals over the age of 44. The occurrence of this disorder is higher among Native Americans, Alaska Natives, and Hispanics than whites, blacks, Asians, or Pacific Islanders (American Psychiatric Association, 2013). Some cultures use hallucinogens for medicinal and religious purposes.

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, individuals can

be diagnosed with this disorder if they continue to use hallucinogens despite severe negative consequences. They must experience various symptoms. These include the following. Substance use is increased. There is an inability to decrease usage or stop using. Much time must be spent getting, using, or recovering from the drug, or they must have strong drug cravings. There must be repeated use despite negative consequences at work, home, school, or social life. Drug use must take precedence over other important activities, or it must continue during dangerous situations such as when driving a car or operating a machine. Its use must continue despite the activation or exacerbation of psychological and physical problems. Often, more of the drug is needed to obtain the desired effect. It is important to note that the DSM-5 does not provide any withdrawal symptoms for hallucinogens (American Psychiatric Association, 2013).

The cause of this disorder may be attributed to other substance use disorders. Addiction to alcohol, tobacco, and cannabis may increase the probability of hallucinogen-related disorder. Individuals with major depressive disorder and antisocial personality disorder are also at a higher risk of developing hallucinogen-related disorder. Furthermore, hallucinogens may seem attractive to recreational drug users because they don't have physical withdrawal symptoms, are inexpensive, are easy to access, and, with occasional use, result in few side effects.

Treatment

Hallucinogen-related disorders are treated with psychotherapy, Twelve-Step Group, and possibly medication. Psychotherapy may include cognitive behavior therapy. Involvement in a Twelve-Step Group like NA may be helpful. Medication treatment may be necessary to treat anxiety. An individual brought to treatment under the influence of hallucinogens needs to be kept calm and focused on reality.

Hallucinogens

Hallucinogens are a class of drugs that cause alterations in perception, thought, or mood. They are also known as psychedelic drugs.

Definitions

- **Controlled Substance Act of 1970** lists substances regulated by the Drug Enforcement Administration into one of five schedules. Each schedule reflects a drug's potential for abuse and dependence.
- **Hallucinations** are false or distorted sensory perceptions that appear to be real perceptions. They are generated by the mind rather than by an external stimuli and can be caused by a medication, recreational drug, or mental disorder.
- **Serotonin** is a chemical messenger in the brain that serves to transmit nerve impulses that regulates mood in terms of calmness, happiness, pain, sexuality, and sleep. Low levels are associated with depression and compulsivity.

Description

Hallucinogens are a chemically diverse group of drugs that cause changes in a person's thought processes, perceptions of the physical world, and sense of time passing. The term "hallucinogen" is a misnomer since these drugs do not cause hallucinations at typical

doses. The kind of "hallucinations" induced by this class of drugs is actually modifications of regular perception. During this experience, users are most likely to be aware of the illusory and personal nature of their perceptions. Hallucinogens can be found naturally in some plants and can be synthesized in the laboratory. They are called psychedelic drugs and are abused as recreational drugs. With the exception of MDMA, hallucinogen use peaked in the United States in the late 1960s as part of the counterculture movement. It then gradually declined until the early 1990s, when it began to increase. The 2010 U.S. National Survey on Drug Use and Health reported that 1.2 million individuals had used hallucinogens in the past month, with 695,000 persons taking MDMA, or ecstasy.

The best-known hallucinogens are lysergic acid diethylamide (LSD), mescaline, psilocybin, and MDMA (ecstasy). Phencyclidine (PCP, angel dust) can produce perceptual distortions, as can amphetamines and marijuana. But these drugs are considered dissociative drugs, rather than hallucinogens, and act by a different pathway from classic hallucinogens. Dextromethorphan, the main ingredient in many cough medicines, has become popular among some populations because of the PCP-like effects that it produces. Although the various hallucinogens produce similar physical and psychological effects, they are a diverse group of compounds. However, all hallucinogens appear to affect the brain in similar ways. It is thought that these drugs act by binding to a specific serotonin receptor (5-HT2) in the brain. The effect is that serotonin is blocked, leading to increased free (unbound) serotonin in the brain. The result is a distortion of the senses of sight, sound, and touch; disorientation in time and space; and alterations of mood. With hallucinogen intoxication, users are not delirious, unconscious, or dissociated. Instead, they are aware that these perceptual changes are caused by the hallucinogen.

Unlike most medications, the mental state of the hallucinogen user and the environment in which it is taken can profoundly influence the user's experience. For example, LSD is known for its range of experiences from "good trips" symptoms like mellowness and psychedelic visions to "bad trips" symptoms like anxiety and panic attacks. Previous good experiences with a drug do not guarantee continued good experiences. Those with a history of psychiatric disorders are more likely to experience harmful reactions, as are those who are given the drug without their knowledge.

Specific Hallucinogens, Cautions, and Side Effects

LSD LSD is lysergic acid. It was first synthesized by a researcher attempting to develop a headache remedy. LSD also occurs naturally in morning glory seeds. It is listed as a Schedule I drug (Controlled Substance Act), meaning that it has no medical or legal uses and has a high potential for abuse. Street names for the drug include "acid," "yellow sunshine," "windowpane," "cid," "doses," "trips," and "boomers."

Mescaline. Mescaline or peyote is a naturally occurring plant hallucinogen. It has been used for centuries as part of religious celebrations and vision quests of Native Americans. In 1970, mescaline was listed as a Schedule I drug, but the state of Texas legalized peyote for use in Native American religious ceremonies. In 1995, a federal law was passed making peyote legal for religious ceremonial use in all 50 states.

Psilocybin. Psilocybin is the active ingredient in what are known on the street as "magic mushrooms," "shrooms," "mushies," or "Mexican mushrooms." Psilocybin-containing mushrooms are usually cooked and eaten or dried and boiled to make a tea. Although psilocybin can be made synthetically in the laboratory, there is no street market for synthetic psilocybin, and virtually all the drug comes from cultivated mushrooms. It is legal to possess psilocybin-containing mushrooms, in the United States, but it is illegal to sell them. It is a Schedule I drug.

Generally, mescaline and psilocybin produce uniformly milder symptoms than LSD. During a single drug experience, the user may experience a range of symptoms. Mood can shift from happy to sad or pleasant to frightening and back again several times.

MDMA. MDMA, better known as Ecstasy, is a popular "club drug" (rave and dance clubs). The psychoactive component of it is chemically similar to mescaline, while its stimulant component is similar to methamphetamine. During the time it was legal, many experimented with MDMA as a means of becoming more open and empathetic. Recreational use soon followed, and it was declared an illegal Schedule

I drug. MDMA is often associated with all-night raves or dance parties. It allow ravers to dance for hours with a feeling of empathy, reduced anxiety, reduced inhibitions, and euphoria.

PMMA. PMMA is a hallucinogen, with effects similar to MDMA. It can cause rapid heartbeat, high blood pressure, seizures, kidney failure, hyperthermia, hallucinations, and death. The compound in PMMA is often found in MDMA, making the substance even more potent and potentially fatal.

Salvia. Salvia (*Salvia divinorum*) is a potent psychoactive drug containing a chemical called salvinorin A. It is considered to be up to five times more potent than LSD. It is thought to act on opioid receptors of the brain and cause both physical and visual impairment and hallucinogenic effects. Salvia is not yet regulated by the federal government, but many states are creating legislation to ban the cultivation and sale of this plant.

Jimson weed. Jimson weed is an herb that produces fragrant flowers with a trumpet-like appearance. It can induce delirium, hallucinations, amnesia, and violent behavior. Symptoms of overdose include seizure, coma, and respiratory arrest. Ingesting it may require emergency treatment and hospitalization, since symptoms may be present for up to three days.

Hamilton Anxiety Scale (HAM-A)

The Hamilton Anxiety Scale (HAM-A) is a psychological test for assessing anxiety and its severity. It is also referred to as the Hamilton Anxiety Rating Scale.

Definition

- **Anxiety** is a state of uneasiness and apprehension about future uncertainties that is reflected in psychic (mental) and somatic (physical) symptoms.

Description

The Hamilton Anxiety Scale is a 14-item test that measures anxiety and its severity in children and adults. It measures overall anxiety, psychic anxiety (mental agitation and psychological distress), and somatic anxiety (physical complaints related to anxiety). Seven of the items address psychic anxiety, while the other seven items address somatic anxiety. It is administered by a trained interviewer who asks a semi-structured series of questions about symptoms of anxiety. The individual's responses are then rated on a five-point scale for each of the items. A score of zero represents an absence of the anxiety symptom being measured, while a score of four represents the presence of extreme symptoms. A total score of 17 or less suggests mild or no anxiety, 18 to 24 suggests moderate anxiety, and 25 or higher suggests severe anxiety. It takes about 15 to 20 minutes to administer the test.

Besides its use in assessing the presence and severity of anxiety, the HAM-A is also used as an outcome measure when assessing the impact of psychotherapy and other treatments, including medication. It can be administered before starting an antianxiety medication and during follow-up visits where medication dosage can be adjusted based in part on the individual's HAM-A score.

Developments and Current Status

The HAM-A was developed by Max Hamilton (1912–1988), a psychologist in 1959. He developed the scale by using the technique of factor analysis. With this statistical method, he generated a set of symptoms related to anxiety and determined which symptoms related to psychic anxiety and which related to somatic anxiety. Hamilton also developed the widely used Hamilton Depression Scale to measure symptoms of depression. While there is a tendency for depressed people to also score high on the HAM-A, some researchers have suggested that anxiety and depression

are so closely linked that people can easily score high on measures of both types of symptoms.

The paper and pencil version of this test is in the public domain, which means it can be accessed available without charge. There is also a computer-administered version. One reason that the HAM-A is widely used is that reliability studies have shown that it measures anxiety symptoms in a fairly consistent way. The measure's validity of HAM-A has also been supported by research. Although it was one of the first anxiety-rating scales to be published, it remains one of the most widely used instruments by clinicians.

Hamilton Depression Scale (HAM-D)

The Hamilton Depression Scale (HAM-D) is a psychological test for assessing depression and its severity. It is also referred to as the Hamilton Rating Scale for Depression and the Hamilton Depression Rating Scale.

Definition

- **Depression** is a state of low mood and reduced activity that affects an individual's thinking, behavior, feelings, and sense of well-being. It may be acute or chronic, mild or severe.

Description

The Hamilton Depression Scale is an interviewer-administered and rated measure for assessing the presence and severity of depressive symptoms in children and adults. It consists of symptoms common to depression such as anxiety, insomnia, mood, hypochondriasis, agitation or retardation, weight loss, and somatic symptoms. It is administered by a trained interviewer who asks a semi-structured series of questions about symptoms of depressions. The original version contains 17 items, which takes about 20 minutes to administer. This version, which is the most commonly used, consists of nine items which are scored on a five-point scale, ranging from zero to four; seven items are scored on a three-point scale, from zero to two, and the last item is scored on a two-point scale. The total score can range from 0 to 54. Scores between 0 and 6 suggest little or no depression, scores between 7 and 17 suggest mild depression, scores between 18 and 24 suggest moderate depression, while scores greater than 24 suggest severe depression.

Besides its use in assessing the presence and severity of depression, the HAM-D is also used as an outcome measure when assessing the impact of psychotherapy and other treatments, including medication. It can be administered before starting an antidepressant medication and during follow-up visits where medication dosage can be adjusted based in part on the individual's HAM-D score.

Developments and Current Status

The HAM-D was developed by Max Hamilton (1912–1988), a psychologist, in 1960. It has been revised a number of times, the last being in 1980. Hamilton maintained that the HAM-D should not be used only as a diagnostic instrument but rather used in combination with the patient's history, other tests, and clinician judgment. He also developed a self-report measure of depression in adults called the Hamilton Depression Inventory and the Hamilton Anxiety Scale, which is an interviewer-rated measure of anxiety and its severity.

Long considered the gold standard by those clinical researchers, the HAM-D has been criticized for

its overemphasis on insomnia and underemphasis on suicide thoughts and gestures. For example, it is not uncommon for depressed individuals who are on antidepressant medication to have lower HAM-D scores in part because of their improved sleep but who continue to experience suicidal thoughts.

There is considerable research to support the reliability and validity of the HAM-D. The scale correlates highly with other clinician-rated and self-report measures of depression, such as the Beck Depression Inventory. Despite some criticism, the HAM-D is considered one of the most common clinician-administered tests used to assessing depression.

Hare Psychopathy Checklist-Revised (PCL-R)

The Hare Psychopathy Checklist-Revised (PCL-R) is a psychological test for assessing psychopathic (antisocial) tendencies.

Definitions

- **Psychopath** is an individual who manifests psychopathy.
- **Psychopathy** is a serious personality disorder characterized by antisocial, aggressive, and violent behavior and thoughts, and a lack of empathy.

Description

The Hare Psychopathy Checklist-Revised is a psychological tool used to rate psychopathic or antisocial tendencies in clinical, legal, and research settings. It is a 20-item symptom rating scale used by qualified examiners to compare an individual's degree of psychopathy with that of a prototypical psychopath. The PCL-R items reflect symptoms of psychopathy and include pathological lying, glibness and superficial charm, cunning and manipulativeness, lack of remorse or guilt, egocentricity, repeated violations of social norms, disregard for the law, and a lack of empathy. The interview portion of the evaluation covers the individual's background, including educational and work history, marital status, and criminal background.

The PCL-R is used in clinical, forensic, and research settings. It has long been used to assess individuals arrested or convicted of crimes, particularly adult males in prisons and criminal psychiatric hospitals, and those awaiting psychiatric evaluations or trial in correctional facilities. More recently, it has been also used effectively in diagnosing sex offenders, female offenders, and adolescent offenders. It is also being used as an indicator of the potential risk of psychopathy and in determining the length and type of prison sentences as well as treatment recommendations. The PCL-R is available in many languages, including French, German, Korean, Portuguese, Spanish, Hebrew, Japanese, and Swedish.

Each of the 20 items is given a score of 0 to 2 (does not apply to completely applies). The maximum score is 40. A score of 30 or above suggests a diagnosis of psychopathy, while those with criminal backgrounds typically score about 5. Non-psychopathic criminal offenders score around 22.

Developments and Current Status

The Psychopathy Checklist and the PCL-R were both developed by psychologist Robert D. Hare (1934–). The PCL-R contains two parts, a semi-structured interview and a review of the subject's file records and history. During the evaluation, the clinician, usually a psychologist or other such professional, scores 20 items that measure central elements of the psychopathic

character. The items cover the nature of the subject's interpersonal relationships, his or her affective or emotional involvement, responses to other people and to situations, evidence of social deviance, and lifestyle.

The PCL-R has a demonstrated record of reliability and validity among researchers and clinicians. Several American and European studies support the value of the PCL-R in assessing psychopathic traits and predicting the likelihood of future violent behavior. While there has been some controversy about the test and its use, the PCL-R is considered by the international scientific community an important forensic test for the assessment of psychopathy.

Harlow, Harry (1905–1981)

Harry Harlow (1905–1981) is considered a legend in the field of psychology. As a psychologist, Harlow's experimental studies with rhesus monkeys led to many important discoveries about how primates, including both monkeys and humans, love and socialize with each other.

Description

As one of the most respected psychologists of the 20th century, Harry Harlow is best known for his discoveries of the infant–mother relationship, which he uncovered through experimental studies with rhesus monkeys. Harlow is credited with revolutionizing animal learning and motivation in the 20th century. He is also cited with studying the human need for love and socialization.

Harlow began his career in 1930, after graduating from Stanford. At the time, psychologists were striving to make a difference and to be viewed as "real" scientists in the greater scientific community. This created the need for experimentation and research. At Stanford, Harlow had already experimented with rats in the laboratory. After he graduated, he moved to Madison, Wisconsin, to start his career. However, he had a problem. Harlow did not have a laboratory or rats for his experimental work. On a suggestion, he visited the local Madison Zoo. It was there he discovered his life's work and what he called his first important discovery—rhesus monkeys. Rhesus monkeys presented a more intriguing test subject than rats. Harlow invented a specialized instrument called the Wisconsin General Test Apparatus (WGTA) to test the intelligence of his rhesus monkeys. With this instrument, Harlow discovered his monkeys learned through problem solving—something that had never before been established.

By the late 1950s, Harlow was already breeding rhesus monkeys. In fact, Harlow had the only self-sustaining colony of monkeys in the United States. This gave Harlow the perfect condition for his studies into the mother–infant relationships of his rhesus monkeys. Harlow wanted to determine what inspires an infant to love its mother. At the time, leading authorities believed that infants instinctually loved their mothers because mothers fed them. To test this, Harlow separated infant rhesus monkeys from their mothers. He gave these infant monkeys surrogate, artificial mothers made of wire and cloth. The wire "mother" provided food, while the cloth "mother" provided comfort and warmth. Harlow observed as the infant monkeys continually huddled to the cloth "mother" instead of the wire, food-bearing "mother." Thus, he concluded that a mother's nurturing is what inspired her infant's love.

As these separated infants grew up, Harlow and his researchers observed they exhibited antisocial and other strange behavior, including the lack of desire

to mate or raise their young. Therefore, Harlow concluded that a mother's love was just one type of desired affection. After many additional studies with his rhesus monkeys, Harlow concluded there are five types of affectional patterns exhibited in primates: (1) the affection of infant and mother, (2) the affection of a child to child, (3) heterosexual affection, (4) maternal affection, and (5) paternal affection. Should any of these affections not be available, Harlow concluded another form of affection would fill its void.

Impact (Psychological Influence)

In 1975, Harlow became the first psychologist to ever win the Kittay International Scientific Foundation Award for this work with rhesus monkeys. Harlow's other notable achievements include serving as the U.S. Army's chief psychologist; helping establish the Human Resources Research Office; inventing the WGTA, which psychologists across the country started using; serving as the editor of the *Journal of Comparative and Physiological Psychology* in 1951; and being elected a member of the National Academy of Sciences and, in 1958, becoming the president of the American Psychological Association. Today, Harlow is remembered as one of the greatest psychologists of the 20th century.

Hayes, Steven (1948–)

Steven Hayes is an influential psychologist who is most recognized for his work in applied behavior analysis and for developing acceptance and commitment therapy (ACT).

Description

Steven C. Hayes (1948–) is a clinical psychologist who received his training at West Virginia University. Currently he conducts research and teaches on the application of emotional acceptance in therapy. He has been recognized as one of the psychologists with the highest impact between 1986 and 1990. His background and experience in psychology include behavior analysis, addiction treatment, single-case design, and prevention. He is also recognized as the founder of both relational framework theory (RFT) and ACT.

Relational framework theory is an analysis of human language and learning. The theory is based on many of the principles of applied behavior analysis (ABA), a science that aims to understand and improve human behavior. The theory asserts that both language and learning help people to relate to others. Human development is our ability to create links or relationships between things and people. Context, or the relational frame, provides hints that allow people to learn from new information that may be different from what they already know. RFT has been used as the basis for early intensive behavior intervention (EIBI) with young children. For children with language delay or disorders, like autism, EIBI is an essential part of treatment and helps teach effective communication and social skills from a young age.

Relational framework theory also provides the theoretical underpinnings for the therapeutic approach known as acceptance and commitment therapy. The bulk of cognitive behavior therapy focuses on changing behavior through changing thoughts. ACT comes from a different perspective. Instead it does not try to change thoughts or judge them as right or wrong, but rather it evaluates them on whether the thoughts lead to a better quality of life. Acceptance of negative emotions and thoughts leaves people free from the struggle to change them. It also allows them to accept who they

are here and now. In this context ACT is practical in its approach to judgment-based thinking and decision making.

Impact (Psychological Influence)

Through the work of Steven Hayes and many others, the practice of ACT has become widely accepted. There are now numerous controlled studies and randomized clinical trials on the effectiveness of ACT for a variety of problems. Some of the most promising are in the area of chronic pain control. Most study results have been positive, but in a few studies the measurable effects have been questioned. Overall, these studies provide growing support for the effectiveness of ACT.

The impact of Steven Hayes's work in psychology is most significant through behavior therapy and ACT. Hayes has worked directly to advance behavior therapy, specifically ABA. He has also contributed to the organization and continuation of a coalition to develop guidelines for empirical therapeutic practices.

Hazing

Hazing is any ritual or activity where members of a particular group engage in the harassment and abuse (physical, verbal, or emotional) of nonmembers as a means for them to gain possible membership or acceptance into that group.

Definitions

- **Bullying** describes deliberate, repeated acts of aggression that are inflicted directly or indirectly over time by one or more dominant persons.
- **Harassment** means creating a hostile environment or unpleasant situation for a person by consistently exposing him or her to acts that make him or her feel uncomfortable; these attempts or advances from the perpetrator are uninvited and unwelcomed.

Description

"Hazing" refers to abusive acts carried out by members of a select group on nonmembers as a means of initiation. Hazing is known by different terms in several other languages, though all follow the same overall theme, referring to a rite of passage or the christening of a newcomer (e.g., in French the word "bapteme" meaning "baptism" and in Spanish the word "novato" meaning "newcomer" are used). Groups may consider these rituals a rite of passage, but hazing is prohibited by law as it can be extremely damaging to victims. Hazing acts may be comprised of physical violence, verbal humiliation, psychological abuse, and/or sexually oriented offenses. A wide range of behaviors can fall under these categories. Alcohol is commonly used in hazing practices, such as binge drinking. Over 80% of reported hazing rituals are associated with alcohol. Other behaviors include personal servitude, verbal demeaning, public insults, physical harm such as beating, spanking, paddling, or branding, and sleep or hygiene restrictions.

Various social groups have been known to engage in the practice of hazing, including fraternities, sororities, sports teams, military units, and gangs. Those subject to hazing may feel compelled to comply with orders they are given. Others are willing to participate even when they are subject to the most degrading and dangerous circumstances. In the United States, hazing is most often reported at the postsecondary, or college, level. Greek-letter organizations, social clubs, service groups, and sports teams have all been known to engage in hazing activities. From small acts of humiliation

and intimidation to full-blown ceremonies in front of large groups of people, hazing remains a current problem. Of most concern is when these practices extend over a prolonged period of time, hours, days, weeks, or even months. An example would be "Hell Week," which refers to the harassment of pledges over the course of several days. At the high school level, hazing is seen less frequently, though it has been known to occur there as well. Hazing practices in the military date back to World War I, though leaders maintain to not condone the behavior. The U.S. military defines hazing as the unwarranted affliction of cruel, abusive, oppressive, or harmful behavior on a fellow soldier. Similar practices have been reported in other rescue lines of work, including police forces, firefighters, and lifeguards. However, hazing is not limited to these workplaces. Regardless of setting, hazing is a complex social problem entailing the abuse of power, similar to other forms of harassment like bullying.

Hazing is poorly understood due to the secretive nature surrounding it. Victims are not likely to report practices as this would damage the chances of their admittance into the desired group. Experts have questioned why perpetrators engage in hazing rituals as well. Some report using hazing as a way to test potential members' toughness, loyalty, and compatibility levels, while others report that it provides pure entertainment. The question remains as to where the line gets crossed from a rite of passage used for bonding purposes to outright harassment and abuse. Though forms of hazing have occurred for centuries, recent consensus distinguishes it as socially inappropriate.

Impact (Psychological Influence)

Though forms of hazing have occurred for centuries, recent consensus distinguishes it as a socially inappropriate behavior. Since 1970, there has been at least one hazing-related death on a college campus each year. At present, 44 states in the United States have anti-hazing legislation. Several countries also have laws banning hazing practices. In 2008, a large-scale investigation surveying over 11,000 undergraduate students and 300 staff members at 53 colleges and universities throughout the United States reported that more than half of students involved in teams, clubs, and other organizations had experienced hazing. Additional results indicated that nearly half of these students had experienced hazing in high school. While one out of five students reported that they had witnessed hazing firsthand, 95% cited that they did not report the situation to anyone.

Health Counseling

Health counseling is a set of distinct methods and approaches used to impact a wide variety of patient health concerns and conditions through education, counseling, and psychotherapy.

Description

"Health counseling" is a general term referring to a variety of methods for effecting health behavior change. Five approaches to health behavior change have been identified, each with a distinct provider, focus, strategy, and duration.

Medical care counseling (MCC) is most often provided by physicians with the focus on providing information about prescribed treatment. MCC is very brief, sometimes lasting just a few seconds. Patients are expected to comply with instructions, and there is usually no educational component or follow-up monitoring

of the treatment. MCC includes descriptions of how often to take a prescribed medication, and advice to lose weight and get some exercise.

Patient care counseling (PCC) is most often provided by nurses, dieticians, or nurse practitioners in order to strengthen a patient's ability to self-manage his or her health condition. The focus of PCC is to increase patient understanding, improve health skills such as self-monitoring, and increase compliance to treatment. PCC usually provides short-term support and assistance to patients as they learn how to deal with significant health conditions such as diabetes, irritable bowel syndrome, asthma, and other chronic health problems.

Health promotion counseling (HPC) is most often provided by health counselors and nurse practitioners. The goal is to improve lifestyle and health behaviors by collaborating with the patient and developing interventions tailored to the needs and expectations of the patient. Individuals may or may not have signs or symptoms of disease. People seek HPC for a variety of reasons, including concerns about physical conditions such as weight loss, management of chronic medical conditions such as diabetes, concerns about aging, getting or staying fit, and relapse prevention for chronic conditions such as irritable bowel syndrome.

Health-focused counseling (HFC) is provided to patients who have been unsuccessful with MCC, PCC, or HPC in managing chronic health problems with low to moderate severity. The goal of HFC is to reduce symptoms by improving adherence to treatment requirements. HFC is usually provided at the doctor's office, most often by physicians and nurse practitioners who have some formal training in counseling. HFC focuses on assessing and reducing barriers to treatment compliance and increasing self-management. Treatment includes assessing and changing maladaptive thinking patterns leading to noncompliance. Psychotherapists such as social workers, psychologists, and mental health counselors also provide HFC and frequently use some form of cognitive restructuring therapy.

Health-focused psychotherapy is used in severe and complex cases in which the health condition is severely debilitating and progressive, causes severe pain, or is life threatening. Illness management and progression of these types of severe medical conditions are greatly affected by personality and family dynamics that run much deeper than just maladaptive thinking. Highly trained psychotherapists who understand how to assist individuals in modifying their core personality dynamics are needed in order to improve the health status of the patient.

Hip-Hop Music

Hip-hop music is a variety of rap music consisting of chanting, rhythm, and rhyme created mostly by young black musicians and often used to communicate feelings of oppression due to racial conflict or social injustices.

Description

Music is an important reflection of society, its challenges and changes. Hip-hop is often identified with the music genre of rap, which consists of chanting, rhythmic, and rhyming speech. Hip-hop music has a broader cultural influence than rapping alone. Because it heavily emphasizes rhythm and the role of the beat, it includes elements such as deejaying, scratching, break dancing and beatboxing. The language used in hip-hop often chops up words, uses short forms, and embraces broken English and slang expressions.

Hip-hop music developed in the African American community or "in the ghetto" where many of its musicians were raised. Hip-hop emerged from and traces

its origins to jazz and rock and roll during the 1950s and 1960s. It was recognized and named by the west coast musician Keith Cowboy in the 1970s as a way of imitating the rhythmic structure of soldiers marching. It spread quickly and diversified, and many of its leading musical figures became prominent cultural icons. Many of these icons, such as Tupac Shakur and Notorious B.I.G., were controversial and associated with violence and the defamation of women.

Some of the most successful contemporary icons of hip-hop are Dr. Dre, Snoop Dogg, Jay-Z, and Kanye West. Jay-Z has characterized hip-hop in this way, ". . . hip-hop was this youthful music that didn't have those boundaries outside of America. More specifically hip-hop had a voice. Jazz hit great notes and things like that but hip-hop spoke directly to the people, it spoke to their heart and how they were feeling" (Peterson, 2014).

Impact (Psychological Influence)

Hip-hop's influence has become worldwide, across all nations and musical genres. Its vibrancy and force have renewed interest in language and a kind of raw poetry that represents the attitudes, hopes, and fears of young people. Its rhythm and colorful phrases now influence the language of the entire culture.

Hip-hop is also a genre that includes negative and positive effects from a social and psychological perspective. The lyrics of the music often contain sexually graphic and violent themes. Some male hip-hop performers are routinely sexist, and some advocate violence against women. It has been linked to gang activity and drug use. Often young people who imitate hip-hop music can offend others with negative hip-hop attitudes and language, and by violating certain dress codes.

This music has also had positive cultural influences. Many hip-hop artists spread messages that stress the cultural richness that comes out of the African American heritage and its struggle for freedom and equality. Beyond this, many artists have begun to apply these same ideas to gender equality and the stupidity of violence, gang wars, and the use of drugs. The hopes, fears, and themes of hip-hop have broad cultural appeal. Although it may have started in the African American community, it now has a diverse audience in the United States and around the world.

Histrionic Personality Disorder

Histrionic personality disorders is a personality disorder in which individuals first appear to be charming, likable, energetic, and seductive. But as time passes, others find them to be emotionally unstable, immature, and egocentric.

Definitions

- **Borderline personality disorder** is a personality disorder characterized by unpredictable, impulsive, and self-destructive behavior, anger, mood swings, and troubled relationships.
- ***Diagnostic and Statistical Manual of Mental Disorders*** is the handbook mental health professionals use to diagnose mental disorders. The current edition (fifth) is known as DSM-5.
- **Histrionic** refers to behavior that is very dramatic or excessive.
- **Hysterical personality** comes from the word "hysteria" which referred to a medical condition caused by the uterus (in Greek: "hysteria" means uterus). The belief was that various symptoms were caused by the movement of a uterus throughout various locations within a woman's body.

- **Personality disorder** is a long-standing pattern of maladaptive (problematic) behavior, thoughts, and emotions that deviates from the accepted norms of an individual's culture.
- **Psychotherapy** is a psychological method for achieving desired changes in thinking, feeling, and behavior. It is also called therapeutic counseling.

Description and Diagnosis

Individuals with histrionic personality disorder may initially seem charming, likable, energetic, and seductive. In time, however, they are likely to be viewed as emotionally unstable, immature, and egocentric. Such individuals can function well both socially and professionally and have developed good social skills. However, they tend to use them to manipulate others into making them the center of attention. In the past, the histrionic personality was referred to as the hysterical personality. With the publication of the third edition of the *Diagnostic and Statistical Manual of Mental Disorders* in 1978, histrionic personality disorder replaced hysterical personality. Individuals with this disorder make up 2%–3% of the general population and about 15% in mental health treatment settings.

This personality disorder is more common in females than males. Females with histrionic personality disorder command center stage. They are exhibitionistic and use their charm, physical appeal, and seductiveness to get their way. Their emotions and relationships are intense, but they are also shallow. Males with this disorder also command attention but in a different way. They will brag about their business success or display their athletic ability prowess in golf or tennis. Their interests and attitudes are easily influenced by others. Their emotions and relationships are also intense, but neither lasts long; then they feel unappreciated. In its severe form this disorder can be mistaken for the borderline personality disorder.

The clinical presentation of this disorder can be characterized with the following: behavioral and interpersonal style, thinking style, and feeling style. The behavioral style is often dramatic and expressive while also being demanding, self-indulgent, and inconsiderate. Persistent attention seeking, shifting moods, and superficiality further characterize individuals' behavior. Interpersonally, these individuals tend to be exhibitionistic and flirtatious in their manner, along with attention seeking and manipulativeness. Their thinking style is generally impulsive and thematic (global), rather than being analytical and precise. They are easily suggestible and tend to rely on hunches and intuition. They are likely to deny their dependency on others but need and demand the approval of others. Their emotional style is characterized by exaggerated displays of feelings, including irrational outbursts and temper tantrums. Although they constantly seek others' reassurance that they are loved, at best they can respond only with superficial warmth and charm. In addition, they are very sensitive to rejection.

The cause of this disorder is not clear, and various factors appear to influence the development of the histrionic personality. These include childhood events such as deaths, divorce, or illnesses in the immediate family; genetics and parenting may be involved. As to parenting, such individuals are likely to have had parenting that involved minimal or inconsistent discipline. They may have grown up with at least one manipulative or histrionic parent who reinforced their attention-seeking behavior. In addition, individuals with a histrionic personality disorder tend to have characteristic view of themselves, the world, and others, and a basic life strategy. They typically view themselves sensitive and in need of others' admiration and approval. They tend to view the world and others as making them nervous, and so they believe they are entitled to special care and consideration. Accordingly, their basic life strategy is to do whatever it takes to attract attention and the approval of others.

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, individuals can be diagnosed with this disorder if they exhibit a pervasive pattern of attention seeking and emotionality. More specifically, they tend to be uncomfortable in situations where they cannot be the center of attention. Their emotional reactions are usually shallow and rapidly shifting. Typically, they draw attention to themselves with the way they dress. Their manner of speech tends to be impressionistic with few details. They are

easily influenced by others or circumstances. They are likely to believe that their relationships are more intimate than they really are. In addition, they may engage in provocative and inappropriate seductive sexual behavior. Furthermore, they are dramatic and overly exaggerate their emotional expressions (American Psychiatric Association, 2013).

Treatment

The clinical treatment of the histrionic personality disorder usually involves psychotherapy. Such psychotherapy is likely to be effective if it has specific and focused treatment goals, limits, and interventions. The overall treatment goal is to assist individuals to moderate their emotional expression, to integrate gentleness with strength, and to encourage them to develop more genuineness, warmth, and empathy. Therapy is successful when these individuals are able to rely on their own self-acceptance rather than demanding approval and acceptance from others. Because this disorder can present as impulsive with potential for suicidal gestures, the clinician needs to discuss the matter of limits, boundaries, and personal responsibilities early in the course. Unless a concurrent acute psychotic or major depressive episode is present, psychotherapy is the principal mode of treatment.

HIV/AIDS

HIV stands for human immunodeficiency virus, a virus that results in significant deterioration of the immune system that can eventually lead to AIDS, or acquired immunodeficiency syndrome and various mental symptoms.

Definitions

- **Acute retroviral syndrome** results from the immune system's response, typically three to four months, to HIV viral replication.
- **Antiretroviral therapy** is regarded as the main type of treatment for HIV or AIDS consisting of drug combinations taken on a daily basis to counteract and prolong the spread of the disease.
- **Opportunistic infections** are infections caused by bacteria, fungus, or viruses that take advantage of a weakened immune system.
- **Pandemic** refers to the outbreak of a disease that spreads to a vast number of people in a relatively short period of time.
- **Sexually transmitted disease** is a type of infection or disease that is passed from person to person through some type of sexual contact (oral, anal, vaginal).

Description

HIV, or the human immunodeficiency virus, is a contractible infection that can lead to AIDS, or acquired immunodeficiency virus. Presently, there is no cure for HIV, meaning once a person contracts the virus, it remains in the body. HIV attacks the immune system, specifically the CD4 cells or T cells, which assist in fighting infection and boosting immunity. As the HIV virus progresses, it continues to destroy these cells, eventually resulting in AIDS and ultimately death.

Origins of HIV have been traced back to apes and chimpanzees in West Africa as far back as the late 1800s. This version of the virus, called simian immunodeficiency virus, or SIV, was believed to be contracted

by humans when they hunted these animals for meat. Existence of the virus in the United States was first reported during the 1970s. At the time, HIV/AIDS was viewed as a global pandemic. Over the past several decades with research, education, and prevention on the topic increasing, these diseases have seen a decline.

HIV is primarily transmitted from an infected person to another person through unprotected sexual contact (not using condoms). The HIV virus is contained in bodily fluids such as semen, pre-seminal fluid, rectal fluids, and vaginal fluids that are exchanged during intercourse. When infected fluids come in contact with a mucous membrane (rectum, vagina, opening of the penis, and mouth), transmission of the virus is likely to occur. The highest likelihood of transmission results from anal sex, followed by vaginal sex, and oral sex. A person's chances of contracting HIV increases dramatically if he or she has other sexually transmitted diseases/infections (STD/STI) such as syphilis, herpes, and HPV. Risk of HIV infection can also occur with blood-to-blood contact. The virus can be transmitted through an opening in the skin such as a cut, abrasion, sore, or incision site. In addition, transmission can happen if a contaminated needle or syringe is directly injected into the bloodstream, either from an accidental prick, from a faulty transfusion, or from sharing needles. Though HIV can also be passed from mother to child during pregnancy, birth, or breast-feeding, these cases are not as common. Cases of HIV being transmitted through saliva are extremely rare, and there is no evidence to suggest that one can contract the virus from kissing or sharing drinks with an infected person alone.

The only sure way to know if one has been infected with the HIV virus is to be tested for it. This can be done through a simple blood test; there are also home-based kits that gather saliva to detect the existence of the disease. Signs and symptoms of the virus vary; however, most people report experiencing flu-like symptoms, referred to as *acute retroviral syndrome*, within two to four weeks of contracting HIV. Other symptoms include fever, sore throat, swollen lymph nodes, and rash. During this initial period, the virus may not show up on a routine screening, so individuals are advised to repeat testing and refrain from unprotected sex or other risky behaviors, as the virus is highly contagious during this time. Furthermore, levels of the HIV virus are highest in concentration at this time, resulting in considerable diminishing of C4 cell counts. Normal CD4 counts range from 500 to 1,600 cells/mm^3.

The progression of HIV takes place over several stages from time of contraction to full-blown AIDS. Early detection and proper treatment can significantly delay progression of the disease from one stage to the next. However, the virus is still active during all of the stages and can be transmitted to others at any time. The initial stage of HIV is referred to as *acute infection* and occurs within two to four weeks after being infected with the virus. The majority of those infected report feeling sick as the virus multiplies very quickly and destroys healthy cells. In the next stage, *clinical latency* (inactivity or dormancy), people report being asymptomatic as the virus reproduces at very low levels during this time. This period can range from months to years to even decades. The final stage of HIV progression results in AIDS, or *acquired immunodeficiency syndrome*. Here, the immune system has become completely compromised exposing the person to increased infections, termed "opportunistic infections," and diminishing the person's chances of successfully fighting off disease.

Individuals with HIV/AIDS also can experience a range of mental health issues. The most common are feelings of acute emotional distress as well as depression and anxiety. Because the HIV/AIDS virus directly infects the brain, impairment in memory and thinking is also common. In addition, anti-HIV drugs can produce mental health side effects.

Impact (Psychological Influence)

Estimates suggest that 50,000 people are infected each year with HIV. Approximately a million people are currently living with HIV/AIDS in the United States alone and over 30 million people worldwide. In terms of risk factors, race and ethnicity play a role, with African Americans being the group with the highest incidence rates of HIV infection followed by Latinos/Hispanics. Age is also a factor, with young people aged 13 to 24 at the highest risk for contracting the virus. Type of transmission is another contributor, with men who have sex with men (MSM) being most affected followed by individuals who become infected through unprotected

heterosexual intercourse. Lastly, those who have STD/STI are much more likely to contract and pass along HIV than those in the general population.

There is no cure for HIV/AIDS; however, early diagnosis and adherence to effective treatment protocol can have a significant impact on one's life expectancy. Antiretroviral therapy, developed in the mid-1990s, remains the most common form of treatment and consists of daily oral doses of medications, including azidothymidine, to counteract symptoms and spread of the disease. Recent research is focused on the effectiveness of administering these medications in injection form. Other prevention strategies include behavioral interventions, including sex education, condom distribution, and counseling. Scientists have been studying HIV/AIDS for several decades and are hopeful that a cure will be developed one day.

Hoarding Disorder

Hoarding disorder is a mental disorder characterized by persistent difficulty discarding or letting go of possessions regardless of their actual value.

Definitions

- **Cognitive behavior therapy** is a form of counseling and psychotherapy that focuses on changing maladaptive (faulty) behaviors, emotions, and thoughts. It is also known as CBT.
- **Compulsions** are repetitive behaviors or mental acts that an individual feels compelled to perform in response to an obsession or to rules that must be followed rigidly.
- **DSM-5** stands for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, which is a diagnostic system used by professionals to identify mental disorders with specific diagnostic criteria.
- **Obsessive-compulsive disorder** is a mental disorder characterized by persistent thoughts and compulsive actions, such as cleaning, checking, counting, or hoarding. It is also called OCD.

Description and Diagnosis

Hoarding disorder is a compulsion to save items or to keep an excess of certain items. There is a significant degree of distress associated with getting rid of or parting with possessions. Hoarding disorder is one of a group of obsessive-compulsive and related disorders in DSM-5 because of its compulsiveness and because of the effect of hoarding on those who hoard and on their relationships. Hoarding results in clutter that limits the living space of the hoarder and other family members. Individuals with this disorder may appear quite normal in public. However, as family and friends become aware of the hoarding and attempt to reduce the clutter, distress increases in hoarders and in their close relationships.

Hoarders are often perfectionistic and have difficulty making decisions and organizing their lives. They procrastinate and are easily distracted. They are convinced that the items they have collected or bought have real value. Also, they may feel emotionally attached to these items. These beliefs and emotional attachments make it difficult for them to part with these items.

This disorder affects about 4% of the U.S. population. It affects both males and females, although in treatment settings, the majority of hoarders are female. Hoarding is three times more common in those over the age of 55 in comparison to those between the ages of 34 and 44 (American Psychiatric Association, 2013).

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, individuals can be diagnosed with this disorder if they exhibit a

persistent and strong desire to keep and save items. They experience anguish when confronted with a need to discard items, regardless of their worth or necessity, or available space in their living area. The clutter that causes significant distress for the individual and family members takes time to reach a significant level. In addition, the hoarding is not the result of a brain injury or other medical condition, or because of another mental disorder (American Psychiatric Association, 2013).

The cause of this disorder is not well understood. However, it does seem to be more common in those with a family history of hoarding. This means that genetics and upbringing are causative. Psychologically, those who hoard often worry that they will be without needed items or that desired items will be taken away from them. They believe that the minute something is discarded it will be essential to have it back, and, of course, then it will be too late. The influence of family and friends may also be a causative factor. They may believe they are helping the hoarder by clearing away clutter. But this may increase the hoarder's distress and lead to the reclaiming or repurchasing of these "needed" items.

Treatment

The clinical treatment of this disorder usually involves cognitive behavior therapy (CBT). It teaches individuals to view the objects around them in a new light and to change their hoarding behaviors. CBT sessions can help hoarders make better judgments and quicker decisions on whether to keep or discard objects. Most important, it helps them practice discarding items as they sort through the intense emotions that trigger hoarding. When family members are involved or living with the hoarder, they may be invited to become involved in the treatment process.

Holland, John Lewis (1919–2008)

John Lewis Holland is a psychologist best known for his creation of a career development model referred to as *The Holland Codes*, which align one's career alternatives with one's underlying character types.

Description

Psychologist and career development model creator John Lewis Holland was born on October 21, 1919, in Omaha, Nebraska to an advertising executive and elementary school teacher. He was one of four children. Holland's father emigrated from England to the United States where he initially worked as a laborer while attending night school at the YMCA. With his parents' encouragement, John also pursued an education, as did each of his siblings. In 1942, he graduated from the Municipal University of Omaha (now the University of Nebraska at Omaha) where he studied psychology, French, and Math.

After graduation, Holland served as a personnel clerk for a few years in the army during World War II. During this time, he received extensive experience in test administration and assessment under the advisement of social workers, psychologists, and physicians. He spent countless hours recording biographical information on soldiers. These experiences contributed to the eventual development of his own hypotheses about personality types. He decided to continue studying to be a psychologist and then sought a doctoral degree in counseling psychology at the University of Minnesota.

John Holland went on to create the career development model known as the *Holland Codes*, or *Holland's Occupational Themes*. His theory referred to person–environment explanations for vocational behavior. He also posited that people's career choices revealed aspects about their personality types and

underlying character. This is part of the psychological study called *typology*, founded on the premise that one can be classified based on certain characteristics or traits that are in common.

There are six Holland Codes, or schemes, each letter (RIASEC) representing a particular "type." "R" stands for Realistic (Doers), "I" for Investigative (Thinkers), "A" for Artistic (Creators), "S" for Social (Helpers), "E" for Enterprising (Persuaders), and "C" for Conventional (Organizers). These six types also generate 720 different personality patterns. The foundational principle behind Holland's Occupational Themes is that people seek out and flourish in careers that best fit their individual personality types. Holland also developed two interest inventories commonly used in career assessment—The *Vocational Preference Inventory* in 1953 and the *Self-Directed Search* (SDS) in 1970. The SDS is a career assessment tool and intervention to be used by persons interested in exploring themselves, specifically their interests, abilities, and vocational options. The SDS has undergone several revisions in 1977, 1985, and, most recently, 1994. The SDS is still readily used in career counseling practice today. A variety of inventories have incorporated aspects of the SDS, including the *Position Classification Inventory* in 1991 and the *Career Attitudes and Strategies Inventory* in 1994, both of which were developed by Holland and colleague Gary Gottfredson.

Holland continued working and developed his career theory at various places: Western Reserve University, the Veteran's Administration Psychiatric Hospital (1953–1956), the National Merit Scholarship Corporation (1957–1963), the American College Testing Program (1963–1969), and finally at Johns Hopkins University (1969–1980) where he earned the distinction of professor emeritus of sociology. He died on November 27, 2008, at the age of 89, at Union Memorial Hospital in Baltimore, Maryland.

Impact (Psychological Influence)

In addition to the inventories he created, Holland published several works that are regarded as foundational writings in career theory. These include *The Psychology of Vocational Choice* (1966), *Making Vocational Choices* (1973, 1985, 1997), and *The Dictionary of Holland Occupational Codes* (1982, 1989, and 1996, with Gottfredson). He was also awarded several merits for his contributions in the field. In 1994, he was given the American Psychologist Association's Distinguished Professional Contributions to Knowledge Award. In 1995, the American Counseling Association honored him with the Extended Research Award. Lastly, in 2008, APA again recognized his efforts by bestowing upon him the Award for Distinguished Scientific Applications of Psychology.

Homelessness

Homelessness is characterized by a lack of permanent housing. It may involve living on the streets, staying in a shelter, mission, single-room occupancy facilities, or other unstable or nonpermanent situation.

Description

Homelessness is a severe and increasing problem. It's estimated that approximately 1% of Americans are homeless, including nearly 1.5 million children. In 2009, 1 out of every 38 children living in poverty in the United States ended up in a shelter or on the street. Though homelessness has many causes, the major

factors are lack of affordable housing and extreme poverty. Both of these factors have increased during the past decade. Other factors include substance abuse issues and mental health challenges.

Being homeless disrupts a person's sense of community belonging. It's difficult to maintain normal life activities like working and spending time with family when homeless. When people are homeless or living in low-quality housing, they tend to withdraw from their networks, which creates social and psychological isolation.

The effects of homelessness are often made worse by the stigma in media and health-care services. Many people have negative attitudes toward homeless people, more so than toward poor people who still have homes. This stigma can lead to less funding for social programs, or people being too embarrassed to seek the help they need. Another issue is that federal policy is aimed at homeless adults, instead of the families or children who are more likely to become homeless.

At special risk are homeless mothers. Homeless women with young children often have emotional issues or a major depressive disorder, such as post-traumatic stress disorder , and up to one-third of homeless mothers have been suicidal at some point. These women are also more likely to become victims of violence or to be substance abusers. Homeless families are much more likely to have mental health difficulties, substance abuse challenges, and unhealthy levels of stress.

Since children's emotional well-being is dependent on their parents, a mother's mental problems can lead to an increase in mental problems for her children. Homeless children are also at risk for lower grades in school and relationship problems, due to moving and a disruption of their routines.

According to numerous studies, being homeless increases the risk of mental issues in young people. Homelessness can trigger mental problems or can make them worse. Nearly half of homeless youth have been diagnosed with one or more psychiatric conditions, and most aren't getting any treatment. Having psychiatric problems tends to make young people more vulnerable to becoming homeless again in the future. The longer a child is homeless, the worse his or her condition can become.

Homeless kids are more likely to have witnessed violence in their families or communities, which contributes to their risk of mental problems. As many as one-fifth of all homeless preschoolers have emotional problems that need treatment, and by the time they reach the age of eight, one-third of children will have a major mental health disorder.

Children who are homeless also tend to have problems in school. They have lower test scores than other kids and have a higher rate of learning disabilities, and less than one in four homeless children graduates from high school. The longer kids remain homeless, the worse their problems at school. They often have low attendance rates and poor grades, and face social stigmatization.

Another disturbing trend among homeless children is they are more likely to use cigarettes, alcohol, or marijuana. Kids who use these substances before adulthood have more psychological and physical problems, and cigarette smoking among teens has been linked to major depressive disorder, disruptive behavior disorders, and other substance addiction problems in young people. Adolescent substance abuse also increases the risk of substance abuse as an adult. Children who are homeless are likely to experience hunger, stress, and abuse, or have a parent who abuses drugs or has mental or psychiatric disorders. All of these factors increase a child's risk of substance abuse. Homeless kids are also unlikely to take part in school programs designed to reduce or stop drug use, because they change schools often or miss classes.

Current Status

More needs to be done not only to cut down on homelessness but also to identify and treat mental health issues among homeless adults and children. Addressing and treating mental problems in homeless children especially can help improve their health and may help reduce the risk of future homelessness.

Homework in Psychotherapy

"Homework" refers to a psychotherapeutic technique that is frequently employed to extend treatment benefits into the real-life environment of clients. Homework assignments are most frequently used in cognitive behavioral therapies and are designed to be completed between psychotherapy sessions.

Description

The use of homework assignments is frequently utilized in psychotherapy. Homework assignments have several positive benefits to the psychotherapy process and have been shown to positively impact treatment outcomes. Homework allows clients to develop new insight and practice new skills in the real world outside of the treatment office. Homework also provides an opportunity for clients to experience success and develop confidence in the skills they have attained. Homework assignments allow clients to extend the therapeutic work and use between-session time to gain skills and insights. This extension of the therapy process results in gains that clients would otherwise pay for during a psychotherapy session resulting in cost savings to the client. In the early stages of psychotherapy, the therapist most often assigns homework. As treatment progresses, clients are encouraged to develop their own homework tailored to their specific needs.

There are many types of homework assignments. Reading assignments are a frequently employed task that provides psychoeducational benefits. Clients are often provided with reading material that will help them gain a deeper understanding of the issues they are addressing. For instance, frustrated parents of a child who has been newly diagnosed with attention-deficit hyperactivity disorder might be given a book to read on the challenges of parenting a hyperactive child. The therapist is confident that reading the book will be beneficial to the parents because the book is written from a parent's perspective and addresses many of the difficulties the client/parents are experiencing.

Between-session monitoring of behaviors, thoughts, feelings, physiological changes, interpersonal interactions, and a variety of other personal characteristics are frequently employed depending on the treatment goals and needs of the client. Evaluating and modifying inaccurate and dysfunctional thoughts while they are occurring are also frequently used in homework assignments. For instances, a client who presents with anxiety over taking exams reports that she has difficulty studying because she worries so much about the importance of the exam. The therapist helps her understand how thoughts and beliefs are what are causing the anxiety and inability to concentrate. She is given the tasks of writing down her thoughts about the exam and monitoring her emotions that correspond to those thoughts. During this process she discovers that her thought of "I'll never understand this" and "what if I fail?" are quite irrational given that she has consistently scored well in all of her previous exams. She is also given the tasks of finding more positive thoughts resulting in an increase in her ability to concentrate and a decrease in her anxiety.

Homework assignments are a very useful and frequently employed technique in psychotherapy.

Homework offers clients a way to extend the benefits of psychotherapy to between-session time periods and result in more positive and rapid treatment outcomes.

Homophobia/Heterosexism

Homophobia/heterosexism describes the irrational fear of, aversion to, or discriminatory beliefs, attitudes, and behaviors toward homosexual and gender-variant persons.

Definitions

- **Gender identity** is the way in which one self-identifies one's gender, or personal sense of being male or female.
- **Gender identity disorder,** or gender dysphoria, is a formal clinical diagnosis given to those experiencing significant social, emotional, or psychological stress from not identifying with their assigned gender.
- **Heterosexuality** describes the sexual orientation of people who are attracted to, aroused by, or romantically interested in members of the opposite sex/gender.
- **Homosexuality** describes the sexual orientation of those who are attracted to, aroused by, or romantically interested in members of the same sex/gender.
- **Transgender** describes individuals who are experiencing gender dysphoria and who do not personally identify with the gender they were assigned at birth.

Description

Homophobia describes discriminatory feelings, opinions, and actions against individuals who are gay, lesbian, bisexual, or transgender. Homophobia combines the words "homosexual," meaning "same sex," and "phobia," meaning "fear." Psychologist George Weinberg is credited with coining the term in the 1960s. Other terms/phrases related to homophobia are "heterosexism," "sexual prejudice," and "homosexual panic." Heterosexist views assume that all people are, or should be, heterosexual and that those who aren't are not "normal." Variations of the word "homophobia" include *homophobic*, an adjective describing these types of views or behaviors, and homophobe, a noun used to refer to a person who possesses homophobic views or displays homophobic actions. Homophobia can be expressed both covertly (believed or felt but not shared or displayed openly with others) and overtly (verbally and behaviorally expressed in public). Both are damaging to victims, breeding fear, prejudice, contempt, and hatred. Two recognized types of homophobia are *institutionalized homophobia*, in which same-sex discriminations are bred by religious, local, state-, or national-level organizations, and *internalized homophobia*, which describes when a person represses or hides his or her personal same-sex attractions out of fear, disgust, or shame. Extreme cases of homophobia have resulted in violence or hate crimes.

Homophobia has a long history dating back to ancient Greece. Social reformer and the first gay rights activist Jeremy Bentham wrote that homosexuality was a victimless crime back in 1785, though his writings weren't published until 1978, out of fear for retaliation. Homosexuals were another group targeted by the Nazis during the Holocaust. Homophobia became a topic of

mainstream debate in the late 1960s and early 1970s. The first gay march was held in front of Independence Hall in Philadelphia, Pennsylvania, in 1962, marking the beginning of the gay rights movement. Brenda Howard, a bisexual activist known as the "Mother of Pride," is credited with coordinating the first LGBT pride march in New York in 1970. The 1972 book *Society and the Healthy Homosexual* brought attention to the oppression suffered by gay people who were classified as having a disorder simply due to their sexual orientation. In it, Weinberg argued that homophobia was more appropriately categorized as a disorder than homosexuality was. Soon after, the American Psychiatric Association removed homosexuality from the list of mental disorders and has since worked to reduce the social stigma associated with homosexuality. Though this increased understanding and acceptance, prejudice against people who are homosexual continued. Traditionally, Southern states, where the majority of people hold conservative views, and identify as primarily Republican, are less accepting of LGBT people.

Some religious denominations, particularly the Roman Catholic Church, have been public about their stance on homosexual behavior. The Catholic Church teaches that homosexual behavior is morally wrong as it is unnatural, not engaged in for the purpose of producing children. The Bible refers specifically to the destruction of Sodom and Gomorrah for their people's homosexual activity. However, recently the church's statements, influenced by Pope Francis, have encouraged members to refrain from passing judgment and breeding contempt. All major Islamic sects forbid homosexual behavior, and most of them deem these acts as criminally punishable under law.

Current Status and Impact (Psychological Influence)

The passing of several policies and laws have improved living, working, and social conditions for homosexuals. The Netherlands was the first country to legalize same-sex marriage in 2001. Since that time other countries have followed, including Sweden, Belgium, Canada, South Africa, Spain, France, and Mexico. In the United States, legalization of same-sex marriage is determined by each state. As a result of the landmark ruling by the U.S. Supreme Court ruled on June 26, 2015, same-sex marriage is legal in all states. In 2011, the 1993 "Don't ask, don't tell" policy that forbids homosexuals from serving in the U.S. military was repealed. LGBT people continue to gain acceptance and equality. Gay pride celebrations now happen worldwide every June.

Homosexuality

Homosexuality describes the sexual orientation of those who are attracted to, aroused by, or romantically interested in members of the same sex/gender.

Definitions

- **Gender identity** is the way in which one self-identifies one's gender, or personal sense of being male or female.
- **Gender identity disorder,** or gender dysphoria, is a formal clinical diagnosis given to those experiencing significant social, emotional, or psychological stress from not identifying with their assigned gender.
- **Heterosexuality** describes the sexual orientation of people who are attracted to, aroused by,

or romantically interested in members of the opposite sex/gender.

- **Homophobia/heterosexism** describes the irrational fear of, aversion to, or discriminatory beliefs, attitudes, and behaviors toward homosexual and gender-variant persons.
- **LGBT** is an abbreviation for lesbian, gay, bisexual, and transgender, used to designate the greater group of nonheterosexual people.
- **Transgender** describes individuals who are experiencing gender dysphoria and who do not personally identify with the gender they were assigned at birth.

Description

"Homosexuality" refers to the sexual orientation of individuals who are romantically or sexually attracted to members of the same sex or gender. The term is derived from both the Greek word "homos," meaning "same," and the Latin "homo," meaning "man." It is recommended that "homosexual" be used as a noun rather than an adjective. Though "homosexuality" is most often used to refer to human beings, it has also been observed in various animal species. There are three categories of sexual orientation: heterosexuality, homosexuality, and bisexuality.

Homosexual or homosexuality may also be used to describe an individual's sexual and/or social identity as well as the individual's membership within the lesbian, gay, bisexual, transgender (LGBT) community. Common terminology used to describe a woman who is homosexual is "lesbian" and a man who is homosexual is "gay," though "gay" may also be generally used to refer to all members of the LGBT community. The process of disclosing to friends and family members one's sexual orientation is referred to as "coming out." Typically, this occurs during late adolescence and early adulthood, though some people may choose to hide their sexual identify for much longer.

Until the early 1970s, mental health practitioners and other medical professionals classified homosexuality a mental disorder. Debate is ongoing as to why a person develops a particular sexual orientation. Scientists support a biological/genetic explanation (nature) versus environmental contributors such as parent style and early childhood experiences (nurture). There is no evidence to support that a person chooses to be homosexual or not. Therefore, psychological counseling aimed at changing one's sexual orientation has been proven not effective by research. The conclusion is that homosexuality appears to be a normal variation in human sexual development.

Sexual relations among people of the same gender can be traced back to ancient time periods in Africa, Asia, and Europe. However, Karl-Maria Kertbeny, an Austrian writer, was the first person to anonymously publish the word "homosexual" in an 1869 pamphlet arguing against an antisodomy law. The book *Psychopathia Sexualis*, written by Richard von Krafft-Ebing in 1886, later popularized the terms "homosexual" and "heterosexual" used to describe sexual orientation. Since that time, these words have become part of common vernacular.

Current Status and Impact (Psychological Influence)

Homosexuals have experienced significant criticism, misunderstanding, and prejudice throughout history and on into the present day. Derogatory terms such as "homo," "faggot," "queer," and "fairy" have been used to refer to men who are homosexual. Likewise, slurs such as "lesbo," "butch," and "dyke" have been used to degrade women who are homosexual. "Homophobia," or "heterosexism," refers to discriminatory views of homosexuals and their lifestyles. Homophobia, however, is often the result of lack of knowledge, understanding, or personal experience with someone who is gay. Many religions continue to condemn acts of homosexuality and reject or seek to convert people who identify themselves as homosexuals. Others have welcomed LGBT people, and there are LGBT people serving as clergy and faith leaders. Significant progress has been made over the past few decades to increase visibility, understanding, and acceptance of those who are homosexual. Legal rights related to marriage, parenting, employment, military service, and equal access to health care have been debated. Anti-bullying legislation has also been passed to protect the rights of LGBT minors.

Horney, Karen (1885–1952)

Karen Horney (1885–1952) was a psychoanalyst who was born in Germany and is most famous for her developments in the area of character and character development, feminine psychology, the conception of the self, and her theories on neurosis.

Description

Horney departed from the Freudian view early on in her career, going on to develop her own psychoanalytic philosophies. During the first half of the 20th century, Horney emerged as a pioneering and well-respected psychologist and psychoanalyst. Like other scholarly analysts of her time, Horney was an active researcher. She used psychoanalysis both as an intervention for her clients and as a research method.

A central theme in Horney's character was her independence of mind. Therefore, she resisted Freudian orthodoxy, instead cultivating her own practical experience as a clinician. Her theory was thus greatly influenced from her own practice. She was quick to react against the domination of men and the male viewpoint in society, and challenged current theories of the role of women, female sexuality, and the institution of marriage. She also disagreed with the emphasis Freud and his followers placed on biology. She argued for the importance of social influences on human development.

Development

As early as 1922, Horney began to question the classical analytic view of women. She pointed out that the psychology of women was described from a man's point of view and that often women would unconsciously yielded to those notions. Horney believed that each person has a central inner force that is common to all people, yet possesses unique character. This force, which she called the real self, is the source of growth.

Horney was born near Hamburg, Germany, in 1885, to a Protestant upper-middle-class family. Her Norwegian father was a sea captain and a diligent Bible reader. Her mother was a free-thinking Dutch woman who encouraged her daughter to pursue medical studies. While growing up, she kept a well-written diary with many insights. Many years after her death her journals were compiled and published in 1980 under the title *The Adolescent Diaries of Karen Horney*.

Horney decided to attend medical school when women doctors were unheard of in Germany. She studied medicine at the universities of Freiburg, Gottingen, and Berlin. After completing her medical education, she became one of the first women to undergo Freud's new treatment of psychoanalysis. After entering analysis with Karl Abraham, she became a founding member of the Berlin Institute of Psychoanalysis. She also practiced and taught there.

In 1932, Franz Alexander asked Horney to join him in Chicago to codirect the first American Psychoanalytic Institute. Two years later, because of theoretical differences with Alexander, she left Chicago for New York, where she joined the New York Psychoanalytic Institute. She was also invited to teach at the New School of Social Research, which had established a reputation for attracting the best minds of European immigrants who had escaped Hitler. The school provided the setting for the development of her novel psychoanalytic notions. Her lectures there were extremely successful and were the basis of her first two books *The Neurotic Personality of Our Time* and *New Ways*

Karen Horney was a psychoanalyst who was born in Germany and is most famous for her work in the area of character and character development, the conception of the self, and her theories on neurosis. (Bettmann/Corbis)

in Psychoanalysis. Another one of her major works is *Self Analysis*.

Anxiety, a central and organizing theme in her work, is present in today's world at a level that Horney and her contemporaries would have been unable to imagine. Her recognition of the role of the family in both engendering and mediating anxiety, as well as in shaping the individual's response to it, is today reflected in systems and developmental theories.

Impact (Psychological Influence)

One of Horney's greatest contributions to the field of psychology is in the area of character and character development. She was especially interested in how basic anxiety gave rise to neurosis. She delineated three major character types, each with its own subdivisions and each a solution to the problem of high anxiety and insecurity. In one type, the individual banks excessively on success and power. In another type, the individual relies heavily on relations and membership in a larger social entity. In the third type, the individual leans heavily toward avoidance, disengagement, and resignation.

Many of the ideas currently circulating in the psychological and psychoanalytic communities correspond directly with the theories Horney put forth during the first half of the 20th century. While radical for her time, her conviction that cultural factors exert a powerful influence on our ideas of gender and development has passed into mainstream thought. The 1940s began a very creative period in American psychoanalysis, and Horney was a major player, opening up the field for ongoing creative development.

Hospitalization

Hospitalization is the act of placing a person as a patient in a formal medical facility.

Definition

- **Chronic** is used to describe a disorder that usually does not have a single cause, a specific onset, nor a stable set of symptoms. While cure may be possible, it is unlikely for advanced levels of the disease process.

Description

Hospitalization is one option available for critical or emergency medical care. "Hospitalization" is the term for medical treatment conducted within a professional clinical setting usually for a serious or life-threatening illness or condition. The picture is complex because there are a variety of institutions with the title hospital, from major medical centers with the highest level of medical expertise to simpler facilities that provide temporary or emergency care. This range also applies to care for those diagnosed with mental disorders. It also refers to inpatient treatment in a facility staffed by caregivers trained in psychiatry, psychology, and other fields.

The traditional full hospital setting is what in today's lingo is called tertiary care. Primary care is the simplest and most basic health care available within communities. An example of this is what a general practitioner can do during a regular office appointment. Secondary care steps up the level of services required. This is usually outpatient treatment, which requires more than one application and short-term, regularly scheduled visits. Tertiary care, or hospitalization, implies a medical facility, which provides a spectrum of choices for treating disease in a clinical setting from major surgery to physical therapy.

Modern hospitalization is an expensive and labor-intensive method of providing health care, and it has two aims. The first is to improve or rehabilitate a patient suffering from a curable illness. The second is the long-term care given to a patient who suffers from a chronic or incurable condition. These goals also apply to people diagnosed with mental disorders who can improve as well as for others who deal with issues chronically or more permanently.

Development

In the Middle Ages, hospitals began as charitable institutions founded by the church. In the 18th and 19th centuries, they came to be viewed as a service of society, not just of religion. Modern hospitals depend on a trained staff of nursing professionals even more than they do on physicians who are usually individual expert entrepreneurs within the health-care system. In fact it is noted that it was the professionalization of nursing that was the most important element in changing hospital life.

From the 18th century on, those judged mentally ill by society were increasingly confined, at times like prisoners, to institutions called asylums for the insane. This was especially true for those who had violent or self-destructive tendencies. Hospitalization was widespread and socially accepted. Many patients lived their whole lives within the confines of institutionalized hospital settings.

After World War II, mood-altering drugs began to supplement and then replace other forms of treatment. Their ability to control symptoms, such as hallucinations, seemed to create new options other than permanent hospitalization. During the 1980s many mental hospitals and institutions were shut down and the patients who had lived there were discharged. These people were sent to lead their lives in the outside world where it was presumed they would integrate into society. Deinstitutionalization was the movement of the day and drastically reduced the use of hospitalization to treat chronic mental disorders.

Current Status

While hospitalization remains an option for the severely mentally ill, it is the exception and not the rule. Controversies about costs, treatment protocols, and control within the health-care environment occur often. Because of this, hospitalization is now seen as the option of last resort. This is especially true for health-care insurance providers whose rules control payments for services, medications, and other therapies.

One of the greatest challenges in hospitalization is the growing population of elderly patients and the dilemmas that deinstitutionalization causes for caregivers and families of those who are sick and need assistance. This is especially true as the number of elderly patients with dementia or Alzheimer's gets larger. These people cannot live alone and their families often are unable to care for them adequately. It is no surprise therefore that the greatest costs associated with hospitalization are for the elderly in the final years of their lives.

Another hospitalization option that is being used is partial hospitalization. This would be considered a

secondary-care option rather than tertiary care. Successful use of partial hospitalization as a treatment option for patients requiring intensive services is usually determined after more intensive care. Continuing improvements in outpatient community services remain a great social challenge, including partial hospitalization and intensive outpatient treatment.

House-Tree-Person Test

The House-Tree-Person (HTP) test is a projective drawing technique used originally as a measure of intelligence and later as a tool to investigate potential exposure to abuse.

Description

The House-Tree-Person test is often used to gain insight for the presence of abuse and child's perception of safety and security. Although the test was originally developed to assess a child's intelligence, it has since grown to include an assessment of personality dynamics and more.

The House-Tree-Person projective technique was first developed by John Buck in 1948. These three objects were selected as Buck believed that they would be symbolic representations of various aspects of the individual's life. For example, the house represents the subject's home life and family relationships. The tree is the symbolic representation of the relationships the client experiences in his or her environment. The person is associated with the client's interpersonal relationships. Buck felt that creativity represented personality characteristics. It was thought that through drawing, clients would project a self-portrait that can be used to assess personality dynamics.

Development and Current Status

Individuals are asked to draw these three objects and given no further description. After completing the drawing, the clients are sometimes asked to describe the house, tree, and person as well as how they feel about each other. Analyzing a person's drawings dates back to at least 1885, which was the earliest written article on the topic. The testing format originally recommended by Buck was that the client would sketch the picture with pencil and then answer 60 questions about the drawings. Then the client would complete the drawings again only this time he or she would have available eight or more crayons of various colors. Again, this was followed by the 60 questions about the drawings.

Projective tests often have validity and reliability challenges due to the wide variability among drawings, and this test is no different. Attempts to standardize the HTP test have repeatedly fallen short. This specific test has practical uses and is very easy to administer. However, the analyses are extremely subjective.

This projective assessment remains popular as it can be given to anyone over the age of three years. It is quick and easy to use and is considered to be minimally invasive. It is commonly used despite variances in reliability. There continues to be a growing interest in the psychological connections to drawings.

Human Trafficking

The term "human trafficking" refers to the buying, selling, and smuggling of human slaves, mostly women and children, for profit.

Definitions

- **Bonded labor**, also referred to as *debt bondage*, defines when a person (adult or child) is enslaved and ordered to engage in some form of work (service industry, prostitution, sweatshop, or farming) to pay off a debt owed.
- **Forced labor,** or *involuntary servitude*, refers to the exploitation of workers who are vulnerable because of a debt owed, age, gender, or ethnic/cultural background.
- **People smuggling,** also known as *migrant smuggling*, defines the illegal movement of people out of a place, typically across an international border, with their consent.
- **Prostitution** refers to the business of engaging in some type of sexual behavior in exchange for money or some other benefit/compensation.
- **Servile marriage** defines when a person, typically female, is forced to enter into marriage against his or her will.
- **Sex trafficking** refers to the trading or movement of people, usually women, for the purpose of sexual exploitation.

Description

Human trafficking describes the process of purchasing, selling, and smuggling human slaves for the purpose of sexual pleasure, exploitation, forced labor, and/or financial profit. The majority of acts involve sexual exploitation. Most victims are female; half are children. Those who fall prey to trafficking may be runaways, victims of abuse, or refugees. Some are trafficked for the purpose of organ harvesting. Trafficking is considered a modern-day form of human enslavement as these crimes violate and exploit an individual's human rights. The acts often involve abduction, deception, fraud, and abuse of power. Most victims who suffer human enslavement have been coerced by their captors. They may be promised a better life, freedom, safe harbor, or money. Claims made by traffickers are untrue and misleading. Traffickers prey on

victims' vulnerability, make fraudulent claims to lure victims, and then exploit them. Subsequently, victims suffer from significant physical, emotional, and psychological distress related to their experiences, which may include starvation, rape, abuse, neglect, beatings, confinement, forced drug use, prostitution, and involuntary servitude. Most child victims end up evidencing suicidal tendencies.

Human trafficking is an illegal activity that can occur within a country or across borders. It affects almost every country in the world. Belgium, Greece, Israel, Italy, Japan, Thailand, and the Netherlands are among the nations that rank highest in human trafficking. Crimes have also been reported in all 50 U.S. states and some territories. Most of the human trafficking in the United States occurs in California, Florida, and New York.

The United Nations sought to establish consensus among countries by offering a broad, flexible definition that could empower domestic legal systems to respond proactively to trafficking through the *Protocol to Prevent, Suppress, and Punish Trafficking in Persons, Especially Women and Children*, commonly referred to as *Trafficking Protocol*, which was established on December 25, 2003. The document was signed by 117 countries and has since been used as a guiding document in protecting human rights worldwide. Most countries now have laws that criminalize the practice of human trafficking. Article 5 of the *Trafficking in Persons Protocol* requires that human trafficking crimes be prosecuted through domestic legislation. This includes attempts to commit trafficking offenses, participation as an accomplice in these crimes, and organizing or directing others to commit trafficking. Cross-border cooperation in both investigations and prosecutions is encouraged in order to prevent the spread of these heinous activities.

Acts of trafficking are often seen in conjunction with other crimes, including drug smuggling and gun trade. Criminal organizations including the mafia and terrorist units such as the Taliban have been known to engage in human trafficking. These groups are attracted to this type of crime because unlike drugs, humans can be sold over and over again. Natural disasters and epidemics have also been associated with increased incidences of trafficking. Following a hurricane, tsunami, tornado, or storm, people may be displaced from their homes and unable to locate loved ones, leading to increased vulnerability and susceptibility to predators. The AIDS epidemic in Africa also contributed to high incidences of trafficking victims given that many children were left orphaned.

Impact (Psychological Influence)

Human trafficking has become an increasing international concern over the past decade and even been deemed the greatest human rights challenge of this century. Estimates suggest that millions and millions of people are trafficked every year resulting in yearly profits upward of $30 billion. In 2007, U.S. Senate established January 11 as the National Day of Human Trafficking Awareness to shed light on this global problem. Soon after, President Barak Obama declared January National Slavery and Human Trafficking Prevention Month. The United Nations Office on Drugs and Crime's strategic plan is focused on (1) research, education, and consciousness raising, (2) promoting the protocol, and (3) strengthening partnerships and coordination among affected groups. Nonprofit groups have also been established to provide support to victims by offering humanitarian aid, safety relocation programs, and counseling services.

Humanistic Psychotherapy

Humanistic psychotherapies include person-centered psychotherapy, gestalt psychotherapy, existential psychotherapy, and other approaches to helping based on humanistic principles.

Description

The humanistic approach to counseling focuses on the worth and dignity of the individual and the human potential for personal growth, awareness, creativity, choice, and self-direction.

Development

Humanistic psychology began to develop in the 1940s partly in response to behaviorism and psychoanalytic theory, which were the dominant theories of human behavior in the first half the 20th century. Behaviorism and psychoanalytic theories are referred to as "deterministic" theories. This means people have no real choice in how they behave. These theories are also considered "reductionist" theories, meaning they reduce complex human experiences and dynamics into just a few simplified components.

Behaviorism, or the science of behavior, is regarded as the "first force" in psychology as it was the focus of early psychological inquiry. Behaviorism taught that people's behavior was determined by conditioned responses. Just as dogs can be taught or "conditioned" to respond to stimuli, so human behavior is determined by their conditioning. Behaviorists essentially ignored the conscious mind, believing whatever was happening in the here and now had little impact on what had been conditioned. Psychoanalytic theory, the second force in psychology, considered people's behavior to be determined by their unconscious instincts and sexual drives. Psychoanalysts minimized the conscious here and now, believing it was only a weak expression of what was held in the unconscious. Behaviorism and psychoanalytic theory gave little thought to how personal values, consciousness, reasoning, creativity, meaning, or intentions impacted behaviors.

Humanistic psychology provided an alternative to these deterministic and reductionist perspectives of human development and behavior. Lead by individuals such as Abraham Maslow, Rollo May, and Carl Rogers, the humanistic movement emerged as a third force in psychology and has become the dominant philosophy of the helping professions. Humanistic psychology offered a new way of understanding human nature, how to study human behavior, and how to more effectively provide psychological help to individuals. Humanistic principles are found in the majority of current psychological helping theories.

Current Status

A holistic approach and the principle of irreducibility is a core value of humanistic psychotherapy. Irreducibility is the belief that humans are not irreducible to other phenomena. This means that people are understood as whole complex beings that interact and are interconnected with their social and physical environment as they develop and grow.

There are several principles that unify the differing approaches to humanistic psychotherapy. The humanistic approach to psychotherapy is built on the understanding that humans are able to make choices about their lives and are responsible for their own growth and development. A humanistic perspective takes a very positive view of people who are believed to operate from a sense of purpose and are capable of self-understanding, self-direction, and self-healing. They are able to make constructive changes in their lives and strive to become self-actualized and fully functioning. Natural human creativity and resourcefulness is valued as a powerful force in the process of change and growth.

Humanistic psychotherapy is here and now oriented. Fully experiencing the present moment is crucial to the therapy process. Learning to accept oneself and moving toward positive change are emphasized. Client's use of internal resources such as motivation, readiness to change, self-insight, and psychological mindedness are important determinants of change. Humanistic psychotherapy stresses the client's active role and responsibilities in the change process. Change occurs as people move toward congruence between what they wish they were like and what they are actually like.

A positive therapeutic relationship is the primary way change occurs in humanistic psychotherapy. The

role of the therapist is to believe in the client's inner resources and desire to be fully functional while providing a climate of trust and security. The therapist's positive regard, unconditional acceptance, respect, warmth, and empathic attitude toward the client provide a safe environment for self-exploration and change. The quality of the therapeutic relationship is considered to be more important than the techniques utilized in the change process.

Humanistic psychotherapy is based on a positive view of human nature. It relies on the belief that people are self-aware, are self-directing, and strive toward becoming fully functional. Humanistic psychotherapy brought into focus the importance of the client–therapist relationship and the role therapist attitudes and beliefs about clients play in the change process.

Hypersomnia and Hypersomnolence Disorders

"Hypersomnia" refers to difficulty staying awake during the day. Hypersomnolence disorder is a sleep disorder characterized by a recurrent pattern of excessive daytime sleepiness.

Definitions

- **Behavior therapy** is a form of psychotherapy that focuses on identifying and changing maladaptive behaviors.
- **Continuous positive airway pressure (CPAP)** is a device for treating sleep apnea that delivers air into airways through a specially designed face or nasal mask.
- **Insomnia disorder** is a sleep disorder characterized by persistent difficulty in falling asleep and staying asleep.
- **Sleep disorders** are a group of mental disorders characterized by disturbance in the amount and quality of sleep and that cause significant emotional distress or interfere with daily functioning.

Description and Diagnosis

Hypersomnolence disorder is a sleep disorder characterized by difficulty staying awake during the day. Individuals with this disorder can fall asleep at anytime and anywhere. For example, they may nod off at work or even when they are driving. Typically, they experience other sleep-related problems such as low energy and difficulty with concentration. This disorder is the mirror opposite of insomnia disorder in which limited sleep, rather than excessive sleep, is the problem.

Individuals with this disorder report disproportionate sleepiness, despite having slept an appropriate amount of time the preceding night. Individuals may experience periodic drifting into sleep during the day and may report that prolonged periods of sleep fail to be revitalizing (restorative). Difficulties may arise as individuals have difficulty awakening from sleep and may encounter abrupt and unintended sleep during quiet, low-stimulus activities. This increased need for sleep may adversely affect a person's concentration and memory during daily work, social, and school-related activities. Typically, the individual reports arriving late for work or other social engagements, fulfilling typical obligations, and having difficulty driving. These unintentional and intrusive moments of sleep may be dangerous if they occur when the individual operates heavy equipment or drive a car. About 40% of adults experience symptoms of hypersomnia on occasion although only 5%–10% of those evaluated in sleep disorders clinics are diagnosed with the disorder (American Psychiatric Association, 2013).

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, individuals can be diagnosed with this disorder if they exhibit extreme sleepiness, regardless of whether they had at least seven hours of sleep. Individuals reported experiencing repeatedly falling asleep during the day, sleeping excessively (more than nine hours per day) without feeling refreshed, and having difficulty fully awakening after being suddenly aroused from sleep. Individuals with this disorder may also have difficulty with concentration, connecting with others, and work-related activities. This sleep difficulty must have occurred three times per week or more and have lasted for three months or more. This difficulty must also cause significant distress for the individual or result in significant level of impaired functioning. In addition, the disorder cannot be the result of a substance, medication, other medical condition, or another sleep disorder (American Psychiatric Association, 2013).

As with other sleep disorders, the cause of hypersomnia and hypersomnolence disorder can be varied. It may be caused by another sleep disorder such as narcolepsy or sleep apnea. It can be due to drug or alcohol abuse. Sometimes, a medical condition such as multiple sclerosis, epilepsy, clinical depression, or obesity can contribute to it. Certain medications that are sedating can cause it. Lifestyle and environmental factors can also cause or exacerbate (worsen) it. These include poor sleep hygiene habits, such as watching television in bed or not having a regular bedtime schedule. It can also include changes in sleep habits and surroundings such as noise, temperature, light, or sleeping in a different bed. Common environmental factors that might be involved include jet lag or working a late shift.

Treatment

Treatment of hypersomnolence should begin with a medical evaluation, which might include a polysomnography and other sleep tests. Treatment depends on the cause of this sleep disorder. For instance, if it is caused by sleep apnea, the treatment is likely to be continuous positive airway pressure (CPAP). If it is due to a medication that causes drowsiness, another medication may be prescribed instead. If a cause is not determined, behavior therapy interventions and sleep hygiene may be used. Establishing better sleep hygiene may be sufficient. For example, going to bed earlier and getting more sleep at night may help considerably. This may also include reducing or eliminating alcohol and caffeine consumption. Specific medication to treat hypersomnia may be tried. These include antidepressants, such as Prozac, or stimulants like Ritalin or Provigil. Xyrem that is used to treat excessive daytime sleepiness related to narcolepsy might be considered.

Hypnotherapy

Hypnotherapy is a form of psychotherapy that uses a hypnotic state to increase motivation or change behavioral patterns.

Definitions

- **Anxiety** is a negative emotional state characterized by feelings of nervousness, worry, and apprehension about imagined danger.
- **Cognitive behavior therapy** is a type of psychotherapy that focuses on maladaptive (problematic) behaviors, emotions, and thoughts. It is also called CBT.

- **Depression** is an emotional state characterized by feelings of sadness, low self-esteem, guilt, or the reduced ability to enjoy life.
- **Guided relaxation** is a technique used for relaxation and mental visualization (imagery) in order to improve an individual's mood and physical well-being.
- **Hypnotic state** is an induced state of relaxation and concentration that permits deeper parts of the mind to become more accessible.
- **Psychotherapy** is a psychological method for achieving desired changes in thinking, feeling, and behavior.
- **Stress** is a state of emotional or mental tension or strain, which results from very unfavorable or demanding circumstances.
- **Subconscious** is that part of the conscious mind which consists of information that is not in awareness unless attention is directed to it. It is also called the preconscious.

Description

Hypnotherapy is a form of psychotherapy used to promote subconscious change in an individual by implementing new thoughts, attitudes, responses, feelings, or behaviors. Hypnotherapy may be used to help relieve symptoms an individual is experiencing. Some of these symptoms include emotional pain, chronic pain, and dysfunctional behaviors and habits (e.g., smoking, difficulty sleeping, overeating).

There are two theories of what occurs during hypnotherapy. The altered state theory suggests that hypnotherapy is an altered state of mind. The non-state theory suggests that hypnotherapy is a form of a role enactment that is imaginative. Hypnotherapy uses several techniques to bring a heightened state of awareness to an individual. Some of these techniques include intense concentration and guided relaxation. During the process of hypnosis (hypnotherapy) an individual's attention becomes very focused, while in the hypnotic state, anything occurring around the individual becomes ignored. While an individual is in a hypnotic state, a trained therapist will help guide the individual to focus on specific tasks or thoughts. During this process an individual will examine and explore painful feelings, thoughts, and memories that may be masked in his or her conscious minds. Furthermore, hypnotherapy assists individuals in understanding things differently, such as blocking the awareness of pain. Hypnotherapy has shown to be effective for individuals who experience depression and anxiety.

Developments and Current Status

Hypnotherapy was developed by James Braid (1795–1860). Braid was a Scottish surgeon who is best known for his theory and practice of hypnotism. Hypnotherapy continues to be effective in reducing anxiety and pain. Currently, hypnotherapy may not be a form of treatment used alone. Many individuals who are being treated with hypnotherapy are participating in psychotherapy. Although hypnotherapy can generate an extremely developed relaxed state of concentration and focused attention for an individual, it may not be the only form of treatment used for individuals who are experiencing difficulties. Cognitive behavior therapy is another form of therapy that can be used concurrently with hypnotherapy for treatment. A benefit to hypnotherapy is that individuals can learn to eventually hypnotize themselves outside of a hypnotherapy session. This can become more cost effective for an individual in addition to being able to improve sleep, reduce pain, and ease some symptoms of anxiety and depression on his or her own.

Hypochondriasis

Hypochondriasis is a condition characterized by a preoccupation with having a serious medical condition based on a misinterpretation of bodily symptoms.

Definitions

- **Cognitive behavior therapy** is a type of psychotherapy that focuses on maladaptive (faulty) beliefs, behaviors, and emotions.
- **DSM-5** stands for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, which is a diagnostic system used by professionals to identify mental disorders with specific diagnostic criteria.
- **Illness anxiety disorder** is a mental disorder characterized by severe anxiety and a preoccupation of having a serious medical condition. Previously, this disorder was called hypochondriasis.
- **Malingering** is the practice of intentionally exaggerating or faking physical or psychological symptoms for personal gain. It is also referred to as fictitious illness.
- **Mindfulness practices** are intentional activities that foster living in the present moment and awareness that is nonjudgmental and accepting.
- **Somatic symptom disorder** is a mental disorder characterized by bodily symptoms that are very distressing or result in disrupted functioning,

Description

Hypochondriasis is a condition characterized by an obsessive preoccupation about one's health, especially as it pertains to the misinterpretations of bodily sensations or symptoms. Individuals with this disorder spend significant times analyzing and interpreting insignificant physical sensation. An example of this is that while experiencing a brief headache, the individual becomes concerned that she has a brain tumor. Those with this disorder tend to research symptoms of illnesses and make their own diagnosis about medical conditions. While they may seek medical evaluation, they are likely to discount or reject the physician's professional opinions and formal diagnoses. They are also likely to seek numerous second opinions, if given a clean bill of health. It is believed that some use this behavior as a way to get attention. Typically, those who have such a preoccupation about their health are not engaging in purposeful malingering.

Before DSM-5, hypochondriasis was a formal diagnosis. When it was a formal diagnosis, it was estimated to affect approximately 4% of the population. It should be noted that hypochondriasis differs from two similar but different DSM-5 diagnoses: illness anxiety disorder and somatic symptom disorder. Recall that "hypochondriasis" is a general term for describing a preoccupation about physical symptoms and disease. Illness anxiety disorder involves a concern for symptoms but primarily describes individuals with a distressing level of anxiety about their health. This is in contrast to somatic symptom disorder, which describes those whose primary symptoms are a distressing preoccupation about physical symptoms or result in impaired functioning.

Treatment

Treatment for this condition is similar to what is employed in both illness anxiety disorder and somatic symptom disorder. Most often, individuals will be treated with some form of psychotherapy. It is important to recognize that those with this condition may feel others do not take them seriously. Therefore, it is imperative that the clinician form a strong alliance with the individual in order to foster trust and cooperation. Cognitive behavior therapy (CBT) is an effective approach used with individuals who experience a preoccupation about their health. The focus of CBT is to change the beliefs system surrounding illness and bodily symptoms, thereby reducing the anxiety. Another aim of therapy may be to desensitize the individual to his or her physical sensations, thereby reducing the focus on his or her body. Another form of therapy used with this condition is mindfulness. It can help individuals both cope with and

accept the anxious feelings regarding both their body and preoccupation about illness. If effective, the result of both treatments is a reduction in preoccupation and misinterpretation and an increased sense of well-being.

Hypomania

Hypomania is a mental state characterized by an abnormally and persistently elevated or irritable mood and increased activity or energy.

Definitions

- **Antidepressants** are prescription medications that are primarily used to treat depression and depressive disorders.
- **Bipolar disorder** is a mental health disorder characterized by a history of manic episodes (bipolar I disorder), mixed, or hypomanic episodes (bipolar II disorder), usually with one or more depressive episodes.
- **Cognitive behavior therapy** is a form of psychotherapy that focuses on changing faulty behaviors, emotions, and thoughts. It is also known as CBT.
- ***Diagnostic and Statistical Manual of Mental Disorders*** is the handbook mental health professionals use to diagnose mental disorders. The current edition (fifth) is known as DSM-5.
- M**ania** is a mental state of expansive, elated, or irritable mood with increased energy or activity.
- **Narcissistic personality disorder** is a mental disorder characterized by a pattern of grandiosity, need to be admired by others, and lack of empathy.
- **Stimulant** is a drug, which increases brain activity and produces a sense of alertness, euphoria, endurance, and productivity, or suppresses appetite. Examples are cocaine, amphetamines, and Ritalin.

Description

Hypomania is a mental state similar to mania but is classified as a milder form of mania. Hypomania is characterized by a period of a persistently and abnormally extensive, elevated, or irritable mood and persistently and abnormally increased activity or energy. These episodes last at least four consecutive days, are present most of the day, and occur nearly every day. Individuals who are experiencing a hypomanic episode are extremely talkative, energetic, and self-assured. Some symptoms associated with hypomania include grandiosity (exaggerated belief in one's importance), decreased need for sleep, distractibility, hypersexuality, and creativity. Individuals in a hypomanic state spend an excessive amount of time in activities that have a high potential for unpleasant consequences (e.g., engaging in buying sprees, sexual indiscretions, or unwise business deals). It can become problematic if the individual engages in such risky behaviors. Hypomania does not normally interfere with occupational functioning or interaction with others.

Hypomania is most often associated with bipolar disorder. Hypomania can also be caused from side affects of several medications used to treat bipolar disorder (e.g., antidepressants). When hypomania occurs from the side effects of medications, usually the health-care provider will discontinue the use of the drug or antidepressant that prompted the episode. In most cases, the use of a stimulant will return the individual to a normal mood. Hypomania has also been linked to narcissistic personality disorder, which is a

personality disorder listed in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*. In this disorder, individuals engage in grandiose behaviors, are preoccupied with power and success, and believe that he or she has a sense of entitlement.

Treatment

In addition to medication treatment, cognitive behavior therapy (CBT) has been shown to be effective for individuals with hypomania. CBT can help individuals control their impulses during hypomanic episodes. Having an individual keep a daily journal of his or her thoughts can be helpful. This technique can assist the individual in taking a realistic look at his or her thoughts and actions. For example, an individual can begin to recognize the negative impact of underestimating risky situations (e.g., sexual indiscretions, shopping sprees). Talking such situations through with someone whom the individual trusts can assist the individual in testing the reality of his or her thoughts and beliefs

Hypomanic Personality Disorder

Hypomanic personality disorder is a mental disorder characterized by an enduring pattern of hypomania that shapes cognition, attitudes, and identity. This pattern predictably shapes an individual's behavior and relationships with others.

Definitions

- **Cyclothymic disorder** is a mental disorder characterized by alternating cycles of hypomanic and depressive periods with symptoms like those of some depressive disorders but of lesser severity.
- **Depressive disorders** are a group of mental disorders characterized by a sad or irritable mood and cognitive and physical changes that significantly disrupt an individual's daily functioning. These disorders include bipolar disorder, major depressive disorder, and persistent depressive disorder.
- **Depressive personality disorder** is a mental disorder characterized by a persistent and pervasive pattern of unhappiness, low self-esteem, pessimism, guilt, and an inability to relax and experience pleasure.
- **Hypomania** is a mental state similar to mania but less intense.
- **Mania** is a mental state of expansive, elevated, or irritable mood with increased energy or activity.
- **Personality disorder** is a long-standing pattern of maladaptive (problematic) behavior, thoughts, and emotions that deviates from the accepted norms of an individual's culture.

Description and Diagnosis

Hypomanic personality disorder is a mental disorder characterized by an enduring pattern of hypomania that shapes cognition, attitudes, and identity, and which significantly influences an individual's behavior and relationships with others. Individuals with this personality are described as cheerful, exuberant, articulate, overly optimistic, and carefree. These individuals tend to be overconfident, self-assured, boastful,

and grandiose. They are also described as extroverted, people-oriented, and energetic. Potentially troubling is their propensity for being uninhibited, thrill seeking, overinvolved, meddlesome, and occasional episodes of rageful anger. While they may show considerable charm and wit, their relations with others tend to be superficial.

This disorder is similar to hypomania and cyclothymic disorder. All three of these disorders are characterized by elevated moods. However, hypomania and cyclothymic disorder are episodic disorders, In contrast, hypomanic personality disorder is a consistent, enduring pattern of elevated mood and energy, movement, and self-inflation. It is noteworthy that hypomanic personality disorder is listed among the personality disorders in the *Psychodynamic Diagnostic Manual* (PDM). However, it is not listed in the *Diagnostic and Statistical Manual of Mental Disorders*, *Fifth Edition*.

According to the PDM, individuals can be diagnosed with this disorder if they exhibit a high energy temperament (biological disposition or pattern). The central tension and preoccupation in their lives is an overriding sense of grief. Their basic emotional state is one of elation, rage, unconscious sadness, and grief. They tend to have a characteristically maladaptive belief about themselves: "If I stop running and get close to someone, I'll be traumatically abandoned, so I'll leave first." Their maladaptive belief about others tends to be, "Others can be charmed into not seeing the qualities that make people inevitably reject me." Their primary ways of defending themselves include denial, self-inflation, and devaluation of others. According to the PDM, this disorder is the converse or polar opposite of the depressive personality disorder (PDM Task Force, 2006).

The exact cause of this personality disorder is not well understood. However, a variety of factors may be causative. These include an energetic temperament, as well as needing and enjoying pleasure while at the same time fearing and being distressed by grief and depression. According to the *Psychodynamic Diagnostic Manual* (2006), this disorder is found in individuals with underlying depressive dynamics, which are obscured by denial of depression. This denial produces a relatively stable state of mood inflation, lack of guilt, and self-inflation.

Treatment

The clinical treatment of this disorder usually involves psychotherapy. Therapists tend to find these individuals initially quite interesting and entertaining but soon feel confused, overstimulated, irritated, and distanced by them. These individuals are typically highly resistant to psychotherapy. They are difficult to engage in the process of therapy because of their tendency to leave relationships in which they are tempted to attach and commit to. Instead, they become unconsciously terrified of being abandoned by the therapist and react to this fear by abandoning the therapist and leaving treatment. Knowledge of the dynamics of this disorder allows therapists to point out the lifetime pattern of abrupt flight from relationships. They can then attempt to preempt a similar flight from therapy by negotiating an agreement that the individual will continue coming for a given number of sessions after any abrupt, unilateral decision by the individual to stop treatment.

Ideas of Reference

Ideas of reference are the belief that events, the behaviors, or remarks of others have a particular significance to oneself when, in fact, they do not.

Definitions

- **Bipolar disorders** are a group of mental disorders characterized by changes in mood and in energy (e.g., being highly irritable and impulsive while not needing sleep). These disorders include bipolar I disorder, bipolar II disorder, and cyclothymic disorder.
- **Delusions** are fixed false beliefs that persist despite contrary evidence.
- **Delusions of reference** are strongly held belief that events, the behaviors, or remarks of others have a particular and unusual significance to oneself, when, in fact, they do not. Unlike ideas of reference, delusions of reference must disrupt daily functioning.
- **Depressive phase** is a mental state of sad mood, reduced ability to enjoy life, and decreased energy or activity seen in during the course of a bipolar disorder.
- **Manic phase** is a mental state characterized by expansive, elevated, or irritable mood with increased energy or activity seen in during the course of a bipolar disorder.
- **Psychosis and psychotic disorder** is a severe mental condition in which an individual loses touch with reality. Symptoms can include hallucinations, delusions, and disordered thinking.

Description

Ideas of reference are beliefs that have a particular significance for an individual but are not delusions. In contrast, ideas of delusion are delusions with special personal significance. The terms "ideas of reference" and "delusions of reference" are often used interchangeably. Even though they share some similarities, they are different and it is useful to differentiate them. When ideas of reference reach the point of causing impairment of functioning, they are called delusions of reference. In other words, when a belief is held with delusional conviction, it is a delusion of references (American Psychiatric Association, 2013). In delusion of reference, individuals mistakenly believe that they are the object of remarks, behaviors, or ridicule that is actually benign or has nothing to do with them. These delusions are common in those with bipolar disorder.

Here are some examples of ideas of reference. An adolescent male who has the sense that a radio deejay is talking directly to him even though this is not the case. Or, take the young mother who feels she is not a very good parent. She regularly follows an Internet blog on parenting and believes it has hidden meanings for her. Another example is a nervous teenager who somehow believes that everyone in a small group of students is talking about her when she enters the school cafeteria. But later she is able to acknowledge that is unlikely that the group was talking just about her. This suggests the belief was not strongly held, which makes it an idea of reference rather than an idea of delusion.

By comparison, here are some examples of a delusion of reference. An elderly female would rarely leave her apartment because she came to believe that all the conversation and laughter she would hear when she was outside was directed at her. A wheel chair–bound male insists to his caregiver that secret messages about him are being broadcast in a weekly television program. So, he records each programs and watches them repeatedly. In both examples, there is a disruption in functioning for both individuals. For the elderly female, it is being confined to her apartment to feel safe even though there is no obvious threat. For the male, it is spending hours a week trying to find clues that are not there.

Delusions of reference are common in bipolar disorder. Those with bipolar disorder manifest this type of delusion by projecting themselves into conversations and remarks for which they believe that they are being targeted. Such delusions add to the other paranoid thoughts which further trouble them and impair their daily basis. These delusions tend to deepen as they enter into a manic phase. However, such delusions may also remain in the depressive phase and heighten the psychosis these individuals are already experiencing.

Identity and Identity Formation

Identity formation is the psychological concept of how an individual's personality is developed and forms a unique identity from all other people.

Description

Personality and personal identity formation occurs as a developmental process beginning at birth. Erik Erikson (1902–1994) was one of the first psychologists to articulate a comprehensive theory of how an individual's personality is formed. His theory is referred to as Erikson's Theory of Psychosocial Development. Erikson believed that individuals develop throughout their lifespan and that identity and self-awareness form in the unique environment in which a child is raised. Impacted by social, biological, and psychological factors, people are faced with certain age-related task, challenges, and crisis that must be mastered in order for a healthy personality to form. Erikson's "crisis" refers to a time of deep realization, or a turning point, in which lasting change occurs rather than a time of severe emotional distress. Erikson postulated eight distinct age-related challenges that must be mastered in order to successfully move on to the next stage of development. Erikson's fifth stage, Identity versus Role Confusion, is the stage in which a person is challenged with the task of developing a unique sense of personal identity that will help him or her meet the challenges of adulthood or remain confused about who he or she really is and how he or she fits into society.

The stage Identity versus Role Confusion occurs between the ages of 12 and 20 years as adolescents transition from childhood to adulthood. Erikson coined the phrase "identity crisis" to describe a time of particularly deep reflection, confusion, and strife as an adolescent strives to develop a unique and distinct self-identification separate from that of his or her parents. During this time of life, major biological, physical, emotional, cognitive, sexual, and social changes are occurring. It is in this highly active and changing context that the most important question of adolescents is addressed: "Who am I?" Answering this question involves a complex array of social interactions in which feedback and reactions from friends, family, and others become central in the discovery of what is valued and important to the individual. It is a time of intense mental, emotional, and social exploration as the adolescent strives to fit into society and gain acceptance into valued social groups in meaningful and fulfilling ways. This is a time of great exploration in which adolescents explore their independence from their parents, their social roles and what groups to belong to, their own spiritual beliefs and values, occupational and career interest, sexual orientation, ways of expressing oneself, and ways of thinking and behaving. Failure to establish a satisfactory identity results

in role confusion in which the adolescent has no clear understanding of his or her strengths and weaknesses and moves into adulthood without a sense of how he or she fits in or what direction his or her life should take.

Building on Erikson's psychosocial stages, James Marcia, a Canadian developmental psychologist, contended that the level of adolescent identity development was related to the degree to which an individual has explored and committed to an occupational choice, spiritual belief, and political ideology. Marcia defined "crisis" as a period of engagement in choosing between meaningful alternatives and "commitment" as how strongly an individual has identified with the role or value. Marcia identified four possible outcomes, or "statuses," of identity development. "Identity Achievement" consists of a crisis period in which past values are reexamined and present choices evaluated and seriously considered with a clear commitment made to a new role or value. Individuals who experience "Identity Diffusion" may or may not have experienced a crisis period and are undecided, unconcerned, and uncommitted to occupational, spiritual, and ideological choices. There are two statuses that lie somewhere between achievement and diffusion. The first of these is "Identity Moratorium" in which an individual is actively engaged in a crisis and is struggling to make a commitment to a role, value, or ideology. Finally, the "Identity Foreclosure" status is distinguished by individuals who have not experienced a crisis but have expressed a commitment to a role or value. These individuals tend to conform to the expectation of others, such as parents, and have not explored other options.

Identity formation is the process in which an individual develops and establishes a lasting set of personal characteristics distinct from that of his or her parents. Successful identity formation results in a stable sense of belonging to a larger social group with shared values and ideologies.

Illness Anxiety Disorder

Illness anxiety disorder is a mental disorder characterized by severe anxiety and a preoccupation of having a serious medical condition. Previously, this disorder was called hypochondriasis

Definitions

- **Cognitive behavior therapy** is a type of psychotherapy that focuses on maladaptive (faulty) beliefs, behaviors, and emotions.
- **DSM-5** stands for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, which is a diagnostic system used by professionals to identify mental disorders with specific diagnostic criteria.
- **Hypochondriasis** is a mental disorder characterized by a preoccupation with having a serious medical condition based on a misinterpretation of bodily symptoms. In DSM-5 this disorder is replaced by illness anxiety disorder.
- **Malingering** is the practice of intentionally exaggerating or faking physical or psychological symptoms for personal gain. It is also referred to as fictitious illness.
- **Mindfulness practices** are intentional activities that foster living in the present moment and awareness that is nonjudgmental and accepting.
- **Somatic sensitivity** refers to the high level of sensitivity and attentiveness to bodily sensations of emotionally reactive individuals. This sensitivity leads them to overreport physical symptoms.
- **Somatic symptom disorder** is a mental disorder characterized by bodily symptoms that

are very distressing or result in disrupted functioning.

- **Stress management** is a set of psychological techniques for increasing the capacity to better cope with psychological stress. It usually includes relaxation methods.

Description and Diagnosis

Illness anxiety disorder is one of the classes of somatic symptom and related disorders. The characteristic features of this disorder is a high level of anxiety and an unnatural preoccupation with having a serious medical condition but few or no bodily symptoms. Individuals with this disorder tend to misinterpret otherwise insignificant bodily symptoms as evidence of serious or fatal problem. For instance, mild respiratory congestion is interpreted as sign of lung cancer. It is important to note that their misinterpretation is not intentional as it is in malingering. Given their level of concern, individuals with illness anxiety disorder often seek second opinions when no medical findings are present. They may believe that their physician either is incompetent or has overlooked a serious problem. Needless to say, physicians who fail to convince these individuals that they are well can become highly frustrated and end up discounting or dismissing them. This sets the stage for a problematic cycle of hostility and anxiety.

Illness anxiety disorder was previously referred to as hypochondriasis. Both disorders involve excessive worry and preoccupation with one's health. In DSM-5 the two are differentiated. Those with hypochondriasis have bodily symptoms, whereas those with illness anxiety disorder have no (or a few) bodily symptoms but a high level of anxiety about their health (American Psychiatric Association, 2013). With the new DSM-5 diagnosis of somatic symptom disorder, many who formerly would have been diagnosed with hypochondriasis are now more appropriately diagnosed as somatic symptom disorder.

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, individuals can be diagnosed with this disorder if they exhibit a preoccupation with health in general and a fear of serious illness in particular. This preoccupation occurs despite the fact that there are no or few somatic (somatic) symptoms present. However, those with this disorder experience a high level of anxiety related to their health and believe that they suffer from a serious disease. They engage in excessive behavior such as constantly checking for physical signs of sickness or constantly searching for information or seeking reassurance from others. This constant concern about their health must last for six or more months. This preoccupation is not due to another disorder such as somatic symptom disorder, panic disorder, or generalized anxiety disorder (American Psychiatric Association, 2013).

The cause of this disorder is unknown. It may be that those with illness anxiety disorder are more sensitive to their bodily sensations (somatic sensitivity) than others. They tend to amplify and interpret that these sensations are indicators of physical illness. As a result, when they experience emotional stress, they are likely to interpret it as a physical symptom. From their early years, these somatically sensitive individuals were likely to have been overly concerned about their health. Growing up they learned to distrust those who did not take their health concerns seriously. They came to associate the nonresponsiveness of others to their physical discomfort as physical pain and illness. They also learned that there were advantages to being sick. Faking illness may have been the only way to get the attention of caretakers. They may have also witnessed the attention and caring that others received when they were sick. This impressed them with the value of illness. Still others with this disorder experienced being comforted and validated by overly concerned caregivers who doted over their bruises, fever, or sniffles. All these experiences taught them to be overly impressed by bodily concerns and how to get others to show concern. As a result they learned to worry and be obsessed about their health. They also learned how to they get some physicians and others to focus on their health concerns and to distrust and defeat those who do not take their concerns seriously. In this way, these individuals can remain worried and focused on their health, while demonstrating to others heroic struggle to carry on despite the extent of their perceived illness.

Treatment

Cognitive behavior therapy can be an effective approach with this disorder. Because of their somatic sensitivity and general distrust of health providers, these individuals must be taken seriously. Treatment begins by educating them about their somatic sensitivity and its effects, and ways to reduce are critical to treatment success. As a result they become desensitized to bodily sensations and lessen their preoccupation with heath concerns. Teaching them to accept their symptoms in a nonjudgmental way helps to minimize their impact. Mindfulness practices may also be an additional intervention in reducing and maintaining this reduced sensitivity. It also can help patients to not "fight" their symptoms, which often only makes them feel worse. Moreover, teaching stress management can not only help reframe physical sensations but help give them a sense of self-efficacy in helping themselves feel better.

Imagery Rescripting and Reprocessing Therapy (IRRT)

Imagery rescripting and reprocessing therapy (IRRT) is a psychotherapeutic treatment technique utilizing a client's visual memories and imagination to reduce distress from traumatic experiences.

Definitions

- **Mental imagery** includes visual and bodily sensation images that take place within one's mind and imagination.
- **Phobias** are extreme or irrational fears of objects or situations.

Description

Imagery rescripting and reprocessing is used to help transform recurring and distressing mental images into more benign or positive images. Originally developed by American psychologist Mervin R. Smucker in the 1990s for treating adult survivors of child sexual abuse, IRRT has been successfully used to treat a number of mental health disorders, including depression, anxiety, phobias, and personality disorders. IRRT has been most widely used in the treatment of post-traumatic stress disorder and other trauma-based difficulties. IRRT is most effective for individuals who are able to recall or reexperience a traumatic memory; most of the memory is visual along with the painful emotions and most of the emotions are considered non-fear emotions, such as guilt, shame, and self-blame.

Development

Imagery rescripting and reprocessing therapy is based on the theory that mental imagery is deeply connected to emotions and emotional disorders. Mental images evoke powerful emotions, and visual image memories are highly associated with traumatic stress disorder, depression, phobias, and anxiety. Perhaps the most recognized type of mental image is that of a "flashback" in which a person is emotionally overwhelmed by an intrusive and vivid memory of a traumatic event. Flashbacks, and less severe graphic memories, contain much of the original emotional impact of the actual event. Both positive and negative memories that are visual in nature, that is, you can see them in your mind's eye, are more powerfully experienced than are verbal representations of similar events. The goals of IRRT are to decrease physical and emotional upset; eliminate trauma symptoms such as fear, guilt, and shame; transform traumatic imagery into empowering imagery; strengthen the ability for the client to self-calm, self-nurture, and self-regulate emotions; and modify negative self-beliefs (I am bad, I will never be safe, I am unlovable, I am worthless, etc.) that often result from traumatic experiences.

Current Status

Imagery rescripting and reprocessing is considered a brief therapy requiring approximately eight 60- to 90-minute psychotherapy sessions. Treatment includes three phases. Phase one is referred to as "imaginal exposure" or "imaginal reliving." In this phase clients are asked to visualize, imagine, and describe their distressing imagery, including sounds, sensations, smells, and the emotions that accompany the memory. The therapist's role is to provide a supportive safe environment to allow the client to reexperience the painful experience in order to reprocess the associated emotions. Phase two is the rescripting phase in which clients create "master imagery" in which they modify the memory, write a new script so to speak, and picture a new ending. For instance, an adult client who was sexually abused as a child would be instructed to visualize the beginning of the abuse scene but would be instructed to visualize her adult self entering the scene. The therapist would guide the scene by asking the client what she would do as an adult to the perpetrator and how her adult presence changes what happens. The role of the adult in rescripting is to rescue the child, drive out the perpetrator, remove the child from the perpetrator, and protect her from further abuse. The therapist does not tell the client what she should do but facilitate the rescripting to enable the client to choose how best to create the master imagery. Phase three is the development of self-calming and self-nurturing imagery. In this phase clients are encouraged to directly interact with and comfort, nurture, and teach the traumatized child. The therapist may ask, "What would you the adult like to say or do to the child?" and "How does the child feel at this time?" This is a time of deep emotion and healing as clients reprocess the trauma and bring mastery to the memories. As therapy progresses the rescripting and reprocess is repeated, and homework is given in order for clients to gain additional insights and healing from the treatment.

Imagery rescripting and reprocessing therapy is a highly effective tool used by psychotherapists in helping individuals overcome traumatic and debilitating experiences. IRRT is also being studied in the treatment of depression, anxiety, and other mental health disorders.

Immigration, Psychological Factors of

Immigration has a social and psychological impact on people specifically when they are disadvantaged by financial, medical, or housing challenges in their nonnative country.

Definitions

- **Acculturation** is the process of blending a person's native culture with another culture.
- **Immigration** occurs when people move and settle into a country outside of their native country.

Description

The cultural and psychological impact of immigration has been a problem both for cultures and individuals throughout history. In our society it is important for mental health professionals to be aware of the scope and dimensions of the problem, as well as how it may affect their diagnostic and therapeutic work with clients. Immigration creates special psychological pressures and anxieties. These can result from differences in climate or geography, social and cultural norms, language differences, different income levels, and other experiences such as education and training.

Many of the issues immigrants experience center around the difficulty of distinguishing between

prejudice and stereotype. Adjusting to a new culture is a challenge for immigrants. Many face the problem of adjustment and the need to find limits and make choices that affect their daily lives, their culture, and traditions when they are suddenly exposed to or unfamiliar with the customs, culture, and expectations of the existing community. The process of adjusting well and achieving mental health is called acculturation. Psychological acculturation is the ability to blend the new and old cultural priorities in a way that doesn't negatively impact the immigrant.

This issue of forced choices between cultures not only affects the whole of the immigrant community; it can tear apart individual immigrant families. This can happen when members of the younger generation, who can acculturate more quickly, make forced choices that may not be in agreement with their elders. Elders may begin to feel that younger children have lost their culture of origin, and both generations suffer through differently based feelings of powerlessness and isolation.

Current Status and Impact (Psychological Influence)

One in five persons currently residing in the United States is a first- or second-generation immigrant. Nearly a quarter of children under the age of 18 have an immigrant parent. Today about 14% of the U.S. population is identified as immigrants.

The immigrant population is diverse and scattered and can vary based on location. There are cities and areas where one or another immigrant group is dominant and has a radical effect on the culture of the area. Still the general impact on society and social structures in terms of education, income, health-care issues, and law enforcement is an ongoing and significant challenge for some immigrants.

Immigrants who find themselves in low- or middle-income levels of society experience more psychological stresses than wealthier immigrants. They also tend to report more negative life events, social problems, and health issues. In addition, immigrants in the preteen years tend to show more distress than immigrants who are either younger or older.

The two immigrant groups who have notably excelled in American schools are Asians and Cubans. These groups seem to have more established contacts in the community and have been able to garner greater social and cultural support. Among those groups that encounter language problems in school, feelings of nonacceptance and prejudice are common. There are many barriers to culturally sensitive and appropriate mental health services for racial or ethnic minorities and immigrant populations. The need for immigrant counseling and services will continue to be important to help immigrants achieve acculturation and success in different areas of their lives.

Impaired Professionals

Impaired professionals are individuals with mental or medical condition or substance use disorders adversely affecting their ability to practice their profession.

Definitions

- **Addiction** is a chronic disease of the brain, which involves compulsive and uncontrolled pursuit of reward or relief with substance use or other compulsive behaviors.
- **Dialectical behavioral therapy** is a psychotherapy approach, which focuses on coping with stress, regulating emotions, and improving relationships.
- **Family therapy** is a type of psychotherapy approach that is used to help family members resolve conflicts and improve their communication skills.

- **Group counseling** is a type of psychotherapy approach in which a small group of individuals meet regularly with a therapist.
- **Impairment** is a mental or medical condition that interferes with an individual's ability to engage in tasks of daily living, such as work and personal care.
- **Meditation** is a technique used by individuals for the purpose of focusing upon a sound, object, visualization, and breath movements in order to increase awareness in the present moment.
- **Psychoeducation** is a psychological treatment method that provides individuals with knowledge, about the condition as well as advice and skills for reducing their symptoms and improving their functioning.
- **Relapse prevention group** is a behavioral self-help program that teaches individuals with addiction how to anticipate and cope with the potential for relapse.
- **Spirituality-oriented psychotherapy** is a type of approach that attempts to help an individual understand and experience that he or she is a part of something bigger than himself or herself.
- **Substance use disorder** is a disorder in which one or more mind-altering substances lead to clinically significant distress or impairment in an individual.
- **Twelve-Step Programs** are self-help groups whose members attempt recovery from various addictions based on a plan called the Twelve Steps.

Description

Health-care professionals who are impaired have the inability or imminent inability to practice within their profession according to acceptable standards as a result of mental health problems or substance use disorder (e.g., addiction). An impaired professional (e.g., counselor) cannot function adequately and provide competent care to individuals he or she is working with (e.g., a client). Professionals who have a substance use disorder can result in adverse social and professional consequences. Addiction manifests as physiological and behavioral symptoms related to a dysfunctional pattern of substance abuse. This negatively impacts not only the professional but anyone he or she is are treating or helping. Impaired professionals can cause harmful effects to other individuals. For example, a counselor who is impaired (by a substance use disorder) and is treating a client may provide inadequate and harmful care to the client. The client may not be receiving the appropriate treatment from a counselor and can result in damage to the client. Impaired professionals, who seek help for their difficulties, can have the opportunity to address unique issues specific to their field. For example, an impaired professional will develop the skills of how to tell his or her employer, knowing when to return to work, setting boundaries, establishing work and life balance, and participating in continued care.

There are several causes of impairment. They include burnout, stress, relationship problems, mental health issues, and addiction. Fatigue, vicarious traumatization, and secondary traumatic stress may also cause a professional to become impaired.

Treatment

There are various treatment programs for impaired professionals. Such programs often have a high recovery rate and are designed to help a professional reenter into his or her clinical practice. Usually, these programs involve several modalities. These include group counseling, individual therapy, family therapy, dialectical behavioral therapy, and spirituality-oriented psychotherapy, which can be effective forms of treatment. In addition, Twelve-Step Programs, psychoeducation groups, medication management, relapse prevention groups, and meditation have been found to be effective forms of treatment.

Individual Psychology

Individual Psychology is an approach to psychology that understands individuals to be social beings with a need to belong and strive for significance. It is also known as Adlerian psychology.

Definitions

- **Alfred Adler** was an Austrian psychiatrist who created Individual Psychology, also called Adlerian psychology.
- **Early recollections** are a projective therapeutic technique that examines the first memories that an individual can recall. Themes about individuals' personality and their view of themselves and others are hypothesized with this technique.
- **Family constellation** includes information about individuals' relationships with other family members, family values, and the way they found a sense of belonging in their family.
- **Inferiority feelings** are feelings that occur when an individual believes he or she is incompetent or inadequate.
- **Lifestyle and lifestyle convictions** are conclusions an individual makes about his or her inner world based on his or her interpretations of previous experiences.
- **Psychological birth order** is the perceived position or role that an individual takes or is given in a family system.
- **Rudolf Dreikurs, MD,** was an American psychiatrist and educator known for advancing Adlerian psychology through his writings and professional publications.

Description

Individual Psychology, also known as Adlerian psychology, is a psychological approach that assists individuals to increase their sense of belonging to others and to increase their constructive actions toward goals in their lives. Individual Psychology assumes that suffering results from individuals lacking a sense of belonging and from feeling discouraged due to feelings of inferiority. It also assumes that individuals' lifestyle convictions are influenced by their psychological birth order, family constellation, and how they safeguard (protect) themselves from feelings of inferiority.

Human suffering is conceptualized through understanding that discouragement results from inferiority feelings that occur as a result of unhelpful lifestyle convictions. Adlerian psychology techniques assist individuals in modifying their faulty lifestyle convictions and also increasing their sense of belonging. Individual Psychology utilizes four basic principles. Individuals are viewed holistically (body-mind-spirit). Behavior is goal-directed or purposive. Individuals give their own meaning to life experiences. Finally, individuals are social beings who want to belong. In short, this is how personality develops normally and how it becomes dysfunctional.

Developments and Current Status

Alfred Adler (1870–1937) is the founder of Individual Psychology. He was born in Austria and became a physician. Adler had been a colleague of Sigmund Freud (1856–1939) and a member of his Vienna Psychoanalytic Society. In 1911, Adler left the society due to increasing differences in their explanations of human behavior. Freud believed that individuals experience psychological issues due to repressed sexual feelings. However, Adler believed that problems develop from individuals' perceptions of their shortcomings and their difficulties with social belonging. Rudolf Dreikurs (1897–1972) was a student and eventually close colleague of Alfred Adler. After Adler's death in 1937, Dreikurs went on to promote the use of Individual

Psychology around the world. Individual Psychology is considered one of the most influential theories on contemporary counseling theories. While the approach is criticized for having limited empirical research, the approach has thousands of active members in Adlerian societies around the world.

Individualized Education Plan (IEP)

An Individualized Education Plan (IEP), also known as an Individual Education Program, is a living document mandated by the Individuals with Disabilities Act (IDEA), which outlines the learning needs, objectives, accommodations, and services that will be provided to a student with a qualifying disability(ies) in a public school setting.

Definitions

- **Free appropriate public education** is an educational right of every child with a disability, as outlined under the Rehabilitation Act of 1973 and IDEA, which ensures that educational programming and services are unique to the child, specific to the child's needs, provide access to the general curriculum, meet grade-level standards, and are of educational benefit.
- **Individuals with Disabilities Education Act (IDEA)**, a federal law reauthorized and signed into law by President George Bush on December 3, 2004, ensures special education programs and support services to children and youth with disabilities.
- **Least restrictive environment (LRE)** is a requirement outlined by IDEA that states that individuals with disabilities be provided the opportunity to be educated with nondisabled peers to the greatest extent possible.

Description

An Individualized Education Plan is a written document developed by a special education team that details, outlines, and monitors the educational services provided to a student with a qualified disability or disabilities. The acronym "IEP" can refer to an Individualized Education Plan, Individualized Education Program, or Individualized Education Program Plan. The purpose of the IEP is to list out the student's unique learning goals and provide information about how the school district plans to support the student's educational success through the services it makes available. Every child who receives special education programming in a public school setting is required to have an IEP on file. Federal regulations established under the Rehabilitation Act of 1973 and the Individuals with Disabilities Education Act (2004) ensure the educational rights of disabled youth and require that public schools provide these students with a free and appropriate education in the LRE. When appropriate, students who are disabled should be educated with peers who are nondisabled in a "normal" general education classroom setting. Alternative placement settings may include a resource classroom, a separate classroom, specialized school, or residential facility.

In order to be eligible for special education services and a resulting IEP, an individual must have a documented disability, which impedes his or her learning. To determine this, a full evaluation of the suspected impairment must be conducted by a qualified professional. This impairment must fall under IDEA requirements. Based on the evaluation, an IEP is then

developed by a student support team comprised of the child's parents, at least one regular education teacher, the special education teacher, a school district representative, a psychologist or other qualified individuals who can interpret and relay the child's psychoeducational evaluation results, other support service personnel, the school guidance counselor, and, if deemed appropriate, the child himself or herself. Having the child present is meant to inform the child so he or she is better able to advocate on his or her own behalf once he or she transitions out of high school and into adulthood. Parental attendance and input are critical in the IEP process. School personnel are expected to make every attempt to contact, inform, and obtain consent from parents prior to initiating an IEP plan. Meetings in person are strongly encouraged, and translators should be provided when necessary.

Development (Purpose and History)

The IEP was first developed after the passage of the 1975 Education for All Handicapped Children's Act (EHA), also referred to as Public Law 94-142, ensured equal opportunity to an education for children with disabilities by requiring that special education services be provided to support these students' success. Subsequent reauthorizations of the law further articulated and amended IEP requirements. The 1986 EHA Amendment, Public Law 99-457 included infants and toddlers to those eligible for early intervention services. In 1990, the law was renamed the Individuals with Disabilities Education Act, or Public Law 101-476. In 1997, Public Law 105-017 was introduced to align IDEA requirements with the Elementary and Secondary Education Act and mandate that students with disabilities participate in state and district-wide assessments. In December 2004, President George W. Bush reauthorized the law (Public Law 108-446) and adjusted the name to the Individuals with Disabilities Education Improvement Act, placing more pressure on accountability requirements (i.e., "highly qualified teacher") that resulted from his No Child Left Behind initiative. Several provisions specific to the IEP process resulted from the 2004 reauthorization, attempting to make the process more efficient while placing less stringent demands on IEP team members including reduced paperwork requirements and the need for fewer meetings. On February 17, 2009, President Barak Obama signed into law the American Recovery and Reinvestment Act, a stimulus package meant to increase funding to key areas including education.

Current Status and Results

Specific information is contained in every IEP document: the child's present levels of functioning and academic achievement; the child's specific, measurable annual goals; supplementary services and special education programs available, time devoted to these services and when those will be delivered, how they will be delivered, by whom, and for how long; expected participation, if any, in district and state-wide standardized assessments; and how the student's progress toward his or her annual goals will be measured and reported. IEP team members are required to assemble and document the plan's initiation within 30 days of the establishing the student's eligibility under IDEA. A reevaluation is to be administered every three years. The IEP plan is continually monitored and revised annually based on the child's needs and progress up until his or her graduation from high school or prior to the 22nd birthday. If the student goes on to pursue a postsecondary education, the university's own procedures and system then take over.

Though federal law mandates adherence to IEP protocol, little research has been conducted in this area. Most local and state agencies, however, strongly recommend the use of a standard form in developing the IEP that meets federal requirements. Advances in computer-based technology have allowed for the IEP process to be even faster and more accessible.

Inhalant-Related Disorders

Inhalant-related disorders are a group of mental disorders characterized by physical dependence on inhalants, drug-seeking behavior, increased tolerance, and social withdrawal.

Definitions

- **Antisocial personality disorder** is a mental disorder characterized by a pattern of disregarding and violating social norms (rights of others). An individual must be 18 years and older for this diagnosis.
- **Cognitive behavior therapy** is a type of psychotherapy that focuses on maladaptive (problematic) behaviors, emotions, and thoughts. It is also called CBT.
- **Conduct disorder** is a mental disorder characterized by a pattern of disregarding and violating social norms (rights of others). An individual must be under the age of 18 for this diagnosis.
- **DSM** is the abbreviation for the *Diagnostic and Statistical Manual of Mental Disorders*, which is the handbook mental health professionals use to diagnose mental disorders. The current edition is DSM-5.
- **Inhalants** are substances that emit chemical vapors. They are inhaled for their psychoactive effects.
- **Other substance use disorders** include problematic use of substances other than alcohol, caffeine, cannabis, hallucinogens, inhalants, opioids, sedatives, hypnotics, anxiolytics, stimulants, or tobacco. Use must result in clinically significant impairment.
- **Psychoactive** refers to a drug or other substance that produces mood changes and distorted perceptions.
- **Psychotherapy** is a psychological method for achieving desired changes in thinking, feeling, and behavior. It is also called therapy and therapeutic counseling.
- **Substance-related and addictive disorders** are a group of DSM-5 mental disorders that include substance disorders characterized by physiological dependence, drug-seeking behavior, tolerance, and social withdrawal. This group also includes the non-substance disorder of gambling.
- **Tolerance** refers to the need for higher doses of a substance or more frequent engagement in a behavior to achieve the same effect.

Description and Diagnosis

Inhalant-related disorders are one of the DSM-5 substance-related and addictive disorders. Individuals with this disorder intentionally inhale vapors from products or chemical agents to become intoxicated. Vapors may be inhaled straight from a product's container, from a cloth saturated with the substance, or from a bag containing the substance. Inhalants may include, but are not limited to, glue, shoe polish, toluene, gasoline, lighter fluid, and spray paints. There are hundreds of commercial products that can be used as inhalants. Individuals may use one substance or a combination of several substances to achieve the desired psychoactive effects. Intoxication happens very quickly and does not last long. Inhalant abuse of nitrous oxide (laughing gas), amyl nitrite (chemical compound that dilates blood vessels), butyl nitrite (also called poppers that increase sexual desire), and isobutyl nitrite (chemical compound that dilates blood vessels) are not considered to be inhalant-related disorders but rather other substance use disorders.

The occurrence of this disorder is relatively low in the American population. Approximately 4 out of 1,000 teenagers between the ages of 12 and 17 meet the conditions for inhalant-related disorders. In this age group the rate of occurrence is higher among Native Americans and lowest among African Americans. Approximately 1 out of 1,000 individuals between the

ages of 18 and 29 have the disorder. In adults 18 years and older, around 2 out of 10,000 meet the criteria for a diagnosis. Females are rarely diagnosed with this disorder (American Psychiatric Association, 2013).

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, individuals can be diagnosed with this disorder if they are physically dependent on inhalants. Over the previous year, the individual has increased the substance dose in order to obtain the desired psychoactive effect. Attempts to control use or decrease use have failed. Strong cravings are experienced and excessive amounts of time are spent obtaining inhalants. Use of the substance continues despite negative consequences experienced in occupational, social, and interpersonal areas. Substance use continues despite any psychological or physical problems that have occurred as a result of the substance. The substance is repeatedly used during situations that may result in physical harm. Inhalant-related disorders are not characterized by withdrawal symptoms (American Psychiatric Association, 2013).

The cause of this disorder is linked with the co-occurrence of another substance use disorder (non-inhalant) usually along with conduct disorder or antisocial personality disorder. Other situations that increase the likelihood of inhalant abuse include use of inhalants at an early age, a history of mental health treatment, childhood abuse or trauma, and behavioral disinhibition (tendency to break the rules and take risks).

Treatment

Treatment for inhalant-related disorders is based on the individual's age, extent of drug problem, other addictions, and co-occurring disorders. Treatment can include psychotherapy and medication. Psychotherapy may consist of cognitive behavior therapy. Medication therapy may help reduce the psychotic side effects of inhalants.

Inhalants

Inhalants are ordinary household products that are sniffed or inhaled for their mind-altering effects (getting high).

Definition

- **Gateway drugs** are the first drugs that are used before moving on to other substances such as alcohol, marijuana, cocaine, or oxycodone.

Description

Inhalants are breathable chemical vapors that users intentionally inhale because of the chemicals' mind-altering effects. Inhalants are a class of drugs that include a broad range of chemicals found in hundreds of commonly available products. Such chemicals include volatile solvents (liquids that vaporize at room temperature) and aerosols (sprays that contain solvents and propellants). Examples include glue, gasoline, paint thinner, hair spray, lighter fluid, spray paint, nail polish remover, correction fluid, rubber cement, felt-tip marker fluids, and cleaning fluids such as spot removers, computer keyboard cleaner, and carburetor cleaner. These chemicals can be inhaled directly from a container (sniffing), from the fumes of the substance placed in a bag (bagging), or from a cloth soaked in it (huffing). The mind-altering effect is quickly achieved because the substance enters the bloodstream almost instantaneously via the lungs. High from inhalants is typically brief, necessitating repeated inhalants. This pattern of use and abuse can be dangerous, and can result in unconsciousness or even death.

Inhalant use is more commonly used by younger children than older ones. Estimates are that 10%–20% of youths aged 12 to 17 have tried inhalants. About 6% of the U.S. population of all admits to having tried inhalants prior to fourth grade. The peak time for it is between the seventh and ninth grades. Generally, males use inhalants more frequently than females. Children younger than 12 and adults who use inhalants are more likely to be male (Erickson, 2011). The use of inhalants is often influenced by peers. Typically, inhalants are used in group settings. The solitary use of inhalants is associated with heavy, prolonged use; it may indicate that the individual has a more serious problem with these substances. Furthermore, inhalants may serve as gateway drugs for such users.

Types of Inhalant Use, Precautions, and Side Effects

Inhalant dependence. Inhalant dependence, or inhalant addiction, is a syndrome in which an individual continues to use inhalants despite significant problems caused by, or made worse by, the use of these substances. Those with heavy, recurrent inhalant use may develop tolerance to the drug. This is a positive indicator of physical dependence. Individuals dependent on inhalants may use these chemicals several times per week or every day. They may have problems with unemployment or with family relationships, and/or such physical problems as kidney or liver damage caused by the use of inhalants.

Inhalant abuse. Inhalant abuse is a less serious condition than physical dependence. However, recurrent use of inhalants can have negative consequences. For example, the use of inhalants may contribute to poor grades or school truancy.

Inhalant intoxication. "Intoxication" refers to the behavioral or psychological changes following ingestion of a mind-altering substance. Symptoms of intoxication depend on the type of inhalant, the amount used, and other factors. There is, however, a predictable set of symptoms of inhalant intoxication. Typically, they have a depressant effect on the central nervous system. Similar to the effects of alcohol, they produce feelings of euphoria (feeling good), excitement, dizziness, and slurred speech. In addition, those intoxicated by inhalants may feel as if they are floating, or a sense of increased power. Excessive ingestion or inhalation of the chemical can cause overdose and result in coma or death.

Insanity Defense

The insanity defense is a claim of not being responsible for one's actions because of a mental disorder. It is also referred to as "not guilty by reason of insanity."

Definitions

- **Diminished capacity** is a lesser degree of mental malfunctioning than insanity wherein emotional distress or other factors reduce one's capacity to fully comprehend the nature of the accused criminal act.
- **Incompetent to stand trial** is a court's determination that a defendant's mental condition makes him unable to understand the legal proceedings or to help in his defense.
- **Insanity** is a significant degree of mental malfunctioning considered to be sufficient to relieve the accused of legal responsibility for the criminal act committed.

Description

The insanity defense is a legal defense (reason) in which defendants (accused individuals) claim they are

not responsible for their actions because of a mental condition or disorder. This defense is also referred to as "not guilty by reason of insanity" (NGRI). There are specific requirements for this defense. First, the individual who is charged with a crime must admit to the criminal act. Second, the individual's attorney must claim that the individual lacked the capacity to intend to commit the crime because of significant mental malfunctioning at the time of the crime. Third, it requires that the court set a trial on the issue of insanity. A finding of insanity results in a verdict of NGRI. Assuming the mental condition still exists, the court may order the individual be confined to a mental facility for the criminally insane or a psychiatric hospital. If the insanity no longer exists (was temporary insanity), the judge has the option to require some psychiatric treatment. NGRI differs from incompetence to stand trial. Here the defendant is adjudged to be insane at time of trial. This determination results in a postponement of the trial—often indefinitely—and confinement to a mental facility pending recovery.

Developments and Current Status

Exemption of those determined to be insane from full criminal punishment dates back to the Code of Hammurabi, which is the earliest known legal code. There are different definitions of legal insanity, such as the M'Naghten rules, the Durham rule, and the American Law Institute Formulation. The M'Naghten rule emphasized a "defect of reason from disease of the mind as not to know the nature and quality of the act he was doing, or, if he did know it, that he did not know that what he was doing was wrong" (Ewing, 200). The Durham rule emphasized that "an accused is not criminally responsible if his unlawful act was the product of mental disease or mental defect." The American Law Institute Formulation's definition is that "a person is not responsible for criminal conduct if at the time of such conduct as a result of mental disease or defect he lacks substantial capacity either to appreciate the criminality [wrongfulness] of his conduct or to conform his conduct to the requirements of the law."

The use of the insanity defense is relatively rare in the United States. Instead factors not eligible for the insanity defense, such as like intoxication or diminished capacity, are used in efforts to reduce charges or to reduce sentences. The diminished capacity plea is primarily raised to remove the element of premeditation or criminal intent. This defense may result in a conviction for a lesser crime, such as manslaughter instead of murder. In other words, a plea of diminished capacity is different from a plea of insanity in that "reason of insanity" is a full defense while "diminished capacity" is simply a plea to a lesser crime.

The insanity defense is based on evaluations by forensic specialists (psychologists or psychiatrists) involving specialized psychological tests. Some jurisdictions (courts) require the evaluation to address the defendant's ability to control his or her behavior at the time of the offense. If successful, the defendant pleading "not guilty by reason of insanity" or "guilty but insane or mentally ill" may be committed to a psychiatric facility for an indeterminate period.

Insecure Attachment

Attachments are primarily identified as either secure or insecure, with three breakdowns within the concept of insecure attachments. Attachment styles are rooted in the theory first developed by John Bowlby, with significant contributions from Mary Ainsworth. Insecure attachments develop in infancy and childhood impacts the development throughout the lifespan, as well as how an individual interacts with others. Bowlby's belief was that a child's attachment was connected to his or her interactions and ability to form and maintain emotionally stable relationships later in life.

Definition

- An **insecure attachment** is a lack of trust or consistency in the relationship between a caregiver and child. The caregiver may fail to respond to the infant's needs where the child may become distressed or anxious.

Attachment styles were first explored by John Bowlby and bolstered by key contributions from Mary Ainsworth, notably her strange situation paradigm in which Ainsworth explored infants' responses to being separated from their caregiver as well as their reaction to the return of the caregiver.

Babies who are identified as anxious-ambivalent display high levels of anxiety. These babies struggle with gaining a sense of security even when their caregiver is still present with them. These babies are stressed and distressed when separated from the caregiver. However, what truly identifies these babies is that when their caregiver returns these babies greet him or her angrily and resist efforts to comfort them. These babies rarely explore the room even after their caregiver's return. Children with insecure attachments may refuse to interact with others or may simply avoid others. They may also exaggerate distress as well as have strong displays of anger, anxiety, or fear.

There are three subsets within the concept of insecure attachments. Insecure attachments can be anxious-ambivalent, avoidant, or disorganized-disoriented. Avoidant babies fail to cry when separated from their caregiver. When the caregiver returns, the babies ignore or avoid him or her. These babies are unemotional during both separation and reunification with their mother. They would rather direct their attention toward toys or other objects present in the room.

Disorganized-disoriented babies were initially difficult to identify and categorize and were left out of the inclusion as being classified. These infants display contradictory behaviors. They have a desire to approach their mother when stressed but also avoid her when she approaches them. Children who display this pattern of attachment are more likely to have experienced unstable or difficult home environments, such as filled with abuse or neglect. There is concern that children who display this attachment style may have their learning ability impacted and be at risk academically. This group is also more likely to experience or demonstrate behavior problems such as strong displays of aggression.

When children are insecurely attached, they may be wary of strangers or show no preference for their parents over strangers. They are distressed when their parents or key figures leave and don't appear to be comforted when they return. As adults they are hesitant to become close to others. They worry that their partner doesn't love them and become distraught in relationships. They struggle with intimacy and invest little emotion into their relationships.

Attachment is continuous and can be modified with understanding. In recent years there has been a curiosity in exploring attachments in adulthood and the impacts they have on social and romantic relationships. There have been studies exploring those with insecure attachments as a predictor of depression and anxiety in adolescents and adulthood. Insecure attachments can also lead to lower self-esteem and difficulty with self-regulation and emotional stability, as well as impact social and romantic relationships as an adult.

Insomnia and Insomnia Disorder

"Insomnia" refers to difficulty falling asleep. Insomnia disorder is a sleep disorder characterized by a persistent pattern of difficulty falling asleep and staying asleep.

Definitions

- **Behavior therapy** is a form of psychotherapy that focuses on identifying and changing maladaptive behaviors.
- **Polysomnography** is a medical test that records aspects of sleep (circadian rhythms, REM, NREM, number of arousals) as well as breathing patterns, heart rhythms, and limb movements.
- **Sleep disorders** are a group of mental disorders characterized by disturbance in the amount and quality of sleep and that cause significant emotional distress or interfere with daily functioning.
- **Sleep hygiene** refers to the habits, practices, and nonmedical treatments for insomnia and which improve the quality of sleep.

Description and Diagnosis

Insomnia is a sleep disorder characterized by difficulty falling asleep, staying asleep, or both. Often, individuals experiencing this disorder wake up during the night and then have difficulty falling back asleep. Or, they may wake up too early in the morning. In either case, they are likely to be tired upon waking and throughout the day. Insomnia can be short-term (acute) or can last a long time (chronic). It can also come and go, with periods of time when an individual experiences no sleep problems. Acute insomnia can last from one night to a few weeks. Chronic insomnia is longer, lasting at least three nights a week for a month or longer.

It is not uncommon for those with this disorder to be frustrated and distressed about sleep. The longer this continues, the more they are likely to feel hopeless in resolving their inability to sleep. They also experience increased fatigue, lower energy, and significant changes in mood. This further complicates their erratic and maladaptive sleep pattern. The result is increased difficulties with social, work, academic, and other areas of functioning (American Psychiatric Association, 2013).

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, individuals can be diagnosed with this disorder if they exhibit a persistent pattern of difficulties and dissatisfaction with falling asleep and or remaining asleep. Individuals may experience sleep-onset insomnia, in which they have difficulty falling asleep. They may have experienced sleep maintenance insomnia in which they have difficulty falling back asleep after awakening. Or, they may experience early morning awakening where they are fall back asleep after awakening early in the morning. This sleep difficulty must have occurred three times per week or more and have lasted for three months or more. They must also cause significant distress for the individual or result in significant level of impaired functioning. In addition, the disorder cannot be the result of a substance, medication, other medical condition, or another sleep disorder (American Psychiatric Association, 2013).

Several factors appear to cause this disorder. Genetic and family factors may be involved since insomnia is more common among first-generation family members. It is more common among females. Insomnia in females often begins with the birth of a child or with the onset of menopause. Psychological and environmental factors are often involved. These include the following: stress caused by a single event, such as giving a speech, or ongoing stress, such as worry about work or a health matter. Depression, anxiety, and other mental or medial conditions may trigger or complicate sleep problems. Lifestyle and environmental factors can also cause or exacerbate (worsen) it. These include poor sleep hygiene habits such as watching television in bed or not having a regular bedtime schedule. It can also include changes in sleep habits and surroundings such as noise, temperature, light, or

sleeping in a different bed. Common environmental factors that might be involved include jet lag or working a late shift.

Treatment

Effective treatment of insomnia requires a multifaceted approach to treatment. Treatment should begin with a medical consultation and sleep study, including polysomnography. The medical consultation should identify any medical conditions and co-occurring psychological disorders that may cause or contribute to insomnia. After the medical evaluation, a treatment plan is established, which usually includes behavior therapy, sleep hygiene, and/or medication.

The National Sleep Foundation recommended behavior therapy and behavior modifications in developing good sleep hygiene. This involves establishing a consistent sleep schedule and exposure to bright light in the morning and avoiding it at night. It also recommends engaging in regular exercise and establishing a bedtime routine. Also, it suggests creating a comfortable sleep environment, keeping stress out of the sleep area, and avoiding caffeine, nicotine, alcohol, and stimulating medication. Initially, medications may be prescribed but usually for only a few weeks since the mainstay of treatment is changing sleep patterns and environments. A natural sleep remedy like melatonin might be considered. Prescription medications such as Ambien, Lunesta, Sonata, or Rozerem may help in bringing on needed sleep while the behavioral interventions and sleep hygiene are being established.

Integrative Health

"Integrative health" refers to a system of health care in which behavioral health professionals and interventions are integrated with medical professionals and interventions.

Definitions

- **Behavioral health** is a phrase referring to mental health and substance addictions services and issues.
- **Comorbid** means to have more than one simultaneous medical condition.
- **Primary care** is health care that is provided by nonspecialist physicians such as family doctors and pediatricians.
- **Providers** mean both medical and mental health-care providers.
- **Treatment noncompliance or nonadherence** is the phrases used when individuals fail to follow treatment instructions, regimens, or advice.

Description

Integrative health is an approach to health care that merges and coordinates behavioral health with primary medical care. Integrative health is an emerging service delivery system, which recognizes that physical and behavioral health problems often occur at the same time. In addition, many behavioral health issues are at the root of many physical symptoms. For instance, stress often results in physical symptoms such as headache, stomach upset, fatigue, and insomnia, all common physical complaints frequently treated in primary care settings. A family physician who is not a behavioral health expert may fail to recognize that stress is the underlying cause of the physical symptoms and that cognitive behavior therapy would be indicated for the most effective treatment. The reverse is also true: many physical illnesses have a mental health impact. For example, a person who is newly diagnosed with a chronic disease such as diabetes may succumb to a state of psychological denial and refuse to follow dietary restrictions, resulting in repeated hospitalizations and further health decline. In this case, a behavioral health professional trained in assisting newly diagnosed individuals and their families can assist the patient come to terms with and accept their disease while helping them redevelop a sense of well-being that incorporates the illness into a new lifestyle.

Development

According to the Substance Abuse and Mental Health Services Administration people with mental and substance use disorders may die decades earlier than the average person. These early deaths are most often the result of untreated and preventable chronic illnesses such as hypertension, diabetes, obesity, and heart disease that are aggravated by poor health habits and substance abuse. In addition, approximately 50% of Americans experience chronic medical symptoms and 75% of adults over the age of 65 suffer from more than one chronic illness. Behavioral health interventions that target treatment compliance and health-promoting behaviors can greatly increase the health and well-being of individuals suffering from chronic illness.

Current Status

There are six levels of integrated care, ranging from minimal collaboration to fully integrated and merged systems of care. The key element of levels one and two is that of coordinated communication. Level one involves minimal collaboration between medical and mental health-care providers. Providers work in separate facilities and rarely communicate. Level two is basic collaboration but at a distance. Providers maintain separate service sites but periodically communicate about shared patients, usually by telephone, secure e-mail, or fax.

The key element of levels three and four is colocated physical proximity. Level three is basic onsite collaboration in which providers have separate systems but are in the same facilities, although not necessarily the same offices, and engage in occasional face-to-face interaction. Level four is close collaboration in a partly integrated system. Providers share facilities and office space, have a basic understanding of each other's roles, and share some systems such as scheduling and patient records. There is regular communication between providers who coordinate treatment plans for patients with complex treatment needs.

The key element in levels five and six is that of integrated practice. Level five is close collaboration approaching a fully integrated practice. Providers share the same space and actively work toward shared systems. They communicate frequently in person, collaboration is driven by a desire to be a member of a care provider team, providers have regular team meetings, and they have an in-depth understanding and appreciation of each other's roles. Level six is full collaboration in a transformed and merged integrated practice with completely integrated systems. Providers at this level not only share facilities and systems but also have a shared vision and an in-depth understanding of each other's roles and expertise.

Integrative health is a health delivery system that incorporates behavioral health into primary care settings. The goal of integrated health care is to provide individuals with an increased range and availability of health-enhancing treatment options. Integrating behavioral health care into medical practices presents a clear path to increased health and well-being of all patients.

Intellectual disability

"Intellectual disability" is the term used to describe people who have below-average intelligence and incomplete skills for daily living.

Definitions

- **Disability** means a physical or mental condition that limits a person's movement, sense perception, or participation in normal physical or mental activities.
- **Intellectual** refers to the ability to think and understand ideas.
- **Intelligence** is the capacity a person has to learn and understand information and solve problems.

Description

"Intellectual disability" (IND) is defined as an impairment that affects a person's ability to function well in daily life. This condition was once diagnosed as mental retardation. IND impacts a person's functioning in three areas of life: cognitive, social, and functional.

The cognitive issues that usually present in people diagnosed with IND are in language, reading, writing, math, and other academic or intellectual areas. Generally, they perform below average in one or several of these areas. The social domain refers to empathy, social judgment, interpersonal communication skills, and similar capabilities. Typically people with IND are socially naïve and do not have a good sense of safety or familiarity with others. The functional domain focuses on areas such as personal care, job responsibilities, money management, recreation, and organization.

The detailed diagnosis of IND is distinct for each person based on how much he or she is affected by the condition. Some are severely impacted and therefore have more trouble, while others are less affected and can function similarly to most others. For a true diagnosis of IND, it must manifest itself sometime during childhood or early adolescence and last throughout a person's lifespan. IND is measured based on intelligence and assessments that identify problems and provide a comprehensive picture of the limits of their capabilities. It is estimated that about 2% of the population in the United States are diagnosed with some form of IND.

Causes and Symptoms

The cause of intellectual disabilities is lined to poorly developed brain functions, but why this occurs is not always clear. In some cases, genetic issues, chromosomal conditions, or problems during pregnancy may be the cause. These instances include the presence of conditions such as Down syndrome and fetal alcohol spectrum disorders. Some of the causes that can contribute to IND are medical in nature. This includes issues such as seizure disorders, unusually low birth weight, or severe illness in early childhood, which directly affect the brain.

Diagnosis and Prognosis

Indications that children have IND may appear during infancy, or they may not be noticeable until a child starts school. It often depends on the severity of the disability. IND is divided into four classifications: mild, moderate, severe, and profound. Levels of classification are determined by intelligence tests, and it is based on a person's test results that he or she is placed into one of these four classifications.

Among the most common signs of IND are physical delays. This includes a child's difficulty to learn how to sit, crawl, or walk when he or she is developmentally

expected to do so. Communication issues are also common for people with IND. This includes difficulty talking and expressing themselves or developing speech much later than expected. Children with intellectual disabilities are also delayed in potty training, dressing, or feeding themselves. Other symptoms include poor memory skills and inability to connect their actions to consequences. Parents and professionals should bear in mind that each child develops at a different pace and no one of these symptoms by itself is conclusive evidence of IND. The diagnosis can only be determined finally by medical professionals who administer assessments of IQ and other tests.

Learning will be a lifelong challenge for those diagnosed with IND. But there are therapeutic and educational interventions that may help to improve the quality of life and capacity for those who are diagnosed with an IND. Many people diagnosed with mild to moderate forms of IND are able to work, socialize, and care for themselves with the support of others. They can benefit from services such as job coaching and training, social skills treatment, and personal care assistants. Unfortunately for those who are classified as profoundly intellectually disabled, lifetime care from family members and professional caregivers may be the only choice.

Treatment

For those who are diagnosed very young and can benefit from early intervention, there is a better prognosis. Parents often seek out professional help to create a treatment plan that will involve family, therapists, and educators. This plan should clearly identify the child's specific needs and what services are likely to help the child develop. Early intervention may include a long list of programs such as speech therapy, occupational therapy, physical therapy, family counseling, training with special assistive devices, or nutritional services.

Children with intellectual disabilities who are able to attend school are eligible for free special education programs through the public school system. The Individuals with Disabilities Education Act mandated by the federal government ensures the provision of these programs. Parents and educators will work together to create an Individualized Education Program that outlines the child's needs and the services the child will receive at school. The point of special education is to make adaptations, accommodations, and modifications that allow a child with an IND to succeed in the academic setting.

When a person with IND exits the school system, the options for assistance and support are limited. Adults with this condition can enroll in job training programs or rehabilitation services to help them gain as much independence as possible. The majority of the programs that place adults with IND into these services are government funded, although private programs also exist. These educational and therapeutic programs often employ counselors, aids, and medical staff in order to properly serve this population. Adult services are often criticized for being difficult to access and unsuccessful in the goal of creating more independence for clients with disabilities.

Intelligence

Intelligence is the capacity to learn and understand information and to solve problems.

Definitions

- **Emotional intelligence** is the type of intelligence that assesses the ability to assess, express, and use one's emotions and those of others to determine one's thoughts and actions.
- **Intelligence quotient** is a measure of intellect to determine a person's level of cognitive ability. It is commonly referred to as IQ.

- **Intelligence testing** is a method of evaluating and scoring various aspects of intelligence such as abstract reasoning, verbal and quantitative ability, and processing speed and fluency. It specifies a numerical value to the score to be compared with others.

Description

Intelligence has been defined as an individual's capacity to learn, understand, and acquire knowledge. It also includes the ability to solve problems and to be able to reason. Intelligence and intelligence testing have been an important consideration in school and work settings since the beginning of the 20th century. Since then it has become increasingly clear that ethnicity, social class, and cultural factors influence intelligence and its assessment. Accordingly, efforts have been undertaken to clarify the meaning of intelligence and its assessment. The goals are to reduce cultural bias and develop more accurate measures of it. For example, individuals who do not understand the prevailing language and/or social interactions can be given either a nonverbal test or one in their native language.

Development

In 1983, Howard Gardner's book *Frames of Mind: The Theory of Multiple Intelligences* altered the prevailing view of intelligence. In it he proposes that instead of there being a single type of intelligence, there are many kinds of intelligences. He argued that most of these types of intelligences are neglected by standard intelligence testing and teaching methods. Gardner described eight types of intelligence:musical–rhythmic, visual–spatial,verbal–linguistic,logical–mathematical, bodily–kinesthetic, interpersonal, intrapersonal, and naturalistic. According to Gardner's theory of multiple intelligences, individuals have several different ways of processing information, and these ways are relatively independent of one another.

Another view of intelligence has been proposed by the American psychologist Robert Sternberg (1949–). He describes three main types of intelligence. The first is practical intelligence, which is the ability to do well in informal and formal educational settings. It also involves the ability to adapt to and shape one's environment. This form is often called "street smarts." The second is experiential intelligence, which is the ability to deal with novel situations, the ability to effectively deal with novel situations so they are easily handled in the future, in other words, the ability to think in novel ways. The third is componential intelligence, which is the ability to process information effectively. Sternberg notes that often individuals who are very talented in one type can be less talented in the other two.

Current Status

For the past decade, interest in intelligence has centered largely on emotional intelligence. Emotional intelligence (EQ) is the capacity to recognize, understand, and manage personal emotions and to identify and respond to the emotions of others. It influences how individuals think, behave, interact with others, and make decisions. Emotional intelligence is different from intelligence (IQ) which is the capacity to learn, reason, and problem solve. Intelligence remains relatively stable throughout life, whereas emotional intelligence can be learned and developed.

The term "emotional intelligence" was originally used in 1964 by Michael Beldoch (1931–). However, it became better known because of psychologist Daniel Goleman's (1946–) best-selling book *Emotional Intelligence—Why It Can Matter More Than IQ*. It has been a best seller since its publication in 1995. Goleman contends that emotional intelligence is equally important, if not more important than IQ. A number of measures of EQ have appeared in the past decade. These measure are routinely used in business and the corporate world.

Intelligence Testing

Intelligence testing is a method of evaluating and scoring various aspects of intelligence such as abstract reasoning, verbal and quantitative ability, and processing speed and fluency. It specifies a numerical value to the score to be compared with others.

Definition

- **Intelligence quotient**, or IQ, coined by German psychologist William Stern, is an overall score derived from standardized measures of human intelligence.

Description

Assessing aspects of human intelligence has been an area of interest for centuries. The process of intelligence testing seeks to evaluate different components of intellect using standardized measures, which can then be compared between individuals of similar age, ability, and background. The overall score derived from these measures is commonly referred to as one's IQ, or intelligence quotient. Current standardized instruments used to assess IQ have been normed using wide, diverse samples resulting in a median IQ score of 100 with a standard deviation of 15. Thus, an IQ score ranging from 85 to 115 would be considered "normal" or "average." Further, it has been determined that some 95% of the population falls between two standard deviations of the mean, or scores ranging from 70 to 130. There is believed to be a biological or hereditary component to intelligence, though this has been a controversial topic. IQ has been associated with academic achievement, special needs, social behavior, career selection and success, and mortality rates, as well as affective and perceptive indicators of happiness, life satisfaction, and self-esteem.

Development (Purpose and History)

Intelligence testing began in the late 1800s with the work of English statistician Sir Francis Galton. He hypothesized that intelligence had a high genetic component but was unable to prove this assertion. The first standardized intelligence measure, the Binet–Simon Intelligence Scale, was developed by French psychologist Alfred Binet and his student Theodore Simon, which was used to detect mental retardation in school-age children. This work gained popularity throughout the international psychological community, and Binet went on to create the Stanford-Binet Intelligence Scale with Stanford psychologist Lewis M. Terman, a revised version of the Binet–Simon and an instrument still in use today. In 1912, German psychologist William Stern coined the term "Intelligence Quotient" or "IQ" to define an overall, standardized measure of human intelligence, a score that could be determined using the Stanford-Binet. The Stanford-Binet remained the most popular instrument for decades until American psychologist David Wechsler, influenced by the work of Charles Spearman and Alan Kaufman, developed the Wechsler Adult Intelligence Scale in 1939. Wechsler opposed Binet's view of a single score for intelligence and proposed rather that intelligence be divided into two main categories, verbal and nonverbal abilities, each evaluated with different subtests.

Wechsler later went on to publish the Wechsler Intelligence Scale for Children (WISC), a revision; the WISC-III remains a preferred instrument of the day. Wechsler's colleague, Alan S. Kaufman and his wife Nadeen, would later develop the Kaufman Assessment Battery for Children, the Kaufman Test of Educational Achievement, and the Kaufman Brief Intelligence Test during the late 1970s. Around the same time, Richard Woodcock and Mary E. Bonner Johnson released the Woodcock–Johnson Tests of Cognitive Abilities, another assessment that has experienced several revisions and is still in current use.

Current Status

Intelligence testing remains prevalent worldwide though some have suggested alternative theories for how intelligence should be conceptualized. Psychologist Daniel Goleman proposed that an individual's emotional intelligence, or EQ, is a more valuable indicator of future success and happiness. Harvard psychologist Howard Gardner's work offers seven distinct intelligences, which account for variations in student aptitude, learning outcomes, and performance. Current educational policies, programs, and teaching practices seek to incorporate these multiple intelligences. IQ scores also appear to be rising at an average rate of 3 points per decade since the early 20th century, a phenomenon referred to as the Flynn Effect, after researcher James R. Flynn who first documented this trend. Experts have proposed that this may be a result of environmental characteristics, including improved nutrition, schooling and parenting practices, and the increased use of technology. According to the "IQ-achievement discrepancy model," individuals whose achievement scores are one standard deviation or more below their IQ scores are diagnosed as learning disabled. Critics contend that this model fails to provide a comprehensive picture of how a person learns. Concerns have also been raised surrounding whether intelligence instruments accurately account for variations in race, gender, socioeconomic status, and culture as well.

Intermittent Explosive Disorder

Intermittent explosive disorder is a mental disorder characterized by impulsive, aggressive, violent behavior, or angry outbursts.

Definitions

- **Antisocial personality disorder** is a mental disorder characterized by a pattern of disregarding and violating the rights of others.
- **Borderline personality disorder** is a mental disorder characterized by a persistent pattern of instability in interpersonal relationships, self-image, affect, self-harm, and a high degree of impulsivity.
- **Cognitive behavior therapy** is a form of psychotherapy that focuses on changing faulty behaviors, emotions, and thoughts. It is also known as CBT.
- **Disruptive, impulse-control, and conduct disorders** are a group of DSM-5 mental disorders characterized by problems with emotional and behavioral self-control. They include oppositional defiant disorder, conduct disorder, and intermittent explosive disorder.
- **Domestic abuse** is the abuse by one partner against the other in an intimate relationship.
- **DSM-5** stands for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, which is a diagnostic system used by professionals to identify mental disorders with specific diagnostic criteria.
- **Impulse control** is the degree to which an individual can control the impulse to act or the desire for immediate gratification.
- **Physical abuse** involves inflicting, or threatening to inflict, physical pain or injury on individuals or depriving them of a basic need.
- **Psychodynamic therapy** is a form of psychotherapy that focuses on unconscious processes as they are manifested in an individual's present

behavior. It is also known as insight-oriented therapy.

- **Road rage** is an extreme form of angry or aggressive behavior by a driver of a car or other road vehicle.

Description and Diagnosis

Intermittent explosive disorder is one of the DSM-5 disruptive, impulse-control, and conduct disorders. The core feature of intermittent explosive disorder is a failure in self-control in response to being intentionally provoked by another. It is by impulsive, aggressive, violent, and angry outbursts. The outbursts usually last for nearly 30 minutes and typically occur in response to being provoked by another individual. Outbursts are generally impulsive or anger-based and not premeditated (intended). Aggressive episodes may be accompanied by irritability, rage, increased energy, tremors, and racing thoughts. Some signs of this disorder include road rage, domestic abuse, and throwing or breaking objects. Individuals with intermittent explosive disorder engage in verbal aggression, or assault individuals, objects, and animals. They may feel embarrassment, regret, or remorse following an assault.

The occurrence of this disorder in the United States is approximately 2.7% for the entire population (American Psychiatric Association, 2013). Intermittent explosive disorder is more common among males and more common in individuals younger than 40 years old (American Psychiatric Association, 2013). This disorder is also more common in individuals with a high school education or less (American Psychiatric Association, 2013). Individuals with intermittent explosive disorder are at greater risk of engaging in self-harm, having difficulty in interpersonal relationships, and having trouble at home, work, or school. The disorder may occur from time to time, with repeated periods of impulsive aggressive outbursts. Typically, it tends to be chronic and persistent over the course of many years.

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, individuals can be diagnosed with this disorder if they have a failure to control aggressive impulses as manifested by verbal or physical aggression. The recurrent aggressive outbursts are impulsive, are out of proportion with the precipitating stressor, and cause marked distress with the individual and his or her interpersonal and occupational functioning. The individual must be at least six years old and the disorder must not be better explained by another mental disorder. The individual who engages in verbal aggression or physical aggression toward objects, animals, or other individuals must exhibit this behavior twice weekly for a period of three months. Behavioral outbursts that damage an object or cause physical injury to an animal or other individuals must occur at least three times within a 12-month period (American Psychiatric Association, 2013).

The exact causes of this disorder are unknown. Environmental factors may be involved. For example, individuals who grew up in families where explosive behavior and verbal and physical abuse occurred may be more likely to develop this disorder. Another potential cause is genetic or physiological factors. A genetic component may be an influence. There may also be differences in the way serotonin (a chemical messenger in the brain) works in individuals with intermittent explosive disorder. Depressive disorders, substance use disorders, and anxiety disorders are most commonly associated with this disorder. Also, individuals with borderline disorder, antisocial personality disorder, or a history of disruptive behaviors have a higher risk of being diagnosed with the disorder (American Psychiatric Association, 2013).

Treatment

Treatment for this disorder typically involves psychotherapy in order to help individuals understand and control their thoughts and behaviors. Psychodynamic therapy may be helpful in that it involves having an individual focus on feelings and motivations. This type of therapy may uncover underlying feelings and reasons behind anger and rage and help an individual to develop a better way to think about and control his or her behavior. Cognitive behavior therapy (CBT) may also help individuals with intermittent explosive disorder. CBT focuses on conscious thought and noticeable behaviors, which may help the individual to recognize the urge to explode, to identify triggers, and

to develop ways to prevent explosive behaviors from occurring. Several medications can reduce aggression and prevent angry outbursts. These medications include antidepressants, antianxiety medications, mood stabilizers, and antipsychotic drugs.

International Classification of Diseases

The International Classification of Diseases is the standard diagnostic classification system in the world for the diagnosis, treatment, and reporting of medical and mental conditions. It is also referred to as ICD.

Description

The International Classification of Diseases (ICD) is the standard diagnostic classification system used throughout the world for the diagnosis, treatment, and reporting of human health conditions. In addition to medical disorders, it includes mental and behavioral disorders. ICD is developed and published by the World Health Organization (WHO). Its primary value and utility is that it provides a common diagnostic language across cultures. In this classification system, medical and mental health conditions are organized in a comprehensive taxonomy and coding system. Each disease or disorder entity is identified by a specific diagnostic code. At present, the ICD is in its 10th edition (ICD-10), and revisions are currently under way for ICD-11. The ICD-10 is published in 42 languages, and while print versions are available for sale, it can be downloaded free of charge from the WHO website (WHO, 2004).

Developments and Current Status

In 1893, the International Statistical Institute approved a standardized system for classifying deaths. The list was prepared by a French statistician Jacque Bertillon (1851–1922) and was called the Bertillon Classification. By 1900, 26 countries had implemented the Bertillon Classification. In 1928, a study sponsored by the Health Organization of the League of Nations discussed how the Bertillon Classification could be expanded to include the tracking of diseases. In 1949, the WHO supported the development of a global system for tracking mortality (deaths) and the causes of diseases. The Manual of the International Classification of Diseases, Injuries and Causes of Death (ICD) has served as the foundation for the modern practice of medical coding. Starting with the Bertillon Classification, this list is revised every 10 years. The latest revision is ICD-10.

While most mental health providers in the United States rely on DSM to one degree or another, the official U.S. diagnostic system for mental illness is the ICD. This means that DSM diagnoses must be recoded or translated via computerized "crosswalks" into ICD codes for third-party billing and epidemiological purposes. For example, Medicare requires that claims be submitted with ICD codes and the Health Insurance Portability and Accountability Act requires ICD codes for electronic information transfer. Furthermore, while ICD-10 is the current and most widely used edition of the ICD system, U.S. health care relies on the ICD-9-CM. The ICD-9-CM is an American modification of the ICD-9 developed by the National Center for Health Statistics. It is required for most clinical, billing, and reporting purposes. Presumably, DSM-5 will be more consistent with ICD-11 than previous versions.

While both DSM and ICD systems share commonalities in structure, format, and content, there are noteworthy differences between them. One is that both may use different terms for the same disorders. For

example, attention-deficit hyperactivity disorder in the DSM is hyperkinetic disorder in the ICD. Another is that same disorder can have somewhat different criteria for diagnosis. Basically, the ICD has more flexible and general diagnostic guidelines, while the DSM has stricter and categorically defined diagnostic criteria.

Internet Addiction Disorder

Internet addiction disorder is a mental disorder characterized by excessive use of a computer that interferes with normal living and causes severe stress on family, friends, and work environment. It is also known as cyber addiction.

Definitions

- **Addiction** is a chronic disease of the brain, which involves compulsive and uncontrolled pursuit of reward or relief with substance use or other compulsive behaviors.
- **Antianxiety medications** are prescribed drugs that relieve anxiety symptoms. They are also called anxiolytics or tranquilizers.
- **Antidepressant medications** are prescription drugs that are primarily used to treat depression and depressive disorders. They are known as antidepressants.
- **Cognitive behavior therapy** is a type of psychological treatment that focuses on maladaptive (problematic) behaviors, emotions, and thoughts. It is also called CBT.
- **Conditions for further study** is the section in the DSM-5 which describes conditions that do not currently meet the criteria for a mental disorder. Further research is required before they can be considered for inclusion in future editions of the DSM.
- **DSM** stands for *Diagnostic and Statistical Manual of Mental Disorders*. It is the handbook mental health professionals use to diagnose mental disorders. The current edition (fifth) is known as DSM-5.

Description

Internet addiction disorder is extreme computer usage and preoccupation with computer usage that consumes a considerable amount of time and negatively affects personal functioning. Computer usage can include Internet access but does not have to. There are several types of Internet or cyber addiction. Cybersexual addiction entails watching, downloading, or exchanging online pornography. It also includes acting out sexual fantasies in chat rooms. Cyber-relational addiction occurs when online relationships become consuming and take precedence over real relationships. It may also occur when an individual has an online affair. Net compulsion involves excessive online gambling, shopping, or stock market transactions that result in personal, monetary, or work-related distress. Information overload (addiction) is compulsive web searching for the collection of information. Internet gaming disorder is excessive Internet usage to play games. The inability to control or cut down on game time leads to distress in important areas of life. Internet addiction disorder is not a DSM-5 mental disorder. Although Internet gaming disorder is not currently designated as a mental disorder, it can be found in the DSM-5 under the section labeled "conditions for further study" (American Psychiatric Association, 2013).

The cause is not well understood. However, it may be that a combination of biological, psychological, social, and cultural factors play a role in this disorder. Biological influences may involve problems with serotonin and dopamine neurotransmitters. Psychological causes may include maladaptive thoughts, low self-esteem, and low self-efficacy. Additional psychological factors are comorbid psychiatric disorders such as depression, anxiety disorder, or impulse disorders. Inadequate social skills or a lack of social competence may contribute to this disorder. Cultural influences include where an individual lives. Computer and Internet access is readily available in many developed countries. Poor countries have very little, or no, technology availability.

Treatment

A comprehensive assessment is necessary to differentiate problematic computer usage from normal usage. Treatment may consist of cognitive behavior therapy (CBT), self-help groups, and/or medications. CBT is commonly used to treat various addictions, including this disorder. Self-help groups and Twelve-Step Programs can also be helpful and is commonly used in conjunction with CBT. Medications may involve antidepressant and antianxiety medications.

Internet-Based Therapy

Internet-based therapy is a form of psychotherapy accessed via telephone, cellular phone, or the World Wide Web.

Definitions

- **Browsing** means using a web browser such as Internet Explorer, Safari, or Firefox to access the Internet.
- **Internet** is the global communication network that allows almost all computers worldwide to electronically connect and exchange information.
- **Online** means to be on the Internet or to access through the Internet.
- **Protocols** are computer languages used to send and receive information via the Internet, such as the World Wide Web (www) for online browsing, or SMTP for e-mail.
- **Web based** refers to applications that are delivered online via the Internet.
- **Web browsers,** or browsers for short, are computer-based applications that make access to the World Wide Web possible and user friendly through the World Wide Web protocol.
- **World Wide Web** (WWW), or web for short, is most often used as a synonym for the Internet but is actually the protocol a computer uses to access the Internet. The WWW is just one way to use the Internet.

Description

The widespread use of the Internet and the advancement of affordable computer software, hardware, and telecommunications technologies have led to new methods of delivering online psychotherapeutic services. Online mental health services are an emerging form of psychotherapeutic intervention and consist of two broad types of delivered services. The first is web-based interventions, which provide content that may be educational, such as information about a particular mental health disorder, or an interactive application, such as filling out self-assessments that lead to more detailed and specialized information. The second way in which mental health services may be provided

is through real-time interactive online videoconferencing, that is, a video counseling session.

Web-based interventions include self-guided educational, self-guided therapeutic, and human-supported therapeutic interventions. Web-based educational interventions are self-guided online programs accessed through specific websites. The interventions are content focused and provide varying degrees of automated feedback but no human-supported guidance or feedback. These interventions attempt to create positive change by increasing knowledge, awareness, and understanding. For instance, someone suffering from anxiety searches the Internet and finds a website that contains a broad description of the different types of anxiety disorders. The individual fills out an online questionnaire, which indicates he or she may suffer from a social phobia. Upon clicking that link the individual is able to access more detailed information, including treatment options for social phobias. Web-based, self-guided therapeutic interventions add comprehensive, theory-based, highly structured interventions modeled on effective face-to-face treatment. For instance, the individual suffering from a social phobia would be provided a structured learning module focused on understanding cognitive behavioral dynamics, learning how thoughts are related to feelings and behaviors. These interventions can be quite sophisticated in providing automated feedback tailored to specific responses to instructions. Human-supported web-based interventions incorporate a human, usually a mental health professional, to provide support, guidance, and feedback.

Online counseling and therapy is provided by mental health professionals and may include individual or group contact and can be provided in real time or in a nonlinear time frame. Online counseling may be primarily textual, such as a private chartroom, or video conferencing face to face. Real-time video counseling is provided via teleconferencing applications. Nonlinear counseling may be provided via e-mail or text post. There are advantages and limitation to both forms of online counseling. Advantages included flexibility in time and location, and reduced cost. Limitations include the ability for clients to conceal their true identity or impersonate an individual; difficulty providing emergency assistance if needed; difficulty in expressing accurate emotions in text-based therapy; cultural misunderstandings; and difficulties in billing and fee collection.

Current Status

Because Internet-based treatments are still relatively new and therefore have not been standardized, it has been difficult to measure their outcomes with consistency or certainty. However, early research indicates that Internet-based therapy is an effective change agent. Studies have indicated that an empathic and warm therapeutic relationship can be created and maintained and that online counseling sessions have a substantial and positive impact on clients. Research also indicates that Internet-based therapy in the treatment of addictions, mood disorders, and other mental health difficulties results in positive behavioral changes.

Interpersonal Psychotherapy (IPT)

Interpersonal psychotherapy (IPT) is a type of insight-oriented talking therapy shown to be effective in the

treatment of a variety of mental health disorders, including depression, anxiety, and eating disorders.

Description

Interpersonal psychotherapy is grounded in attachment theory and communication theory. The focus of IPT is on interpersonal issues that are factors in the creation and maintenance of psychological distress. Targets of intervention include symptom reduction, improved interpersonal functioning, and increased social support. A typical course of treatment is from 6 to 20 weekly psychotherapy sessions.

Development

Interpersonal psychotherapy was developed in the 1970s at Yale University by psychiatrists and researchers Gerald Klerman (1928–1992) and Myrna Weissman (Weissman, 2006). Both Klerman and Weissman treated patients with depression and anxiety disorders. Finding that many patients being treated for depression with tricyclic antidepressants relapse after they stopped taking the medication, the researchers began to investigate the impact of psychotherapy in the prevention of relapse. Research studies of psychotherapy at the time (1970s) were limited in size and scope, and few studies included diagnostic criteria for depression or standardized outcome measures. Their research models addressed these issues and included the development of a standardized form of psychotherapy used in the clinical trials of maintenance treatment. IPT was influenced by psychodynamic, person-centered, and cognitive psychological theories. The psychotherapy they developed was manualized, meaning that the specific process was written down and followed by each of the psychotherapists treating patients in the clinical trial. Manualized treatment assures that all of the patients received the same psychotherapy no matter which psychotherapist provided the treatment. The manualized psychotherapy was initially modeled from supportive psychotherapy as might be delivered by clinical social workers. As the treatment was more fully developed, it was renamed interpersonal psychotherapy. Further clinical trials were conducted and found that a combination of medication and IPT was the most effective treatment for depression. Since those early clinical trials, IPT has been found to be effective in the treatment of a wide variety of mental health disorders, with people of all ages and from diverse populations.

Current Status

Interpersonal psychotherapy is based on the premise that psychological distress and symptoms are associated with a person's social and interpersonal relationships (Weissman, 2006). IPT was developed on a model of psychological distress referred to as the "Interpersonal Triad." The Interpersonal Triad consists of (1) an acute interpersonal crisis or stressor, (2) biopsychosocial vulnerabilities, and (3) social factors.

Interpersonal crises consist of a variety of mood states such as depression, anger, and anxiety, and other psychological distresses. The ability of a person to manage psychological distress is impacted by biopsychosocial vulnerabilities which consist of genetic vulnerability to illness, personality, temperament traits, and attachment style, all of which may contribute to, or diminish, symptoms. Social factors such as marital and family relationships, friendships, work relationships, religious membership, and other social support systems provide the context of the interpersonal psychological distress. In addition, communication patterns between social systems can impact the level of distress.

The linking of psychological distress to interpersonal conflicts and social relationships is a key focus of IPT. Psychotherapeutic elements of IPT include talking about interpersonal incidents, communication analysis, processing emotions, and role-playing. IPT is a here-and-now approach grounded in a strong therapeutic alliance between the client and therapist. Collaboration, consensus on goals, and positive regard expressed toward the client are key therapeutic components. Treatment goals include the identification of emotions, understanding where the emotions come from and why they exist, and the healthy expression of emotion. Treatment also includes linking current emotional functioning to "emotional baggage." Emotional baggage includes unresolved issues from past relationships and learned behavioral responses from childhood. IPT is appealing to clients who may find

psychodynamic therapy confusing and cognitive behavior therapy too demanding.

Interpersonal psychotherapy is an evidence-based practice that has demonstrated effectiveness in the treatment of a variety of mental health disorders. It is also effective in helping individuals recover from distress caused by interpersonal conflicts, grief, role transitions, and lack of social support.

Interpretation of Dreams, The (Book)

A classic work by psychoanalyst Sigmund Freud (1856–1939), *The Interpretation of Dreams*, published in 1900 in German, introduced the theory of the unconscious mind (id, ego, superego) and its impact on behavior.

Definitions

- **Dream analysis** refers to the process of assessing a dream's manifest and latent content to uncover its true meaning; Freud believed dreams to be "the royal road to the unconscious."
- **Oedipus complex** refers to the controversial concept proposed by Freud that describes a child's repressed sexual desire for his or her parent of the opposite sex.
- **Psychoanalysis,** developed by Freud, is both a theory and an approach to treatment that ascertains that people's thoughts, feelings, and behaviors are influenced by unconscious thoughts and the only way to resolve these conflicts and psychological well-being arises from bringing unconscious thoughts into awareness and making them conscious.

Description

The Interpretation of Dreams, literally *Die Traumdeutung* in German, is considered the most famous original work written by psychoanalyst Sigmund Freud. Freud is known to have revised the book at least eight times developing core psychoanalytic concepts, including the unconscious mind, dream analysis, and the foundations of what would later be referred to as the *Oedipus complex*. It was translated from German into English by psychoanalyst A. A. Brill in 1913; later translations by James Strachey and Joyce Crick followed. Though it took a few years to sell 600 copies in its first edition, the text grew in popularity in subsequent editions. Seven editions were published over Freud's lifetime, the final in 1929. Following the 1900 release of *The Interpretation of Dreams*, Freud wrote a more concise version of the book called *On Dreams* published in 1901.

Freud began writing *The Interpretation of Dreams* in 1895 while summering at manor Belle Vue near Grinzing, Austria, and later referred to the importance of the book in a letter to his contemporary Wilhelm Fliess in 1900. Dream interpretation sought to uncover, in Freud's words (1913), "the royal road to the unconscious." Dreams thus contain both manifest (surface) and latent (hidden) content. In Freud's estimation, dreams were forms of wish fulfillment, revealing unresolved conflicts that get pushed down in everyday life yet expose themselves in masked forms when one is in the dream state. Freud reached this conclusion after dreaming his own dream, commonly known as "Irma's Injection" on July 23, 1895. Attributing meaning to dreams, however, requires the careful analysis

of a trained psychoanalyst. Freud regularly conducted dream interpretation on himself as well as others, providing what he believed to be countless examples of this phenomenon. The process consists of a period of free association, listening, and questioning, followed by careful analysis incorporating what is known about the patient's past and present.

Impact (Psychological Influence)

Most people cite *The Interpretation of Dreams* as classic Freudian text that provides the basis for dream interpretation. Though it took several years to gain popularity, it has since been translated into multiple languages and is a common source used in psychology, psychiatry, and counseling courses. Freud, however, has been criticized for his claims as well as for the credibility of the evidence he provided in support of his dream theory; most of the case studies he referenced were his own patients or himself. Furthermore, his views and interpretations have been regarded as misogynistic and highly focused on sexual aspects.

Intervention

Intervention is a type of confrontational technique used to persuade someone to seek psychological or medical treatment. The term "intervention" also means a course of action or protocol provided for a person in treatment.

Description

In the mental health field an intervention often refers to a carefully planned process where family, friends, work colleagues, or psychological professionals confront a person struggling with an addiction, most commonly alcohol or drugs. In an intervention an ultimatum or choice is offered the person with an addiction to either seek treatment or that he or she will no longer receive support from loved ones. By talking directly to the person about the consequences of addiction for him or her and for his or her circle of friends and family, it is hoped that he or she will agree to enter a treatment program. Confrontational therapies were once in widespread use by psychologists and other health-care professionals in the United States. Over the past 20 years these techniques have not been as popular as more collaborative therapies. This is due to the harsh nature of the procedures and because research with people abusing substances seems to show that confrontational approaches have been less effective in rehabilitating them than other therapeutic methods.

Development (History and Application)

During the 1940s and 1950s, Dr. Harry Tiebout observed patients in treatment for alcohol abuse. His observations resulted in the recommendation to utilize confrontation and confrontational therapies with this population of patients. Dr. Tiebout believed that an alcoholic was incapable of accurately understanding and perceiving himself or herself. He claimed the defense mechanisms these patients demonstrated led them to justify their alcohol abuse in order to protect their self-esteem. This meant that the task of the therapist or mental health professional would be to help them reconstruct their personality and defense mechanisms. The goal with confrontational therapy was to have the patient surrender to the reality of the disease and then accept the need for the development of a new way of life.

Treatment for alcohol and substance abuse and addiction was spearheaded in Minnesota. In the 1970s the Reverend Vern Johnson developed the idea of family intervention. In this intervention a group of loved ones would confront an addict with the harsh effects of the

addiction on him or her and the community. This served as a reality check and an invitation to seek treatment. Family intervention received positive nationwide publicity when it was used by the Ford family to successfully confront the addiction problems experienced by First Lady Betty Ford. The intervention approach has been criticized for its all or nothing, confrontational approach and for the fact that it many times has not shown effective results. In the past 30 years more gentle approaches have been applied with greater success as evidenced by lower levels of recurring addiction.

Current Status

Intervention and confrontational techniques in therapy, when properly and non-abusively applied, can still be an effective way to reach out to help someone who is suffering. But like many other popular and utilized treatments in substance abuse and addiction, intervention has a low success rate for helping a person abstain from his or her drug of choice. The use of confrontation in intervention and more generally in addiction treatment was not based on any research that showed its effectiveness. Family education about addiction remains important and is an integral part of such family support. More research needs to be done in the area of long-term effectiveness of pretreatment interventions and confrontational therapies when applied to drug and alcohol abusers in order to develop effective alternative treatments.

Intimacy

Intimacy is the experience of emotional and physical closeness with another person.

Description

Intimacy involves activity in close interpersonal relationships. Intimacy is often associated with romantic relationships. However, the idea of intimacy readily applies to any type of relationship, whether it is romantic, family, or friendship. It is considered to be a process since it develops over a period of time. Many believe it to be a deep, biological need. Humans by nature are social beings and have a need for comfort and connection with others. The extent of this need often varies based on the individual.

In relationships, intimacy involves one partner's need to care about and be close to other as well as the fear of being vulnerable. The most critical part of intimacy is the ability and willingness to open oneself up to another. This includes exploring and sharing feelings, thoughts, insecurities, and vulnerabilities. The level of intimacy within a relationship is strongly rooted in trust. The person must have a feeling of safety to share these things with the other. This sharing allows for the person to feel close and connected to the other person in the relationship. On any given day multiple attempts are made by individuals toward achieving or maintaining intimacy at home, school, or even work. The level in which they may be looking to connect varies based on the type of intimacy and the individual.

Intimacy has several major components. These include nonverbal and verbal communication, presence, time, and boundaries. There are also several different types of intimacy, including intellectual, emotional, experiential, and sexual.

Current Status

The topic of intimacy holds importance to multiple fields. In psychology it connects into relationships and even developmental theory. Erik Erikson (1902–1994), an American psychologist, spoke of the importance of intimacy in his psychosocial stages of development. Erikson spoke of the important developmental

component of being able to share oneself with another human being whether it is in a romantic or platonic format. Failure to achieve intimacy in some capacity leads to the risk of isolation for the individual.

Introversion

See Extraversion and Introversion and Personality Type

Involuntary Hospitalization

Involuntary hospitalization is the legal process whereby individuals are placed in inpatient mental health treatment against their will because they are a danger to themselves or to others.

Definitions

- **Disability** is a physical or mental impairment that substantially limits one or more of the major life activities of an individual.
- **Mania** is a mental state of expansive, elevated, or irritable mood with increased energy or activity.
- **Psychotic features** are characteristics of psychotic disorders: delusions, hallucinations, disorganized thinking and speech, grossly disorganized or abnormal motor behavior, and negative symptoms, for example, lack of initiative and diminished emotional expression.
- **Substance-related and addictive disorders** are a group of mental disorders that include substance disorders characterized by physiological dependence, drug-seeking behavior, tolerance, and social withdrawal. This group also includes the non-substance disorder of gambling.

Description

Involuntary hospitalization involves placing individuals in inpatient treatment against their will. This is done through a court order and is sometimes referred to as civil commitment. The process is used for those who are dangerous to themselves or to others. It is also used for individuals who are unable to care for themselves and are without proper judgment. This may be due to a mental disorder, disability, or plans to commit suicide. This includes individuals with substance-related disorders and those who exhibit mania or psychotic features. The assumption behind involuntary hospitalization is that forced treatment is better than no treatment at all. Most states in the United States have some form of involuntary hospitalization law. These vary but generally require that there is proof of individuals' dangerousness and that the risk is immediate. The procedure can be initiated by those close to the individuals, such as a family member, friend, or doctor. Law enforcement officials are commonly called to assess the initial danger. If they determine that the individuals are at risk, then they will take the individuals into custody. This is followed by a psychiatric evaluation by mental health professionals in a hospital. There is generally a court hearing 24 to 72 hours after hospitalization to determine if the individuals are still a risk to themselves or others. This is to make sure that their rights are not violated and they are not unnecessarily detained. A judge may extend the length of the commitment or order a release depending on information provided by the mental health professionals.

Involuntary hospitalization is a controversial practice. Some argue that it goes against basic civil rights and deprives individuals of their freedom. It one of the few ways an individual can be denied liberty in a free society. Others believe that the benefits of this process far outweigh the risks. Supporters of involuntary hospitalization maintain that it is necessary for those who cannot care for themselves. They also hold that it protects society from potential dangers.

J

James, William (1842–1910)

William James was a major influence on the modern views of cognitive neuroscience. He wrote extensively on many subjects still studied in modern psychology, including attention, emotion, and perception. Though he was one of America's first psychologists, history generally views him as a philosopher.

Description

By the 1890s, James was established as the foremost American philosopher. He popularized pragmatism as a new philosophy. Pragmatism is what allows us to consider the practical effects of an idea when giving it meaning. Through his ideas, James coined the now widely used expression "stream of consciousness." His writings on the subject brought the idea of consciousness into focus. Though James did most of his work in the 19th century, his philosophy was influential and his work is still cited extensively today.

James had many interests and studied many subjects early in his life. He finally decided to pursue medicine and earned his degree in 1869. He taught physiology at Harvard and in 1875 taught the first course in psychology in America. James was a gifted teacher and a good communicator, and his lectures were well attended. Students found him charming and appreciated his friendliness and interest in them as people.

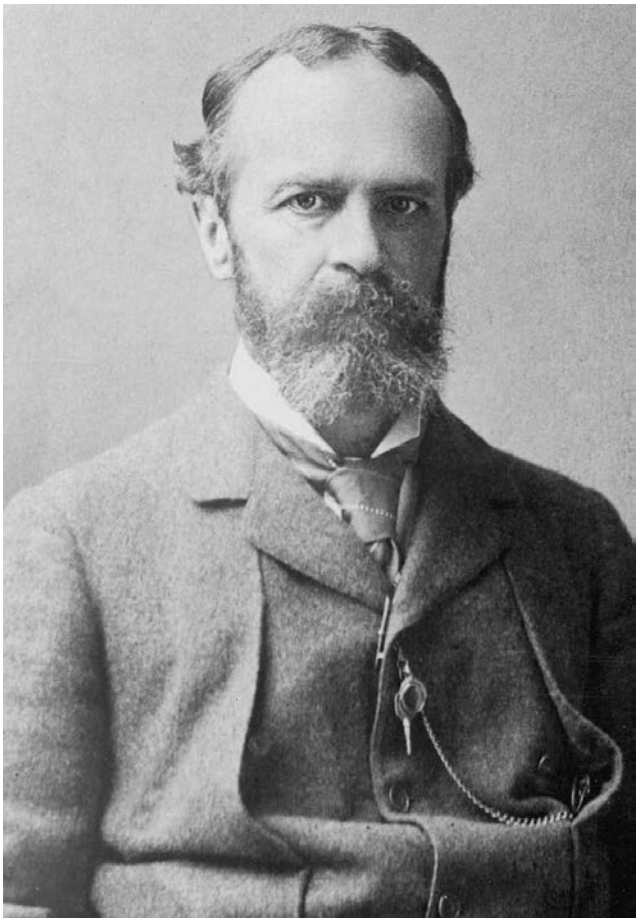
Impact (Psychological Influence)

One of James's major influences was how we look at psychology today. His book *Principles of Psychology* (1890) was one of the first to treat psychology as a science. He had many groundbreaking theories, including the belief that ideas are neither completely true nor completely false, because the universe is open ended and fluid. This principle became part of his functional psychology and philosophy of pragmatism.

Darwin's theory of evolution greatly influenced James's own work. James introduced and made popular the concept of habit as the main governing principle of an individual's mental organization. He wrote that humans, like animals, adapt to their ever-changing environment, and their behavior is controlled by habit. As the world changes, habits begin to break down and people must use consciousness to reestablish their connection to their surrounding environment. This interaction with the environment leads to experience. James's idea about the principle of habit is one of his most important and influential.

His work on brain function pointed to the division between short-term and long-term memory, 50 years before the idea was established as an accepted belief. He defended free will as a concept rather than that of a deterministic principle at work in the universe. Free will allows for the human condition to improve rather than staying locked into repeating the past. His work also established instinct as essential to the study of the human mind. It was his writings that brought instinct to the forefront of psychology.

His philosophy had an influence over other fields, including physics. He put forth that truth is what is experienced by the observer, and because of this, an objective truth is not possible. This concept is still accepted by physicists. In addition, James made a major contribution to education. He believed the study of psychology influences how teachers teach. Psychology itself is a science, while teaching is an art made up of



William James had a major impact on modern views of cognitive neuroscience. He wrote extensively on many subjects still studied in modern psychology, including attention, emotion, and perception. (Paul Thompson/FPG/Getty Images)

many different aspects. Effective teachers know psychology, though there are other skills required as well.

James even had an impact on religious thought. He wrote that religious belief should come from experience and not simply from what the church says. Many New Age churches have incorporated this idea into their teachings. A prolific writer, James's books include *Principles of Psychology* (1890), *Text-book of Psychology* (1892), *The Will to Believe* (1897), *Talks to Teachers on Psychology* (1898), *Human Immortality* (1899), *The Varieties of Religious Experience* (1902), *Pragmatism* (1907), *A Pluralistic Universe* (1908), and *The Meaning of Truth* in 1909.

James's ideas laid the foundation for modern psychology in areas such as emotions and brain function. Today, his conclusions are still stimulating contemporary research and debate in a variety of disciplines.

Journaling/Journal Therapy

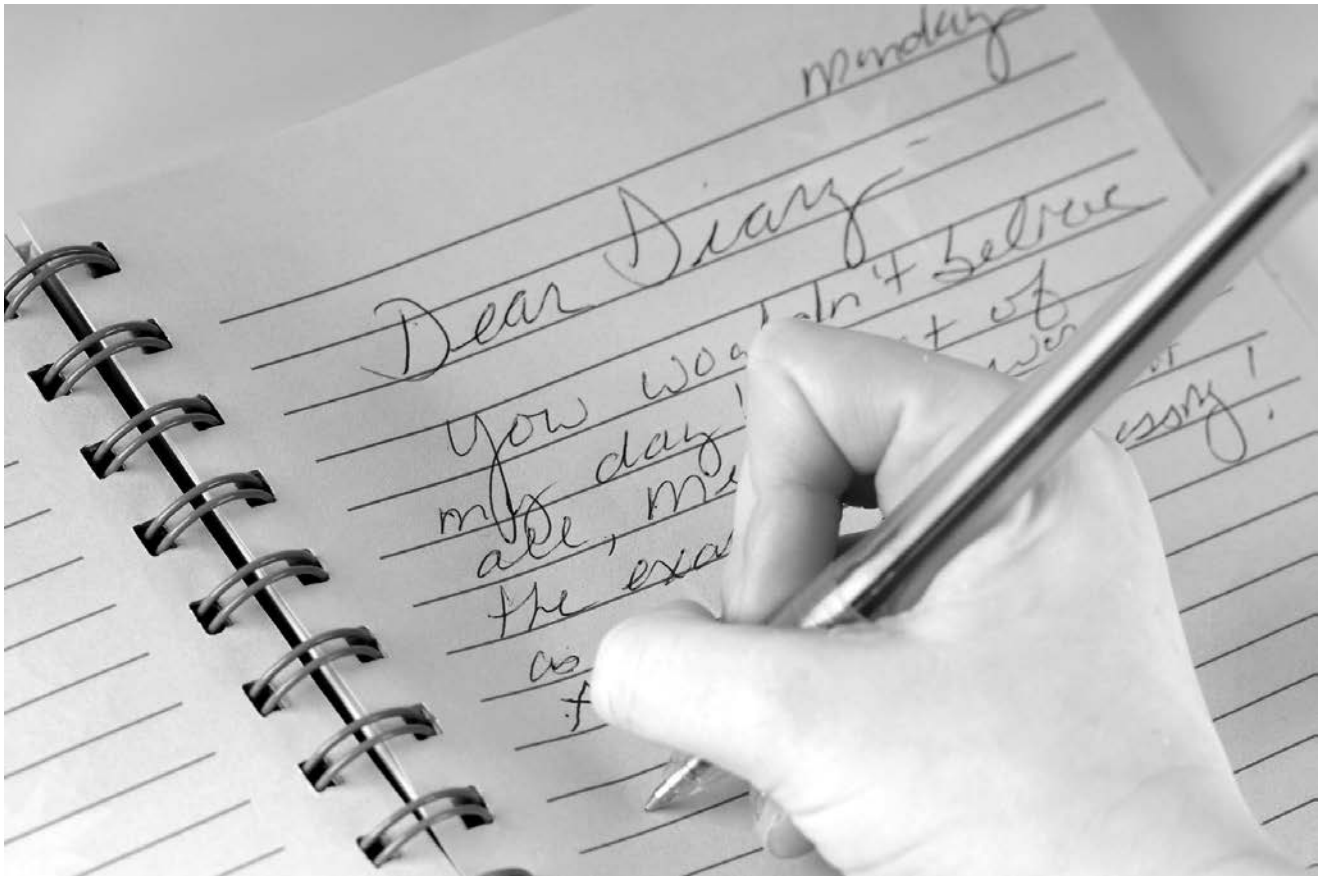
Journaling is a writing process used to openly express one's thoughts and feelings, reduce anxiety, and/or to produce greater self-awareness.

Definition

- **Online journaling** is an expressive writing technique where one accesses a journal via the Internet or other computer program to write about one's thoughts, feelings, ideas, problems, and goals.

Description

Journal therapy, also referred to as "writing therapy" or "reflective therapy," is a particular type of journaling used within the therapist–client relationship in which the counselor provides the client with specific directions, prompts, or guided writing exercises as a means of helping him or her achieve certain therapeutic goals. Journaling describes when an individual writes down his or her ideas, thoughts, and feelings on paper for the purpose of emotional catharsis, gaining clarity, or working through a particular problem. Journal entries are often kept in a recording device referred to as a journal. Journaling can be done individually or in groups. One may begin journaling on one's own, without the direction or urging of another, or one may



Journaling is a writing process used to openly express one's thoughts and feelings, reduce anxiety, and/or produce greater self-awareness. (Cheryl Casey/Dreamstime.com)

be required to journal as part of a teaching or counseling experience. When journaling is used as a means of therapy, it should be done only under the direction of a licensed or certified mental health professional with training or experience in this technique. Journal therapy describes a therapeutic process whereby the counselor instructs his or her client to engage in journaling to help accomplish some of the goals set in therapy. A client may be told to respond to specific prompts within the therapy session itself, or the client may be asked to write about his or her experiences between sessions. Journaling can provide the client with insights or observations about his or her own thoughts, feelings, and behavior patterns. In addition, it can assist the therapist in determining what progress has been made and in gauging what steps to take next. Therapists are cautioned against using journal entries as part of their analysis. Rather, journaling should be used as an additional source of information that can prompt discussion.

Journaling is a positive coping mechanism that can provide one with both mental and physical health benefits. One can use journaling to gain insight and mental clarity, or develop a deeper sense of personal awareness. It can also help to motivate a person to change negative behavior patterns or achieve a goal. The process of physically writing something down makes the goal more tangible and provides a measure of accountability. Keeping a journal can also help relieve stress or anxiety. In addition, journaling can help to repair relationships when it is used in family, couples, or marital counseling.

Development

Though journal writing has been around for centuries, journaling as a therapeutic technique gained

popularity in the 1960s by psychologist Dr. Ira Progoff. His method of intensive journal writing was used to develop a "psychological notebook" documenting his clients' lives over the course of several years. Some key books published during the late 1970s further popularized journal writing in mainstream culture, *At a Journal Workshop* by Dr. Progoff, *One-to-One: Self Understanding through Journal Writing* by Christina Baldwin, and *The New Diary* by Tristine Rainer. Journaling began to be incorporated into education during the 1980s, with many teachers noting the benefits of this practice with increasing students' comprehension, writing, and critical thinking skills. The added benefit of reducing anxiety and stress was also noted. Later studies by Dr. James Pennebaker in Texas confirmed these health benefits. In the late 1980s, psychotherapist Kathleen Adams provided education and workshops on the power of journaling to the general public at the Center for Journal Therapy in Colorado.

Current Status

Journal therapy has been used effectively with individuals suffering from grief and loss, relationship issues, anxiety disorders, coping with health problems and chronic illness, and addiction issues. Certified instructors in journal therapy are now available throughout the United States and several other countries. They typically hold advanced degrees in psychology, mental health counseling, social work, or other related helping professions. Advancements in the area include online journaling, which now allows for this technique to reach a wider range of people.

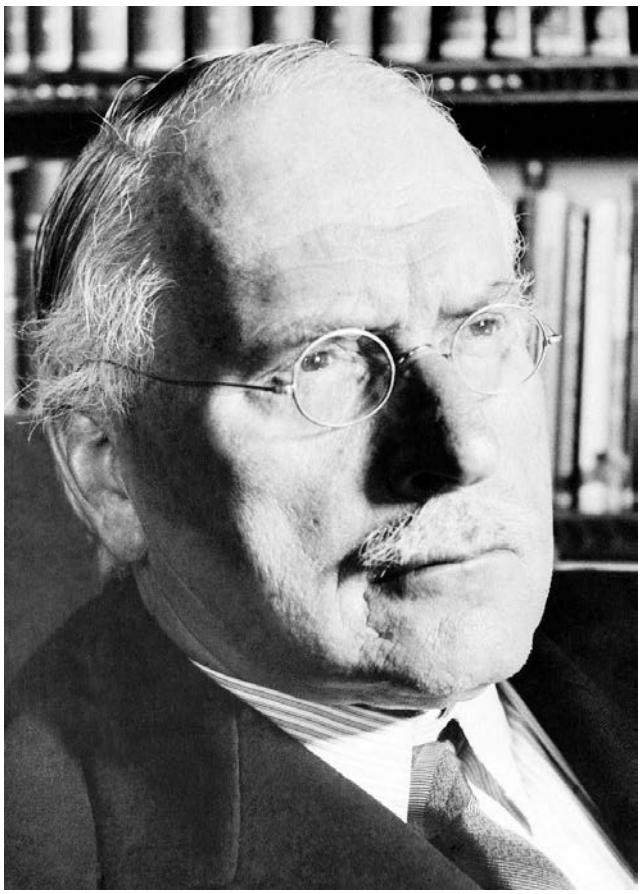
Jung, Carl (1875–1961)

Carl Gustav Jung (1875–1961) was a Swiss-born psychiatrist and psychotherapist who is recognized as the founding father of analytical psychology. A practicing clinician and scientist, Jung focused on spirituality and religiousness. He is most commonly known for proposing and developing many psychological concepts that remain relevant even today. These concepts include extraversion and introversion, archetypes, the collective unconscious, psyche, collective unconscious, anima and animus, complex, individuation, and synchronicity. He also contributed significantly to dream analysis and symbolization, as well as personality typology.

Spirituality and creativity were two deeply held concepts by Jung. In fact, he wrote about the collective patterns of symbolic expressions in his memoir



Carl Gustav Jung was a Swiss-born psychiatrist and psychotherapist who is recognized as analytical psychology's founding father. He is perhaps best remembered in popular culture for his work on archetypes. (AP Photo)

Memories, Dreams, Reflections. He believed that meaning can be expressed by those who are living a symbolic life and a life that is meaningful.

Jung saw the human psyche as religious by nature and so made religiousness the focus of his explorations. He spent considerable time exploring areas such as Eastern and Western philosophy, alchemy, astrology, sociology, literature, and the arts.

Upon entering his university studies, Jung chose to study medicine. During his studies, he stumbled upon a psychiatric textbook, which led to his belief that psychoses are diseases of the personality. Combining the biological and spiritual immediately captured Jung's interest. His training in psychiatry began at the world-renowned Burghölzli clinic in Zurich. This particular medical clinic was known for factoring in social and biological research in the treatment of psychiatric issues. At the clinic, Jung's research focused on the study of the phenomena of conscious as part of a spectrum, including dissociation, trance states, and splitting. Jung's research on the complex behavior patterns that he showed could be revealed through word associations led to his first taste of international fame.

Jung was born the fourth, but only surviving child of a poor rural pastor in the Swiss Reformed Church and the daughter of a wealthy Swiss family. He was a solitary and introverted child who was convinced from childhood that, like his mother, he had two personalities. The first was that of a typical schoolboy living in the era of the time. The second was a dignified, authoritative, and influential man of the past.

In 1903, he published a dissertation on the psychology and pathology of the occult phenomena. In 1906, he published his book *Studies in Word Association*, a copy of which he later sent to Sigmund Freud, sparking a six-year friendship with the famous psychologist. Jung and Freud bonded over their work on dreams and unconscious phenomena. Ultimately, Jung led the development of psychoanalysis and was the first president of the International Psychoanalytic Association, at the request of Freud. After the two split over theoretical differences, Jung again focused on his consciousness research, including the development of individuality through increased self-awareness. However, one of Jung's biographers asserted that Jung never recovered from his traumatic break with Freud. In fact, Jung states in his own words in *Memories, Dreams, Reflections* that the break was traumatic and led to a profound disorientation that was further complicated by psychosis.

In 1908, Jung became an editor of the *Yearbook for Psychoanalytical and Psychopathological Research*. He traveled with Freud and Sandor Ferenczi to the United States in 1909 to speak about psychoanalysis and in 1910 he became chairman for Life of the International Psychoanalytical Association.

In 1912, Jung published *The Theory of Psychoanalysis* and his *Psychology of the Unconscious*. The latter resulted in a theoretical divergence with Freud, which consequently fractured their friendship. He was drafted into the army in World War I.

At the age of 38, Jung experienced what he called a horrible confrontation with the unconscious. He saw visions and heard voices. Deciding it was a valuable experience, he induced hallucinations in private. He recorded everything he felt in small journals. He then transcribed his notes into a large, red, leather-bound book, on which he worked intermittently for 16 years.

In 1925, Jung embarked on the ambitious Bugishu Psychological Expedition to East Africa. Together with a group of three others, he traveled through Kenya and Uganda where Jung hoped to increase his understanding of primitive psychology through conversations with the culturally isolated residents.

In 1937, he took an extensive tour of India where he felt himself under the direct influence of a foreign culture for the first time. Hindu philosophy became an important element in his understanding of the role of symbolism and the life of the unconscious. Jung had a close relationship with the Chinese religions of Buddhism and Taoism. Jung offered several valuable concepts and ideas to Western psychology of spirituality that were based on Chinese religious characteristics.

Jung died at the age of 85 in his home at Keusnacht, Switzerland, after a short illness. He is remembered and still revered in the fields of psychology, psychoanalysis, and psychotherapy. He is remembered as one of the pioneers of contemporary dynamic psychiatry and physiological research in consciousness and self-regulation.

Jungian Therapy

Jungian therapy was developed by Carl Jung (1875–1961). "Jungian therapy" is the common term for analytical psychology, which was the term Jung used to describe his theory and approach to psychology. This term was used to differentiate his theory and practice from Sigmund Freud's form of psychotherapy commonly known as psychoanalysis. Jung and Freud collaborated for several years until a rupture in their relationship over theoretical differences drove Jung to develop his own theory.

"Jungian therapy," "Jungian psychoanalysis," and "Jungian analysis" are terms frequently used interchangeably. Jungian therapy is a form of therapy in which the client ideally progresses toward psychological balance and wholeness. The goal of psychoanalysis is to bring the patient awareness and understanding of what was formerly unconscious. This is achieved by directing therapeutic efforts at bringing the psyche's conscious and unconscious elements into a better alignment and balance. In contrast, the aim of therapy is often symptom relief.

When a client progresses toward psychological balance and wholeness, the result is the creation of new values and purposes. The process can be used to treat a broad range of emotional disorders and can also help anyone who wants to pursue psychological growth. This form of therapy requires intensity and regularity. For example, the frequency of sessions is decided between the analyst and the patient but can range anywhere from one to four or more times a week. Typically, it extends over a period of several years.

Each session focuses on patients' experiences in their daily lives, their memories, their feelings and reflection of such experiences, their dreams, or other forms of expression. The therapy explores a number of aspects of the psyche. The psyche is often defined as the sum total of all psychological processes, including those that are conscious and those that are unconscious. At the center of consciousness is the ego, while the self is at the center of the psyche, which comprises both consciousness and unconsciousness. Jungian analysis and therapy moves beyond the ego to establish a relationship between the ego and the self.

Jung also defined the inner feminine side of a man—the anima—and the inner masculine side of the woman—the animus. These two archetypes in the unconscious often appear in dreams and fantasies. When we become conscious of these inner contra-sexual figures, their energy opens us to new areas of thinking, feeling, and expression. When these figures remain unconscious, they sabotage our efforts for growth and fulfillment. The Jungian therapist works with the patient to identify these archetypes to ensure the person can find balance.

Jungian analysis requires a significant commitment of time and resources as sessions can be once a week or four or more times per week. Each client is different and so the frequency is determined by the analyst and client based on individual needs and presentation. In addition to the frequency, Jungian analysis can extend over a period of several years or more.

Jung was a Swiss-born psychiatrist and psychotherapist who is recognized as the founding father of analytical psychology. A practicing clinician and scientist, Jung focused his attention on spirituality and religiousness. He is most commonly known for proposing

and developing many psychological concepts that remain relevant even today. These concepts include extraversion and introversion, archetypes, the collective unconscious, psyche, collective unconscious, anima and animus, complex, individuation, and synchronicity. He also contributed significantly to dream analysis and symbolization, as well as personality typology.

In 1903, he published a dissertation on the psychology and pathology of the occult phenomena. In 1906 he published his book *Studies in Word Association*, of which he later sent a copy to Sigmund Freud, sparking a six-year friendship with the famous psychologist. In 1912, he published *The Theory of Psychoanalysis* and his *Psychology of the Unconscious*.

Since the 1990s, Jungian therapy has been the focus on many empirical studies aimed at proving its effectiveness in treating emotional disorders and psychoses. As such, there is evidence of the positive effects of this approach. It has been shown to lead not only to a significant reduction of symptoms and of interpersonal and other problems, but also to a restructuring of the personality with the effect that the patients can deal with upcoming problems much better after therapy has ended. The effects of the therapy appear to be long lasting and touch all areas of a patient's life.

Juno (Movie)

Juno is a Canadian American comedy-drama feature-length movie starring Ellen Page.

Description

Juno is a 2007 Canadian American comedy-drama starring Ellen Page, Michael Cera, Jason Bateman, Jennifer Garner, J. K. Simmons, and Allison Janney. *Juno* was directed by Jason Reitman and written by Diablo Cody. *Juno* is the story of a 16-year-old Minnesota high school girl coping with her unplanned pregnancy. The story follows Juno's relationship with her boyfriend, parents, school friends, and the adoptive parents of the yet-to-be-born child. *Juno* is best known for its depth of writing and characters, Juno's wisecracking and sardonic character, comedic dialogue and one-liners, poignancy, and excellent acting, especially that of Ellen Page. Themes include teen pregnancy, woman's choice, adoption, coming of age, romance, family, and authenticity.

The story opens with Juno (Ellen Page) finding out she is pregnant after having sex with her best friend Paulie Bleeker (Michael Cera), an introverted admirer of Juno. After considering abortion, Juno decides to keep the baby and find a couple for adoption. She tells her father Mac (J. K. Simmons) and stepmother Bren (Allison Janney) who are supportive, wise, earthy, intelligent, and pragmatic of her plan to give the child up for adoption. With the help of her father, Juno finds an adoptive couple, Mark and Vanessa Loring (Jason Bateman and Jennifer Garner), a middle-class couple who live in an expensive neighborhood and are unable to have children of their own. They are stereotypic yuppies, with Vanessa being somewhat materialistic and consumed with being a mother. Mark, pushing 40 years old, is pining over his lost youth and rock and roll days and works from home as a jingle composer for television commercials. Juno enters into an agreement regarding the care and adoption of the child.

Juno is the story of a 16-year-old Minnesota high school girl coping with her unplanned pregnancy. The 2007 film explores important issues such as teen pregnancy and relationships. (Fox Searchlight/Photofest)

The movie follows Juno through all nine months of her pregnancy and focuses on two main storylines: her relationship with Paulie and her relationship with the Lorings. As her pregnancy progresses Juno struggles with her feelings regarding Paulie who is clearly in love with her and will readily acquiesce to whatever Juno wants. Juno is distant and at times rejecting, while Paulie remains loyal and supportive. As Juno struggles with her relationship with Paulie, she makes several unannounced visits to the Lorings where Mark is most often the only one home. Mark and Juno share taste in movies and music and develop an overly close relationship. Mark eventually confesses to both Juno and Vanessa that he is not ready to be a father and intends to divorce Vanessa. Juno is devastated by this news but eventually tells Vanessa that she still wants Vanessa to adopt her child.

Reception and Criticism

Juno was a box office hit grossing over $143 million in the United States and scoring a 94% Rotten Tomatoes rating. *Juno* won numerous nominations and awards, including being nominated for four Academy Awards (including Best Picture and Best Actress for Ellen Page) and winning for Best Original Screenplay. The movie was also praised by critics and appeared on many top 10 lists of best films in 2007. Roger Ebert (2007) wrote "Jason Reitmans's 'Juno' is just about the best movie of the year." *Juno* brought teen pregnancy

into national focus, with both pro-choice and pro-life factions claiming the movie represented their position. *Juno* was also referenced in political debates after Alaska governor and Republican presidential running mate Sarah Palin's teenage daughter announced her unplanned pregnancy.

Juvenile Offenders

A juvenile offender, also known as a *juvenile delinquent* or *youth offender*, is a minor person under the age of 18 who commits a status offense, engages in delinquent behavior, or commits a violent or other serious crime.

Definition

- **Juvenile delinquency,** otherwise referred to as *juvenile offending* or *youth crime*, defines a violation of the law committed by a person under the age of 18, which would have been prosecuted as a crime if the minor were an adult.

Description

A *juvenile* is a minor person who is younger than the statutory age of majority, 18 years old. "Juvenile offender" is a term used to describe a minor who is found to have violated the law or committed a serious crime. Other terminology used to identify these youngsters includes "juvenile delinquent" and "youth offender." Youth who engage in delinquent, violent, or criminal activities are typically subject to different penalties and punishments than adults who have committed the same crimes. Consequences for violations committed by minors are often less serious and less harsh, and the focus tends to be on rehabilitation, providing these youth with an eventual "second chance" to turn their lives around, as opposed to punishments that are awarded to adult criminals. Minors may not be aware of how their actions impact themselves and others. Adolescents in particular commonly make mistakes, commit errors in judgment, and act impulsively without thinking. Thus, juvenile delinquency may be considered by some to be normal adolescent behavior.

While both males and females engage in youth delinquency and crime, the majority of juvenile criminals are males. Offenders are primarily of African American and Latino decent living in poor socioeconomic communities where lower parental involvement, higher substance abuse rates, and increased gang activity are common. Research indicates that both biological (genetics, chemical makeup, personality) and environmental factors (family dynamics, modeling, exposure to abuse) contribute to the youth crime problem.

Delinquency and criminal behavior can range on a continuum from less severe to more severe. Less severe violations may include status offenses such as underage smoking, drinking, or violating curfews. More serious crimes may involve vandalism, theft, drug trade, and violent behaviors (assault, rape, murder). Depending on the case, the circumstances surrounding it, and those involved in determining the severity of the offense, it is possible for a minor to be charged and tried as an adult.

Impact (Psychological Influence)

Youth violence rates peaked in the early 1990s, but a decrease in aggressive crimes committed by minors has been noted over the past two decades. Statistics indicated, however, that arrest rates for juvenile offenders have risen, though this increase may be attributed to improved law enforcement efforts and stricter, harsher penalties being imposed for first-time offenses. Even though these offenses tend to be primarily nonviolent, concerns have been raised regarding engaging in juvenile delinquent behaviors and one's propensity for future violent behavior and/or criminal involvement. This topic has been studied extensively, with studies showing that the frequency and severity of offending behaviors are critical elements. Delinquency may be viewed as normal adolescent behavior; therefore,

some level of mischief, rule breaking, and opposition to authority should be expected. Most youth who engage in these types of behaviors as minors "grow out" of it as adults and are able to adapt and conform. However, those who consistently and habitually commit offenses, especially violent offenses, during these formative years have a more difficult time breaking the pattern and often end up involved in criminal behavior later on. Youth offending has consistently been linked to at-risk behaviors, including gang involvement, increased dropout rates, experimenting with alcohol and drugs, and sexual promiscuity. Juvenile offenders are also more likely to experience certain psychiatric disorders including post-traumatic stress disorder, conduct disorder, and depression, which may be attributed to increased exposure to violence.

Preventing youth offenses requires comprehensive efforts comprised of educational programming, parental support, and community outreach. School staff may begin by targeting students who display academic, behavioral, or emotional problems and exhibit warning signs including truancy, failing grades, vandalism, and a propensity for violence. Parents of juvenile offenders also need support as they often lack skills needed to deal effectively with their children. Counseling services can be provided for the minor themselves, their parents, and families. Outreach on behalf of community leaders and organizations is also necessary. Churches, state-funded agencies, and other nonprofits entities can assist youth by providing essentials such as food, clothing, and shelter, in addition to offering safe, caring, and positive outlets for adolescents to go. Struggling families need exposure to and assistance from positive, pro-social networks in order to break the cycle of crime and violence.

K

Kaufman Adolescent and Adult Intelligence Test (KAIT)

The Kaufman Adolescent and Adult Intelligence Test (KAIT) is an intelligence test for individuals between the ages of 11 and 85 years.

Definitions

- **Intellectual** refers to the ability to think and understand ideas.
- **Intelligence** is the capacity a person has to learn and understand information and solve problems.

Description

The Kaufman Adolescent and Adult Intelligence Test is designed to assess mental functioning for people beginning at age 11 through late adulthood. The KAIT is one of several intelligence tests developed by Drs. Alan and Nadeen Kaufman. Like several other IQ tests, the KAIT is aimed at measuring both fluid and crystallized intelligence. Fluid intelligence evolves and describes new problem-solving skills people develop to identify and understand patterns of relationships. Crystallized intelligence is the already acquired information and education an individual has based on reasoning with words and numbers. The six subtests of the KAIT core battery are composed of three sections to measure fluid knowledge and three to measure crystallized knowledge. Together they help build a comprehensive picture of an individual's intellectual capability. During the test, a person is asked to respond to randomly chosen samples of behavior. This approach has good results because it targets both how and if a person is able to respond to a situation. The result is a determination of both a person's developmental level and intellectual maturity. The KAIT must be administered according to a strict procedure. It usually takes about an hour to complete. The KAIT also has an extended battery of 10 subtests, which can be used to expand the information about the subject's intelligence especially in regard to delaying a response to tasks.

Development (Purpose and History)

Following the groundbreaking work of Alexander Luria and Jean Piaget, a young Dr. Alan Kaufman had the opportunity to work with Dr. David Wechsler on revisions to the Wechsler Intelligence Scale (WISC). Later while teaching at the University of Georgia and the University of Alabama, he and his wife Nadeen led a team that developed several different kinds of intelligence tests. The first was one for children, the Kaufman Assessment Battery for Children.

This was followed by a series of other tests that provided screening and skills assessments. The Kaufmans were interested in developing an intelligence test which followed the distinctions made by Horn and Cattell about fluid and crystallized intelligence. The Kaufmans wanted to use broader definitions of fluid and crystallized abilities that would especially take into account developmental changes in intelligence.

In 1993, the Kaufmans published the first Kaufman Adolescent and Adult Intelligence Test. The test was validated for a wide population of people beginning with teens and eventually going as far into adulthood as the 90s. The KAIT was intended as an intelligence test which would measure both adolescent

and adult intelligence as well as provide clinical and neuropsychological data on the individual who took the test.

Current Status and Results

The KAIT itself has been tested repeatedly over the years. It shows both strong reliability and validity in the research. One of its strong points is that it includes both visual and auditory formats, which can give more accurate results for different types of learners. It is one of the most widely used tests in educational, clinical, and vocational settings.

Alexandra Cunningham, PhD, and William M. Cunningham, MA

Kaufman Assessment Battery for Children (K-ABC)

The Kaufman Assessment Battery for Children (K-ABC) is an intelligence test for children between the ages of 2 and 18 years.

Definitions

- **Intellectual** refers to the ability to think and understand ideas.
- **Intelligence** is the capacity a person has to learn and understand information and solve problems.
- **Intelligence quotient** is a measure of intellect to determine a person's level of cognitive ability.

Description

The Kaufman Assessment Battery for Children was designed to measure the intellectual functioning and processes of children. The K-ABC intelligence test is based on determining how a child solves a problem instead of what kinds of problems he or she can solve. Other intelligence tests focus on what kind of verbal or nonverbal questions children can answer, which means that the K-ABC is a departure from many other intelligence tests. These test results give what is called a general mental processing composite, which is equivalent to an intelligence quotient score.

The K-ABC has been adapted and revised and is now in its second version. The K-ABC-II has four regular scales and one optional scale. The simultaneous tests include such tasks as facial recognition, pattern reasoning, and block counting, while the sequential tests include hand movements, number recall, and word order. The K-ABC-II was normed for an expanded age range, children 3 to 18 years of age. It includes a nonverbal battery option.

Development (Purpose and History)

The K-ABC was developed in the late 1970s by Alan and Nadeen Kaufman. The two were working with a team at the University of Georgia where Alan Kaufman taught. The test was first published in 1983. These tests were developed to be appropriate for use with nonverbal and non-English-speaking children. Therefore, the K-ABC differs from more traditional tests of intelligence because it reduces the emphasis on verbal abilities and knowledge of specific content. It does however also include a brief screening of achievement defined as knowledge acquired through schooling or experience.

Current Status and Results

Originally the K-ABC caused some controversy since it excluded language subtests from the overall intelligence calculations. This does however make it useful for measurement of intelligence in diverse populations. Its construction makes it less susceptible to cultural biases that might be inherent in tests based on language. The K-ABC is also known for not being influenced in

its results by the personality or temperament of the individual taking the test.

The K-ABC is a test that has become widely used in France and Germany. In the 1990s its use in the Democratic Republic of the Congo validated the distinction between sequential processing and simultaneous processing. In the United States, the K-ABC is now a well-accepted alternative or addition to the Wechsler Intelligence Scale for Children (WISC). Because of its reduced dependence on personality factors, it has become a popular choice to test the intelligence of children with disabilities and those who may express their abilities nonverbally.

Kava Kava

Kava kava is an herbal remedy used to reduce stress and anxiety. Also called kava, it has many other uses, ranging from promoting sleep to reducing muscle stiffness and menstrual cramps.

Definitions

- **Food and Drug Administration** is a federal agency that is responsible for protecting the public health by assuring the safety and security of drugs, medical devices, food supply, and cosmetics. It is also called the FDA.
- **German Commission E** is a scientific advisory board that evaluates the safety of herbal medicines. It is equivalent of the FDA.

Description

Kava kava, also known as kava, is a natural remedy used to reduce stress, anxiety, and restlessness and a wide range physical symptoms and medical conditions. These include insomnia, sore and stiff muscles, toothache and sore gums, menstrual cramps, epilepsy, jet lag, and attention-deficit hyperactivity disorder. Kava kava is a plant native to the Pacific Islands. Natives prepare kava by pounding or grinding its roots and mixing them with coconut milk or water. Western manufacturers use alcohol or acetate in making liquid kava preparations. It is also available in capsule, tablet, powdered, or crushed forms. The active ingredients in kava are kavalactones and kavapyrones. Kavalactones have antianxiety properties and appear to affect the brain in the same way as benzodiazepines, such as valium. Kavapyrones have anticonvulsant and muscle relaxant properties.

For years, kava has been widely recommended as a mild tranquilizer due to its painkilling properties However, safety warnings have been issued by the U.S. Food and Drug Administration. It had been approved as a nonprescription dietary supplement for the relief of anxiety, stress, and restlessness by the German Commission E. But in fall of 2001 the commission withdrew its approval due to reported health risks associated with it. Kava has been banned from the market in Switzerland, Germany, and Canada. This ban has hurt the economies of Pacific Island countries that export kava. The irony is that while clinical trials have shown it to be unquestionably effective in treating anxiety and in reducing withdrawal symptoms in benzodiazepine users, its safety is questioned.

Precautions and Side Effects

Kava has been linked to several cases of severe liver problems, including hepatitis, cirrhosis, and liver failure. Using kava for as little as one to three months has resulted in the need for liver transplants. Early symptoms of liver damage include fatigue, dark urine, and yellowed eyes and skin (jaundice). If kava is taken despite warnings to the contrary, frequent liver function tests are necessary. Because of its effects on the central nervous system, it should be used with care when driving or operating heavy machinery, and those undergoing surgery should stop taking kava kava two weeks

prior to their procedure. Kava can worsen any existing depression and should not be taken by persons with a history of depression. For these reasons, its use should be medically monitored.

The most common side effects of kava are numbness in the mouth, depression, insomnia, headaches, dizziness, and skin rashes. More serious side effects include liver damage and tremors. It can reduce the effectiveness of levodopa, a drug used in the treatment of Parkinson's disease. Because of serious interaction effects, kava can significantly increase the sedating effect of certain medications. These include benzodiazepines like Xanax, Klonopin, Ativan, and Ambien, and barbiturates like phenobarbital (Donnatal). Individuals should inform their physician that they are taking kava as well as any other supplements.

Kim Berg, Insoo (1934–2007)

Insoo Kim Berg was an American social worker who was the co-developer of solution-focused brief therapy, a form of psychological treatment that focuses on an individual's strengths and solutions rather than on problems and pathology.

Description

Insoo Kim Berg was born in Korea in 1934 and moved to the United States to attend college at the University of Wisconsin. After completing her master's degree in social work, she received additional postgraduate training at the Family Institute of Chicago. Along with her husband, Steve de Shazer (1940–2005), she is credited with developing and promoting solution-focused brief therapy. Her strengths-based training and positive view of human behavior lead to the creation of this unique therapeutic approach.

Impact (Psychological Influence)

Berg's contributions to contemporary psychotherapy are significant. Her theory focuses on the solutions, not problems or pathology. The therapy is known for techniques such as (1) the miracle question, an assessment strategy from solution-focused brief therapy that examines an individual's desired outcome of therapy; (2) presuppositional questions, or therapeutic questions from solution-focused brief therapy that suggest possibilities or expectations of a positive outcome; for example, "what will be different when you are feeling better?"; and (3) building on strengths. Solution-focused brief therapy focuses on client strengths, their exceptions to the problem, and examines past solutions. Her therapeutic approach is practiced around the world and is a very popular form of brief therapy. She published 10 highly acclaimed books in her lifetime and was known for traveling internationally to train, teach, and consult with other professionals about solution-focused brief therapy. In 1978, Berg and de Shazer founded the Brief Family Therapy Center in Milwaukee, Wisconsin. While the center was closed the year of Berg's death in 2007, her approach continues to be practiced worldwide.

Klein, Melanie (1882–1960)

Melanie Klein was an influential pioneer in the psychoanalysis of children. Many list Klein as second only to Freud in her influence on modern psychoanalysis. She took analyzing young children to a level that had never before been seen. As a result of her work, more is understood about the nonverbal communication of children and patients at all ages.

Description

Melanie Klein was born in Austria in 1882, the daughter of a physician-turned dentist. She wanted to be a doctor herself but got married at 21 and never studied medicine. Klein is known for her work with children and her development of child analysis. She discovered that children could express themselves and their fantasies through free play, which allowed analysts to interpret their nonverbal communication.

Melanie Klein was an influential pioneer in the psychoanalysis of children. (Keystone-France/Gamma-Keystone via Getty Image)

Klein sought personal help through psychoanalysis in her 30s. She was analyzed by Ferenczi, who encouraged her to follow through on her desire to understand and help children by analyzing them. She presented her first paper *The Development of the Child* to the Hungarian Psychoanalytic Society in 1919.

She also was analyzed by Karl Abraham, who taught her his theories on oral impulses as a source of mental pain and conflict. She began to take his work further and developed her own technique for child analysis in 1921. Klein helped to develop the object-relations theory in the 1920s, by tracing the origins of anxiety to the baby's first experiences with a part-object, the breast. In 1926 she moved to London, where she made many original contributions to both child and adult analysis and continued her work there until her death in 1960.

She was one of the first psychologists to work with babies and young children, and to understand they may suffer from severe anxiety. Her work with children led to observations that influenced her theory of human emotional development. Working with patients of all ages confirmed to her that normal development depends on the ability to overcome psychotic anxiety.

Her technique for analyzing children was a major breakthrough in psychotherapy. One of the barriers to working with children was their inability to verbalize complex ideas. She got around this by using their natural instinct to play. Klein offered toys to her young patients and observed their play. She noted that all behavior exhibited by children, such as play, drawing, and even silence, conveyed the content of their fantasies. Analysts could then interpret these fantasies the way they did with adults, and children as young as two or three years old could understand the source of their fear. Knowledge of these unconscious fantasies benefits patients of all ages in dealing with their anxiety and environment. Klein's work opened the door not only for analyzing children but also for analysts to use nonverbal communication with other patients who couldn't verbalize, such as those with selective mutism or psychosis.

Another of Klein's theories is that infants divide themselves and their external world into good and bad parts at a young age. This is part of their healthy development. The good part is made up of the sense of

being loved, loving, and gratification, while the bad part is made up of frustrating or hated feelings. Infants initially identify with the good side so they can cope with the bad. When they develop the ego, they are able to combine the bad with the good and deal with conflict.

Klein believed infants feel they are in danger the first few months of life. This can lead to one of two stages of infant anxiety, which she called the paranoid-schizoid position or the depressive position. In paranoid-schizoid position, infants experience paranoia and fear for the self. The depressive position is made up of anxiety of destruction and loss.

Infants form an early, primitive superego in their development that plays a major role in psychoses, manic-depressive illness, and paranoia. They also undergo an omnipotent fantasy she referred to as projective identification, which is part of all normal and pathologic developmental processes.

Another of Klein's breakthroughs was to explain the difference between jealousy and envy. Jealousy is pain suffered from loss of love experienced in a three-person relationship. Envy is found in a two-person relationship, where the patient experiences pain due to inequality. Her theories on early envy are important because they explain how envy can limit success in therapy, which has helped the treatment of difficult patients.

Klein experienced some hostility toward her ideas about infantile anxiety, mainly because they didn't fit with the ideal mother–child relationship that was a popular belief at the time. She saw anxiety in infants as directly related to the infants' own violent oral sadistic fantasy. Babies are terrified of their own aggression that they project outward and are in a state of anxiety because of it. Babies recognize their own behavior as cruel and experience depressive anxiety because of it. Since her ideas didn't agree with those of many other analysts of the day, her work was often criticized.

In 1932, Klein published her first book *The Psycho-Analysis of Children*. Two of her most important papers from her work on infantile anxiety are *A Contribution to the Psychogenesis of Manic-Depressive States* (1935) and *Notes on Some Schizoid Mechanisms* (1946). Her final book *The Narrative of a Child Analysis* was published posthumously in 1961.

Impact (Psychological Influence)

Klein's work and discoveries have stimulated an important school of thought and analysis. Her work is seen as an extension of Freud's psychoanalytic method and has influenced generations of analysts. She was a caring practitioner who was concerned with the well-being of children, and saw patients up until her death at the age of 78.

Kleptomania

Kleptomania is a mental disorder characterized by the inability to resist the urge to steal things. The items are not stolen for personal use or for their financial worth, but for other reasons.

Definitions

- **Antisocial personality disorder** is a mental disorder characterized by a pattern of disregarding and violating social norms (rights of others).
- **Cognitive behavior therapy** is a type of psychotherapy that focuses on maladaptive (problematic) behaviors, emotions, and thoughts. It is also called CBT.
- **Conduct disorder** is a mental disorder characterized by the repeated disregard for the right of others and for rules and laws.

- **Disruptive, impulse-control, and conduct disorders** is a group of disorders that entail difficulties with the regulation of emotions and/or behaviors. These difficulties lead to behaviors that infringe upon the rights of others. They may also lead to legal trouble.
- **Endorphins** are brain chemicals that inhibit sensations of pain and produce feelings of well-being or happiness.
- **Manic episode** is a mental state characterized by expansive, elevated, or irritable mood with increased energy or activity seen in during the course of a bipolar disorder.
- **Opioid antagonists** are medications that block the pleasure receptors in the brain. They inhibit the pleasure response to opiates and endorphins.
- **Psychotherapy** is a psychological method for achieving desired changes in thinking, feeling, and behavior. It is also called therapy and therapeutic counseling.
- **Self-help groups** are a group of individuals, sometimes led by a therapist, who provide each other emotional support, information, and advice on problems relating to some shared concern such as an addiction.
- **Twelve-Step Programs** are self-help groups whose members attempt recovery from various addictions based on a plan called the Twelve Steps.

Description and Diagnosis

Kleptomania is one of the DSM-5 disruptive, impulse-control, and conduct disorders. Individuals with this disorder do not plan in advance to steal. Yet they spontaneously experience powerful urges to steal. Such urges create anxiety and tension. The stealing results in relief of these symptoms and feelings of pleasure. Afterward, the individual may feel guilt and remorse. The stolen items are not needed or valued by the individual and are usually stored away or given away. Biological factors may play a significant role in this mental disorder. Decreased levels of neurotransmitters (brain chemicals) have been associated with impulsive behavior. A family history of obsessive-compulsive disorder is also linked with kleptomania.

The occurrence of this disorder is extremely low in the general population (0.3%–0.6%). The rates increase to 4%–24% among individuals who are caught for shoplifting. Females are three times more likely than males to be diagnosed with kleptomania (American Psychiatric Association, 2013).

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, individuals can be diagnosed with this disorder if they repeatedly give in to the urge to steal. Prior to stealing, tension builds up. During the act of stealing, there is a sense of pleasure, satisfaction, or relief. The items stolen do not have any personal or monetary value. The items are not stolen as a means of expressing anger or for revenge. The individual is not delusional or experiencing hallucinations. The stealing cannot be due to conduct disorder, a manic episode, or antisocial personality disorder (American Psychiatric Association, 2013).

Treatment

Treatment for kleptomania includes psychotherapy, medication, and self-help groups. Cognitive behavior therapy is widely accepted as the best type of psychotherapy for this disorder. Possible medications include antidepressants, mood stabilizers, antiseizure medications, and opioid antagonists. Self-help groups, particularly Twelve-Step Programs, can provide support and a social network.

Klonopin (Clonazepam)

Klonopin is a prescribed medication for nervousness, tension, anxiety, and some types of seizures. Its generic name is clonazepam.

Definitions

- **Antabuse** is a medication used to treat alcohol dependence.
- **Anterograde amnesia** is a type of amnesia in which new memories cannot be formed while existing memories remain intact.
- **Benzodiazepines** are a group of central nervous system depressants that are used to relieve anxiety or to induce sleep.
- **Epilepsy** is a medical condition involving episodes of irregular electrical discharge within the brain that causes impairment or loss of consciousness, followed by convulsions.
- **Glaucoma** refers to a group of eye diseases with increased pressure within the eye, significant enough to damage eye tissue and structures. If untreated, glaucoma results in blindness.
- **Seizure** is a sudden convulsion or uncontrolled discharge of nerve cells that may spread to other cells throughout the brain.

Description

Klonopin belongs to a class group of drugs called benzodiazepines. It is used to treat nervousness, tension, symptoms of anxiety, and some types of seizures. Benzodiazepines work by blocking the specific chemical involved in the transmission of nerve impulses in the brain, which decreases the excitability of nerve cells and results in reduced anxiety. Klonopin's primary use is in the treatment of panic disorder and some types of epilepsy. It is also used to treat social anxiety disorder, mania, post-traumatic stress disorder, and medication-induced movement disorders.

When Klonopin is used to treat panic disorder, it is more sedating than Xanax, another benzodiazepine drug used to treat panic disorder. However, unlike Xanax, Klonopin may trigger depressive episodes in patients with a previous history of depression. In those who experience social anxiety disorder, treatment with Klonopin also reduces depressive symptoms.

Precautions and Side Effects

Women who are pregnant should not use Klonopin, because it may harm the developing fetus. Klonopin should never be taken by people who have had an allergic reaction to it or another benzodiazepine drug such as diazepam (Valium). People with narrow-angle glaucoma or severe liver disease should not take Klonopin. People who have kidney disease may need to take a reduced dosage of the drug. Saliva production may increase while taking Klonopin. Because of this, people with respiratory disease or an impaired gag reflex should use Klonopin with close physician supervision.

Because Klonopin is a nervous system depressant, it should not be taken with other such depressants, such as alcohol, other sedatives, sleeping pills, or tranquilizers. People taking Klonopin may feel unusually drowsy and mentally sluggish when they first start taking the drug. They should not drive, operate machinery, or engage in activities that require mental alertness until they see how Klonopin affects them. Because of a loss of coordination, elderly patients are at risk for falls. This excessive sedation usually goes away after a short time on the drug.

Those with an underlying depression should be closely monitored while taking Klonopin, especially if they are at risk for attempting suicide. Klonopin treatment should not be stopped abruptly, as patients may experience withdrawal symptoms, including tremor, insomnia, anxiety, and seizures. Klonopin can be habit-forming.

The main side effects of Klonopin are sedation, dizziness, impaired coordination, depression, and fatigue. Some people experience decreased sex drive while taking Klonopin. The drug may also cause

short-term memory loss or amnesia. A small number of people develop sinus problems and upper respiratory tract infections while taking Klonopin. One of the side effects of Klonopin may be increased salivation. This may cause some people to start coughing while taking Klonopin. Klonopin may also cause anorexia and dry mouth. It may cause either constipation or diarrhea. There are a few reports of Klonopin causing menstrual irregularities or blurred vision.

Klonopin may increase the sedative effects of other drugs that depress the central nervous system, such as certain strong pain medicines (opiates such as codeine, oxycodone, and hydromorphone) and antihistamines (found in many cold and allergy medications).

Kohlberg, Lawrence (1927–1987)

Lawrence Kohlberg was an American psychologist best known for his theory of moral development. He is listed in the top 100 most eminent psychologists of the 20th century.

Description

Lawrence Kohlberg was born in Bronxville, New York, on October 25, 1927. His father, Alfred Kohlberg, was a Jewish German entrepreneur and his mother, Charlotte Albrecht, a Christian German chemist. The youngest of four children, his parents separated when Kohlberg was almost four years old and divorced 10 years later. Kohlberg grew up in an affluent family due to his father's successful import business. He graduated from Phillips Academy, an elite preparatory high school in Andover, Massachusetts. Kohlberg attended high school during World War II and given his Jewish German heritage, as well as his father's involvement in aiding Holocaust victims, he was deeply affected by the plight of European Jews. He was also impacted by incidents of anti-Semitism. At the end of World War II Kohlberg graduated from high school, joined the merchant marines, and traveled to Europe. After completing his tour of duty, Kohlberg became a crewmember on the *S.S. Redemption*, a ship outfitted to smuggle European Jewish refugees into Palestine, a British-controlled territory. Kohlberg was in Palestine during the 1948 Arab–Israeli War, which established the state of Israel. Being in Europe at the end of the war, meeting with Holocaust survivors, and smuggling Jewish refugees through a British blockade raised many questions for Kohlberg regarding how morality develops. Returning to the United States Kohlberg completed an undergraduate degree at the University of Chicago. Given all that he had experienced, he was very interested in social justice and considered becoming a lawyer before deciding to become a clinical psychologist.

Impact (Psychological Influence)

Kohlberg's doctoral dissertation, considered groundbreaking at the time, focused on the moral reasoning and judgment of adolescent boys when presented with a moral dilemma. The dilemma was of a man, Heinz, whose wife was dying of cancer and only one druggist knew how to make the drug that could save her. The druggist charged a very high price and made a lot of profit from the drug. Heinz was able to raise only half of the amount demanded by the druggist, who refused to sell it for less than full price. The boys were asked if Heinz should steal the drug to save his dying wife or obey the law and let his wife die. Kohlberg asked many questions of the boys and discovered distinct age-related differences in the complexity of their moral reasoning and justification for their answers. Kohlberg was the first psychologist to examine how morality develops and his dissertation was highly regarded by his peers. His dissertation work became the basis for his best-known work, the six stages of moral

development, which continues to be taught in graduate schools throughout the world.

After completing his doctorate in 1958, Kohlberg became assistant professor of psychology at Yale University before joining the psychology and human development department at the University of Chicago in 1961. In 1968 he was appointed professor of education and social psychology at the Harvard Graduate School of Education where he remained until his death. Kohlberg married Lucille Stigberg while working on his dissertation in 1955 and had two sons, David and Steven.

Kohlberg had contracted a parasitic infection while conducting cross-cultural research in Belize on the coast of Central America in 1971. The infection caused chronic physical pain and depression that he lived with for over 16 years. On January 19, 1987, Kohlberg took a one-day leave of absence from the hospital he was being treated at, left identifying documents in his car, and walked into the frigid waters of Boston Harbor and drowned himself. He was 59 years old.

Lawrence Kohlberg wrote several books on his theories of moral development, childhood moral education, and social justice. Perhaps his most important publications were his two-volume collection of "Essays on Moral Development."

Kübler-Ross, Elisabeth (1926–2004)

Elisabeth Kübler-Ross was an American psychiatrist and author best known for her groundbreaking work in creating awareness about how society cares for the terminally ill and approaches the grieving process.

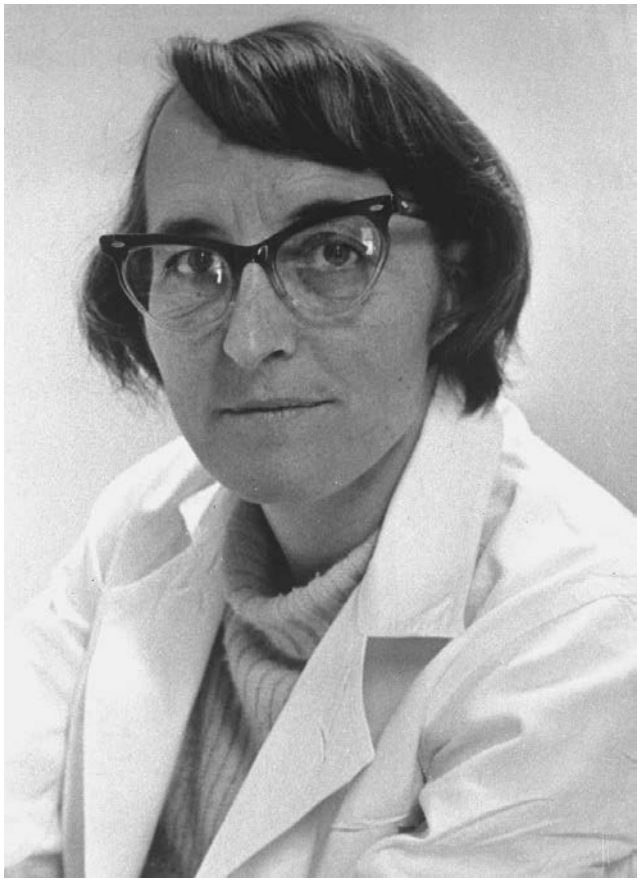
Description

Author and psychiatrist, Elisabeth Kübler-Ross's research was instrumental in changing how the medical community cared for the terminally ill. Physicians have since used her writings as a guide for discussing the topic of death with their patients. Hospice care was also established as a result of Kübler-Ross's work. She

developed the Five Stages Theory, outlining distinct stages that people go through when suffering through the grieving process: denial, anger, bargaining, depression, and acceptance. This model has been applied to the patients diagnosed with terminal disease as well as the survivors of those who have died.

Elisabeth Kübler was born on July 8, 1926, in Zurich, Switzerland. She was one of three triplet girls and weighed only two pounds at birth. Kübler's first experience with death came at age five when she was hospitalized with pneumonia and witnessed the peaceful death of her hospital roommate. Around the same time, a close neighbor of hers passed away after suffering a severe neck injury. These early experiences led Kübler-Ross to begin thinking about how death is simply another stage of life and that people need assistance in dealing with this process. At the onset of World War II, when Elisabeth was just 13 years old she began volunteering at a hospital assisting Polish war victims. By 1945, she had become an activist for the International Voluntary Service for Peace.

Experiencing the bitterness of war firsthand affected Elisabeth immensely. She went on to volunteer rebuilding war-torn communities in France, Poland, and Italy. Another profound experience came during her visit to the Majdanek concentration camp when she met a young girl who showed compassion and forgiveness toward those who had wanted to send her to the gas chambers. Elisabeth decided then to devote her life to helping others. A career in medicine was against her father's wishes, however, Elisabeth decided to enroll in medical school anyway, entering the University at Zurich in 1951 and graduating from there in 1957. It was there that she met her future husband Emanuel Robert Ross, an American medical student. The two married in 1958. They later moved to New York to pursue their internships at Glen Cove Community Hospital in Long Island. Kübler-Ross then went on to specialize in psychiatry and completed her residency at Manhattan State Hospital. She received further training at Montefiore Hospital in the Bronx. After the birth of their first child, the couple accepted teaching positions at the University of Colorado Medical School and relocated to Denver. Kübler-Ross continued researching the topics of death and dying and became increasingly disturbed that the courses in medical school did not address these areas adequately. In 1965, after the birth of their second child, they moved to Chicago where Elisabeth became an instructor at the University of Chicago's medical school. During this time, Elisabeth began a series of seminars about the dying process. The lectures featured candid interviews with terminally ill patients who relayed their innermost fears about their impending death. These experiences offered the basis of her first and most popular book *On Death and Dying*, published in 1969. In this book, Kübler-Ross outlined five stages that terminally ill patients experience: denial, anger, bargaining, depression, and acceptance. Her work raised public awareness and prompted much-needed discussion in the medical community to issues that had previously been



Elisabeth Kübler-Ross's research was instrumental in changing how the medical community cared for the terminally ill. considered taboo. Later writings included *Living with Death and Dying* in 1981 and *The Tunnel and the Light* in 1999. In 1977, she founded "Shanti Nilaya" (Home of Peace) in Escondido, California, which served as a healing center for the dying and their families. The Elisabeth Kübler-Ross Center was also formed around the same time. Kübler-Ross retired after suffering a severe stroke in 1995 which left her partially paralyzed. She died in hospice care on August 24, 2004, in Scottsdale, Arizona, of natural causes, surrounded by those she loved.

Impact (Psychological Influence)

Kübler-Ross's research, though it had a profound impact in the fields of medicine, psychiatry, social work, and counseling, was both praised and criticized. During her career, she authored more than 20 books on death and dying, including her final work *On Grief and Grieving* (2005), which she finished right before her death. Kübler-Ross played an integral role in the start of the hospice care movement, made a significant impact in providing compassion to AIDS patients during the start of that epidemic, and was a cofounder of the American Holistic Medical Association. In 2007, she was inducted into the National Women's Hall of Fame, and throughout her lifetime, she was the recipient of 20 honorary degrees.

Language and Thought of the Child, The (Book)

The Language and Thought of the Child is a book about language development in children written by Jean Piaget in 1923.

Description

In *The Language and Thought of the Child*, Piaget addresses two significant challenges. The first is understanding the nature of children's thinking as revealed in their language and the second is understanding the relationship between that and the development of socially important qualities, such as the ability to communicate clearly and truthfully, the power to distinguish romance from reality, and the consideration of other people's point of view. Piaget was the first to apply the insights of social psychology and psychoanalysis to the observation of children, uncovering the ways in which a child actively constructs his or her understanding of the world through language.

Piaget believed that the mind of the child is composed of two levels: a lower plane of subjectivity, which is most important during the child's first years, and a higher plane of objectivity and logical ideas (also known as the plane of reality), which develops slowly during the child's first years. He used psychoanalytic concepts to distinguish two functions of language: egocentric language (not directed toward others, or monologue) and socialized language (directed toward others, or dialogue). The former inevitably disappears with the development of the latter.

Piaget insisted that language cannot be reduced to that of simply communicating one's thoughts. He maintained that there is pleasure and excitement that is derived from talking to oneself, on the magical role of words, and on verbalization. He further believed that the child consciously desires to influence the hearer. Such directed communication is acquired late in the child's development, usually after the age of seven or eight.

Piaget presented these views in a series of clinical pictures in his book *The Language and Thought of the Child*. He carefully studied children playing and talking freely together and found that almost half of the spontaneous talk of children from six to seven years old is completely nonsocial. That is, it doesn't make any real sense. Rather it is a celebration of the self, a playing with sound. Developing the ability to discuss and argue takes time, but the growth of power in this region of the child's mind is not natural or inevitable.

Piaget (1896–1980) started his scientific career at the age of 11, studying mollusks, and was recognized by the scientific community when he was still quite young. During the 1920s, he developed a strong interest in Alfred Binet's theories. In fact, in January 1920, at a conference organized by the Alfred Binet Society, Piaget gave an introductory lecture on the relationship between psychoanalysis and child psychology.

Impact (Psychological Influence)

Piaget's book (and his theories) have widely influenced the concepts of child development and thought. Understanding the child's mind and the role it plays in the development of language is important for teachers, especially those who engaged in teaching language. While Piaget had his critics, his work and particularly

this book is well respected in the realms of psychology, psychoanalysis, and education.

Lavender

Lavender is a natural remedy used as a mild sedative and antispasmodic.

Definitions

- **Antispasmodic** is a drug for controlling muscle spasms.
- **Food and Drug Administration** is a federal agency that is responsible for protecting the public health by assuring the safety and security of drugs, medical devices, food supply, and cosmetics. It is also called the FDA.
- **German Commission E** is a scientific advisory board that evaluates the safety of herbal medicines. It is equivalent of the FDA.
- **Sedative** is a drug that calms and causes sleepiness.

Description

Lavender is from the aromatic plant *Lavandula officinalis*. The essential oil derived from lavender is used primarily as a mild sedative and antispasmodic. It is also used in aromatherapy to treat fatigue, anxiety, difficulty sleeping, nervousness, and restlessness. Lavender is native to the Mediterranean region and has many species and subspecies. The preferred lavender for medicinal use is *L. officinalis* or true lavender. In Europe lavender has been used as a healing herb for centuries. It is used both externally and internally in healing. Externally the essential oil is used in aromatherapy as a relaxant and to improve mood. Aromatherapy can be enhanced through massage, used in the bath, placed in potpourri jars, and burned in specially designed oil burners. Pillows stuffed with lavender have been used as a sleep aid in Europe for many years. Lavender oil applied to the forehead and temples is said to ease headache.

Research has identified the active compounds in lavender. The most important of these is an aromatic volatile oil. Lavender also contains small amounts of coumarins, which are chemicals that dilate the blood vessels and help control spasms. The German Commission E has approved the use of lavender tea or lavender oil to treat restlessness and insomnia. Despite conflicting scientific claims, this organization has also endorsed the internal use of lavender for stomach upsets, loss of appetite, and excess gas.

Precautions and Side Effects

Unlike prescribed medications that are regulated by the U.S. Federal Drug Administration, herbal and dietary supplements are not subjected to rigorous scientific testing for safety and effectiveness. The strength of active ingredients varies from manufacturer to manufacturer, and the label may not accurately reflect the contents. Problems with lavender oil revolve around substitution of oil from species of lavender other than *Lavandula officinalis*, the preferred medicinal lavender. Most often true lavender oil is adulterated with less expensive lavender oil. Although it has a pleasant lavender odor, its chemical composition and healing action are different from true lavender oil. There are no studies on interactions of lavender with prescribed medications. Often, lavender has been used in combination with other herbs such as tea oil and lemon balm without adverse interactions.

Lazarus, Arnold (1932–2013)

Arnold A. Lazarus, PhD, was an internationally known author and therapist who pioneered behavior therapy and brief psychotherapy. Some of his main contributions to the profession include showing that breadth is usually more important than depth for effective psychotherapy, emphasizing the value of technical eclecticism and stressing the dangers of theoretical integration, and developing the multimodal BASIC I.D. model that spawned several unique assessment strategies.

Description

Dr. Lazarus's theoretical underpinnings rest mainly on social and cognitive learning theory. He adapts techniques from several disciplines, without necessarily accepting all the theoretical notions behind them. He is known for having a dynamic and innovative approach to working with clients. He was a firm believer in emphasizing treatments of choice for specific conditions, tied to empirically supported methods.

A prolific writer, Dr. Lazarus authored 17 books and more than 200 professional articles. His books include *Marital Myths* and the updated *Marital Myths Revisited* (2001), *In the Mind's Eye* (1984), and *Brief but Comprehensive Psychotherapy* (2006). His book *Behavior Therapy and Beyond* is one of the first books on what is now known as cognitive behavior therapy, and it humanized the field. His books *Multimodal Behavior Therapy, The Practice of Multimodal Therapy* (1989), and *Brief but Comprehensive Psychotherapy: The Multimodal Way* encouraged clinicians to practice in a humane, yet systematic and broad-spectrum way.

He received the Distinguished Service Award from the American Board of Professional Psychology and two Distinguished Professional Contributions Awards from the American Psychological Association. He was also the first recipient of the meritorious First Annual Cummings PSYCHE Award for exemplary contributions to time-effective psychotherapy. He was a firm believer in being precise about the methods applied in treating patients, otherwise known as manual-based therapy. Rather than falling back on generalizations, stating the specific steps used during a session allows others to see how various techniques can be used and the affect they have on the case at hand.

On several occasions, Dr. Lazarus was accused of crossing client–therapist boundaries because his views on the matter are not as black and white as many others of the profession. In his view, the primary boundary was to do no harm, then to never exploit a patient, and then to never show disrespect. He believed dual relationships with patients can be useful, provided there is no conflict of interest.

Dr. Lazarus was born and educated in Johannesburg, South Africa. He received his master's degree in experimental psychology in 1957 and his PhD in clinical psychology in 1960, after which he ran a full-time private practice for three years in his home city. In 1963, he moved to California, where he taught at Stanford University for one year before returning home to continue his private practice. In 1996, he moved back to California, where he became head of the Behavior Therapy Institute. In 1967, he was appointed a full professor at Temple University Medical School in Philadelphia. Three years later he became the director of clinical training at Yale University, and in 1972 he was awarded the rank of distinguished professor at Rutgers University, where he taught until 1998 in the Graduate School of Applied and Professional Psychology. In 2001, he maintained a private practice in Princeton, New Jersey, and was president of the Center for Multimodal Psychological Services. He died in Princeton in 2013.

At the beginning of his career Dr. Lazarus was heavily involved in testing. Nearly all his clients filled out various questionnaires, including a range of personality, neuroticism, and adjustment inventories. However, he very quickly found such psychometric instruments unhelpful in treatment planning. What he

has found useful is careful history taking, meticulous observation, and corroboration or refutation from the clients' significant others.

Impact (Psychological Influence)

Dr. Lazarus tried to remain current with cutting-edge findings across disciplines. In keeping with the need to find treatments of choice, he kept current with research on empirically supported methods and applied them when feasible. He believed that treatment fidelity is important. That is, for anyone to claim that a treatment method was ineffective, he or she must first show whether said treatment was carried out properly and correctly applied.

Learned Helplessness

Learned helplessness is the state or condition of a human being or animal, where they behave as if they are helpless or have no control over their current situation.

Description

Learned helplessness describes a way that humans or animals behave when they perceive that they have no control over avoiding negative circumstances or hope of gaining positive rewards. This theory has attempted to explain the occurrence of clinical depression and other related mental illnesses. It was based on the foundational experiments conducted back in 1967 by American psychologist Martin Seligman and colleagues at the University of Pennsylvania. Seligman's work using Pavlovian classical conditioning with dogs sought to test the validity of B. F. Skinner's principles of behaviorism, which was a leading theory in the field of psychology at the time. The first of these experiments placed three groups of dogs in various situations. Group 1 was strapped to a harness but later released, Groups 2 and 3 were placed in yoked pairs, with the dogs in Group 2 being subject to electric shocks from which they could escape by pressing a lever, whereas the dogs in Group 3 were subject to the same electric shocks but were not given a means to escape that stressor. Results indicated that the dogs in Groups 1 and 2 exhibited no long-term psychological distress, whereas the dogs in Group 3 were severely impacted, even refusing to escape harm and discomfort when they were placed in situations where they were in fact capable or able to do so. In Part 2 of the experiment, the same three groups of dogs were tested in a shuttle-box apparatus where they could escape the electric shocks simply by jumping over a low partition. The dogs in Groups 1 and 2 easily navigated this task, but the dogs in Group 3 refused to even try and rather lay down and whined. Seligman and his colleagues likened this to a phenomenon known as "retardation of learning," when a human being or an animal instinctively knows and is physically able to react in a given situation but refuses to after being psychologically conditioned to believe that their actions will not affect a resolution. The trauma that the dogs in Group 3 experienced could only be remedied by forcibly reconditioning these dogs to believe that their actions could effectively produce a positive outcome.

Later experiments found similar results. All findings confirmed that a strong predictor of the subject behaving helplessly was its perceived lack of control over aversive stimuli. An experiment conducted by Watson and Ramey in 1969 observed this psychological state in human babies. With group one, a sensory pillow was used so that the babies could control the movement of a mobile by moving their heads, while

the other group of babies had no means to effect the movement of the mobile. Babies in the first group continued to move their heads when placed in a different crib, whereas babies from the other group did not.

Current Status and Impact (Psychological Influence)

Though the phenomenon of learned helplessness has been confirmed in humans, it is not always the case and cannot be generalized to all people in all situations. Much relies on a person's attribution style, meaning what they attribute circumstances and factors to. A person with an external or pessimistic attribution style would perceive himself or herself as having little to no control over determining situational outcomes. An internal or optimistic attribution style would be the opposite, meaning that the person believes that he or she has the power to effect change in the desired direction. Also observed in human beings alone is the salience of modeling, meaning it is not necessary for a person to experience a situation firsthand to be conditioned to respond helplessly; the person can simply observe that behavior in another person and then act the same way.

Learned helplessness has recently been studied from a neurobiological perspective. Researchers have discovered a spike in serotonin levels as well as involvement in certain parts of the amygdala, prefrontal cortex, hippocampus, and hypothalamus during states of learned helplessness. These findings have spawned follow-up studies addressing the role that psychotropic medications, exercise, nutrition, sleep, and stress can play in deterring helpless mind-sets. Though states of learned helplessness can resolve over time, consultation with a health professional along with therapy is recommended.

Learning Disorders

"Learning disorders" (LDs) is a general term used to describe several specific categories of problems that people have with learning different subjects.

Description

"Learning disorders" is the phrase used to describe a situation where an individual's achievement on standardized academic tests is significantly below the scores expected for peers of similar age, education, and levels of intelligence. LDs were once referred to as academic skills disorders. As a classification in the DSM, LDs refer specifically to substantially lower scores on individually administered, standardized tests in certain subjects. These include reading, mathematics, and writing as well as being applied to other learning problems that are categorized as unspecified. The diagnoses were previously separated into these subjects, but all now fall under Specific Learning Disorder. Other disabilities include disorders such as dyslexia and developmental coordination disorder.

Learning disorders and their specific subtypes usually arise in childhood. Approximately 25% of children with other disorders (e.g., conduct disorder, oppositional defiant disorder, attention-deficit hyperactivity disorder) may also be diagnosed with a learning disorder. The occurrence of a learning disorder in combination with these other disorders can sometimes be attributed to a child's difficulty coping with his or her learning challenges. Although LDs are usually associated with childhood and adolescence, they may also

persist into adulthood. Adults with LDs may often experience difficulties in finding or keeping jobs and in social relationships.

Causes and Symptoms

Developmental problems, prenatal injury and genetics are all suspected to contribute to the development of LDs. But the presences of these don't always lead a child to be diagnosed with an LD. More closely associated with LDs are medical issues such as lead poisoning, fetal alcohol syndrome and chromosomal defects. In some cases genetic risk of LDs seems to be compensated for by protective environmental factors. Given this variation it seems more appropriate to consider a causal model that is based on multiple cognitive deficits.

Learning disorders mean much more than just difficulty with learning. They indicate neurological process disruptions that affect the brain's ability to receive, process, store, and respond to information in specific ways that vary from individual to individual. The key symptom of LDs are unusually low scores in academic performance. This is usually recognized through age-adjusted standardized testing when no medical issues are present or identifiable. Those who suffer from LDs tend to drop out of school at higher rates. Other symptoms of LDs include emotional problems such as demoralization, low self-esteem, and deficits in social skills.

Diagnosis and Prognosis

The National Center for Learning Disabilities offers links on its website with information about specific LDs. These include reading, writing, and math and can help people assess themselves if they suspect that they have an LD. It is important to be clear that a formal evaluation by a trained and licensed professional is required for accurate diagnosis. Professionals such as clinical or educational psychologists can conduct the necessary tests. It is a good idea to seek a professional who specializes in LD. The initial testing determines the scope of the LD so that appropriate help can be found. Each person's diagnosis and prognosis varies and often depends on whether the diagnosis indicates that the LD is mild, moderate, or severe.

Treatment

The Americans with Disabilities Act (ADA) protects all those who are formally identified as learning impaired, including those diagnosed with LDs. Under ADA, people with LDs have rights and options regarding the support they can receive. This includes tutoring and assistive technology devices to help people with LDs perform as well as possible academically. With proper accommodation, many people with LDs achieve higher levels of education, including college or university.

For those unable to pursue higher education, there are opportunities to enroll in programs that help people who suffer from LDs master the skills needed for employment, socialization, and independent living. Many communities have services through not-for-profit, community-based agencies that help people with disabilities achieve and maintain independent lives within the community. Among the many programs available are such offerings as workplace literacy, social skills development, career counseling and training, and time management, as well as the basics of economics in relation to banking and other financial tasks.

Lexapro (Escitalopram)

Lexapro is a prescribed medication used to treat a broad range of mood- and stress-related psychiatric illnesses. Its generic name is escitalopram.

Definitions

- **Antidepressant medications** are prescription drugs that are primarily used to treat depression and depressive disorders. They are known as antidepressants.
- **Selective serotonin norepinephrine reuptake inhibitors** are medications that act on and increase the levels of serotonin and norepinephrine in the brain that influences mood. They differ from selective serotonin reuptake inhibitors, which act only on serotonin.
- **Serotonin syndrome** is a serious medication reaction resulting from an excess of serotonin in the brain. It occurs when medications that increase serotonin are taken together. Symptoms include high blood pressure, high fever, headache, delirium, shock, and coma.
- **SSRI discontinuation syndrome** results from the abrupt discontinuation of an SSRI medication. It is characterized by withdrawal symptoms such as anxiety, agitation, insomnia, nausea, vomiting, diarrhea, fatigue, vivid or bizarre dream, dizziness, and other sensory disturbances.

Description

Lexapro is an antidepressant medication and one of the selective serotonin reuptake inhibitors (SSRI). Its primary use is to treat anxiety and depression. It is also used in the treatment of premenstrual syndrome disorders, irritable bowel syndrome, and bulimia nervosa (eating disorder). A decrease in serotonin levels, a neurotransmitter (chemical messenger) in the brain, is associated with depression and anxiety disorders. It is believed Lexapro works by increasing serotonin.

Precautions and Side Effects

Lexapro should not be used by those with bipolar disorder since it can trigger manic symptoms. Since it can lead to respiratory problems, gastrointestinal problems, seizures, and feeding problems, it should be used during pregnancy only when clearly needed. Lexapro use during the last three months of pregnancy infrequently results in withdrawal symptoms in newborns. These include seizures, muscle stiffness, or constant crying. Lexapro passes into breast milk. For that reason women should talk with their doctor before breast-feeding. Discontinuing Lexapro requires that the dose be tapered down slowly to avoid withdrawal symptoms known as SSRI discontinuation syndrome. Lexapro overdose may result in a condition known as serotonin syndrome. The risk of gastrointestinal bleeding may be increased when Lexapro is combined with nonsteroidal anti-inflammatory drugs such as Motrin, aspirin, Excedrin, and Aleve. Alcohol should be avoided while taking this drug. Using herbs such as St. John's wort or Yohimbine while taking Lexapro may also cause toxicity.

Like other SSRIs, there can be side effects with taking Lexapro. Less serious side effects may include drowsiness, dizziness, sleep problems, nausea, heartburn, upset stomach, constipation, weight changes, ringing in ears, decreased sex drive, impotence, or difficulty having an orgasm. More serious side effects should be reported immediately to a physician. These include mania, worsened depression, high fever, rigid muscles, tremors, overactive reflexes, loss of coordination, hallucinations, fainting, seizure, aggressiveness, and thoughts about suicide or hurting oneself.

Lies and Deceit

Lies and deceit is the central theme in current research on detecting dishonesty through facial expressions.

Definitions

- **Deceit** is the intentional misrepresentation of information for the purpose of misleading another individual.
- **Lies** are untruths that are told with the intent to deceive another individual.
- **Micro expressions** are very brief facial expressions that are involuntary. They are subtle representations of emotions that reflect emotions being experienced.
- **Paralinguistic** refers to the parts of communication that do not involve spoken words. Nonverbal components of speech include inflection, pitch, and tone.

Description

Lies and deceit is the basis of recent research in the recognition of facial micro expressions and detection of lies. Lies can be deliberate or unintentional. A deliberate lie is intended to mislead or deceive an unsuspecting individual. Willfully withholding information is considered a form of lying. Liars make a conscious decision to lie. An unintentional lie can simply be misinformation given by an honest individual.

There are many reasons why individuals may choose to lie. It may be they are attempting to avoid some type of negative consequence or punishment. Or they are trying to prevent another individual from experiencing a negative consequence or getting punished. It may be to get a reward that may not otherwise be within reach. The goal of lying may be to receive approval from others or to avoid embarrassment. Individuals may lie to get out of unwanted or uncomfortable social circumstances. Or they may do it to preserve their privacy. Lies may be a way of exerting power over others by maintaining control of what information is shared with them.

A lie may fail if the liar does not make sufficient advance preparations or if his or her emotions become involved. If the lie is not well rehearsed, the liar may not remember it. Or he or she may have forgotten a previous lie that is inconsistent with the present lie. Earlier lies may contradict the present lie being told. In this case, the target individual the liar intends to deceive may catch the discrepancy in the spoken content. Inadequate preparation may also leave the liar unprepared to respond to unanticipated questions. This may be indicated by long pauses in speech, avoiding eye contact, flattening of tone, changes in speech, and use of more hand gestures. Emotions can also interfere with lying. Emotions that are faked to facilitate a lie may appear phony. On the other hand, real emotions that are felt may need to be hidden to avoid ruining a lie. Emotions such as fear, guilt, and excitement create changes in an individual's behavior that can be noticeable to others. Therefore, a liar experiencing these emotions will show signs in the face, body, voice, and paralinguistic behavior. Discrepancies between verbal content and facial expressions provide clues to potential lies and deceit.

Paul Ekman (1934–) is a pioneer in the detection of emotions through facial expressions. Together with Wallace V. Friesen (1913–1987), he developed Pictures of Facial Affect, an instrument used to record facial micro expressions and to assist in lie detection. Ekman is well known for his forensic work in helping officials catch liars on a national and international level. He has worked for American and foreign

government agencies. He conducts training workshops worldwide on how to detect lies and deceit.

Lifestyle and Lifestyle Convictions

Lifestyle and lifestyle convictions are conclusions individuals make about their inner world based on their interpretations of previous experiences.

Definitions

- **Adlerian psychology** is an approach to psychology that understands individuals as social beings with a need to belong and to strive for significance. It is also known as Individual Psychology.
- **Alfred Adler** is the original creator of Individual Psychology. His theory has had significant influence on contemporary counseling approaches.
- **Early recollections** are a projective therapeutic technique that examines the first memories that an individual can recall. Themes about an individual's personality and his or her view of himself or herself and others are hypothesized with this technique.
- **Family constellation** includes information about an individual's relationships with other family members, his or her family values, and the way that he or she found a sense of belonging in his or her family.
- **Family dynamics** are the roles, relationships, structure, and functions of a family system.
- **Life strategies** are behaviors individuals choose as a result of their self and worldview.
- **Ordinal birth order** is the true order that an individual is born in his or her family, for example, being the first born, second born, or only child.
- **Private logic** is the reasoning that an individual creates to justify his or her style of life.
- **Psychological birth order** is the perceived position or role that an individual takes or is given in a family system.
- **Rudolf Dreikurs, MD,** was an American psychiatrist and educator known for advancing Adlerian psychology through his writings and professional publications.
- **Self-view** is the perception an individual has about himself or herself, his or her abilities, and the degree that he or she can be successful in different contexts.
- **Worldview** is an individual's perception about whether the world is dangerous and harmful, or if the world is helpful and safe.

Description

The term "lifestyle" or "lifestyle convictions" was originally used by Austrian psychiatrist Alfred Adler (1870–1937). A student and later a colleague of Adler, Rudolf Dreikurs (1897–1972) advanced the theory and practice of Adler's ideas and also expanded the understanding and practice of using lifestyle convictions in psychotherapy. Adler viewed memories as expressions of an individual's "private logic" and as metaphors of the subjective meaning an individual determines about his or her life. Lifestyle convictions are conclusions an individual makes about his or her inner world based on family constellation, psychological birth order, and early recollections. Individuals interpret events in their lives, and they make subjective meaning of those situations. The private and subjective meaning

that individuals make about their lives becomes their lifestyle. Lifestyle convictions are a cognitive map (mental picture) that guides an individual's perceptions and actions. This includes personalized beliefs about self-view and worldview. In addition, lifestyle convictions influence how individuals go about living their lives based on their beliefs.

Human suffering is conceptualized in Adlerian psychology as discouragement that results from inferiority feelings that occur as a result of unhelpful lifestyle convictions. For example, if an individual has the belief that she should not ask for help and deals with her problems in isolation, she may suffer during times of significant stress. When a therapist understands that individual's lifestyle convictions, the therapist can help her to better understand how her beliefs and perceptions influence her suffering. In addition, Adlerian psychology treats individuals seeking counseling by assisting individuals in modifying their faulty lifestyle convictions and also increasing their sense of belonging.

Lifestyle convictions are conclusions that individuals make about themselves and the world based on their previous life experiences. They represent the individual's basic pattern and life strategies that "drive" the individual's daily thoughts, feelings, and actions. Here is a formula that summarizes life convictions into a pattern:

- I am . . . . (self view)
- Life is . . . . People are . . . . (world view)
- Therefore . . . . (life strategy)

For example, an individual may view himself or herself as dumb, unattractive, and boring, while the individual views others as harsh, critical, and demanding. Their life strategy might be to avoid others because "people are harsh and demanding, so I will avoid them to prevent them from discovering my flaws and criticizing me." Lifestyle convictions come from an individual's interpretations of his or her past experiences; these convictions inform the individual's future behaviors and decisions.

Light Therapy

Light therapy is a type of treatment that uses artificial light exposure to treat individuals who suffer from seasonal patterns of depression and sleep difficulties.

Description

Light therapy, also called phototherapy or bright light therapy (BLT), is a form of therapy used to treat symptoms of depression and some forms of sleep disturbance disorders. Light therapy derives its name from use of artificial bright lights clients are exposed to during treatment.

Development

Light therapy consists of exposure to intense levels of bright light, which affect certain hormones and brain chemicals that can impact mood and sleep patterns. Light therapy has been studied since the 1980s and has been the subject of multiple research studies. BLT has been found to be effective in decreasing depressive symptoms of seasonal pattern depression, sometimes referred to as winter depression, seasonal affective disorder, or seasonal depression. Seasonal depression is a condition that consists of a pattern of depression occurring in the fall and winter but is not present throughout the rest of the year. Light therapy has also been found to diminish symptoms of nonseasonal depression with effects similar to antidepressants.

Light therapy is conducted with specially designed light boxes that reduce glare and filter harmful ultraviolet light. Light boxes produce an intensity of up to 10,000 lux. Lux is a standard measurement of light

intensity and is calculated as equal to the illumination of a surface one meter away from a single candle. For comparison, sunlight ranges from 32,000 to 100,000 lux, and moonlight represents about 1 lux. Research indicates that dosage consists of the combination of the intensity of the light and the duration of exposure. An effective minimum dosage varies depending on this combination. For instance, exposure to 2,500 lux for 2 hours per day, 5000 lux 1 hour per day, or 10000 lux for 30 minutes per day, are equivalent dosages.

Current Status

Bright light therapy has several advantages over psychotherapy and psychopharmacology (the use of medications to treat psychological/psychiatric disorders). BLT produces antidepressant-like benefits faster than medications and psychotherapy. Light therapy is also considerably less expensive than several months of psychotherapy or antidepressant treatment. BLT also has fewer and less severe side effects than antidepressant medications. In spite of these advantages, light therapy has received less research focus on how best to utilize phototherapy than have other forms of more traditional psychotherapy and psychiatric interventions. This research gap may exist due to light therapy not being as financially supported and marketed as pharmacological treatments.

Light therapy is frequently used to treat individuals suffering from sleep difficulties, such as not being able to fall asleep or waking up too early and not being able to fall back asleep. BLT is frequently used in the treatment of phase disorders, which are sleep difficulties due to a disruption in sleep patterns such as occurs with people who work on night shifts and must sleep during the day. Light therapy is also used to assist individuals with circadian rhythm disorders. "Circadian rhythm" is the term used to describe a person's biological internal clock. People who suffer from circadian rhythm disorder have no problem sleeping but are unable to sleep and wake at times required for work or school. In other words their internal clocks are off. The use of artificial bright lights in a therapeutic setting has been found to be a safe and cost-effective method in assisting individuals recover from seasonal depressive disorders and sleep disturbance disorders.

Linehan, Marsha (1943–)

Marsha M. Linehan, born in 1943, is the driving force behind the development of dialectical behavior therapy (DBT), which *Time* magazine noted as one of the top 100 most important discoveries. Her writings on the treatment is the most cited work in the field of mental health in the past 25 years. She is professor of psychology, adjunct professor of psychiatry and behavioral sciences at the University of Washington, and director of the Behavioral Research and Therapy Clinics.

Description

Marsha Linehan's DBT began as a treatment primarily for suicidal and self-injurious behavior. It has expanded to include many other areas, including addictive and eating disorders, depression, and family conflict. It is now being studied and applied as a skills-based curriculum in classrooms with school-age children and is currently the gold standard treatment for borderline personality disorder. DBT is a comprehensive, multimodal cognitive behavior treatment that Linehan developed in the early 1980s for the comorbid and difficult-to-treat client. It includes principles of acceptance, mindfulness, and validation.

Marsha Linehan is the founder and organizer of the Dialectical Behavior Therapy Strategic Planning Group, which meets annually, and the Suicide

Strategic Planning Group, which meets periodically. Both groups meet at the University of Washington. She is also the founder of the Linehan Institute, which focuses on nurturing psychotherapists and conducts contemplative and Zen mindfulness retreats for caregivers.

Marsha Linehan's DBT has been applied with highly suicidal individuals who meet borderline personality disorder criteria and has been adapted for adults who meet both borderline personality disorder and substance dependence criteria, suicidal adolescents with borderline personality disorder features, suicidal elderly individuals with major depressive disorder, victims of domestic abuse, stalking offenders, families of highly suicidal individuals, and difficult-to-manage correctional populations.

Dialectical behavior therapy is based on three philosophical pillars: dialectics, Zen, and behavioral science. To balance the change needed for a patient's life to improve, he or she is encouraged to let go of attachments to what he or she thinks reality should be like and find the middle path through means of acceptance, self-validation, and tolerance.

Development

Marsha Linehan was born in Tulsa, Oklahoma, the daughter of Marston Linehan, an oil company executive, and Ella Marie (Tita) Linehan, an active participant in the Tulsa community. She is one of six children. When she was 17, she was admitted as a patient at the Institute of Living, where she began her journey through what she refers to as the hell of mental illness and back. She was released at the age of 20.

At age 21 she moved to Chicago, where she worked during the day as a clerk typist for an insurance company and at night as a catechism teacher in her local Catholic church. In 1965, she was accepted as an undergraduate at Loyola University of Chicago, where she was a premed student majoring in psychology. Until her senior year, her plan was to become a psychiatrist and work at a state mental hospital. However, at the last minute, she realized that there were very few interventions that worked for mental disorders, so she changed her focus from being a clinician to becoming a scientist. In 1968, she entered the social psychology program at Loyola University. She then switched to experimental personality psychology and received her doctoral degree in 1971. To get clinical training, she organized a one-year internship with the Suicide Prevention and Crisis Clinic in Buffalo, New York, followed by a postdoctoral fellowship in behavior modification at the State University of New York at Stony Brook.

Linehan started her academic career as an assistant professor at The Catholic University of American in Washington, D.C. She worked in that position between 1973 and 1977. While there, she conducted her first clinical trial targeting suicidal behavior. She also conducted her first component-analysis clinical study evaluating the relative importance of cognitive interventions versus behavioral interventions in assertiveness training. In 1977, she took a position of professor of psychology at the University of Washington.

Impact (Psychological Influence)

Her primary research is in the application of behavioral models to suicidal behaviors, drug abuse, and borderline personality disorder. She developed DBT, which is considered the gold standard of treatment for borderline personality disorder. This research-based approach has also been modified for use with other psychiatric disorders.

Lithium

Lithium is a prescription medication that has long been used to treat bipolar disorder. It has several brand names, including Lithobid and Eskalith.

Definition

- **Antimanic medications** are prescription drugs that are primarily used to treat bipolar disorder (manic depression). They are also called antimanics and mood stabilizers.

Description

Lithium is a naturally occurring element that is classified as an antimanic drug. Lithium has long been used to treat mania and bipolar depression. It has also been used to treat schizoaffective disorder, aggressive behavior, and emotional instability in children and adults. On occasion lithium is used in combination with other antidepressant medications to treat depression in the absence of mania. It is available in the United States under the brand names Lithobid, Lithonate, Lithane, Lithotabs, and Eskalith, as well as under its generic name. The therapeutic benefits of lithium are believed to be related to its effects on balancing electrolytes, such as sodium, potassium, magnesium, and calcium.

Precautions and Side Effects

Because lithium can be toxic and even life threatening, blood levels of lithium are monitored weekly during the first month of treatment and less often after that. Thyroid function must also be monitored. Lithium should be used only under close medical supervision by those with kidney impairment, by those with heart disease, or those who are taking diuretics. Pregnant women should not take lithium in the first trimester. It should be discontinued 24 hours before major surgery, but its use can be continued for minor surgical procedures.

Tremor is the most common neurological side effect. Lithium tremor is an irregular twitching of the arms and legs that varies in both intensity and frequency. Lithium-induced tremors occur in about one half of those taking it. The chance of tremors decreases if the dose is reduced. Acute lithium toxicity (poisoning) can result in neurological side effects, ranging from confusion and coordination impairment to coma, seizures, and death. Other neurological side effects associated with lithium include lethargy, memory impairment, difficulty finding words, and loss of creativity. Lithium increases the chemical messenger called serotonin. Taking lithium along with medications for depression can overly increase serotonin and cause serious side effects, including heart problems, shivering, and anxiety. These antidepressant medications include Prozac, Paxil, Zoloft, Elavil, Anafranil, and Tofranil.

Locus of Control

Locus of control (LOC) is a psychological concept referring to a personality trait related to how much control individuals feel they have over their lives.

Description

"Locus of control" refers to how individuals experience a sense of personal control over their lives. The word "locus" is Latin, meaning "location." People generally have either an internal or external LOC.

Individuals with an internal LOC believe they can control their own lives and that their actions and choices are most responsible for what happens in their life. In other words, the internal process of how they think, believe, make choices, and behave provides control over their lives. People with an external LOC believe that their lives are more controlled by outside forces such as chance, circumstances, fate, luck, or powerful others. People with high levels of internal LOC, referred to as *internals*, believe they make things happen whereas people with high external LOC, referred to as *externals*, believe other people, forces, or processes are responsible for what happens to them. For instance, take two students who make a poor grade on an exam. The student with an internal LOC thinks: "If I had studied more I could have done better, next exam I'll start studying earlier." A student with an external LOC thinks: "That teacher doesn't know how to teach and doesn't like me, that's why I got graded down."

Current Status and Impact (Psychological Influence)

The concept of LOC was developed Julian Rotter in the 1950s and 1960s. Rotter studied rewards and punishment reinforcements of behavior and the beliefs held by individuals as to whether they, chance, or the experimenter caused the reinforcement to occur. Since Rotter's early research, LOC has been extensively studied across a wide spectrum of psychological, social, educational, and organizational fields of study. LOC has been associated with many aspects of work, personal, and social functioning.

In terms of work, internals are more likely than externals to set challenging goals and persist in attaining those goals regardless of obstacles. In terms of social skills, internals are more considerate of others and are more effective in influencing people. Internals are also more likely to engage in problem-focused coping behaviors such as seeking help from others, or making and following plans to reduce or eliminate stressors. All of these factors contribute to internals being generally more successful than externals. An internal LOC has been repeatedly associated with successful leaders.

Locus of control and its relationship to health factors have also been highly researched. Internal LOC has been linked to health benefits, including seeking health information, smoking cessation, weight control, medical compliance, effective birth control, and dental hygiene. Research into LOC and education has shown that internals earn better grades, work harder, and study longer than do externals. High external LOC has been associated with lack of motivation. Students with high internal LOC are more likely to work harder to improve grades, whereas student with high external LOC are more likely to give up. LOC has also been found to be associated with mental health variables, with external LOC associated with higher levels of psychological distress. External LOC is also associated with higher levels of depression and anxiety compared to internals. It is important to note that an individual's LOC does not predict mental health functioning, success, or ability to achieve. For instance, even though externals may experience higher levels of depression, the fact remains that regardless of a person's LOC, those who are internals can also experience debilitating depression.

Locus of control is a psychological concept referring to how much control individuals feel they have over their lives. LOC has been extensively studied and has broad application in understanding human coping, performance, and motivation.

Logotherapy

Logotherapy is a form of therapy that is based on the meaning-focused, existential philosophy of that which

emphasizes the importance of meaning, faith, hope, and humor.

Description

The word "logotherapy" is derived from the Greek words "logos" (meaning) and "therapy" (treatment). Logotherapy was developed by Viennese psychiatrist Viktor E. Frankl (1905–1997). Frankl introduced the idea of logotherapy and popularized it in his famous 1946 book *Man's Search for Meaning*, which sold more than 10 million copies and has been translated into two dozen languages. At its essence, logotherapy involves healing and the enhancement of one's well-being through changing one's attitude and beliefs. Sometimes logotherapy is referred to as the Third Viennese School of Psychotherapy since it was developed based on the works of two fellow Viennese theorists, Sigmund Freud and Alfred Adler.

The underlying goal of logotherapy treatment is for the therapist to help the patient change his or her attitude or point of view about a particular situation. A central construct of logotherapy is tridimensional ontology, the conceptualization of human beings along three overlapping dimensions: physical, psychological, and spiritual. People often respond with conditioned or automatic reactions in the first two dimensions. The third dimension of spirituality is what distinguishes us from animals. When we neglect that third dimension, an existential vacuum develops, which can lead to disturbances that violate social norms (aggression), create distress symptoms (depression), and lead to addictions. A sense of personal life meaning is critical to logotherapy. Its basic tenets assert that human life has meaning, that people long to experience their own sense of personal life meaning, and that people have the potential to experience life meaning under any and all circumstances.

Development and Current Status

According to Frankl, who spent several years of World War II in four Nazi death camps, including Auschwitz and Dachau, humans are motivated to seek meaning in their lives. They find such meaning in three main ways: (1) through accomplishment or achievement in work or an activity, (2) through experience or loving someone, and (3) by the attitude a person takes when there is unavoidable suffering. He once wrote that during his time in the concentration camps he realized that it was not important what a person expects from life but what life expects from us.

Frankl believed that we all have the uniquely human potential to turn a personal tragedy into triumph. One of his most famous examples is when he worked with a man who was suffering tremendous grief after the loss of his wife. The man looked to Frankl for comfort, solace, and meaning. After listening to the man's story, Frankl asked what would have happened to his wife if he had preceded her in death. The man replied that his wife would have suffered terribly. Frankl asked the man if her dying first had saved his wife from the painful experience of living without him. This helped the man to see the meaning in his experience that by her passing first, she had been spared the grief he was now feeling.

Logotherapists regard their clients as equal human beings. This therapeutic approach involves four main steps: (1) to differentiate the client from his or her symptoms, (2) modify the client's attitude about the symptoms, (3) reduce the symptoms, and (4) maintain mental health. Logotherapeutic techniques include attitude modification (where the therapist asks the client questions to facilitate internal exploration), paradoxical intention (incorporating humor to counteract anxiety), dereflection (reorienting a client's attention away from a preoccupying problem), and logoanalysis (mental and written exercises to help the individual set a life direction and achievable goals based on personal life meaning). Lesser-known techniques include the Mountain Range Exercise, the Movies Exercise, and the Family Shoebox Game. Logotherapy has several psychometric instruments, including the Purpose of Life test, the Life Purpose Questionnaire, and the Seeking of Noetic Goals test.

Research and case studies show that logotherapy is an effective form of psychotherapy. It is also used in cognitive therapy, cognitive behavior therapy, humanist psychotherapy, and existential psychotherapy, and is advocated in appraisal theory. It has also been explored in relation to rational emotive behavior therapy and acceptance and commitment therapy. It is a technique that mental health professionals can readily integrate with those they frequently use. Thus,

logotherapy has much to offer mental health professionals, regardless of their theoretical orientation. In fact, Frankl himself saw logotherapy as an addition to other therapies with the goal of enhancing techniques instead of replacing them.

Logotherapy has proved useful in the treatment of alcohol and drug addiction, depression, anxiety, psychoses, and despair associated with incurable illness. It also has applicability in areas such as rehabilitation, mental retardation, developmental disabilities work, pastoral psychology, aging, family therapy and relationship counseling, and daily work-/life-related issues.

Love, Courtney (1964–)

Singer-songwriter, musician, and actress, Courtney Love is known for her rise to fame during the early 1990s as leader of the band Hole. In 1992, she married and had a child with grunge music legend Kurt Cobain, leader of Nirvana. Love also dabbled in acting, finding acclaim for her role in the 1996 film *The People vs. Larry Flynt*. Though Love's musical and artistic talents are noted, she is best known for her bizarre antics off stage.

Description

Courtney Michelle Harrison was born in San Francisco, California, on July 9, 1964, to Linda Carroll, a psychotherapist, and Hank Harrison, a writer and first manager of The Grateful Dead. In 1969 Courtney's parents divorced and her mother was granted full custody after alleging that Harrison had fed Courtney LSD. Life was not typical and the family moved often, traveling from one hippie commune to the next, throughout Oregon. In 1972, Courtney moved with her mother and then-husband to New Zealand. At the age of 16 she became legally emancipated from her mother and traveled through Europe living off a small trust fund left to her by grandparents. (Love later met her mother's birth mother, the noted writer Paula Fox, and therefore Love's grandmother.) Soon after, Courtney returned to Portland to pursue music, seeing minimal success with groups such as Babes in Toyland and Faith No More. She worked intermittently on her acting career during this same time. Alex Cox gave her bit parts in two of his films, *Sid and Nancy* (1986) and *Straight to Hell* (1987). In 1989, Courtney made her big break in the music industry after starting her own band, Hole, and releasing the album *Pretty on the Inside* (1991). While touring, she met and fell in love with Kurt Cobain, the lead singer and songwriter of Nirvana. They married in Hawaii in 1992 and had a daughter, Frances Bean Cobain, that same year (August 18).

The state of Cobain and Love's marriage remained in question, as did the stable care of their daughter, due to the couple's ongoing struggles with drug addiction. This was also a contributing factor in Cobain's 1994 suicide. After Cobain's death, Hole released two more albums, *Live Through This* (1994) and *Celebrity Skin* (1998). In 1996, Love gained

Singer-songwriter, musician, and actress Courtney Love is known for her rise to fame during the early 1990s as leader of the band Hole. (Michael Lunceford/Dreamstime.com)

acting acclaim after receiving a Golden Globe nomination for her portrayal of Althea Flynt in *The People vs. Larry Flynt*. When Hole broke up in the first part of the millennium, Love went on to pursue some minor roles in other films such as *Trapped* (2002). However, her drug use and unpredictable behavior once again surfaced, resulting in further health and legal troubles. After several unsuccessful attempts, Love was finally mandated to a three-month lockdown in rehab by a Los Angeles county court. Upon her release, Love put out a diary recounting her life, *Dirty Blonde: The Diaries of Courtney Love*, and touted her sobriety to the public. In 2009, after losing custody of Frances Bean for unrelated reasons, Love re-formed Hole and the band then released its first album in nearly 10 years, *Nobody's Daughter*.

Impact (Psychological Influence)

Courtney Love's band, Hole, had a significant impact on the "Riot Grrrl" movement of the 1990s. She was voted "Best Female Performer" in the 1994 Metal Edge Reader's Choice Awards, beating out Lita Ford, who had won the title the previous seven years in a row. Love's acting career, though sporadic, has also been a success. She continues to pursue both her music and acting careers.

Loxitane (Loxapine)

Loxitane is a prescription medication used to treat schizophrenia and various other mental disorders. Its generic name is loxapine.

Definitions

- **Antipsychotic medications** are prescription drugs used to treat psychotic disorders. They are sometimes referred to as antipsychotics or neuroleptics.
- **Extrapyramidal symptoms** are a group of side effects associated with antipsychotic medication use, which are characterized by involuntary muscle movements, including rigidity, contraction, and tremor.

Description

Loxitane is an antipsychotic medication that has been licensed to treat schizophrenia. It is also used to treat various other mental disorders, including anxiety, mania, depression, and other psychotic disorders. It belongs to a class of drugs known as "typical antipsychotics." Typical or first-generation antipsychotics first appeared in the 1950s. Although clinically effective, these medications caused severe neurological side effects, including extrapyramidal symptoms similar to those of Parkinson's disease. Second-generation or atypical antipsychotics, such as Clozaril, were claimed to be less likely to cause these extrapyramidal symptoms. However, recent research has demonstrated the side effect profile of both typical and atypical is basically the same. While it is not entirely clear how Loxitane works, it is believed to block or lessen the effects of dopamine, a neurotransmitter or chemical messenger in the brain.

Precautions and Side Effects

Like other antipsychotic medications, Loxitane carries a warning regarding use in elderly people with dementia, who suffer from an increased risk of death from its use. Loxitane should not be used by women who are pregnant, trying to become pregnant, or breast-feeding. Infants born to mothers who had taken Loxitane during pregnancy may develop extrapyramidal symptoms and withdrawal symptoms, including agitation, trouble breathing, and difficulty feeding.

Common side effects associated with Loxitane use include difficulty swallowing, restlessness, stiffness of arms and legs, trembling, and loss of balance. Less common side effects include urination problems, muscle spasms, skin rash, and severe constipation. Rare side effects include uncontrolled twisting and movement of the neck, fever, sore throat, unusual bleeding, yellowing of the eyes or skin, and changes in facial expression. Seizures have also been reported. Overdose symptoms include significant drowsiness, severe dizziness, significant breathing difficulties, severe weakness, trembling muscles, and severe uncontrolled movements. Loxitane should not be combined with other substances that depress the central nervous system, such as antihistamines, alcohol, tranquilizers, sleeping medications, and seizure medications. Loxitane should not be combined with anticholinergic drugs because of the potential of decreased antipsychotic effects. Also, Loxitane should not be combined with lithium or Ativan.

Luvox (Fluvoxamine)

Luvox is a prescribed medication used to treat obsessive-compulsive disorder. Its generic name is fluvoxamine.

Definitions

- **Antidepressant medications** are prescription drugs that are primarily used to treat depression and depressive disorders. They are known as antidepressants.
- **Obsessive-compulsive disorder** is a mental condition characterized by obsessions (a persistent idea or image that dominates one's thinking), which cause marked anxiety, and/or by compulsions (strong impulse to repeat an action), which serve to reduce anxiety.
- **Selective serotonin reuptake inhibitors (SSRI)** are medications that act on and increase the levels of serotonin in the brain that influences mood.
- **Serotonin syndrome** is a serious medication reaction resulting from an excess of serotonin in the brain. It occurs when a number of medications that increase serotonin are taken together. Symptoms include high blood pressure, high fever, headache, delirium, shock, and coma.

Description

Luvox is in a class of antidepressant medications known as selective serotonin reuptake inhibitors (SSRIs). Luvox was the first SSRI to be approved for the treatment of treating obsessive-compulsive disorder (OCD) in children, adolescents, and adults. Depression and OCD are thought to be caused by low levels of serotonin, a chemical messenger (neurotransmitter) that is released and transmitted in the brain. Like other SSRI medications such as Prozac, Zoloft, and Paxil, Luvox is believed to work by increasing the level of serotonin in the brain. Increased levels can benefit those with OCD, depression, panic disorder, post-traumatic stress disorder, mood swings, premenstrual tension, alcoholism, and certain kinds of headaches.

Precautions and Side Effects

Those taking Luvox should be monitored closely for insomnia, anxiety, mania, significant weight loss, and seizures. Its use should be also be monitored in children and adults up to age 24 because they are at an increased risk of developing suicidal thoughts. Caution should also be exercised when prescribing Luvox to those with impaired liver or kidney function, those over age 60, children, individuals with known bipolar disorder or a history of seizures, those with diabetes, and individuals expressing ideas of committing suicide. The risks and benefits of Luvox should be considered by women who are or might become pregnant, and those who are breast-feeding. Those with diabetes should monitor their blood or urine sugar carefully, since Luvox can affect blood sugar. Alcohol should not be used while taking Luvox. Care must be taken in driving, operating machinery, or participating in hazardous activities when taking this medication. Luvox use should not be stopped abruptly since it can cause withdrawal symptoms. A group of serious side effects, called serotonin syndrome, has resulted from the combination of SSRI drugs such as Luvox and members of another class of antidepressants known as monoamine oxidase inhibitors.

Common side effects of Luvox include decreased sex drive and diminished sexual performance. Less common side effects are changes in mood, behavior, or thinking; difficulty breathing; difficulty urinating; and twitching or uncontrollable movements of the body or face. Luvox interacts with several other medications. Those considering taking Luvox should review the other medications they are taking with their physician for possible interactions. Also, those who are taking Luvox should inform all their health providers, including dentists. When other medications are taken together with Luvox, the effect of several drugs may be increased. These include benzodiazepines, beta blockers, Clozaril, antiseizure drugs Dilantin and Tegretol, tricyclic antidepressants like Tofranil, and cholesterol-lowering drugs such as Lipitor and Zocor.

M

Magnesium

Magnesium is a mineral involved in nerve and muscle functioning, bone formation, and immunity. It is used as both a medical treatment and a natural remedy.

Description

Magnesium is a mineral that is present in relatively large amounts in the body, more than half of which is in the bones. Magnesium is involved in some 350 enzyme (chemical) reactions necessary for optimal functioning. Dietary intake is the primary source of magnesium, and supplements are needed when magnesium levels are too low. Magnesium deficiency is common in about one half of all Americans, particularly in women, African Americans, and in the elderly. Magnesium is a powerful relaxation mineral and stress antidote. It is a life-saving treatment and is a critical medication on crash carts in hospitals and emergency department. Intravenous magnesium is regularly used to treat fatal arrhythmias (irregular heartbeat). Magnesium sulfate is regularly used in the preparation of colonoscopy. As a natural remedy magnesium is used for many conditions. It is used for heart and blood vessel problems, including chest pain, irregular heartbeat, high blood pressure, cholesterol problems, heart valve disease (mitral valve prolapse), and heart attack. Magnesium is also used for treating attention-deficit hyperactivity disorder, anxiety, chronic fatigue syndrome, Lyme disease, fibromyalgia, leg cramps during pregnancy, diabetes, kidney stones, migraine headaches, weak bones (osteoporosis), premenstrual syndrome, altitude sickness, urinary incontinence, restless leg syndrome, asthma, hay fever, and multiple sclerosis, and preventing hearing loss. It is also used as a laxative and as an antacid. The primary action of magnesium is to reduce irritability, spasms, and cramping. It is thought to work by lowering calcium levels in cells, leading to relaxed and more flexible muscles, nerves, and blood vessels.

Precautions and Side Effects

At recommended dose, magnesium appears to be safe for women who are pregnant or breast-feeding. High doses of magnesium should not be given to people with heart block. Taking high doses of magnesium can cause it to build up to dangerous levels in individuals with kidney problems. This could result in kidney failure.

Side effects are rare with magnesium when doses are less than 350 mg per day. Common side effects might include stomach upset, nausea, vomiting, or diarrhea. Higher doses can result in more serious side effects, including an irregular heartbeat, low blood pressure, confusion, slowed breathing, coma, and death.

Magnesium interferes with the absorption of digoxin (a heart medication), some antibiotics, and certain antimalarial drugs, which could potentially reduce their effectiveness. When taking medications used to treat osteoporosis, magnesium should be taken two hours apart so that the absorption of these medications is not inhibited. Magnesium has also been found to reduce the efficacy of Thorazine (a tranquilizer), penicillamine, oral anticoagulants, and tetracycline. High doses of Lasix and some diuretics may result in magnesium depletion. Other medications may also result in renal magnesium loss.

Magnetic Resonance Imaging (MRI)

Magnetic resonance imaging is a medical diagnostic test that uses magnetic field to produce detailed images of the brain and internal organs. It is also referred to as MRI and nuclear magnetic resonance imaging.

Definitions

- **Hydrogen** is the element with one electron (negatively charged particle) circling a nucleus consisting of one proton (positively charged particle). This nuclear proton makes MRI possible by resonating (interacting) with radio waves in a magnetic field.
- **Ionizing radiation** is electromagnetic radiation that can damage living tissue by disrupting and destroying individual cells. Radio waves do not damage organic tissues they pass through.
- **Magnetic field** is the three-dimensional area or field surrounding a magnet, in which its force is active.
- **Radio waves** are electromagnetic energy of the frequency range corresponding to that used in radio communications. They are the same as visible light, x-rays, and other types of electromagnetic radiation but are of a higher frequency.

Description

Magnetic resonance imaging (MRI) is a type of diagnostic imaging that uses electromagnetic radiation and a strong magnetic field to produce detailed images of the brain and internal organs. MRI works by producing a map of hydrogen distribution in the body. Because it can be magnetized, hydrogen will align itself with a strong magnetic field, like the needle of a compass. By using strong magnets and pulses of radio waves to modify the natural magnetic properties in the body, MRI can produce higher-quality images of organs and soft tissues than other scanning techniques.

Once an individual's hydrogen atoms have been aligned in the magnet, pulses of specific radio wave frequencies are used to knock them back out of alignment. The hydrogen atoms alternately absorb and emit radio wave energy, vibrating back and forth between their resting (magnetized) state and their agitated (pulsating) state. This is the "resonance" part of MRI. The MRI device records the duration, strength, and location of the signals emitted by the atoms as they relax, and translates the data into an image on a monitor. This is "imaging" part of MRI. The state of hydrogen in tissue that is diseased differs from that in healthy tissue of the same type. Because of this, the MRI is valuable in identifying tumors and other lesions. A single MRI exposure produces a two-dimensional image of a slice through the target area. This series of closely spaced images (usually less than half an inch) appears as a virtual three-dimensional) view of the area.

MRI is particularly useful for imaging the brain and spine as well as the soft tissues of joints and the interior structure of bones. The entire body is visible to the technique. Because it does not use ionizing radiation, MRI poses no significant health risks. It is being used increasingly during surgical operations, particularly those involving very small structures in the head and neck, as well as for preoperative assessment and planning. Intraoperative MRIs have shown themselves to be safe as well as feasible, and to improve the surgeon's ability to remove the entire tumor or other abnormality. They are valuable because an image can be produced during the procedure so that, for instance, a missed portion of tumor can be removed immediately,

during the initial surgery, rather than having to return for a second procedure.

Developments and Current Status

In 1971, the American inventor Raymond Damadian (1936–) developed the first magnetic resonance scanning machine for safely scanning human tissue. The first MRI image was published in 1973, and the first studies on humans were performed in 1977. In 2003, American chemist Paul Lauterbur (1929–2007) and English physicist Peter Mansfield (1933–) won the Nobel Prize for their discoveries involving magnetic resonance imaging. Since then, there have been several refinements of MRI. One of the most promising has been functional magnetic resonance imaging (fMRI).

fMRI was developed to measure the change in blood flow related to neurological activity in the brain and spinal column. It works by detecting the changes in blood oxygen levels that occur in response to neural activity. When a brain area is more active, it uses more oxygen resulting in increased blood flow. Based on this increased activity, the fMRI produces activation maps, showing which parts of the brain are involved in a particular mental process. The most active areas show up as red and orange, while the least active appear in blue. fMRI has become a favored tool for imaging normal brain function. In the past few years, researchers have used it to increase their understanding of processes involved in the forming of memories, in language acquisition and learning, and in the experience of pain. Unlike other imaging techniques, fMRI does not require individuals to be injected with contrast material or be exposed to radiation. For that reason it has come to be the principal tool in brain mapping research.

Major Depressive Disorder

Major depressive disorder is a mental disorder characterized by a depressed mood and other symptoms that interfere significantly with an individual's daily functioning. It is also referred to as clinical depression.

Definitions

- **Behavioral activation** is a brief, structured treatment approach that activates those who are depressed so they can again experience pleasure and satisfaction.
- **Bipolar and related disorders** are a group of mental disorders characterized by changes in mood and in energy (e.g., being highly irritable and impulsive while not needing sleep). These disorders include bipolar I disorder, bipolar II disorder, and cyclothymic disorder.
- **Depression** is a sad mood or emotional state that is characterized by feelings of low self-worth or guilt and a reduced ability to enjoy life. It is not considered a mental disorder unless it significantly disrupts the individual's daily functioning.
- **Depressive disorders** are a group of mental disorders characterized by a sad or irritable mood and cognitive and physical changes that significantly disrupt the individual's daily functioning. These disorders include persistent depressive disorder, premenstrual dysphoric disorder, and major depressive disorder.
- **SSRI** stands for selective serotonin reuptake inhibitors. They are a class of antidepressant

medications that work by blocking the reabsorption of serotonin in nerve cells and raising its level in the brain resulting in symptom reduction.

Description and Diagnosis

Major depressive disorder is one of a group of depressive disorders. It is characterized by a depressed mood or anhedonia (loss of pleasure in all or nearly all activities) and other symptoms that are sufficiently severe to interfere significantly with the individual's everyday functioning. Depression is a normal emotional reaction to perceived loss and hopelessness. However, this disorder differs considerably from the occasional "down" feelings or "blues" that are fleeting. It also differs from the normal period of grief or bereavement following the loss of a loved one. Instead, major depressive disorder causes a lengthy period of gloom and hopelessness, and the individual may no longer take pleasure in activities or relationships that were previously enjoyable. Those experiencing this disorder usually cannot "snap out of it" even when something positive happens. In some cases, depressive episodes are triggered by an obviously painful event, but in other instances it can develop without a specific stressor. It is considered a mental disorder only when it is sufficiently severe to disrupt the individual's ability to meet normal demands of life.

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, individuals can be diagnosed with this disorder if they exhibit a depressed mood or a loss of pleasure in previously enjoyed activities. They must have experienced symptoms such as sadness, emptiness, or hopelessness. Weight loss or weight gain, changes in appetite, and sleep problems are common. Agitation or periods of slowed mental and physical activity may also have been experienced. Fatigue, indecisiveness, and concentration problems can also be present. So can feelings of worthlessness or guilt, and thoughts of death, including thoughts of suicide. Such symptoms must have been experienced for at least two weeks most of each day. These symptoms must be significantly distressing and impair the individual's ability to function in important areas of life. This episode cannot have been caused by substance use or a medical condition or other mental disorder. Finally, to make this diagnosis, there cannot have been a manic or hypomanic episode. Before DSM-5 the depressive disorders and the bipolar disorders were considered mood disorders and described in a single chapter. However, recent research indicates that these disorders are considerably different. For this reason, DSM-5 has separate chapters for the depressive disorders and the bipolar and related disorders (American Psychiatric Association, 2013).

The exact cause of depression is not fully understood. As with many mental disorders, genetic, physiological, biochemical, environmental, and psychological factors may be involved. For example, this disorder seems to run in families, suggesting a genetic basis. Those with this disorder may have physical and other changes in their brains. These include changes in brain chemistry in which there is an imbalance in neurotransmitters (chemicals in the brain), particularly serotonin. Changes in the balance of hormones may also cause or trigger depression. These changes can result from thyroid problems, menopause, or other conditions. Likewise, significant stressors such as the death or loss of a loved one, financial problems, high stress, or childhood traumas can trigger depression in some.

Treatment

The clinical treatment of this disorder usually involves medication, psychotherapy, and lifestyle factors. The longer and more severe, and the more depressive episode, the more difficult this disorder is to treat. In such situations, the more likely all three treatment modalities need to be involved. Treatment often begins with medication that blocks the biological processes that activate the painful and debilitating symptoms. Medications used to treat major depressive disorder include the antidepressants that affect serotonin, called SSRIs, such as Prozac and Celexa. Other antidepressants include Pristiq and Cymbalta.

Once symptoms have been sufficiently reduced by medication, psychotherapy to process psychological issues can begin. Before then it is not uncommon for the individual to be so distracted by debilitating symptoms to effectively engage in therapy. For some, the emotional relief from medication is considerable

and they may decide there is no need for therapy. For others, there is little or no emotional relief, or the side effects of the medication become unbearable. In these situations or when the individual is unable to engage in daily activities, a type of therapy called behavioral activation may be indicated. Other forms of therapy, such as cognitive behavior therapy (CBT), are useful in dealing with current stressors and for providing psychological tools to deal with depressive symptoms and future stressors. Education about depression and underlying psychological issues is also the focus of CBT.

In addition to medication and therapy, lifestyle changes may be necessary for treatment to be successful. Because everyday behaviors can increase or decrease depression symptoms, certain lifestyle changes may be recommended. These might include maintaining a regular daily schedule that includes exercise, a healthy diet, avoiding alcohol, and improving sleep.

Male Development

"Male development" refers to the psychological concept of how male identity is developed.

Description

Identity development is a multistage process that takes place as adolescents interact with their world in a variety of context. Adolescence is a time that males develop a deepening sense of the qualities, roles, and characteristics associated with masculinity as they seek the answer to the question "Who am I?"

Male development is influenced by many factors. Environmental, media, peer group, social, parental, and family influences are all associated with the development of gender roles and masculinity. Identity formation and masculine development involves developing a sense of self separate from all others while at the same time belonging to a group. Perceptions of gender roles help the adolescent navigate this separate versus belonging dilemma by experimenting with male stereotypes, such as being strong, aggressive, fearless, and emotionally aloof. Positive feedback and group acceptance serve to reinforce the qualities the individual, and group, considers manly.

Peer groups have been identified as major influence on male development. Researchers have noted that adolescents spend more time with friends and classmates than with their families and other adults. Peer groups are comprised of individuals who share common interest and values and who are in the same developmental period. These groups have a strong influence on masculine development as they provide direction, advice, and boundaries for attitudes, behaviors, and emotional expression. These rules establish what it takes to belong and in many ways define the concept of "peer pressure."

Current Status

Male development and its relationship to male privilege and gender inequalities is a topic of intense investigation and concern. "Male privilege" refers to physical, economic, political, and cultural advantages men have over women as a result of being male. "Gender inequalities" refer to unequal treatment of individuals based on gender. Gender inequalities impacting women, sometimes referred to as the "gender gap," have been clearly identified. These inequalities include unequal wages and chance for promotion; less

political representation and policy-making opportunities and power; and a host of other social attitudes that impact women more so than men, such as manner of dress, personal hygiene, and appearance expectations. Significant research has been focused on how male development impacts gender inequalities, with the central question being, is masculinity culturally constructed or biologically determined? The implications are that if male privilege is biologically determined then men have a natural superiority over women. If masculinity is culturally constructed, then male privilege and gender inequalities can be positively impacted through social interventions such as education.

The struggle for gender equality will continue to be a focus of research that will bring greater clarity to how male identity is developed. The importance of men's responsibilities and roles in achieving greater gender equality is essential to this process.

Male Hypoactive Sexual Desire Disorder

Male hypoactive sexual desire disorder is a mental disorder characterized by low or complete absence of erotic thought or fantasy in men.

Definitions

- **DSM-5** stands for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, which is a diagnostic system used by professionals to identify mental disorders with specific diagnostic criteria.
- **Erectile disorder** is a mental disorder characterized by difficulty obtaining or maintaining a rigid erection during sexual activity.
- **Psychotherapy** is a psychological method for achieving desired changes in thinking, feeling, and behavior. It is also called therapy or therapeutic counseling.
- **Sexual dysfunctions disorders** are a group of mental disorders characterized by significant difficulty in the ability to respond sexually or to experience sexual pleasure. Disorders include delayed ejaculation, and genito-pelvic pain/penetration disorder.

Description and Diagnosis

Male hypoactive sexual desire disorder is one of the DSM-5 sexual dysfunctions disorders. It is characterized by the absence of or decreased interest in sexual thoughts, fantasy, or activity when compared to other men with similar age and cultural influences. Some males may experience the symptoms of this condition with certain partners or in specific circumstance. Others may experience these symptoms at all times. Some may develop this disorder in later life, while others may have the disorder their entire lives. The prevalence of this disorder in the United States varies greatly with age. It is relatively uncommon in younger men, affecting less than 2% of those under the age of 44. However, approximately 41% of men over the age of 44 may experience difficulty with sexual desire (American Psychiatric Association, 2013).

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, for individuals to be diagnosed with this disorder, they must meet certain criteria. Individuals must experience an ongoing absence of thoughts or interest related to sex or sexual activity. This lack of interest must be present for a minimum of six months, although it may have been present throughout their life. Most important, it must cause significant distress and cannot be explained by a medical condition or a different mental disorder. Some individuals may express a discrepancy between their sexual interest and their romantic partners. This alone

is not sufficient for the diagnosis to apply (American Psychiatric Association, 2013).

The cause of this disorder is understood in terms of biological, social, cultural, and psychological factors. One biological factor is that the disorder is the result of aging. If so, the diagnosis can be made if it causes significant distress. Another biological factor is low levels of the hormone testosterone. It is also associated with erectile disorder, which can be the cause of hypoactive desire disorder in some males. Other factors may play a role in the development of this disorder. These include relationship or partner issues, history of abuse, stress, and cultural and religious issues.

Treatment

For this disorder to be treated effectively, a clinician must first ascertain the most applicable cause of this disorder. If the disorder is most likely caused by partner or relationship issues, then joint psychotherapy aimed at resolving the couple's issues is an effective option. If the disorder is lifelong without a biological cause, then it may be very difficult to treat. In such cases, the goal of therapy is to help the couple adapt to the disorder. In contrast, if the disorder has a biological explanation, then some drug or hormone therapies may be employed to improve sexual desire.

Malignant Narcissism

Malignant narcissism is a combination of narcissistic, paranoid, and antisocial personality traits.

Definitions

- **Antisocial personality disorder** is a mental disorder characterized by a pattern of disregarding and violating social norms (rights of others).
- ***Diagnostic and Statistical Manual of Mental Disorders*** is the handbook mental health professionals use to diagnose mental disorders. The current edition (fifth) is known as DSM-5.
- **Narcissistic personality disorder** is a mental disorder characterized by a pattern of grandiosity, lack of empathy, and a need to be admired by others.
- **Paranoid personality disorder** is a mental disorder characterized by a pattern of a high level of distrust and suspiciousness of the motives of others.
- **Personality disorder** is a long-standing pattern of maladaptive (problematic) behavior, thoughts, and emotions that deviates from the accepted norms of an individual's culture.
- **Personality traits** are stable and consistent behavior patterns that characterize an individual.
- **Psychoanalytic theory** is a psychological theory that explains behaviors and perceptions as the result of unconscious, sexual, and biological instincts. It was originally developed by Sigmund Freud.
- ***Psychodynamic Diagnostic Manual*** is a diagnostic framework that characterizes individuals in terms of their psychodynamics (view of self and others). It is also known as PDM.
- **Psychopathic personality** is a mental disorder characterized as amoral (unconcerned with moral standards) behavior, inability to love and understand another's feelings (empathy), extreme self-centeredness, and failure to learn from experience. It is also known as psychopaths.

- **Sadistic** refers to the enjoyment, which may include sexual gratification, gained from causing physical pain or humiliation.
- **Sadistic personality disorder** is a mental disorder characterized by sadistic behavior (enjoyment in being cruel) and domination.

Description

"Malignant narcissism" refers to a cluster of personality traits characteristic of a severe personality disorder. It includes features of the narcissistic personality disorder, paranoid personality disorder, and the antisocial personality disorder. Such individuals are self-centered, grandiose, sadistic, suspicious, and disregard the rights of others. They also lack empathy and seek power through exploitation and abuse. They are sometimes referred to as psychopathic personalities. Malignant narcissists are likely to see themselves as superior, which justifies their harmful treatment of others.

Malignant narcissism is not listed as a personality disorder in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*. However, the *Psychodynamic Diagnostic Manual* does describe the sadistic personality disorder which contains certain features of malignant narcissism.

Psychoanalyst Erich Fromm (1900–1980) first described malignant narcissism in his 1964 book *The Heart of Man: Its Genius for Good and Evil*. Fromm characterized this personality trait as "evil." Others expanded on malignant narcissism to include features such as paranoia (suspiciousness) and sadism, or finding pleasure in harming others. The American psychiatrist M. Scott Peck (1936–2005) considers such individuals to be a distinct form of narcissistic personality disorder who exhibit psychological evil. He describes this as the use of "power to destroy others for the purpose of defending or preserving the integrity of one's sick self" (Peck, 1983). He also proposes diagnostic criteria for diagnosing this distinct personality disorder. Many consider Adolph Hitler to be an example of the malignant narcissist. These individuals are also found in everyday life. The fictional main character in the film *American Psycho* has been classified as a malignant narcissist.

The causes of this disorder are not fully understood. Several factors may be involved, including early childhood experience and the way individuals were parented. Their childhood may have involved physical and verbal abuse. The parenting style they experienced growing up was likely to be hostile, cruel, or neglectful. Their parents and siblings may have engaged in and modeled sadistic, suspicious, and antisocial behavior. In addition, these individuals are likely to have characteristic view of themselves and others. They tend to see themselves as being entitled to hurt, humiliate, and cause suffering on others. They are also likely to view others as objects for their domination. As a result they look for situations in which they can express their contempt and inflict pain and suffering. At the same time, they experience immense pleasure and glee watching others suffer.

Treatment for malignant narcissism can involve psychotherapy. Unfortunately, individuals with malignant narcissism are not likely to successfully respond to therapy. The reason is that these individuals have little or no willingness to change.

Malingering

Malingering is an act of intentionally faking or exaggerating physical or psychological symptoms for motives involving external incentives.

Definitions

- **Antisocial personality disorder** is a mental health disorder characterized by a pattern

of disregarding and violating social norms (rights of others).

- **Cognitive behavior therapy** is a form of psychotherapy that focuses on changing faulty behaviors, emotions, and thoughts. It is also known as CBT.
- **Conversion disorder** is a mental health disorder characterized by paralysis, seizures, or other neurologic symptoms that cannot be explained by medical evaluation. It is also referred to as functional neurological symptom disorder and hysteria.
- **DSM-5** stands for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, which is a diagnostic system used by professionals to identify mental disorders with specific diagnostic criteria.
- **Factitious disorders** are a group of mental disorders in which individuals intentionally act as if they are physically or mental ill for no obvious benefit.
- **Fatigue** is a feeling of extreme tiredness and has a gradual onset.
- **Histrionic personality style** is characterized by the constant need for approval and praise, attention-seeking behaviors, exaggerated emotional outbursts, and extreme impulsiveness.
- **Hypochondriosis** is a mental disorder characterized by a preoccupation with having a serious medical condition based on a misinterpretation of bodily symptoms. In the DSM-5 this diagnosis has been replaced by illness anxiety disorder.
- **Minnesota Multiphasic Personality Inventory** is an assessment tool commonly used by mental health professionals to assess and diagnose mental illness. It is also referred to as MMPI.
- **Personality disorder** is a long-standing pattern of maladaptive (problematic) behavior, thoughts, and emotions that deviates from the accepted norms of an individual's culture.
- **Post-traumatic stress disorder** is a mental health disorder characterized by nightmares, irritability, anxiety, emotional numbing, and recurrent flashbacks of a traumatic event that an individual experienced or witnessed. It is also referred to as PTSD.
- **Psychotherapy** is a psychological method for achieving desired changes in thinking, feeling, and behavior. It is also referred to as therapeutic counseling.
- **Somatoform disorders** are a group of mental disorders characterized by physical symptoms that cannot be explained by a medical condition. The DSM-5 calls them somatic symptom and related disorders.
- **V codes** are codes listed in the DSM-5, which are used to identify conditions other than a disorder and are used to report significant factors that may adversely affect an individual.

Description and Diagnosis

Malingering is one of the conditions presented as a V code in the DSM-5 "Other Conditions That May Be a Focus of Clinical Attention" section. Malingering is listed under the category of "Nonadherence to Medical Treatment." Malingering is not a mental health disorder although it can occur in the context of other mental illnesses. Malingering is included in the DSM-5 to draw attention to issues that may be of clinical significance (e.g., diagnosis, course, prognosis, and treatment of an individual). Malingering is characterized by intentionally presenting false or exaggerated physical or psychological symptoms, which are motivated by external incentives for personal gain. Some examples of external incentives include avoiding school, work, and military duty, obtaining financial compensation, eluding criminal prosecution, or obtaining narcotics or other drugs (American Psychiatric Association, 2013).

Malingering can be a difficult task for a mental health practitioner to diagnose. Physicians do not want to overlook a treatable disease, yet they also do not want to continue ordering tests and treatment for individuals they believe are faking their symptoms. Some

symptoms individuals often present with on examination include irritable and hostile mood, a vague or evasive attitude toward the examining physician, and preoccupation with the claimed illness or injury. There are not any specific techniques of physical examination that reliably detect malingering. Malingering individuals who are involved in legal cases are often referred for a mental health evaluation. This evaluation is helpful in determining if an individual is faking symptoms. The Minnesota Multiphasic Personality Inventory can be used to detect the presence of malingering. Malingering can be difficult to distinguish from personality disorders, factitious disorder, conversion disorders, hypochondriasis, somatoform disorders, and post-traumatic stress disorder.

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, malingering should be strongly suspected if any combination of the following situations or conditions is noted. This includes the presentation of a medicolegal (medical and legal) situation, such as individual being referred to a clinician for an examination by an attorney. If there is a discrepancy between an individual's claimed stress or disability and the findings and observations, then malingering should be suspected. Lack of cooperation by an individual during a diagnostic evaluation and compliance with the prescribed treatment plan is another red flag for suspecting malingering. Malingering is also associated with antisocial personality disorder and histrionic personality style (American Psychiatric Association, 2013).

The occurrence of this disorder is only for personal gain. Motivation for malingering is always external. Mental health practitioners usually become suspicious to the possibility of malingering when factors exist that might help promote a facade. The symptoms individuals typically claim they are experiencing involve chronic pain or chronic fatigue symptoms. One of the reasons an individual states he or she is experiencing these particular symptoms is objective tests (e.g., x-rays) cannot find any physical cause. Many individuals who are faking physical and psychological symptoms engage in dishonest methods. Some of these symptoms include trying to convince a medical professional that one has a disease after learning the details of the symptoms in medical textbooks and on the Internet. Other dishonest methods include an individual taking medications that provoke certain symptoms common to a disease, overexercising to induce muscle strain or other medical ailments, and overdosing on medications.

Treatment

Since the DSM-5 does not recognize malingering as a legitimate disorder, no structured treatment plan exists. Individuals who are intentionally faking symptoms do not want to be cured of their ailment and will often fail to report any improvement with treatment. One possible treatment that may be helpful includes an individual's participating in individual psychotherapy. One particular method of treatment that has been shown to be effective is cognitive behavior therapy (CBT). The goal of CBT is to have an individual focus on and change his or her thoughts and behaviors.

Man Who Mistook His Wife for a Hat, The (Book)

The Man Who Mistook His Wife for a Hat and Other Clinical Tales is a best-selling book written by

neurologist Oliver Sacks and published in 1985. The book is a collection of several of Dr. Sacks's case studies that explore the worlds of his patients and offer an interesting look at a series of neurological anomalies.

Description

The book's title is from the case study of "Dr. P." Dr. P. has a visual agnosia, and is unable to recognize common objects around him even though there is nothing wrong with his eyesight. Because of his condition, he mistakes hydrants for children and talks to furniture knobs. He also, as the title suggests, doesn't recognize his wife's head and tries to wear her as a hat. Sacks recounts conversations with Dr. P. and also discusses his artwork. Dr. P.'s artistic style progresses from naturalist to more "geometrical and cubist" over time, charting his pathology through the years.

In the four sections of the book, "Losses," "Excesses," "Transports," and "The World of the Simple," Sacks introduces the reader to several other patients. One is an autistic artist who doesn't talk but can sketch delicate images out of nature. Some of the other case studies in the book include autistic twins who communicate with mathematical computations performed at lightning speed, an amnesiac who can't remember what happened to him five minutes ago, and a woman who can no longer feel her own body.

In the case study of a patient, Jimmie G., with Korsakoff's syndrome, Sacks ponders the human condition. Jimmie G. is unable to remember anything after his 19th birthday in 1945, though he is now 49 years old. Sacks describes the frustration of a man who can't identify with what's currently happening, but who is comforted by his spirituality. This is a reminder that a person is more than just the sum of his memories. Sacks practices medicine in a manner where he and the patient are on equal ground. They learn from each other and work together to gain new understanding of the patient's condition and provide treatment. He appreciates what his patients have contributed to the understanding of their own conditions.

Pointing out the complexity of the human brain, Sacks notes as an organ it processes information similar to a computer. Yet unlike a computer, the brain is capable of doing so much more. He points out that neurologists tend to look at the brain more like a mechanical object rather than part of a complex being. He asserts that it's important that physicians understand how the brain works, not just as a system but also as a part of the whole person. The brain is not just abstract, mechanical, and categorizing, but it's also personal, judging, and feeling.

Impact (Psychological Influence)

In this book, Sacks examines the writings of neurological legends Hughlings Jackson and A.R. Luria, and discusses how neurologists are fond of speaking in terms of deficits. Neurology tends to view patients along the narrow concept of loss or lack. One of Sacks's patients, Rebecca, points out that the focus on deficit is detrimental to what is retained by the patient. A shift in thinking would better serve both the patient and the physician.

The patients whom Sacks works with have come up with unique ways of communicating and coping with their environments with respect to the way their brains function. Sacks notes that whether you look at a prodigy or someone with a mental defect, both are out of step with the rest of society. Sacks believes that normal and abnormal are not mutually exclusive, but rather points on a continuum, and are arbitrary at best.

Manic Episode

A manic episode is a mental state characterized by mania experienced during the course of bipolar disorder.

Definitions

- **Bipolar disorder** is a mental disorder characterized by a history of manic episodes (bipolar I disorder), mixed, or hypomanic episodes (bipolar II disorder), usually with one or more depressive episodes.
- **Depression** is an emotional state characterized by feelings of sadness, low self-esteem, guilt, or the reduced ability to enjoy life. It is not considered a disorder unless it significantly disrupts one's daily functioning.
- **Hallucinations** are false or distorted sensory perceptions that appear to be real perceptions that are generated by the mind rather than by an external stimuli.
- **Mania** is a mental state of expansive, elated, or irritable mood with increased energy or activity.
- **Psychosis** is a severe mental condition in which an individual loses touch with reality.

Description

A manic episode is a mental state characterized by a period of an abnormally elated mental state. Typically, it includes feelings of euphoria (high spirits), inappropriate enthusiasm, decreased sleep, racing thoughts, talkativeness, impulsivity, risk taking, and irritability. The mood disturbance associated with manic episodes is noticeable to others and is not characteristic of the individual's usual state or behavior. Individuals who experience an overly joyful or overexcited state are usually experiencing a manic episode. The symptoms associated with a manic episode must be severe enough to cause difficulty or impairment in social, occupational, educational, and other important functioning. Symptoms associated with a manic episode cannot be the result of substance use or abuse or other medical conditions. Manic episodes usually occur before the age of 25 (American Psychiatric Association, 2013).

The cause of manic episodes usually occurs as a symptom of bipolar disorder. Bipolar disorder can include both manic and depressive episodes. Bipolar disorders can cause significant shifts in mood, energy, thinking, and behavior. These shifts range from the highs of mania to the lows of depression. The symptoms of a manic episode may last for days, weeks, or months. The mood changes of bipolar disorder (a manic episode) are so intense that they interfere with an individual's ability to function, and individuals may experience hallucinations or psychosis. During a manic episode, an individual may charge large amounts on credit cards or impulsively quit a job. In extreme cases, individuals having a manic episode may experience hallucinations or psychosis. Hospitalization may be required for an individual exhibiting severe symptoms during a manic episode. For individuals who experience one manic episode, 90% will experience at least one more episode in their lifetime (American Psychiatric Association, 2013). Lifelong treatment is required for individuals with bipolar disorder since it is a chronic condition.

Man's Search for Meaning (Book)

Meaning-focused existential psychologist and psychiatrist, Viktor E. Frankl (1905–1997) wrote his most popular book *Man's Search for Meaning* over a nine-day period in 1945, shortly after his concentration-camp liberation during World War II. It contains a narrative of concentration camp experiences and outlines some

of the basic elements of logotherapy (healing and enhancing well-being through the changing of one's attitudes and beliefs).

Description

Man's Search for Meaning is a book that emphasizes the importance of meaning, faith, hope, humor, and many other adaptive constructs. Frankl believed that human life has meaning, that people long to experience their own sense of personal life meaning, and that they have the potential to experience that meaning under all circumstances.

Originally published in English in 1959 as *From Death-Camp to Existentialism, Man's Search for Meaning* is a prime example of how people may reduce despair in severe circumstances by incorporating personal meaning through attitudes, experience, and behaviors. The book is divided into two parts. In part one, *Experiences in a Concentration Camp*, Frankl relates his personal story, while also analyzing the dynamics of the camp and its impact on those within. He explored the three stages—transport and arrival, daily camp life, and liberation—of the lives of people in the camp, including the prisoners, the guards, the Capos, and the SS Commanders in charge.

In part two, *Logotherapy in a Nutshell*, he detailed how modern man has focused too much on happiness when he should be focusing on the meaning in his life. Throughout the second part, Frankl deals with neurosis and motivations and the more technical aspect of logotherapy, its need, and its applications.

In 1942, Frankl was sent, with his wife and parents, to Theresienstadt Concentration Camp. He was liberated from Turkheim (near Dachau) in 1945. A psychiatrist before the war, he survived his time in the camps by attempting to treat fellow prisoners and mentally rewriting the manuscript that was taken from him on his imprisonment, incorporating his camp experiences into it. The result of his work, Logotherapy, has been dubbed the "Third Viennese School of Psychotherapy."

Impact (Psychological Influence)

Frankl is credited with writing more than 30 books during his lifetime. Many were published originally in German, but there have been translations into at least 32 languages. He also published over 700 articles. In 1984, a postscript entitled *The Case for a Tragic Optimism* was added to the book, creating a third part. The newest edition of the book (2006) indicates its continued relevance to the fields of psychology, psychotherapy, psychoanalysis, and psychiatry as there are more than 12 million copies in print. The book contains historical significance. It gives a vivid account of what a prisoner in a Nazi concentration camp experienced and what mental state he was in during each phase of his imprisonment. It also details the reasons why some survivors were able to endure such mental, emotional, and physical abuse, and why others did not. It also presented a positive approach to psychological treatment, one that many disciplines within the mental health realm have incorporated into their practices.

Marijuana

Marijuana is a common recreational drug that is used to heighten perception, affect mood, and relax. It is also known as cannabis and THC.

Definition

- **Drug Enforcement Agency** is the federal agency responsible for enforcing laws and regulations governing narcotics and controlled substances. It is also known as the DEA.

Description

Marijuana is a common street and recreational drug from *Cannabis sativa*, a hemp plant. Its pharmacologically active ingredient is tetrahydrocannabinol (THC). THC is absorbed into the bloodstream where

it activates proteins in the user's brain and spinal cord. This produces short-term psychoactive effects, including euphoria, a heightened state of awareness, and an increased appetite.

There are over 200 slang terms for marijuana, including "pot," "herb," "weed," "Mary Jane," and "grass." Marijuana is usually shredded and rolled into a cigarette or "joint," or is placed in a pipe or a water pipe and smoked. It can be added to food, as in cookies and brownies, or brewed as a tea. Marijuana is the most commonly used illicit drug in the United States, as well as in the world. As with most other illicit drugs, marijuana use disorders appear more often in males and are most common among people between the ages of 18 and 30 years. Statistics indicate that 17.4 million Americans over the age of 12 had used marijuana a minimum of one time in the previous month. One in three admits to having tried marijuana sometime in their lives. Its use has increased consistently in the past decade, and some 5 million Americans use it almost every day. Approximately 60% of illicit drug users use only marijuana. The health implications of marijuana are considerable. Data on emergency room admissions related to substance use, including marijuana, shows that 376,467 people were admitted to U.S. emergency departments in 2009 as a result of marijuana use, with almost a third of patients under the age of 21 (Substance Abuse and Mental Health Services Administration, 2011).

The debate over the use of "medical marijuana" is intense and highly controversial. THC is known to successfully treat nausea caused by cancer treatment drugs. It also stimulates the appetites of those diagnosed with HIV/AIDS and possibly assists in the treatment of glaucoma (eye problem). Its use as a medicinal agent is still questionable, however. A number of states have legalized medical marijuana use. These states include Alaska, Arizona, California, Colorado, District of Columbia, Delaware, Hawaii, Maine, Michigan, Montana, Nevada, New Jersey, New Mexico, Oregon, Rhode Island, Vermont, and Washington.

Precautions and Side Effects

Marijuana use is generally perceived as benign, but a number of concerning research studies suggest that it has some potentially serious side effects. In addition to the known side effect of a motivational syndrome (decreased interest and motivation), some research shows an increased risk of psychotic disorders among marijuana users. While these associations have been demonstrated, causality is still unclear. The question remains as to whether individuals with these disorders are more likely to use marijuana, or whether individuals who use marijuana have a potentially higher risk of developing these disorders.

Signs of marijuana use include red eyes, lethargy, and uncoordinated body movements. The long-term effects often include decreased motivation. There are a number of harmful effects on the brain, heart, lungs, and reproductive system. Those who smoke marijuana are at increased risk of developing cancer of the head and neck. For that reason, a synthetic form of marijuana, referred to as medical marijuana, is available. It is a prescription medication called Marinol (trade name: Dronabinol). Marinol contains synthetic THC. Since it is in pill form, Marinol eliminates the harmful and cancer-causing chemicals present when marijuana is smoked. It is used to relieve the nausea and vomiting associated with chemotherapy for cancer patients. Marinol is also used to treat loss of appetite in AIDS patients.

Marijuana has a high potential for addiction and dependency. For that reason it is listed as a Class I controlled substance by the Drug Enforcement Agency. The symptoms of addiction to marijuana are similar to those of any other addictive substance. Abruptly stopping marijuana use typically results in withdrawal. The symptoms of marijuana withdrawal are similar to those of other drugs and include irritability, anger, depression, insomnia, drug craving, and decreased appetite.

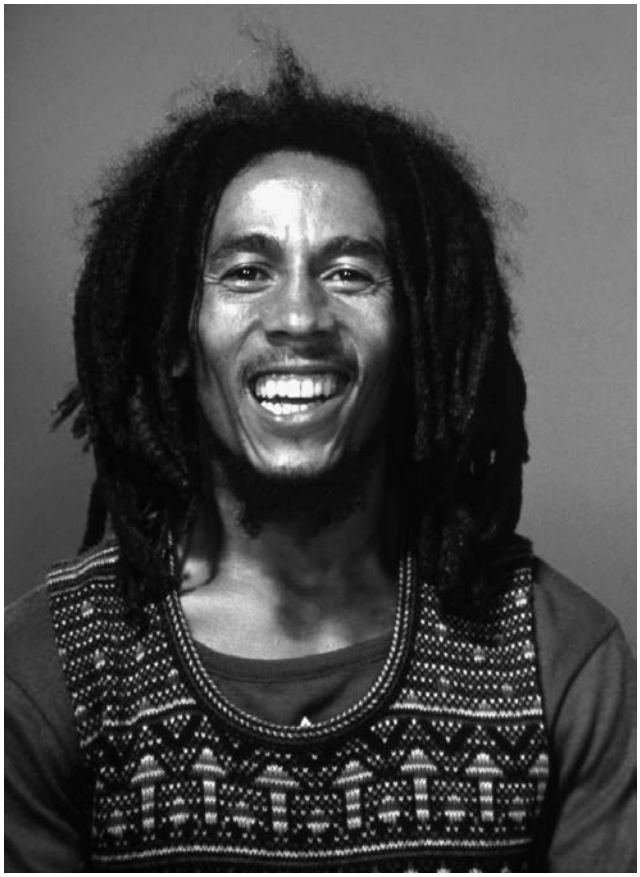
Marley, Bob

Nesta Robert (Bob) Marley (1945–1981) was a Jamaican singer, songwriter, and producer who reached a worldwide audience with his unique style of reggae-based music. Marley was a popular but at times polarizing figure. Treated as an inspiration by many oppressed peoples around the world, he was viewed as a troublemaker by government officials even as he was honored for his music and activism. Since his death in 1981, his image and life have been smoothed over and commercialized with multiple biographies, documentaries, branded products, and feature-length films.



Nesta Robert (Bob) Marley was a Jamaican singer, songwriter, and producer who reached a worldwide audience with his unique style of reggae-based music. (Alamy)

Description

Bob Marley's body of work lifted him out of obscurity in Jamaica to worldwide fame as a singer-songwriter. His career reached its peak in the late 1970s, which coincided with the height of his political power. Controversial during his lifetime, Marley's actions, music, and influence continue to be a powerful but complex cultural force to this day.

At a surface level, Marley has been canonized as a smiling, benevolent Rastafarian figure who assures his followers everything will be all right. However, his smooth reggae beats contain lyrics with edgy, complex integrations of historical events mixed with present-day political and social injustice. Striking deep emotional chords, Marley's music is considered by many oppressed peoples to contain calls to action in the name of freedom, equality, and unity.

Marley was the first to elevate reggae-style music to the world stage. His music touched on the dominant social themes and political issues of his era, particularly the black–white divide and colonialist/imperialist exploitation of emerging nation peoples. As he rose to fame, he was connected with a multitude of social causes around the world, and his influence has continued after his death.

Development

Marley was born in 1945 in Nine Mile, Jamaica, an area noted for its rural poverty. A mixed-race child, Marley's parents never married and his father died when he was 10. His mother moved back and forth between Jamaica and America, allowing him to see different musical styles and cultural norms. From a very young age, Marley sang and performed. He was involved with a

variety of vocal harmony groups and beat-based performers before learning guitar, which would become his signature instrument. His most notable musical collaborators were childhood friends known musically as The Wailers, with whom he had a number of hits.

However, Marley found his greatest success as a solo artist in the mid- to late 1970s. His multiple world tours were often combined with advocacy and activism to support humanitarian and social justice causes. Between his media impact and his musical impact, he was an almost universally recognized voice. A part of what helped his voice stand out was his unique application of the reggae style. Marley's addition of guitar provided a touch of rock-n-roll that made it more accessible to new listeners and extremely popular. This was a surprise to native Jamaicans, especially members of the upper class who considered themselves the custodians of "real" Jamaican culture. Marley's reggae sound was locally considered "rude boy" music, a genre that glorified a certain lawlessness and disrespect for authoritarian figures. Considered second-class or "outlaw" music, those who performed it were often targeted by police and the authorities as troublemakers.

Marley's popularity both puzzled and frightened Jamaican officials, who found his lyrical messages rebellious and countercultural. His Rastafarian beliefs infused his songs and interviews, which troubled traditional religious groups. As a further cultural affront, Marley fathered at least 12 children between his wife and a variety of women and openly smoked an abundance of marijuana. Officials wondered (and worried) at how this man could be an inspiration and hero to anyone, much less revered and sought after. The answer lay with his music. Marley was an extremely talented songwriter. Within a dance chant song, he could embed an uncompromising antiauthoritarian message and skewering of status quo hypocrisies. The energy and intensity of his live performances only added to the power of his verse.

Particularly strong hits for Marley included "No Woman No Cry," "Exodus," and "Redemption Song." The first was a ballad of encouragement to a downtrodden ghetto dweller, while the second was a call for his fellow Rastafarians to leave the tumultuous and dangerous political climate in Jamaica for a better life elsewhere. Both have been broadly adopted as anthems by underprivileged, persecuted, and struggling peoples. "Redemption Song" was inspired by a 1937 speech by Marcus Garvey and Marley's own spreading cancer. Calling on listeners to be the agents of their own liberty, it was released just a year before his death.

Impact (Psychological Influence)

Since his passing, Marley's songs have continued to be popular. However, the edgy antiestablishment element of his image has been commercialized. Some of the "peacemaking" and polishing began before his death. The Jamaican government awarded him the Order of Merit, one of the country's highest honors, and gave Marley a state funeral. His spouse, Rita Marley, worked to secure commercial rights to his image and music. In recent years, Marley has appeared on everything from trading cards to T-shirts. Despite becoming a commodity, Marley's message remains as a voice and a supporter of the black diaspora and underprivileged peoples worldwide. As a result, his music continues to receive heavy play and his image remains an inspiration to those who seek to lift themselves up.

Marriage and Family Therapist

Marriage and family therapists (MFTs) are mental health professionals who specialize in treating couples and families.

Definitions

- **Behavioral health** is an inclusive term referring to both mental health and substance use dynamics.
- **Internships** are required extensive field experiences in which professional knowledge and skills are utilized. Interns are closely supervised as they work directly with client populations.
- **Practicum** is a limited, part-time, field experience in which students are exposed to the "real world" of the profession through direct observation and assisting professionals working in the field. There is limited contact with, and responsibility for, clients.

Description

Marriage and family therapists are mental health professionals who are licensed to diagnose and treat mental health and emotional disorders. MFTs have specialized training in marriage, couples, and family systems theory. MFTs work in private practice, mental health centers, substance abuse centers, nursing homes, and other mental health–related service centers. The Bureau of Labor Statistics estimates the national average salary for MFTs to be $51,690 and projects that employment of MFTs will increase by 31% between 2012 and 2022. Marriage and family therapists have been designated as a core mental health profession by the federal government. Other core mental health professions include psychiatrist, clinical psychologist, clinical social worker, and psychiatric nurse specialist.

Marriage and family therapy is a distinct professional discipline, and all 50 states have regulatory requirements in order to practice as an MFT. Although licensure requirements vary by state, all MFTs are held to strict standards and must have an undergraduate degree and at least a master's degree in a clinical mental health field, such as mental health counseling, social work, psychology, or marriage and family counseling. Accredited graduate programs require up to 60 semester hours of coursework and take a minimum of two years to complete. Coursework includes techniques and theories in counseling, couples counseling, family counseling, and marriage/family systems theory; human development; diagnoses, appraisal, and assessment; substance use theory; treatment planning; psychopathology; ethical and legal standards; and clinical skills instruction. State practicum and/or internship experiences are required in graduate programs and must meet supervisory and clinical requirements.

All states license MFTs, but the regulations vary from state to state. All states require a graduate degree that meets the state's requirements and a passing score on a national licensing exam. All states require post-degree clinical training with ongoing clinical supervision provided by a licensed provider with two or more years of experience, depending on the state. Supervised clinical training requirements vary by state and can be as much as 3,000 hours of supervised clinical experience over a period of no less than two years. A specific percentage of those hours must be in face-to-face counseling, supervision, and case management. All states inquire as to the professional fitness and character of applicants and routinely ask about legal, medical, and behavioral health issues that may impair practice.

The American Association for Marriage and Family Therapy (AAMFT) is a professional membership organization representing over 25,000 members. Founded in 1942, the AAMFT exists to facilitate research, theory development, and education in marriage and family therapy. The AAMFT publishes the *Journal of Marital and Family Therapy* and hosts an annual national training conference. Therapist support services to its members include a wide array of educational materials, job services, online continuing education classes, legal consultation, access to liability insurance, and other services.

The AAMFT accredits graduate programs in Marriage and Family Therapy through the Commission on Accreditation for Marriage and Family therapy Education (COAMFTE). The Association of Marital and Family Therapy Regulatory Boards (AMFTRB)

assists state examiners in evaluating the knowledge of applicants for licensure or certification.

The COAMFTE works with the AMFTRB and state licensing and certification boards to credential marriage and family graduate, doctoral, and post-degree training programs that meet established accreditation standards. COAMFTE accreditation is a voluntary endeavor that once achieved provides the public with assurance that the educational program has been extensively evaluated and meets the standard established by the profession.

Marriage and family therapists are professional mental health practitioners who provide mental health services to individual, couples, and families. MFTs focus on couple and family groups while using the interaction of complex relationships and systems for positive change.

Marriage Counseling

See Couples Therapy

Maslow, Abraham (1908–1970)

Abraham Maslow (1908–1970) was an American psychologist who is best known for developing Maslow's Hierarchy of Needs, which consists of five steps and are often diagramed in the shape of a pyramid. The five stages are physiological, safety, love/belonging, esteem, and self-actualization. He was also a leading contributor to the movement of humanistic psychology.

Description and History

Abraham Maslow, PhD, was born and raised in Brooklyn, New York. His parents were Russian Jewish immigrants who migrated to the United States in the early 1900s. Maslow was the oldest of seven children. Later in life, Maslow identified his childhood as being unhappy and filled with loneliness, with much of his time being spent primarily in libraries. Maslow became interested in education from early on and he believed that education would improve the world. During his career, he held various academic positions as well as maintained affiliation with numerous professional organizations. He was president of the American Psychological Association in 1967.

Maslow was initially drawn to behaviorism but quickly moved away from it, holding onto only the idea of positivity. It was shortly after the bombing of Pearl Harbor in 1941 that Maslow made the decision that he wanted to dedicate his life to using the field of psychology for peace. As a professor, Maslow discovered students were seeking his advice regarding emotional concerns. At that time counseling did not exist as it is known today. He found himself offering informal therapy to students. This process actually helped him to explore human nature and human motivations. He began focusing on creative outlets, health, and the individual push for fulfillment.

Maslow was focused on positivity and emotional health as opposed to an illness or pathology-based model. Maslow was interested in human potential and the need for growth. He is perhaps best known for creating the Hierarchy of Needs, which consists of five steps and which is often diagramed in the shape of a pyramid. One must start at the bottom and cannot move to the next stage until the first has been fulfilled. The five stages of needs are physiological, safety, love/belonging, esteem, and self-actualization. At the highest level of needs, self-actualization is based on the human desire for self-fulfillment once other, more

Abraham Maslow was an American psychologist who is best known for developing Maslow's Hierarchy of Needs, which consists of five steps and are often diagramed in the shape of a pyramid. (Corbis)

basic needs have been met. The original model was modified later to include cognitive and aesthetic needs before self-actualization.

Impact (Psychological Influence)

Maslow has been viewed as being a passionate visionary. Maslow's influence is seen not only in the fields of psychology but also in the fields of counseling, health care, education, and business. His ideas focused on how to lead a meaningful life and helped create what is called humanistic psychology, system based on the idea that people are inherently good. This theory focuses on the exploration of human potential, while emphasizing wholeness and creativity.

He further explored these ideas through founding the *Journal of Humanistic Psychology* with Tony Sutich.

Masochistic Personality Disorder

Masochistic personality disorder is a mental disorder characterized by a lifelong pattern of self-defeating and self-destructive behaviors.

Definitions

- **Cognitive behavior therapy** is a form of psychotherapy that focuses on changing maladaptive (faulty) behaviors, emotions, and thoughts.
- **Depression** is an emotional state characterized by feelings of sadness, guilt, or reduced ability to enjoy life. It is recognized as a mental disorder when it becomes significantly distressing and disrupts daily life.
- **DSM** stands for the *Diagnostic and Statistical Manual of Mental Disorders*, which is a diagnostic system used to identify mental disorders in terms of specific diagnostic criteria.
- **Masochism** refers to finding pleasure in personal suffering or pain.
- **PDM** stands for the *Psychodynamic Diagnostic Manual* and is a diagnostic framework that characterizes individuals in terms of their psychodynamics (forces influencing thoughts and behaviors).
- **Personality disorder** is a long-standing pattern of maladaptive (problematic) behavior, thoughts, and emotions that deviates from the accepted norms of an individual's culture.

Description and Diagnosis

Masochistic personality disorder (MPD) is a personality disorder characterized by a lifelong pattern of masochism. Individuals with MPD often reject opportunities that are pleasurable. Rather, they choose situations and others that lead to pain or suffering. They also discourage others from helping them out when in need. As a result, they find themselves continually suffering. This disorder is described in the PDM but is not included in the DSM.

Those with this disorder can present as angry or excessively guilty. They may be overly sensitive to rejection, feel inferior to others, and find difficulty in feeling and expressing anger directed at others. Interestingly, it is has been suggested that narcissism (excessive self-admiration) is a central component of this disorder. This seems contradictory to masochism but may actually be its cause. The suffering and lack of gratification experienced by an individual with this disorder may serve as the rationale for feeling superior to others who do not tolerate their level of suffering. It follows that if they believes this, by not suffering, they cannot be superior.

There are two subtypes of this disorder. The moral masochist describes an individual whose self-image is dependent on his or her suffering. In contrast to normal functioning, individuals with this subtype feel better about themselves when they experience suffering. The second subtype is relational masochist. Individuals with this subtype are dependent on the victimization or suffering that takes place in relationship with another. These individuals may be in abusive relationships with romantic partner or family member. They may believe that they are being altruistic by accepting pain and abuse from their partner (PDM Task Force, 2006).

According to the *Psychodynamic Diagnostic Manual*, MPD is diagnosable by the following criteria. An individual with this personality disorder is preoccupied with self-esteem and the suffering or loss of a relationship. The contributing developmental patterns for this diagnosis are currently unknown. Individuals with MPD exhibit feelings of anger, guilt, and sadness. Their basic belief is that if they are clearly suffering, they can gain moral superiority and have an attachment to others. Their view of others is that individuals pay attention only when one is in trouble. These individuals defend themselves by internalizing various aspects of the world (e.g., particularly aspects of people). They may take a part of another individual they admire and incorporate that part into their own ego to become more like them. Furthermore, they often turn against themselves and reflect on something that is right or wrong especially in a self-righteous way (PDM Task Force, 2006).

Treatment

It is not uncommon for those with this disorder to be misdiagnosed and treated for depression (PDM Task Force, 2006). Medications used for depression are not likely to be effective with MPD. Therefore, when a depressed individual seems more resentful rather than self-critical and sad, further investigation often reveals masochistic traits. The quicker this is recognized, a more accurate diagnosis and treatment plan can be made.

Most individuals with this personality disorder don't want to be helped and may resent anyone who encourages them to seek treatment. If an individual is willing to participate in treatment, psychotherapy, group therapy, and family therapy have been shown to be effective for this personality disorder. Cognitive behavior therapy has been shown to be particularly effective for MPD. This therapeutic approach can assist an individual in taking a realistic look at his or her maladaptive (faulty) thoughts and behaviors in order to bring about positive change.

Mass Shootings

Mass shootings are criminal acts of extreme violence in which four or more individuals are murdered by gunshot.

Description

"Mass shootings" are defined as homicides with at least four fatalities. When these horrific events occur, they receive heavy media coverage and commentary from national news anchors, politicians, analysts, and experts from a host of fields. This intense media coverage has led to many misperceptions regarding mass shootings, including the frequency in which they occur, the nature of the perpetrators, what causes people to commit these crimes, and how to prevent them.

One misperception is that mass shootings are on the rise. Research using FBI and state crime statistics indicates that since 1976 the number of mass shootings per year has remained relatively stable. On average, over the past three decades there have been approximately 20 mass shootings a year in the United States. Another misperception is that the number of victims is increasing, but this too has remained relatively stable over the past few decades.

Unlike the public perception that mass shooters are people who suddenly snap, mass murderers are rarely enraged. Survivors of mass shootings describe shooters as being calm. Mass killers spend weeks or months in meticulous planning of where, when, how, and who to kill and then methodically follow their plan remaining focused and controlled.

The most common motive in a mass shooting is revenge. Shooters see themselves as victims and seek to punish those they hold responsible, most often family members or coworkers. The primary target can be a place such as a school or company or an entire category of people such as women, or members of specific religions or races. Random attacks are the rarest type of mass shootings. There is a public perception that violent entertainment, especially video games, is linked to mass shootings, but there is no research that has established causality between game play and violent behavior.

Gun control is perhaps the most frequently proposed prevention strategy. Research indicates that the majority of shooters use semiautomatic handguns that were obtained legally, not assault-style weapons. Although the vast majority of shooters did not have a mental illness on record that would have prevented them from purchasing a firearm, many of the killers in

the most deadly mass shootings in recent years have been found to be mentally ill, including the killer in the Virginia Tech University shootings, the Tucson shootings, the Aurora, Colorado, movie theater shootings, and the shootings in the elementary school in Newtown, Connecticut. No gun control laws currently enacted would have prevented the majority of mass shooting perpetrators from purchasing the firearms used in their murders, something that those who advocate for stricter gun laws have questioned.

Another prevention strategy is to identify the warning signs of potential shooters. Shooters are characteristically Caucasian males, exhibit depressed mood, are socially isolated, are resentful, blame others for their problems, prefer violent entertainment, and enjoy weaponry. Unfortunately, these characteristic warning signs are shared by millions of people who will never become violent.

Impact (Psychological Influence)

Mass shootings have had a deep impact on the American psyche generating profound sorrow, grief, fear, and anxiety. The fact that they have prompted a national discussion about gun control, public safety, school security, and mental health is little solace to the loved ones of victims of these terrible acts of violence, although many of them work hard to engage in national policy about these issues as a result of their losses.

Master Therapist

Master therapists are psychotherapists who are considered by fellow therapists to be "the best of the best" in terms of expertise in psychotherapy.

Definitions

- **Countertransference** is the phenomenon where therapists transfer or redirect feelings and expectations from their own unresolved conflicts to their clients.
- **Expertise** is the special knowledge or skills in a particular subject or area learned from experience or training and a high level of proficiency in utilizing that knowledge or skills.
- **Master** refers to one who practices with a high level of expertise or proficiency.
- **Psychotherapy** is a psychological method for achieving desired changes in thinking, feeling, and behavior. It is also called therapeutic counseling.
- **Transference** is the phenomenon where an individual transfers or redirects feelings and expectations from a particular person in his or her life to others, such as a therapist.

Description

Today, the terms "master" and "expertise" are in vogue. The expectation is that professionals will demonstrate expertise and a high level of proficiency. Typically, those who demonstrate these traits are well compensated and esteemed by others. Such expertise reflects mastery in practice which involves a high level of knowledge and skill sets that can be modeled impressively for others, or used as a basis for supervising the practice of others. A master therapist is one who demonstrates expertise in psychotherapy. Psychotherapeutic expertise is the capacity to know and anticipate what happens moment by moment during a psychotherapy session. Based on that knowledge, it is the skill, precision, and finesse to effect client change in those sessions. It also involves the capacity to guide the development of other therapists.

Developments and Current Status

Over the past three decades, psychologist Thomas M. Skovholt (1944–) and colleagues have conducted several research studies to identify the defining

characteristics of master therapists. These studies have been done in the United States, Canada, Korea, Singapore, and Japan. They have identified the cognitive, emotional, and relational characteristics of master therapists. A major finding is that therapeutic mastery involves considerably more than just accumulating years of experience doing psychotherapy. Rather, mastery involves an ongoing effort in improving skills and competencies, gaining new knowledge, and remaining open to experience and others' feedback. Based on these studies, 11 characteristics represent a composite picture or profile of the master therapist. The research found that most master therapists possess many, if not all, of these characteristics.

The first characteristic is that continuous professional development is a hallmark of these therapists. They are enthusiastic learners, who not only want to fully understand their clients but want to know as much as they can about psychotherapy practice. So, they continually read new literature in the field, are curious about the history of the field, and stay current with the newest developments, techniques, and studies.

Second, these therapists, with an average of nearly 30 years of professional experience, regularly draw on their rich personal and professional experiences in their work with clients. These experiences seem to have increased their depth and competence as persons and psychotherapists. Like others, they have also experienced personal and family problems and professional doubts. Unlike some, these therapists have learned to resolve them. Furthermore, they are not afraid to acknowledge these personal experiences and draw from them to better understand and assist their clients.

Third, master therapists do not simply tolerate complexity and ambiguity; they seek it out. They understand that not everything in the human realm follows linear thinking and logic. Rather, they can understand and appreciate the complexity and ambiguity of subjective emotional experiences. From this deep and broadened understanding, they are able to more effectively help their clients. Cognitive complexity is described in detail later in this chapter.

Fourth, these therapists are emotionally open, self-aware, reflective, and nondefensive, and seek out feedback. This openness includes the capacity to accept any feelings that the client brings up, as well as the capacity to recognize and share their own emotional reactions. They are likely to engage in their own personal therapy, seek supervision, and involve themselves in peer consultation to receive feedback to increase their awareness of themselves and others. They value being in touch with their feelings, deal with them constructively, and communicate them effectively.

Fifth, these therapists are emotionally healthy and mature. They strive to act congruently in their personal and professional lives. They view themselves as honest, authentic, and congruent. Like others, they experience emotional distress and subjective discomfort but are able to process their problems and are able to nurture their own emotional and spiritual well-being. They can continue to meet the emotional needs of others without burnout because they have learned how to care for themselves and meet their own needs. As a result, they are excellent at modeling emotional well-being.

Sixth, these therapists are keenly aware of how their own emotional well-being affects others, particularly in the context of psychotherapy. They are able to recognize and use transference and countertransference reactions as a normal process in therapy. They deal with their own countertransference issues by working through them in their own psychotherapy or by seeking consultation with senior colleagues. They are also very aware of personal and professional boundaries and are careful to avoid boundary violations and unnecessary boundary crossings.

Seventh, master therapists have developed the requisite relational skills of listening, responding, negotiating, and caring for others, often from an early age in their family of origin. These already learned relational skills are then honed and extended over the course of their formal therapy training. Besides using these highly developed skills with clients, these skills are valuable in communicating with family members, colleagues, administrators, and others.

Eighth, these therapists hold positive beliefs about human nature that help in building strong therapeutic relationships. They firmly believe in the value of developing and maintaining a strong therapeutic relationship. They also believe in their clients' capacity to heal and change, and in their clients' right to self-determination. It appears that these beliefs somehow instill hope and activate clients' internal resources and sense of self-efficacy.

Ninth, these therapists have the capacity to engage clients fully in the treatment process. Besides providing support and encouragement, they can therapeutically challenge clients when necessary. They are able to carefully and effectively address difficult and painful issues of their clients. Because of their finely honed therapeutic skills and the strength of their character and a personal power, they can face highly sensitive and troublesome issues with relative ease.

Tenth, master therapists were found to implicitly trust that their clients have sufficient internal resources to make positive change. This finding reflects their positive view of human nature and is related to themes that emphasize the importance of relationships, deep acceptance of self, and their intense desire to learn and grow.

Eleventh, these therapists have sufficient knowledge about the cultural background and possess the requisite cultural competencies to assist clients in effecting change in their lives. They use their cultural knowledge and awareness, conceptual framework, understanding of cultural barriers, and culturally sensitive interventions—or referral for such interventions—to provide services to culturally diverse populations.

Mathematics Disorder

Mathematics disorder (MD) is a condition that hinders people from learning age-appropriate mathematical reasoning and calculations.

Definitions

- **Mathematics** is the study of numbers, equations, functions, and geometric shapes and their relationships, as in arithmetic, algebra, geometry, and calculus.

Description

Mathematics disorder, also called dyscalculia, affects a person's ability to learn and apply math. It is included in the category of Specific Learning Disabilities and specified for problems in math. Like most learning disorders, MD is not related to a person's intelligence, as measured by an intelligence quotient. People who have MD may have difficulty in several specific areas. The first is language based since they may find it hard to name and use mathematical terms and concepts. They may struggle with turning word math problems into math problems using numbers and symbols. Second, their ability to recognize mathematical symbols and signs may be limited. A third area of difficulty may be in attention to detail where they find it almost impossible to copy numbers or symbols accurately. In addition, they may not remember to carry over the number when calculating. Finally, they can have great difficulty with mathematical operations, including counting, multiplying, and dividing.

As with other learning disorders, the cause of mathematics disorder is probably genetic but presently the specifics are unknown. In some cases when brain trauma has occurred, MD can be present. Symptoms of the disorder are general difficulty with basic math operations and problems.

There are common issues that surface in the struggle to understand concepts that describe other concepts, for example, the concept of measurement, like the understanding of half, or a relationship, like the meaning of between or instead. The result of a student's confusion will be an inability to tell which parts or details of a mathematical problem are important. Many people with MD also present with symptoms of anxiety and agitation as it pertains to school or academic tasks that they find frustrating. Behavior problems commonly co-occur with learning disorders and MD is no exception.

Diagnosis

Mathematics disorder can be hard to distinguish from associated learning impairments. It is estimated that only about 1% of students warrant a diagnosis of MD. Many more may show evidence of struggling with one or more of the characteristics of MD. The prevalence of MD among children who also have been diagnosed with ADHD is estimated at 18%. MD can be identified through the results of standardized testing, which show that the people tested score substantially below what is expected for their intelligence, age, and level of education.

Treatment

Although the symptoms of learning disorders can change over time, there is no cure for mathematics disorder. Treatments that can help people struggling with MD include special education, tutoring, technology training, and individual therapy. Aside from the educational interventions already mentioned, therapy can be helpful to address the mental health symptoms that may also be present.

Patience and creativity is required to help children deal with the challenges of MD. It is best to consult a specialist in learning disorders for a thorough analysis of the issues involved before developing a treatment plan. In conjunction with math teachers, a program that is tailored to help the child begin to master mathematical concepts, skills, and symbols is important.

Some approaches that have been found useful involve repetition and mnemonic devices to make it easier to memorize formulas. The use of visual approaches such as drawing pictures to illustrate problems has been helpful. Applying mathematical concepts to other subjects they have already learned is also effective. It is also useful to see if there are community or educational services or programs that might benefit children who have MD.

May, Rollo (1909–1994)

American psychologist Rollo May is best known for his work in humanistic psychology and promoting existential thought.

Description

Popular American psychologist Rollo Reece May was born on April 21, 1909, in Ada, Ohio, the first son of six children. May experienced a difficult childhood: his parents divorced and his sister, who suffered from schizophrenia, was involuntarily committed after a psychotic breakdown. These early experiences are believed to have influenced May's later interest in psychology. His postsecondary education began at Michigan State University though he was soon expelled for his involvement in a radical student magazine. He then transferred to Oberlin College where he earned his bachelor's degree in English. May later traveled to Greece and spent three years teaching English at Anatolia College. During his travels he became associated with Alfred Adler, who influenced much of his later work. On his return to the United States he earned a bachelor's degree in divinity at Union Theological Seminary in New York in 1938, serving as a minister for only a short time before deciding to pursue a doctoral degree in clinical psychology at Columbia College. While at Union he became friends with philosopher and theologian Paul Tillich, who also had a profound impact on his life and work. In 1942, May was diagnosed with tuberculosis and sent to a sanatorium. Though near death, he spent this time reading, studying, and developing his own philosophical and psychological theory, based on existential and humanistic principles. He recovered and studied and taught at both the William Alanson White Institute and the New School for Social Research in New York City before moving to Tiburon, California, where he spent the remainder of his life with his wife Georgia. Rollo

May died on October 22, 1994, from congestive heart failure.

Impact (Psychological Influence)

Rollo May, along with colleagues Ernest Angel and Henri Ellenberger, developed and introduced existential psychology to the United States with the release of their 1958 book *Existence*. Influenced by the writings and work of Kierkegaard, Abraham Maslow, Alfred Adler, Viktor Frankl, Otto Rank, and Erich Fromm, May's theory emphasized free will, conscious thought, and authenticity as protective forces against human ailments, including anxiety, self-doubt, and loneliness. Rollo May helped to create the concept of existential psychology, which teaches that all people consciously create their own set of beliefs, values, and behaviors, by which they attribute meaning to their life. May authored several well-known books, including *The Meaning of Anxiety* (1950), *Man's Search for Himself* (1953), *The Courage to Create* (1975), and his most popular *Love and Will* (1969). He also founded Saybrook Graduate School and Research Center in San Francisco, California.

McGoldrick, Monica (1943–)

Monica McGoldrick is a key figure in the research that has studied multigenerational and multicultural families. She is the cofounder and director of the Multicultural Family Institute and has published numerous books on genograms and family development.

Description

Monica McGoldrick, MSW, was born in Brooklyn, New York, and raised in Pennsylvania. McGoldrick originally studied Russian studies and found herself unsure what to do after deciding she didn't want to become a professor. She has frequently spoken of how the day she finished her program she met a man at a coffee shop who happened to be studying psychology and thought that it could be a great field for her. Before returning to school to study she began work at a hospital in an inpatient unit to determine if the field was right for her. This provided the beginning of her realization for her passion for working with families as well as a desire to better understand how families function.

In the early 1970s, McGoldrick was introduced to the work of Murray Bowen who was the pioneer behind what is now known as mainstream family therapy. Bowen's approach was to look at family development over generations and not just immediate family. McGoldrick found his work to be very interesting and influential to her. McGoldrick used his model of family maps to continue the growth and development of genograms as they are currently used by clinicians today. Genograms provide a graphic that tracks usually three or four generations of family members, history, and relationships. McGoldrick emphasizes the importance of exploring several generations of a family as well as the impact of ethnicity and gender. McGoldrick feels that these factors are key in determining and understanding behavior.

Impact (Psychological Influence)

McGoldrick was given an honorary doctorate from Smith College for her extensive contribution to the field of family therapy. She is best known for her contributions to genograms and exploring gender and ethnicity impacts in family dynamics. McGoldrick is considered to be one of the most notable and reliable sources for attending to multicultural and gender issues in family therapy. She has published several books and is highly respected in the field of counseling and family therapy. McGoldrick is currently the director of the Multicultural Family Institute.

Mean Girls (Movie)

Description

The American teen comedy film *Mean Girls* was released on April 30, 2004, and was an overnight hit ranking number one and grossing over $24 million in its opening weekend. Worldwide it has raked in over $129 million. The movie was based on the nonfiction book *Queen Bees and Wannabees* by Rosalind Wiseman, which reveals how female social cliques operate in high school. Lindsay Lohan stars in the film along with Rachel McAdams, Amanda Seyfried, Lacey Chabert, and Lizzy Caplan. The screenplay was written by Tina Fey, who also stars in the film, and produced by *Saturday Night Live* (*SNL*) creator Lorne Michaels. Several other *SNL* cast members appear in the movie, including Tim Meadows, Ana Gasteyer, and Amy Poehler. *Mean Girls* was directed by Mark Waters, who also collaborated with Lohan on the movie *Freaky Friday* in 2003.

Homeschooled, 16-year-old Cady (Lindsay Lohan) has just returned to the United States after spending 12 years in Africa with her zoologist parents (Ana Gasteyer and Neil Flynn). She begins her first day at public high school feeling intimidated, alone, and unsure of her place. Two students soon befriend her, Janis (Lizzy Caplan) and Damien (Daniel Franzese), and teach her all about the school's cliques, including the top-reigning "Plastics," a trio of popular, pretty, yet exclusive, sophomore girls, led by Queen Bee, Regina George (Rachel McAdams). Janis, in particular, hates the Plastics because they previously spread vicious rumors about questioning her sexuality. She hatches a plan for revenge using Cady to infiltrate the group and take them down from the inside.

The Plastics soon befriend Cady, inviting her to join their lunch table and to go shopping with them. Regina also reveals a secret "Burn Book" that she created containing pictures and gossip about fellow students and even teachers. Slowly, with some coaxing from Janis and Damien, Cady begins to ruin Regina's world. She convinces the other Plastics turn against Regina, destroys her beauty by tricking her into eating Kälteen bars that actually cause her to gain weight, and

Mean Girls was based on the nonfiction book *Queen Bees and Wannabees* by Rosalind Wiseman, which reveals how female social cliques operate in high school. (Paramount Pictures/Photofest)

even falls in love with Regina's ex-boyfriend, Aaron. Cady slowly becomes immersed in the Plastics' world, changing not only her looks but her personality. Janis and Damien learn that their plan has backfired when they see Cady become a Plastic for real. Regina finally figures out that Cady has been plotting and vows to ruin her by telling Principal Duval that Cady is responsible for the "Burn Book." The entire class of girls is now enraged and fights are breaking out right and left as the secrets in the book get revealed. Principal Duval calls a mandatory meeting where all the girls are required to share their feelings and apologize for any wrongs they have caused one another. Cady learns the errors of her ways, especially the values of being true to yourself, your real friends, and taking responsibility for your own actions. In the end of the movie, Cady joins the Mathletes after apologizing to the Math teacher, Ms. Norbury (Tina Fey), for the lies she wrote about her in the Burn Book. She is also elected Spring Fling Queen, makes up with Janis and Damien, reunites with Aaron, and calls a truce with the Plastics. The clique is now disbanded, with each going separate ways and the "Girl World" at school finally being declared drama free.

Impact (Psychological Influence)

The movie *Mean Girls* is considered a teen pop culture megahit. Though Lindsay Lohan had already made a name for herself by its debut, it is still her most successful film at number one and her most memorable role to date. *Mean Girls* also received positive reviews from critics. Rotten Tomatoes rated it 83% ("Certified Fresh") based on 167 reviews. In 2006, it was named the 12th best high school movie of all time by *Entertainment Weekly*. Even though *Mean Girls* is a comedy, it brings to light the reality and cruelties of girl-on-girl bullying during adolescence.

Media Violence

"Media violence" refers to the impact of violent content in television, film, video games, music, and music videos.

Description

Exposure to depictions of violence in movies, television, video games, music, and music videos has long been recognized as unhealthy for minors as evidenced

"Media violence" refers to the impact of violent content in television, film, video games, music, and music videos on individuals (usually children and adolescents). There is considerable debate about whether violent actions such as school shootings can be attributed to the large amount of violence in the media today. (Alamy)

by restricted access and restricted labeling of these products. A large number of research studies have documented that minors spend a considerable amount of time engaged in media entertainment. Research into media violence has generally focused on its impact on aggression, but effects can be difficult to interpret. Some researchers contend there is clear evidence of harm, while others insist that the effects are minimal at best.

Impact (Psychological Influence)

Research investigating television violence indicates that depictions of violence are frequent and pervasive. There are 20 to 25 violent acts per hour of programing and over 60% of programming contains violence. In over 70% of the violent scenes, there was neither criticism of, nor remorse over, violent behavior. Numerous research studies, including meta-analytic studies, investigating the effects of television violence have found a significant, meaning not random, association between amount of time spent watching television and aggressive behaviors. The effect size, a measure of the magnitude of the effect, of these studies have been overall small to medium. There is similar research investigating the impact of movie violence. What impacts the ability to instantly view movies on just about any electronic platform, including smartphones, is not clear and warrants further investigation.

Video game and music violence have both been highly investigated. Certain genres of music and music videos also been linked to acceptance of violence against women and with rebelliousness, drug use, aggression, and antisocial behaviors. Video games have come under intense scrutiny and have been associated with aggressive behaviors, decreased empathy, and a decrease in helpful behaviors.

In spite of the consistent findings linking media violence to aggression, some researchers have criticized the conclusions as having no causal effect or influence on any real-life behaviors. Researchers who are skeptical of the findings contend that small effect sizes indicate that the true magnitude of the influence is minimal at best. Research skeptics also make note that the interconnected findings across media types should have a cumulative negative impact on society, yet crime, according to FBI statistics, has been steadily decreasing. Research skeptics also argue that background factors such as family and interpersonal dynamics have not been controlled for and may play a part in the actual findings.

Media is a powerful form of entertainment and communication that impacts people on an individual level. Media violence will continue to be the focus of intense research.

Medically Unexplained Symptoms

Medically unexplained symptoms are those for which the cause has not been identified. They are also referred to as medically unexplained physical symptoms.

Definitions

- **Anxiety disorders** are a group of mental disorders characterized by anxiety as a central or core symptom. The group includes agoraphobia, specific phobias, and social anxiety disorder.
- **Chronic pain disorder** is a poorly understood medical conditions characterized by the experience of local pain of an unknown cause.
- **Depressive disorders** are a group of mental disorders characterized by a sad or irritable

mood and other changes that significantly disrupt the individual's daily functioning. These include major depressive disorder and persistent depressive disorder.

- **Fibromyalgia** is a medical condition characterized by widespread, unexplained pain as well as sensitivity to pressure or touch in specific areas of the body.
- **Psychotherapy** is a psychological method for achieving desired changes in thinking, feeling, and behavior. It is also called therapy and therapeutic counseling.
- **Somatic symptoms and related disorders** are a group of DSM-5 mental disorders characterized by prominent somatic (physical) symptoms and significant distress and impairment. They include somatic symptom disorder and factitious disorder. Previously it was known as somatoform disorders.

Description

"Medically unexplained symptom(s)" is a medical term for a broad category of abnormal physical symptoms for which the cause has not been identified. This does not mean that the symptoms do not have a cause but rather that there is no scientific consensus as to the cause. Typically, such symptoms involve unexplained pain or sensations. Common examples of medically unexplained symptoms are chronic pain disorder and fibromyalgia. Such unexplained symptoms may be present in the various DSM-5 somatic symptoms and related disorders. Also, such symptoms may co-occur (occur simultaneously) with mental disorders such as the depressive disorders and the anxiety disorders.

Even though a specific diagnosis is not made, medically unexplained symptoms can be and are treated. Treatment varies widely and is usually influenced by a known co-occurring medical or mental condition. Psychotherapy is frequently utilized, even if no additional mental disorders are present. Such therapy typically focuses on helping individuals to cope with their symptoms.

Medication-Induced Movement Disorders

Medication-induced movement disorders are medical conditions that occur as the result of treatment with antipsychotic medications.

Definitions

- **Amphetamines** are a potent central nervous system stimulant of the phenethylamine class that is used primarily in the treatment of attention-deficit hyperactivity disorder and narcolepsy.
- **Antidepressants** are medications that are used primarily to treat depression and depressive disorders. They are also referred to as antidepressant medications.
- **Antipsychotic medications** are prescription drugs used to treat psychotic disorders. They are commonly referred to as neuroleptics.
- **Clozaril** is a second-generation antipsychotic medication used in treating schizophrenia and bipolar disorder, as well as other medical conditions and disorders.

- **DSM-5** stands for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, which is a diagnostic system used by professionals to identify mental disorders with specific diagnostic criteria.
- **Haldol** is a first-generation antipsychotic medication used in treating schizophrenia, short-term psychosis, mania, and delirium, as well as other medical conditions and disorders.
- **Hypothyroidism** is a condition in which an individual's thyroid gland does not produce enough hormones and can cause a number of medical problems, such as obesity, joint pain, and heart disease.
- **Malignant catatonia** is an acute onset of fever, instability, excitement, and delirium caused by a neurogenic motor immobility and behavioral abnormality due to the lack of critical cognitive function and level of consciousness.
- **Movement disorders** are a group of medical conditions affecting the ability to produce and control movement. They include degenerative, hereditary, and medication-induced conditions.
- **Neuroleptic malignant syndrome** is a condition that affects movement and difficulty regulating body heat in individuals who have been treated with antipsychotic medications.
- **Neuroleptics** are antipsychotic medications that block dopamine receptors.
- **Parkinson's disease** is a disease of the nervous system that causes tremor, rigidity, slowness of movement, and unstable posture.
- **Risperdal** is a second-generation antipsychotic medication used to treat schizophrenia, schizoaffective disorder, and bipolar disorder, as well as other medical conditions and disorders.
- **Thorazine** is a first-generation antipsychotic medication used to treat schizophrenia and manic depression, as well as other medical conditions and disorders.

Description and Diagnosis

Medication-induced movement disorders are movement disorders that result from treatment with antipsychotic (neuroleptic) medications. They are not mental disorders but are included in Section II of the DSM-5 because of their importance in medication management of mental disorders or other medical conditions. Since they are not considered mental disorders, they have no diagnostic criteria nor diagnostic codes. Newer antipsychotic medications (e.g., Risperdal and Clozaril) have been found to be less likely to cause some medication-induced movement disorders. However, these disorders do still occur. First-generation antipsychotic medications (e.g., Haldol and Thorazine) are more likely to cause medication-induced movement disorders.

There are several separate classifications of the conditions and problems that fall under medication-induced movement disorders. They include neuroleptic-induced parkinsonism and other medication-induced parkinsonism, neuroleptic malignant syndrome, medication-induced acute dystonia, medication-induced acute akathisia, tardive dyskinesia, tardive dystonia and tardive akathisia, and medication-induced postural tremor. Neuroleptic malignant syndrome and tardive dyskinesia are more fully described in their own entries in this encyclopedia.

Neuroleptic-Induced Parkinsonism and Other Medication-Induced Parkinsonism

Both are conditions that include symptoms such as bodily shaking, muscle inflexibility, and difficulty initiating movement or complete loss of movement. These symptoms usually occur within a few weeks of starting a neuroleptic medication or after increasing the dosage of a neuroleptic medication. Symptoms can also appear after reducing the amount of a neuroleptic medication.

Neuroleptic malignant syndrome. Neuroleptic malignant syndrome (NMS) is a serious condition that can occur at any time during the course of neuroleptic treatment. NMS is easily recognized in its full-blown form and is often different in its onset, presentation, progression, and outcome. One recognizable symptom

of NMS is an individual who experiences abnormally low body temperature on at least two occasions that are accompanied by excessive sweating. This particular feature of NMS sets it apart from other side effects found in other conditions with the use of neuroleptic medications. Some other symptoms of NMS include shaking in the body; fever; loss or impairment of voluntary activity; uncontrollable and repetitive twisting movements; sudden twitching of a muscle or group of muscles; weak or non-movement of the muscles of the face, mouth, and respiratory system; and difficulty swallowing.

Medication-induced acute dystonia. Medication-induced acute dystonia is a condition associated primarily with abnormal bodily positions and muscular spasms. The symptoms usually include abnormal positioning of the neck and head in relation to the body, jaw muscle spasms, and having difficulty swallowing, breathing, or speaking. Individuals with this condition often have slurred speech because of the slow movement of their tongue. Some other symptoms individuals may experience are abnormal or prolonged contractions in the muscles in the eyes and abnormal positioning of their limbs (arms and legs) and trunk (middle section of their body). Symptoms usually occur in individuals within a couple of days of starting or increasing the dosage of a neuroleptic medication. These symptoms may also occur after reducing the amount of the neuroleptic medication.

Medication-induced acute akathisia. Medication-induced acute akathisia is a condition that is due to the use of neuroleptic medications. This condition is not due to excessive worry, substance withdrawal, or unbalanced agitation. Symptoms are characterized by restlessness and the need to be in constant motion. For example, an individual may have fidgety movements of the legs and have an inability to sit still. These symptoms usually occur within the first four weeks of beginning or increasing the dosage of a neuroleptic medication. These symptoms may also occur after reducing the amount of the neuroleptic medication.

Tardive dyskinesia. Tardive dyskinesia is a condition that includes involuntary movements usually in the tongue, lower jaw and face, and arms and legs. These symptoms must be present for at least four weeks. A jerky and rapid, continual and slow, or repeated movements are symptoms present in this condition. Symptoms of this condition usually occur within three months of beginning a neuroleptic medication. Tardive dyskinesia cannot be due to other medical conditions (e.g., Huntington's disease and hypothyroidism).

Tardive dystonia and tardive akathisia. Tardive dystonia and tardive akathisia are conditions involving other types of movement difficulties, such as dystonia and akathisia. Dystonia is a state of abnormal muscle tone, which results in muscular spasms and abnormal bodily positioning. Akathisia is a state of distress, agitation, and restlessness. Tardive dystonia and tardive akathisia are characteristic of their late emergence in the course of treatment. These symptoms may last for months to years, even when the use of neuroleptic medications is discontinued, or the dosage of the medication is reduced.

Medication-induced postural tremor. Medication-induced postural tremor is characterized by a fine tremor (bodily shaking) that occurs during attempts to maintain normal bodily positioning in association with the use of a medication (e.g., antidepressants). This tremor is very similar to tremors seen with anxiety, caffeine, and amphetamine use.

Treatment

Treatment for neuroleptic-induced parkinsonism, other medication-induced parkinsonism, NMS, and medication-induced postural tremor is a change in medication. This may include the reduction of or complete discontinuation of a neuroleptic medication. The average recovery time for individuals who discontinue antipsychotic medications is between 7 and 10 days. There are no effective treatments for tardive dyskinesia, tardive dystonia, or tardive akathisia once the symptoms develop.

Meditation

Meditation is the concentrated focus on a sound, the breath, object, or attention itself to increase awareness of the present moment. Its purpose is to reduce stress, promote relaxation, or increase cognitive capacities and spiritual growth.

Definitions

- **Concentration** is the one-pointed awareness or undivided attention of one's consciousness upon a particular point of focus.
- **Consciousness** is the capability for awareness of one's own existence.
- **Mindfulness** is the moment-by-moment awareness of one's thoughts, feelings, sensations, and environment without evaluating or judging them.
- **Practice** is a method or process used to accomplish a goal or objective.
- **Religion** is search for significance through the organized and collective dogma or doctrine that defines the sacred.
- **Spirit** does not have an agreed-upon definition. One way to define spirit is that which is omnipresent, infinite, all-pervading, and all-encompassing.
- **Spirituality** is the personal effort to think, feel, and act in order to find, conserve, or transform the sacred in one's life.
- **Transcendental meditation** is a form of external awareness meditation that takes one's awareness beyond the conventional boundaries of a body-bound self and unites the self with spirit.

Description

Meditation is a spiritual practice that has been described and practiced in various ways. From a mental health prospective, there are two basic forms of meditation. These two forms of meditation are referred to as concentrative meditation and external awareness meditation. The specific techniques or meditative practices associated with these two forms of meditation are infinitely varied. In concentrative meditation attention is focused upon any aspect of reality or imagination. The meditation experience consists of maintaining the concentration and is useful in countering the mind's tendency to wander. As concentration wanes, the goal is to refocus one's efforts to concentrate. Meditation of this kind becomes a sequence of focusing and refocusing one's attention on a preselected object or mental construction. A beginning practitioner of concentrative meditations typically experiences a restless mind. The restless mind is filled with apparently random and uncontrollable mental constructions. This wayward mental experience of novice practitioners is called "monkey-mind" in the Buddhist traditions. It takes will and discipline to train the mind to stay focused. The ability to concentrate develops over time with the deliberate practices associated with concentrative meditation. Concentrative meditation is also known as "object-based" practices. In concentrative meditation there is a distinct experience of duality and separateness between the self that is meditating and the object that one is concentrating upon.

In the second form of meditative practices, external awareness meditation, attention is focused outside of one's self. External awareness meditation is similar to concentrative meditation in that attention is focused on any aspect of reality or imagination. It emphasizes the relationship between the meditator and that which is meditated upon. External awareness meditation focuses on "opening up" one's awareness. The ultimate goal of external awareness meditation is to become totally open to and absorbed in the relationship

between self and other. In this meditative relationship the boundary between self and other is indistinguishable. The self-object duality dissolves into an experience of radical unity.

While different in focus, there is some overlap between these two forms of meditation. In fact, concentrative meditation and external awareness meditation can be viewed on a continuum. The continuum begins with concentrative meditation and self-object duality, and the continuum extends to external awareness meditation and a sense of unification and non-dual self-sacred integration.

Examples of these two forms of meditation are Christianity's Contemplative Prayer, Hinduism's Advaita (Vedanta) meditations, and Zen Buddhism's Dzogchen (Ch'an). These practices are unique because they are object-based concentrative practices to the novice practitioner. Contemplative Prayer, Advaita, and Dzogchen at their rudimentary stages are contemplative or concentrative practices. Through deliberate and steadfast effort, these meditations become objectless external awareness meditations to the advanced practitioner. They are also Transcendental Meditations (TM) at advanced levels of practice. In TM practices, the self and other is not-two or non-dual. "Non-dual" simply means united or yoked sufficiently that the experience of self and other is unintelligible. Contemplative Prayer, Advaita, and Dzogchen are three metaphorical bridges between concentrative meditation and external awareness meditation. Meditation is the practice of eliciting a type of consciousness. Beginning meditators can expect to experience stress reduction and increased relaxation. However, the type of consciousness that meditation ultimately develops is a consciousness united with spirit.

Development and Current Status

Meditative practices outdate recorded history. Meditation was as much a part of prehistory as it is a part of current times. The etiology of meditative practices was passed along through lore until the written word was developed. Various philosophies and religious practices began documenting meditative practices in writing approximately 5,000 years ago. Such writings were first discovered in Egypt, India, China, and Mesoamerica (Mexico and Chile). The earliest forms of written meditation are mantras or rhythmic chants. The oldest forms of modern meditation have their roots in the Hindu traditions of Vedanta. "Vedanta" refers to the scriptural writings of the Vedas. The Vedas are writings devoted to the lore of ancient India. These writings clearly influenced the development of Buddhism in China and Zen Buddhism in Japan. There are theories that claim these same philosophies traveled west as well and influenced the development of Islam and Christianity. In any case, these Eastern "psychologies" have emphasized the cultivation of attention to one's own subjective experience prior to the formal establishment of modern mental health practices. However, meditation is a major aspect of almost all religions and spiritual practices. In other words, meditation is an aspect of human experience and does not belong to any particular ideology. Nevertheless, many of the most popular and effective meditative practices available today originate in the Yogic, Buddhist, and Christian traditions. Students and scholars interested in these meditative traditions might begin with the writings of Adi Shankara (788–820), the Diamond Sutra preserved by Aurel Stein (1862–1943), and the Trappist monk Thomas Keating (1923–), respectively. It is important to note that many forms of meditation are in fact mindfulness practices. These traditions teach that it is most difficult to stay mindful when one is attached to biases, longing for desire, or intensely angry. Many Eastern traditions agree that factors of calmness, tranquility, and balance assist the maintenance of a mindful awareness. Meditation and mindfulness are closely related to loving kindness and compassion.

Meichenbaum, Donald (1940–)

Clinical psychologist Donald Meichenbaum is best known for his contributions to cognitive behavior therapy, specifically for developing the cognitive behavioral modification technique that uses self-instruction to identify and correct negative behavior.

Description

Donald H. Meichenbaum was born in the summer of 1940 in New York City. He grew up in a loving family and attended public schools. In 1962, he graduated with his bachelor's degree from City College and went on to pursue a doctoral degree in clinical psychology at the University of Illinois in Champaign. A self-proclaimed "people watcher," Meichenbaum was always interested in observing human behavior. Though he was initially hired as an industrial psychologist to conduct group observations at a veteran's hospital, he soon decided his true passion was for clinical practice. Drawn to the opportunity to work with renowned psychologist Richard Walters, he accepted a position at University of Waterloo in Ontario, Canada, in 1966. It was during his time at Waterloo that he formalized his approach to cognitive behavior therapy (CBT), one that is considered less direct than Albert Ellis's rational emotive behavior therapy approach. CBT is an alternative approach to traditional psychodynamic therapy in that it associates thoughts, beliefs, and feelings with behavior; changing behavior requires a shift in negative thought patterns.

Meichenbaum used a process of self-instruction accompanied by role-playing activities to assist clients in changing destructive thoughts that lead to unwanted behavior. He went on to develop the therapeutic technique known as *cognitive-behavior modification* which is composed of three phases: (1) observing one's inner dialogue, self-talk patterns, and behaviors; (2) recognizing when self-talk patterns begin and replacing them with positive statements; and (3) learning new skills and coping behaviors based on these new restructured thought patterns. His work in the area of stress inoculation training is also well noted.

Dr. Meichenbaum taught and practiced at Waterloo until he formally retired in 1998. He now splits his time between Ontario, where he still maintains a private practice, and Miami where he helped found The Melissa Institute for Violence Prevention and Treatment in 1996. He currently sits on the board of directors and serves as the institute's research director.

Impact (Psychological Influence)

Dr. Meichenbaum has earned the honor of distinguished professor emeritus at the University of Waterloo and distinguished visiting professor at the University of Miami's School of Education. A survey in the *American Psychologist* reported him "one of the 10 most influential psychotherapists of the 20th century" (Smith, 1982). In 2008, he received a Lifetime Achievement Award from the Clinical Division of the American Psychological Association. His expertise spans a wide range of topics, including cognitive behavioral approaches, student learning, anger control, violence prevention, trauma, and post-traumatic stress. Meichenbaum has authored several important works, including *Cognitive-Behavior Modification: An Integrative Approach* (1977), *Coping with Stress* (1983), *Pain and Behavioral Medicine: A Cognitive-Behavioral Perspective* (1983), *A Clinical Handbook/Practical Therapist Manual: For Assessing and Treating Adults with Post-Traumatic Stress Disorder* (*PTSD*) (1984), *Nurturing Independent Learners: Helping Students Take Charge of Their Learning* (1998), *Treatment of Individuals with Anger—Control Problems and Aggressive Behaviors: A Clinical Handbook* (2003), and *Roadmap to Resilience: A Guide for Military, Trauma Victims and Their Families* (2012). He also lectures and consults on these topics both nationally and internationally.

Melatonin

Melatonin is a chemical messenger in the brain, which regulates the sleep–wake cycle and promotes restorative sleep.

Definition

- **Insomnia** is a chronic difficulty in falling asleep and staying asleep.

Description

Melatonin is a neurotransmitter (chemical messenger) in the brain. Melatonin is made from serotonin which is also a neurotransmitter. Serotonin and melatonin work together in relaying signals between neurons in the brain. A primary role of serotonin is to enhance mood and provide energy. Melatonin is produced in response to darkness and results in nightly sleep. Its primary role is to regulate healthy sleep cycles. There is a link between low levels of melatonin and mood disorders due to the disruption of sleep. In addition, low levels of serotonin can cause insomnia by preventing melatonin production.

Synthetic melatonin is a nutritional supplement that is used to treat various sleep problems. One of its most common uses is to adjust the body's internal clock. It is used for jet lag, for adjusting sleep–wake cycles in those whose daily work schedule changes (shift-work disorder), and for helping those who are blind to establish a day and night cycle. Melatonin is also used for the insomnia, delayed sleep phase syndrome, insomnia due to certain high blood pressure medications called beta-blockers, and sleep problems in children with autism, cerebral palsy, and mental retardation. It is also used as a sleep aid after discontinuing the use of benzodiazepine drugs and to reduce the side effects of quitting smoking. Some use melatonin for Alzheimer's disease, tinnitus (ringing in the ears), depression, chronic fatigue syndrome, fibromyalgia, migraine and other headaches, irritable bowel syndrome, osteoporosis (bone loss), and epilepsy, and as an antiaging agent, and menopause. Other uses include breast cancer, brain cancer, lung cancer, prostate cancer, head cancer, neck cancer, and gastrointestinal cancer. Melatonin is also used for some of the side effects of cancer treatment (chemotherapy), including weight loss, nerve pain, and weakness. It is also a potent antioxidant.

Precautions and Side Effects

Melatonin should not be used by women who are or want to be pregnant. Melatonin might also interfere with ovulation, which makes it more difficult to become pregnant. Since little is known about the about the safety of using melatonin when breast-feeding, it is best not to use it. Melatonin should not be used in most children. Because of its effects on other hormones, melatonin might interfere with development during adolescence. Because it can raise blood pressure in those taking certain blood pressure–lowering medications, melatonin should not be used. Melatonin can increase blood sugar in those with diabetes. This necessitates monitoring blood sugar carefully in those taking melatonin. Melatonin can also worsen depression and increase the risk of having a seizure. Because it can cause drowsiness, refrain from driving or using machinery for five hours after taking melatonin.

Generally, melatonin has a positive and quick effect on sleep and it has no negative side effects. If there are side effects they tend to be mild. They include headache, short-term feelings of depression, daytime sleepiness, dizziness, stomach cramps, and irritability.

Melatonin interacts with some medications and over-the-counter preparations. Taking melatonin along with sedative medications can cause significant sleepiness. These sedative medications include Klonopin, Ativan, Donnatal, and Ambien. Taking melatonin along with birth control pills can result in very high levels of melatonin in the body. Such birth control pills include estradiol, Triphasil, Ortho-Novum 1/35, and

Ortho-Novum 7/7/7. Caffeine also interacts with melatonin and may decrease the effectiveness of melatonin supplements. In contrast, Luvox can increase melatonin levels and the main effects (sleep) as well as the side effects of melatonin.

Mental Competency Evaluation

Mental competency evaluation is a medical examination to determine an older adult's capacity (ability) to understand and make decisions about his or her health, living arrangement, finances, and so forth. It is different from a mental evaluation of competence to stand trial for criminal charges.

Definitions

- **Alzheimer's disease** is a progressive neurodegenerative disease in which dementia results from the degeneration and death of brain cells because of plaques and neurofibrillary tangles.
- **Capacity** is the ability to respond to a particular situation with appropriate appreciation and to act in one's own self-interest.
- **Competency** (or competence) refers to the determination that an individual retains the capacity for a specific action.
- **Conservatorship** is the legal status in which a "conservator" is appointed by the court to make decisions concerning a "conservatee," the individual judged to be incompetent.
- **Dementia** is a group of symptoms (syndrome) associated with a progressive loss of memory and other intellectual functions that interfere with one's ability to perform the tasks of daily life. It impairs memory and reasoning ability, causes disorientation, and alters personality.
- **Testamentary capacity** is the capacity to make a will. It means an individual must understand what a will is, and know the extent of his or her estate.

Description

"Competency" is a legal term that means that an individual has the soundness of mind and mental capacity to be qualified to act legally for himself or herself. Capacity is the cognitive ability to receive, process, and perform mentally. More specifically, it is the ability to understand one's options, one's actions, and the effects of one's actions. An individual can lack capacity for many reasons. He or she may have a memory impairment as in Alzheimer's disease. He or she may be unable to read or understand language because of a stroke. He or she may demonstrate poor judgment, planning, or initiative because of a frontal lobe disorder. He or she may feel hopeless and worthless because of depression. Or, an individual with otherwise intact mental faculties may have compromised capacity because of a drug or alcohol (intoxication).

Competency is not an "all or nothing" attribute. An individual may be able to but can make medical decisions about himself or herself or make a will but might not be able to balance his or her checkbook. In other words, some individuals are competent in some areas but not in other areas. An individual might be competent one day and lack competence the next day. However, steady mental decline over-results in increasing degree of incompetence.

Mental decline interferes with quality of life and the details of daily living such as shopping, paying bills, eating, and keeping one's assets safe. When mental decline is severe, the courts, through conservatorship,

may appoint someone act on behalf of and protect the affected individual.

Developments and Current Status

At least four factors are assessed in determining competency: first, the ability to verbalize the reasons behind one's decisions consistent with one's goals; second, the ability to understand relevant information; third, the ability to understand one's situation and the consequences of one's decisions; and fourth, the extent to which a recent decision is consistent with one's other decisions and basic values. The basic criteria in a determination of competency is whether an individual understands the alternatives that are available and whether the individual can make a decision based on the facts and appreciate the consequences of his or her decision.

Determining mental competency generally involves a formal mental competency evaluation done by a physician or psychologist. Such an evaluation includes clinical observation, an interview, and neuropsychological testing. The most often used of such tests is the mini-mental state examination (MMSE). The MMSE is a standardized method to assess cognitive mental status and to quantify cognitive ability. It is also useful in monitoring changes in cognitive status over time. It assesses orientation, attention, immediate and short-term recall, language, and the ability to follow simple verbal and written commands. The MMSE provides a total score that places the individual on a scale of cognitive function (from 0 to 30). MMSE scores of 0–17 suggest severe cognitive impairment, 18–23 suggest mild cognitive impairment, and 24–30 suggest no cognitive impairment. It takes approximately 10 minutes to administer this test.

Mental Health and Violence

"Mental health and violence" refers to the prevalence, frequency, and risk factors associated with violence and individuals suffering from mental illness.

Description

Horrific crimes receive extensive news coverage that link these events to people suffering from severe mental illness (SMI). This has led to the public perception that violence and mental illness are highly associated. The relationship between violence and SMI has important implications affecting not only public opinion but also mental health policy and clinical practice. Stigma and discrimination impacting those who suffer from an SMI is also affected by public opinion. The relationship between SMI and violence has been the subject of investigation for many years and has yielded mixed results. Some studies have indicated a clear linkage, while others have not. Weak research methodology, definitions of mental illness, and ineffective threat assessment tools have been cited as reason for lack of clearly identified risk factors leading to violent behavior by those suffering from an SMI.

Current Status and Impact (Psychological Influence)

Researchers Eric Elbogen and Sally Johnson conducted a national representative investigation of the link between violence and SMI using data from the National Epidemiologic Survey on Alcohol and Related Conditions. Almost 40,000 respondents were interviewed and tracked on two separate occasions. The researchers found that the presence of an SMI such as schizophrenia, bipolar disorder, or major depression alone did not predict future violent behavior. People

with a mental illness who were abusing drugs or alcohol were a strong predictor of violent behavior. The findings also supported other research that identified non-substance abuse risk factors predicting violence in the mentally ill. Risk factors include growing up in an abusive home and/or suffering from parental neglect while growing up; having a history of violent behavior or juvenile detention; suffering from poverty or homelessness; and suffering from stressful life events such as divorce. The strongest predictor of violence is the combination of an SMI, drug abuse, and history of childhood abuse. SMI alone is not a predictor of future violence. Other research indicates that it is far more likely that people suffering from an SMI will be victims of violence not the perpetrators of it.

The relationship between SMI, violence, and public opinion has an impact on mental health policy and funding guidelines in the treatment of mental health disorders. It also has the potential to affect criminal justice policies such as mandatory treatment and mental health court sentencing guidelines in order to protect public safety. Early identification and treatment of substance use disorders would have the greatest impact on violence prevention.

Mental Health Counselor

Mental health counselors (MHCs), also referred to as licensed mental health counselors, licensed professional counselors, and licensed clinical professional counselors, are behavioral health professionals who provide psychotherapeutic services to individuals, couples, and families.

Definitions

- **Behavioral health** is an inclusive term referring to both mental health and substance use disorders.
- **Internships** are extensive educational field experiences in which professional knowledge and skills are utilized in a training setting. Interns are closely supervised as they work directly with client populations.
- **Postgraduate training** refers to training that is acquired after one has earned a graduate degree.
- **Practicum** is a limited part-time field experience in which students are exposed to the "real world" of the profession through direct observation and assisting professionals working in the field. There is limited contact with, and responsibility for, clients.

Description

Mental health counselors are behavioral health professionals who are licensed to diagnose and treat mental health and emotional disorders. MHCs are trained to work with individuals, groups, families, and couples in treating mental, emotional, and behavioral problems and disorders. MHCs work in private practice, mental health centers, substance abuse centers, nursing homes, and other mental health–related service providers. The Bureau of Labor Statistics (BLS) estimates that the 2013 national average salary for MHCs range from $25,840 (10th percentile) to above $67,020 (90th percentile), with an estimated national average of $43,700. The BLS projects that employment of MHCs will grow 29% from 2012 to 2022.

Mental health counseling is a distinct profession with national standards for education, training, and clinical practice. All 50 states have regulatory requirements in order to practice as an MHC. Licensure requirements vary by state, but all MHCs are held to

strict standards and require a minimum of a master's degree in counseling. Licensure standards for MHCs are the equivalent to clinical social workers, and marriage and family therapists, the other master's level behavioral health providers. Graduate counseling education programs require up to 60 semester hours of coursework and take a minimum of two years to complete. Coursework includes techniques and theories in counseling; couples/marital counseling; family counseling; human development; diagnoses, appraisal, and assessment; substance use theory; treatment planning; psychopathology; ethical and legal standards; and clinical skills instruction. State practicum and internship experiences are required in graduate programs that must meet rigorous supervisory and clinical training requirements.

All states license or regulate MHCs, but the regulations vary from state to state. All states require a graduate degree that meet the state's requirements and a passing score on a national licensing exam. All states require postgraduate clinical training with ongoing clinical supervision provided by a clinical professional with two or more years of licensed practice, depending on the state. Supervised postgraduate clinical training require as much as 3,000 hours of supervised clinical experience over a period of no less than two years. A specific percentage of those hours must be in face-to-face counseling, supervision, and case management. All states inquire as to the professional fitness and character of applicants and routinely ask about legal, medical, and behavioral health issues that may impair practice.

The American Counseling Association (ACA) is the largest professional association of counselors. The ACA was founded in 1952 and represents over 55,000 members with 20 separate specialty divisions such as the Association for Multicultural Counseling and Development, the Association for Assessment and Research in Counseling, and the American School Counselors Association. The ACA is very active in advocating and supporting pro-counselor legislation.

The American Mental Health Counselors Association (AMHCA) represents over 7,000 members and works to set standards of education, training, licensing, practice, advocacy, and ethics. The AMHCA created the first educational and training standards for MHCs. The Council for Accreditation of Counseling and Related Educational Programs adopted and adapted the AMHCA standards and established the first accreditation standards for graduate mental health counseling programs.

Mental health counselors are highly trained professionals who provide behavioral health services in a wide range of settings. MHCs work with individuals, couples, and families and are a vital component of the health-care system.

Mental Health Courts

Mental health courts (MHCs) are specialized courts in which nonviolent offenders who suffer from mental health disorders are mandated for community-based mental health treatment instead of given jail or prison sentences.

Definitions

- **Convicted** means to have been found guilty of a crime.
- **Criminal Justice System** is the set of government agencies, systems, and processes established to control crime and impose penalties on those who violate the law.

- **Defense attorneys** are lawyers who provide legal defense for individuals who are being prosecuted for a crime.
- **District attorneys** are government officials who represent the state or federal government in the prosecution of alleged criminals; they hold the highest office in a jurisdiction's legal department.
- **Incarceration** means to be put in jail or prison.
- **Jurisdiction** refers to the authority to administer justice over a specific area of the law in a specified location or territory.
- **Misdemeanors** are lesser crimes punishable by fine or county jail sentences of less than one year and include crimes such as petty theft, drunk driving without injury to others, various traffic violations, and other non-felony acts.
- **Prosecution** is the act of holding a trail against a person accused of criminal behavior.
- **Recidivism** refers to individuals who relapse back into criminal behavior after having served jail time or some other form of criminal penalty.

Description

Large numbers of offenders in the criminal justice system have underlying serious mental health conditions. Almost 15% of men and 31% of women entering jails have a serious mental health illness. Individuals with mental illnesses, many with co-occurring substance use disorders, cycle repeatedly through courtrooms, jails, and prisons which are not equipped to address their mental health needs, provide treatment, or intervene in the criminal cycle influenced by the mental illness. In addition to the impact on individuals, the influx of large numbers of people with mental illness into the court systems has had a significant impact on court function, use of resources, time, and court staff. Policy makers and behavioral health professionals have sought ways to improve outcomes for offenders suffering from mental illness and break the justice cycle (arrest, conviction, jail, release, rearrests, reconviction, back to jail again). Recognizing that the current system did not address the serious unmet mental health needs that were driving this costly and ineffective cycle, MHCs were created. The Bureau of Justice Assistance (BJA) and the Substance Abuse and Mental Health Services Administration administer the MHC program. More than 150 MHCs exist and more are being planned.

Mental health courts attempt to decriminalize individuals with serious mental health conditions by mandating and supervising community-based mental health services in lieu of jail time or prison sentences. The goals of MHCs are to decrease the frequency of contact with the criminal justice system; provide resources to improve social functioning; provide links to employment, housing, treatment, and support services; improve public safety by reducing criminal recidivism; improve the quality of life for individuals with mental health disorders; increase participation in effective mental health treatment; and reduce cost associated with corrections and incarceration. MHC members include judges, defense attorneys and representatives, the district attorney's prosecution representatives, probation or parole officers, mental health case managers, and other representatives from the mental health system. Defense attorneys, judges, jail personnel, or family members make referrals to MHCs.

Key components of the MHC system include judicial supervision, case management, and periodic review of qualified offenders with mental illness, intellectual disabilities, and co-occurring mental illness with substance use disorders who are charged with misdemeanors or nonviolent offenses. MHCs' delivery of services include specialized training of criminal justice personnel to identify and address mental health needs; development of individualized treatment plans; provision of voluntary outpatient or inpatient mental health treatment in exchange for dismissal of charges or reduced sentencing on successful completion of treatment; and coordination of social services, including life skills training, employment placement, health care, and relapse prevention.

According to BJA existing research indicates that participants in the studied MHCs have significantly lower recidivism rates and are less likely to be arrested for new crimes than are individuals with mental health

conditions who go through traditional courts. Research also indicates that MHCs are more effective at connecting individuals to mental health services than are traditional courts.

Mental health courts are a collaboration between criminal justice systems and community mental health treatment systems. MHCs are successfully providing life-changing services to thousands of offenders who suffer from underlying serious mental health conditions.

Mental Health Laws

"Mental health laws" refer to legal provisions protecting the rights of people suffering from severe mental illness and limiting involuntary commitment to psychiatric treatment facilities.

Definitions

- **Competence** is a legal term designating that a person is capable and able to enter into legally binding contracts, transfer assets, and participate in legal proceedings.
- **Informed consent** means to voluntarily consent in writing, by a competent person, to inpatient or outpatient treatment.
- **Involuntary commitment** is a legal process in which someone suffering from a severe mental disorder can be involuntarily admitted for inpatient psychiatric hospitalization or treatment.
- **Jurisdiction** refers to the authority to administer justice over a specific area of the law in a specified location or territory.

Description

Mental health laws protecting people from involuntary commitment (IC) to psychiatric hospitals or mental health treatment facilities exist in every state in the United States. The states enact these laws, and all jurisdictions have provisions limiting involuntary psychiatric admissions. IC is restricted to those who pose a danger or a risk of harm to themselves or others. Some states require evidence of imminent danger, while others require proof beyond reasonable doubt.

State mental health laws are referred to by different names but share many of the same provisions. An example is Florida's *Baker Act* law that allows for the involuntary examination of individuals who are suffering from a mental illness, are likely to suffer substantial harm, or pose a threat of serious bodily harm to self or others. A person is considered incompetent when he or she lacks the capacity to make a well-reasoned, willful, and knowing decision concerning treatment due to his or her mental illness. A person may not be held in IC for longer than 72 hours at which point they must be released, provide informed consent, or be ordered by a court for involuntary placement.

Professionals authorized to perform examinations varies by state. In Florida, physicians, psychiatrists, licensed clinical psychologists, clinical social workers, mental health counselors, marriage and family therapists, and some qualified psychiatric nurses are recognized mental health professionals who have the required credentials to diagnose and treat mental health disorders.

Impact (Psychological Influence)

Prior to 1970 the presence of a psychiatric illness, with or without threat to self or others, was sufficient grounds for an IC. This led to the possibility for

individuals to essentially be incarcerated with no legal due process. Beginning in the 1970s laws were enacted throughout the United States, restricting IC to those who posed a danger or risk to themselves or to others. As a protective measure mental health laws have saved an untold number of lives of those suffering from severe mental illness.

Mental Measurements Yearbook, The

The Mental Measurements Yearbook (MMY) is a continually updated reference collection of commercially available standardized tests and assessments for use in social research.

Description

It would be difficult to overstate the importance and impact that social research has had on people's lives. Standardized tests and measures, often referred to as "instruments," are essential tools that researchers use in order to explore all aspects of social phenomena. The overall quality of an instrument is associated with how valid and reliable it is and whether it is standardized. Instruments are standardized when all test-takers are required to answer the same questions in the same way and are scored in a consistent or "standard" manner. "Validity" refers to how well an instrument measures what it is designed to measure. For instance, if someone who is very outgoing completes a measure that indicates he or she is shy, that instrument has very low validity. Reliability is a measure of how consistently the instrument measures what it is designed for. For instance, if the outgoing person takes the same personality assessment on two different days and on one day it indicates he or she is outgoing and on the other day he or she is shy, that instrument has poor reliability. Validity and reliability are independent of each other. For instance, if you weigh the same every time you use a bathroom scale, it is reliable. But if the scale is inaccurate, say it measures your weight 5 pounds low every time you use it, it is reliable but invalid. Only if the scale were both consistent and accurate would it be considered to have high levels of both reliability and validity. Researchers use several methods of calculating levels of reliability and validity.

Development and Current Status

The Mental Measurements Yearbook is a widely used reference publication that is designed to assist professionals in selecting and using reliable and valid standardized tests and assessments. Founded in 1938 by Oscar Krisen Buros (1905–1978), the Buros Institute of Mental Measurements is located in the Department of Educational Psychology at the University of Nebraska-Lincoln. The MMY provides factual information, critical reviews, and comprehensive references on the construction, use, reliability, and validity of all standardized tests published in English. It also provides descriptions of the purpose, target population, administration, scoring, price, author, and publisher for all listed instruments. The objectives of the MMY are to provide accurate and factual information of all known tests published in the English-speaking countries of the world; provide candid and critical test reviews written by professionals; and to continually add to earlier editions by providing supplemental, or additional, information, on previously published tests as it becomes available, as well as the inclusion of new testing instruments. The MMY offers evaluations of instruments in the fields of education, psychology, business, law, health care, counseling, and management.

Mental Retardation

Mental retardation (MR) is a disorder that describes people with well below average level of intelligence, an intelligence quotient (IQ) of 70 or below, and who have major limitations in the skills needed for daily living.

Definition

- **Retardation** means the act, process, or condition of being delayed or impaired from an expected course of development.

Description

In the United States about 7 million people are diagnosed with MR. Mental retardation, now known as intellectual disability, is identified by a lower-than-average level of intelligence or IQ. The term "retarded" has been the subject of rejection and shame in our society and therefore makes this diagnosis controversial. Although a below-average intelligence quotient (IQ) contributes to the diagnosis of MR, it is limitations in adaptive skills that characterize most people with MR. This means they have a limited ability to deal with the demands of daily living and self-care. It is this limit that causes them to stand out most obviously from their peers. An estimated 2.5%–3% of the population is diagnosed with some form of MR. It is classified as a disability that begins in childhood and lasts throughout life.

In recent years, due to a stigma related to the word "retarded," there has been a movement away from the diagnosis. Many people in the community who are affected by MR have rejected its application to themselves. The community and professional organizations have changed their terminology from MR to intellectually and developmentally disabled.

There are four degrees of severity that are used to categorize those with MR. Mild MR identifies those with IQ scores between 50 or 55 and 70. This group represents the largest proportion of the four categories of MR at 85% of the population. In addition, it is this group that can be helped most through education and therapy. This is not as true of the other three groups of MR. Those include moderate MR with IQ scores between 35 and 50 or 55, which is about 10% of the MR population. Severe MR represents those with IQ scores between 20 or 25 and 35 or 40 and is 3%–4% of the population. Lastly, there is profound MR with IQ scores below 20 or 25, representing 1%–2% of those diagnosed with MR (American Psychiatric Association, 2000).

Causes and Symptoms

Mental retardation can arise from many different causes. Some of the identified causes are biological, including sickness, such as encephalitis or meningitis, but also accidents that may cause brain damage. Other causes may be psychosocial, but the reasons are nearly impossible to assign in some cases. Common to all MR is some impairment of the functioning of the brain and central nervous system.

Symptoms may appear very early in childhood and vary from person to person. Most individuals have both intellectual and adaptive impairment. Also common are issues and delays in motor and language skills. Some of those with MR are peaceful and passive in personality, while others can be aggressive and impulsive. Sometimes mild MR is not identified until a child enters school and undergoes standardized testing.

Diagnosis and Prognosis

Traditionally, three things are needed for a diagnosis of MR or intellectual disability. The first is that the onset of the condition must occur before the person is 18 years old. The second is that intellectual functioning is below the norm for the population as defined by standard IQ scores. The third is that there are significant limitations in daily living skills such as communication, self-care, social skills, academic skills, work, health, and safety. The condition is lifelong, but the

awareness and treatment for those with MR have improved, which makes for a better quality of life.

Treatment

Mild MR can be treated through special education, which may result in the acquisition of enough knowledge and skills to complete several years of school and eventually to hold employment. People with moderate MR are often trainable but will be limited in educational and work opportunities. Those with severe MR tend to do better in group homes and in situations of structure where their daily living needs can be met. People with profound MR will require extensive care and supervision their whole lives.

Mental Status Examination

The mental status examination (MSE) is a structured assessment of an individual's level of cognitive (intellectual) and behavioral functioning, appearance, mood, speech, alertness, and judgment and insight at the time of evaluation.

Definitions

- **Cognitive** refers to mental activities associated with thinking, learning, and memory.
- **Delusion** is a belief that is resistant to reason or contrary to actual fact.
- **Dementia** is an overall decline in an individual's level of cognitive (intellectual) functioning, including memory loss, difficulties with language, simple calculations, planning, decision making, and motor skills.
- **Dissociation** is the splitting off of certain mental processes from conscious awareness characterized by feelings of unreality or confusion about one's identity.
- **Hallucination** is a sensory (sight or hearing) experience of something that does not exist outside the mind.
- **Organic brain disorder** refers to impaired brain function resulting from damage or deterioration of brain tissue.
- **Thought disorder** is a condition characterized by incomprehensible language (written or spoken).

Description

A mental status examination is a structured assessment of behavioral and cognitive functioning at the time of evaluation. It includes descriptions of the individual's appearance and general behavior, alertness and level of consciousness, motor and speech activity, mood and affect, thought and perception, attitude and insight, and judgment and insight, as well as the reaction evoked in the examiner. Of these factors, the most clinically relevant are alertness, language, memory, abstract reasoning, and judgment. The MSE is the heart of the psychiatric (psychological) evaluation. The purpose of MSE is to assess the presence and extent of an individual's mental impairment. The MSE is an essential part of the diagnosis of dementia and other psychiatric disorders, and is routinely administered to those being evaluated for dementia. It can be regularly administered to monitor and document changes in an individual's condition. MSE results may suggest specific areas for further testing. The most commonly used MSE in North America is the Mini-Mental State Examination (MMSE).

While the MMSE evaluates five areas of mental status or functioning—orientation, registration memory, attention and calculation, recall, and language—the MSE is more comprehensive. It evaluates 10 areas of functioning: appearance, movement and behavior, affect, mood, speech, thought content, thought process, cognition, judgment, and insight. Administration time of the MSE varies depending on the individual's condition, ranging from 5 minutes or less with healthy individuals to 20 minutes to those with speech problems or intellectual impairments, dementia, or other organic brain disorders.

Normal results for an MSE depend to some extent on the individual's history, level of education, and recent life events. Accordingly, a depressed mood is appropriate in the context of a recent death or other sad event in the individual's personal life, but it would be inappropriate following a recent promotion or pay raise. Generally, a normal MSE involves the absence of obvious delusions, hallucinations, or thought disorders as well as the presence of insight, good judgment, and socially appropriate appearance and behavior. Abnormal results for an MSE would include any evidence of organic brain damage, dissociative symptoms, delusions or hallucinations, or thought disorders. It could also include a mood or affect that is clearly inappropriate, thoughts of suicide, or disturbed speech patterns.

Developments and Current Status

The development of the MSE can be traced to descriptive psychopathology and phenomenology, which is based on the work of philosopher and psychiatrist Karl Jaspers (1883–1969). He assumed that an accurate comprehension of an individual's experience requires his or her own description which is elicited through an empathic and nontheoretical enquiry. This contrasts with an interpretive or psychoanalytic approach, which assumes the analyst might understand experiences or processes of which the patient is unaware, such as defense mechanisms or unconscious drives. Rather, the MSE is a blend of empathic, descriptive phenomenology and empirical clinical observation. The most commonly used MSE in North America is the Folstein MMSE, which is much shorter and provides an easily calculated score.

Methadone

Methadone is a synthetically derived prescription drug (an opioid) used in the treatment of opiate and opioid addiction. It is used to ease detoxification and as a maintenance therapy.

Definitions

- **Drug Enforcement Agency** is the federal agency responsible for enforcing laws and regulations governing narcotics and controlled substances. It is also known as the DEA.
- **Opiates** are a class of naturally derived drugs from opium.
- **Opioids** are synthetically derived drugs and are used as opiate substitutes. The term "opioid" is sometimes used to refer to both opiates and opioids. Both are known as narcotics.
- **Heroin** is a highly addictive and illicit drug derived from morphine, which is used to produce euphoria (feeling of excitement and happiness).

Description

Methadone is an addicting substance commonly used in addiction treatment, particularly opioid addiction. While it can produce a slight high, it works by blocking

narcotics like heroin from producing a powerful drug high. Though methadone treatment has its drawbacks, it remains one of the most effective tools that addiction specialists have to help ease addicts off of illicit opiates like heroin.

Even though methadone maintenance treatment became widespread, it remained controversial. Many wanted those on methadone maintenance to eventually be weaned off the drug. However, research showed that once begun on maintenance treatment, it needed to be taken for life. Treatment centers found that it was very difficult to get individuals off of methadone once it was started. There was also concern that methadone would be diverted to the black market. In the 1980s attitudes toward drug abuse hardened. The federal government placed limits on the amount of federal funding for drug programs used for methadone. This led to many programs being cut. When antidrug sentiment reached its zenith under President Ronald Reagan, many in the federal government opposed it as an overly "soft" response to the drug problem. Research in the 1980s, however, found that methadone was effective not only in treating addiction itself but also in addressing the public health problem of HIV/AIDS. It was found it helped heroin users to stop injecting drugs intravenously and sharing needles—a practice that spread the disease. In the 1990s, the federal government began to support methadone maintenance as an important tool in the battle against drug addiction. By 2000, there were nearly 150,000 individuals on methadone maintenance treatments in the United States.

The use of methadone treatments still remains controversial in the addiction community since addicts are prone to develop dependency on the drug. This means that methadone addition replaces heroin (or another opiate) addition. Research shows that less than 20% of individuals who go on methadone are able to stop taking it. Supporters believe it is the best treatment since it stabilizes addicts as they go off of street drugs, helps reduce withdrawal symptoms, and provides a safe, legal environment where they can receive services to help them overcome their addiction. It also reduces their involvement in the black market for drugs, a hallmark of heroin addiction. The Drug Enforcement Administration lists methadone and oxycodone as a Schedule II controlled substance, while heroin is listed as a Schedule I controlled substance.

Microaggression

Microaggressions are insensitive acts such as comments, insinuations, or slights that are primarily directed toward marginalized groups, either intentionally or unintentionally.

Description

The term "microaggression" is an umbrella term used to describe actions or words that are dismissive and hurtful toward marginalized groups of people. These types of interactions are not physically aggressive but are rather evidenced verbally, behaviorally, or environmentally. They communicate feelings of hostility, negativity, or insensitivity toward certain types of people. Members of marginalized groups may be subject to microaggression because of race, ethnicity, gender, sexual orientation, ability, and/or religious affiliation. Perpetrators of these offenses are often unaware of committing them or may become defensive when challenged about these abusive messages. Microaggressions can contribute to inequities in the legal system, education, and health care.

People of color commonly report experiences of microaggression. An example of this may be when a white woman clutches tight to her purse when passing by an African American male on the street (hidden message is that you are a criminal). Another example would be expressing frustration or anger toward Latinos who

converse in Spanish with one another (hidden message is that they are not real Americans and should leave their old traditions/language behind now that they are in America). The implications derived from microaggressions such as this are that the member or members of the marginalized group are not part of the larger majority, are lesser human beings, or are not due the same rights or respect as the majority group. They result in the marginalized member feeling demeaned, disregarded, felt of as less than, or inadequate. Research indicates that microaggressions can cause emotional and psychological harm and that acknowledging their existence and discussing them openly in order to promote understanding and growth is encouraged. Persons committing these acts may not even realize that they are saying or doing something offensive as most people consider themselves fair-minded, non-biased, respectful, and good; therefore, accepting that they may have perpetrated hidden slights, insults, or misgivings is difficult. Defensiveness is a normal response when a person is questioned about a transgression.

Three types of microaggressions exist: (1) microassaults—conscious and intentional discriminatory actions, (2) microinsults—verbal, nonverbal, and environmental communications that more subtly express insensitivity or demean a person's racial heritage or identity, and (3) microinvalidations—communications that exclude, negate, or nullify the thoughts, feelings, or realities of a person with color.

The term "microaggression" was coined by psychiatrist Chester M. Pierce in 1970, but others added significantly to this concept. In 1973, Mary Rowe of the Massachusetts Institute of Technology discussed microinequities specifically related to gender. Landmark research later conducted by Stanford University psychology professor Claude Steele indicated that African Americans and women performed worse on academic tests after being subjected to racial and gender stereotyping. Subsequently, numerous experiments by social psychologists, Jack Dovidio and Samuel L. Gaertner, found patterns of aversive racism among whites and blacks. Most recently, psychologist Derald Wing Sue of Columbia University has been developing a theory and classification system for measuring acts of microaggression to help educate and address these issues.

Current Status and Impact (Psychological Influence)

Microaggressions reflect active manifestations of oppression and readily contribute to the marginalization of many groups of people. No one is immune to their existence. Evidence suggests that incidents of microaggression can have a significant emotional and psychological impact on victims, so acknowledging their existence and effectively counteracting them is critical in promoting social harmony.

Milgram, Stanley (1933–1984)

Social psychologist Stanley Milgram, is famous and best known for conducting controversial studies on obedience (Milgram's Experiments) during the 1960s.

Description

Stanley Milgram was born in New York City on August 15, 1933, to Jewish immigrants. His mother, Adele, was born in Romania and his father, Samuel, was born in Hungary. Both moved to the United States before Hitler's rise to power. Stanley was the second of three children. His sister Marjorie was the oldest

Social psychologist Stanley Milgram is best known for conducting influential studies on obedience to authority during the 1960s. The protocol and procedures he used for conducting research with human participants has since guided standards set forth by the American Psychological Association and other bodies. (Jan Rieckhoff/ullstein bild via Getty Images)

and brother Joel the youngest. Stanley had a modest upbringing as his father worked as a baker until his death in 1953. Adele was a homemaker but assumed work in the bakery after her husband's passing. Stanley displayed academic excellence from an early age, showing a particular interest in science. His leadership skills were also evident. He graduated from James Monroe High School in just three years and went on to attend Queens College, near home, primarily due to the family's financial constraints. Graduating with a bachelor's degree in political science, Milgram went on to apply to Harvard's Social Psychology program, where he was initially rejected. After enrolling in Harvard's Office of Special Students, he was then formally accepted into the program in 1954, working under the guidance of Gordan Allport, and received his PhD in 1960. His research interests focused on social issues affecting the average man or woman; a cross-cultural comparison in conformity between people in Norway and Paris was the focus of his dissertation. He spent a year at the Institute for Advanced Study at Princeton working with Solomon Asch, who was famous for his studies on conformity. This influence prompted him to continue researching social issues such as these. In 1961, he began his obedience studies, also referred to as Milgram's Experiment. During this year, Milgram also met his wife Alexandra, a dancer and social worker, and went on to have two children. Milgram's first teaching position was at Yale, where he became an assistant professor in 1962. He then returned to Harvard's Department of Social Relations from 1963 until 1966 and was hired as a lecturer during 1967. Denied tenure, most likely due to the controversy surrounding his obedience study, Milgram left Harvard, accepting a full professor position at the City University of New York. He was also asked to head up their social psychology program in the Graduate Center. While at CUNY in 1974, he published his book *Obedience to Authority*, which was a compilation of the results of his obedience studies. He went on to publish many other works, record several films based on his research, secure additional grant funding, and serve as a mentor on dissertation committees. Stanley Milgram died of a heart attack at the age of 51 on December 20, 1984, in New York City.

Though Milgram conducted several social experiments throughout his career, he is best known for his groundbreaking studies on obedience, also referred to as "Milgram's Experiments." Following along the lines of Asch's work on conformity, Milgram sought to expand his research to areas of greater interest to the everyday person. An additional component, and not one common in studies at the time, was the fact that Milgram also debriefed his subjects and asked for their input regarding the ethical practices of the study itself. After gaining the approval of the National Science Foundation in 1961, Milgram began his obedience studies. It is believed that these studies were inspired by the 1961 trial of Adolf Eichmann, a high-ranking official of the Nazi party. Milgram sought to understand why human beings blindly conform to those in

authority. The series of obedience studies consisted of pairs of subjects (a teacher and a learner) and the experimenter. The experimenter leads both participants into a room and proceeds to strap one, the designated learner, to a chair and hook up an electrode which the participants are told will administer a shock to the person's arm. The other participant, the teacher, is then taken to a separate room adjacent to the learner's and told to read a list of two word pairs and then instruct the learner to say them back. If the learner answers wrong, the teacher is to push a button administering a 15-volt shock to the learner. Each time the learner answers incorrectly, the teacher administers another shock, increasing 15 volts for every wrong answer, with the highest being 450 volts. The learners were never actually harmed in the experiment but pretended to be. The results indicated that the majority of teachers, two-thirds (26 out of 40), administered the full range of shocks up to the 450 volts and were deemed "obedient subjects." Simply put, the findings of the studies suggested that a majority of people would go against their own moral judgment and, for no personal gain nor malice, harm another human being simply because they were instructed by a perceived person in authority to do so, the key piece being that they were able to shift their perceived personal responsibility in the matter because they were told to perform the act by a person in charge. Milgram related these findings to real life in that people often view themselves as having no personal power or choice and do not view themselves as culpable if they are simply doing what they were told to do.

Impact (Psychological Influence)

The groundbreaking obedience experiments conducted by Stanley Milgram are well-known and incorporated nowadays into nearly every introductory psychology course. His work has been referenced in popular music, movies, television shows, and publications. He is also known for the "Small World" experiment in 1967, which sought to test the concept of "six degrees of separation," positing that any two random strangers in the United States can be linked together by an average of six intermediate acquaintances.

CUNY named him Distinguished Professor of Psychology in 1980. In 1983, he was selected to be a fellow of the American Academy of Arts and Sciences. He also received a Ford Foundation Fellowship, an American Association for Advancement of Science Socio-Psychological Prize, and a Guggenheim Fellowship. In addition to these accolades, the protocol and procedures he used for conducting research with human participants has since guided the standards set forth by the American Psychological Association and the mandating of Internal Review Boards.

Military Mental Health

"Military mental health" refers to the mental health needs and provision of services to military personnel and their families.

Description

Approximately 20% of activity duty service members and as many as 37% of veterans experience symptoms of serious mental health disorders. Rates of post-traumatic stress disorder and anxiety are disproportionately high among veterans, as compared to the civilian population, as are rates of marital distress, domestic violence, divorce, and drug and alcohol abuse. Most alarming is the high rate of depression and suicide among veterans. According to the National Alliance on Mental Illness, one active duty soldier takes

his or her life every 36 hours and one veteran every 80 minutes.

The mental health needs of military spouses and children are equally challenging. As many as 37% of military spouses suffer from at least one mental health disorder, with anxiety, depression, and sleep disorders being the most prevalent. Although most children of active duty personnel adapt to the deployment of a parent, one-third suffer from psychological distress such as depression, anxiety, acute stress reactions, and behavioral disorders.

There are four principal health-care systems available to active duty and veteran military personnel and their families. The Department of Defense (DoD) offers "In Theater" support and mental health services to deployed personnel through chaplains and embedded mental health specialist. The DoD also offers stateside community-based and inpatient mental health care at military installations. Tricare, the military health insurance program, provides online information and referral services through a national network of mental health providers. The U.S. Department of Veteran Affairs (VA) provides inpatient and outpatient mental health services through VA hospitals as well as individual, marital, group, and grief counseling through community-based clinics. Military personnel and their families may also choose to receive services through the civilian health-care system.

Impact (Psychological Influence)

Military personnel are faced with multiple barriers to receiving adequate mental health care. Eligibility requirements for services and benefits, inadequate private health-care coverage that restricts provision of mental health services, and too few qualified practitioners prevent many from receiving needed care. The VA has come under heavy public and governmental criticism for its failure to provide adequate and timely care for veterans. Access to care is another barrier affecting those who live outside of the major cities where most VA service centers are located. Military culture can serve as a deterrent as many active duty personnel and their spouses fear receiving mental health services will hurt their military careers. Both the DoD and VA are addressing the mental health needs of military personnel and veterans by investigating service failures, increasing service capacity, making changes to delivery systems, and developing new service programs.

Millennials

"Millennials" refers to the generation of people born between the early 1980s and the early 2000s. They now surpass baby boomers (born between 1945 and 1964) as the largest generation in the United States, due to deaths among baby boomers and immigration boosting numbers of millennials (Raphelson, 2014).

Description

The exact beginning and ending birth years of the millennial generation is a point of debate. Millennials number approximately 80 million individuals residing in the United States. Millennials have unique characteristics compared to other generations. Authors William Strauss and Neil Howe are most often credited with naming the millennial generation. They wrote the first book about the millennial generation titled *Millennials Rising: The Next Great Generation*. Since the publication of that book, millennials have continued to be studied, researched, and frequently written about.

Millennials have many different names. They are also known as Generation Y because they came after Generation X (Gen X), who were born from the early 1960s to the early 1980s. Millennials are also known as the Peter Pan or Boomerang Generation due to the large number of millennials who return home after college and delay getting a career-oriented job and/or put

off getting married. They have been referred to as echo boomers, the me generation, generation we, generation next, and the net generation, among others.

Millennials have unique values, attitudes, behaviors, and demographic characteristics compared to other generations. The Pew Research Center (PRC) has conducted extensive research into millennials. According to the PRC, millennials are made up of 61% white, 19% Hispanic, 14% black, and 5% Asian. Millennials are confident, self-expressive, tend to be more liberal than GenX, are upbeat, and open to change. They are more ethnically and racially diverse than are GenXers and are on track to becoming the most educated generation in American history. Millennials are less religious and less likely to serve in the military. Self-expression is valued by millennials. About three-quarters of those surveyed in the PRC study of millennials have created a profile on a social networking site. About 40% have a tattoo, with about half of those having two or more tattoos. Nearly 25% have a piercing in a body part other than the earlobe.

Sixty percent of millennials were raised by both parents and place parenthood and marriage above financial success and career. As a group millennials get along well with their parents and respect their elders. Millennials believe that families have a responsibility to care for older parents and would allow an older parent to live with them. Approximately 21% of millennials are married and 34% live in their parent's home (Fry). About a third of all millennials are parents.

The economy has contributed to the uniqueness of the millennial generation. According to the Millennial Civic Health Index, millennials have been particularly impacted by the economic recession of the late 2000s, with only 63% of millennials working. Of that group 31% were working on a part-time basis. Despite the difficulties in finding work, 90% of millennials in the 2010 Pew report said they have enough money or that they will meet their financial goals. The job market influenced household formation, with those millennials holding jobs much more likely to establish independent households. Forty percent of employed millennials are the head of their own households compared to 25% who are not employed.

Millennials are more open and accepting of diversity than are previous generations, with 58% believing that immigrants strengthen the country. They are also more tolerant than previous generations, being far more receptive of interracial marriages and nontraditional family arrangements, mothers working outside of the home, and adults living together without being married.

The millennial generation is the most educated and connected generation of all time. Within their generation, they are the first to not remember a time without computers, cable television, smartphones, and the Internet. Each generation brings a unique combination of values, attitudes, and behaviors to society.

Millon, Theodore (1928–2014)

Theodore Millon was an American Psychologist known for his research and publication on personality disorders.

Description

Theodore Millon was born in New York in 1928. An only child, his parents had immigrated to the United States in the 1920s. Millon's mother Mollie experienced bouts of mood instability and would have been "diagnosed" bipolar had the *Diagnostic and Statistical Manual* (DSM), which mental health professions use to diagnose mental disorders, existed at that time. Bipolar disorder is a mental disorder characterized by a history of manic episodes (bipolar I disorder), mixed, or hypomanic episodes (bipolar II disorder), usually with one or more major depressive episodes.

A bright student, Millon attended a "gifted program" at Hunter College in New York, prior to graduating from high school in 1945. He completed his bachelor's degrees in psychology, physics, and philosophy at the City College of New York. He obtained his PhD at the University of Connecticut in 1953, and his dissertation focused on assessment of authoritarian personalities.

Impact (Psychological Influence)

Millon is known as "the grandfather of personality disorders," disorders that feature a long-standing pattern of maladaptive (problematic) behavior, thoughts, and emotions that deviates from the accepted norms of an individual's culture. He also created a widely used diagnostic assessment, the Millon Clinical Multiaxial Inventory (MCMI). The MCMI is an objective personality test that was first published in 1977. It included 175 true–false questions. This test was designed to quickly categorize patients on more than 20 different scales. It screened for clinical conditions such as depression, drug problems, and personality disorders. A key feature of the computer-generated report of this test is a DSM diagnosis. It is an objective test, because it yields scores that are independent of the opinion or judgment of the examiner. The MCMI is the second most used personality inventory in the world and is now in its third edition, MCMI-III.

Millon was a very influential figure in the field of psychology. He published 50 academic papers and 25 books. Millon was the founding coeditor of the *Journal of Personality Disorders* and was also the president of the International Society for the Study of the Personality Disorders (1988–1992). The American Psychiatric Association gave him a lifetime achievement award in 2008. He continued to publish and research up until his death in 2014, at age 85.

Millon Clinical Multiaxial Inventory (MCMI)

The Millon Clinical Multiaxial Inventory (MCMI) is a psychological test used to assess personality and psychopathology. It is also referred to as the MCMI, MCMI-III, and the Millon.

Definitions

- **Objective personality inventory** is a type of psychological test designed to assess personality traits and behavioral patterns using structured questions. It contrasts with projective personality tests, which uses unstructured stimuli such as the Rorschach Inkblot Test.
- **Personality** is an individual's unique consistent pattern of thinking, feeling, and acting.
- **Psychopathology** is the study of the conditions and processes of a mental disorder and dysfunctional behavior.
- **Scale** is a subset of test items from a multi-item test.

Description

The Millon Clinical Multiaxial Inventory is an objective personality inventory that assesses personality

traits and psychopathology. The third edition of the Millon Clinical Multiaxial Inventory-III (MCMI-III) instrument provides a measure of 24 personality disorders and clinical syndromes for adults undergoing psychological assessment or treatment. The MCMI was designed to assess both Axis I (symptom disorders) and Axis II (personality disorders) and to assist clinicians in making *Diagnostic and Statistical Manual of Mental Disorders* (DSM) diagnoses. In addition, it is helpful in developing a treatment approach based on the individual's personality style and coping behavior, and guiding treatment decisions based on those dynamics. The MCMI-III is composed of 175 true–false questions that take about 25 to 30 minutes to complete. After the test is scored, it produces 24 personality and clinical scales, and 5 correction scales that verify how the individual approached and took the test. Three facet scales have been added for each MCMI-III personality scale to facilitate treatment planning. These scales help therapists pinpoint specific personality dynamics such as self-image, interpersonal conduct, and cognitive style as treatment targets.

The MCMI-III is brief in comparison to other personality inventories, such as the Minnesota Multiphasic Personality Inventory (MMPI-2), and has a strong theoretical basis. Administering and scoring it are simple whether in paper and pencil or computer formats. An interpretive report includes a treatment guide for focusing treatment interventions. It also provides a capsule summary of test results.

Developments and Current Status

The first version of the MCMI was published in 1977 by psychologist Theodore Millon (1928–2014). It was on Millon's evolutionary theory of personality and psychopathology and was keyed to DSM-III. It had 11 personality scales and 9 clinical syndrome scales. The second version, MCMI-II, was published in 1987. It was keyed to DSM-III-R and had 13 personality scales and 9 clinical syndrome scales. The current version, MCMI-III, was published in 1994 and developed by Millon in collaboration with Roger Davis, Carrie Millon, and Seth Grossman. It is keyed to DSM-IV and has 14 personality scales, 10 clinical syndrome scales, and 5 correction scales. A new version that is keyed to DSM-5, MCMI-IV, was introduced in 2015. Overall, the MCMI is a highly regarded objective personality inventory for identifying both personality dynamics and psychopathology.

Mind-Body Medicine

Mind-body medicine is a contemporary form of medicine that emphasizes interactions among physiological, psychological, sociological, and spiritual factors in the diagnosis, prevention, and treatment of medical conditions.

Definitions

- **Behavioral medicine** is an interdisciplinary form of modern medicine that integrates the behavioral, biomedical, and social sciences.
- **Biopsychosocial model** is a way of conceptualizing (thinking about) health and illness in terms of biological, psychological, and social factors rather than purely in biological terms.
- **Consciousness** is the capability for awareness of one's own existence.
- **Meditation** is the concentrated focus on a sound, the breath, object, or attention itself to increase awareness of the present moment. Its purpose is to reduce stress, promote relaxation, or increase spiritual growth.

- **Mind-body psychotherapies** are forms of psychotherapy that emphasize the interrelations among biological, psychological, sociological, and spiritual factors in the diagnosis, prevention, and treatment of mental disorders.
- **Mindfulness** is the moment-by-moment awareness of one's thoughts, feelings, sensations, and environment without evaluating or judging them.
- **Mindfulness practices** are intentional activities that foster mindfulness.
- **Psychoanalytic psychology** is the form of psychology largely developed by the work of Sigmund Freud, which emphasizes the conflicts and compromises between the unconscious and conscious mind.
- **Psychosomatic** refers to the belief that the mind (psyche) influences diseases affecting the body (soma). Psychosomatic medicine is the branch of medicine that emphasizes the role of psychological factors in causing and treating medical conditions.
- **Psychosomatic illness or disorder** refers to a condition characterized by physical symptoms that result from psychological factors.
- **Psychosomatic model** is a way of conceptualizing (thinking about) certain medical conditions as caused by or resulting from psychological factors.
- **Somatoform** is a group of psychopathologies marked by physical symptoms that suggest a general medical condition but do not manifest in an actual physiological disease.

Description

Mind-body medicine is a form of contemporary medicine that is influenced by ancient philosophies. It assumes that human persons are composed of integrated systems. Thus, it emphasizes the interrelationships of physiological, psychological, sociological, and spiritual factors in the diagnosis, prevention, and treatment of medical conditions. Like mind-body psychotherapies, mind-body medicine is informed by the biopsychosocial model. While both utilizes holistic treatment methods, mind-body medicine emphasizes somatic treatments.

The immune system is of special interest in mind-body medicine. It can be significantly effected by extreme emotion or psychopathology. For example, a depressed immune system can compromise mental health. Mind-body medicine includes psychosomatic and somatoform conceptualizations. Mind-body medicine, like psychosomatic medicine, maintains the belief that the mind (psyche) influences diseases affecting the body (soma). Psychosomatic disorders are similar to but very different from somatoform disorders. The primary difference is that psychosomatic diseases are diagnosable by medical testing. In contrast, in somatoform disorders the presenting symptoms are not due to general medical condition. However, unlike the limited stance of psychosomatic medicine, mind-body medicine also believes that the soma influences the psyche. This belief is especially significant in the treatment of chronic and terminal medical conditions where comfort and well-being are of primary importance. Just as psychological factors may initiate, worsen, or maintain psychosomatic illnesses, so too can physiological factors influence psychological factors of health and well-being. Mind-body medicine prescribes alternative adjunctive treatments to modern medical treatments. For example, prescriptions may include mindfulness, meditation, contemplative prayer, yoga, tai chi, hypnosis, and relaxation. An individual's consciousness and awareness of well-being has been scientifically demonstrated to enhance medical treatment of disease. In other words, the subjective experience of the patient influences the prevention and treatment of medical conditions.

Development and Current Status

Since the middle ages, Christianity's view of human nature has influenced both the philosophy of mind-body dualism and the practice of Western medicine based on it. Mind-body dualism views illness as either a medical condition caused by biological dysfunction,

such as an infection, or a psychological dysfunction caused by trauma or evil spirits. The philosophical distinction between mind and body has been an ongoing discussion beginning with the Greek philosophers. But it was René Descartes (1596–1650), the French philosopher and physiologist, who provided the first systematic account of the mind-body relationship. He proposed that the immaterial mind and the material body are distinct substances (entities) but interact causally with each other. This means that mental events can cause physical events, just as physical events can cause mental events. Unfortunately, Descartes was unable to convincingly explain exactly how the mind can cause changes in the body, and vice versa. Mind-body medicine uses modern science to support Descartes's theory.

Starting in the 1940s, Franz Alexander (1891–1964), a Hungarian American physician and psychoanalyst, is credited with advocating psychosomatic medicine. His view was largely a psychological explanation that emphasized the power of the mind over the body. For example, Alexander believed that asthma was the body's response to unresolved dependency. Duodenal (stomach) ulcers were believed to be caused by frustration and emotional stress. Also, the belief was that rheumatoid arthritis was caused by repressed rebellion, while migraine headaches were caused by repressed hostility. This view of psychosomatic model began to wane as research determined that there was, in fact, both biological *and* psychological factors involved. For instance, research identified an infection with the *Helicobacter pylori* (*H. pylori*) bacteria along with psychological stress as causative factors in duodenal ulcers. Around this time, the psychiatrist George L. Engel (1913–1999) wrote about the need for a new medical model in a landmark article in *Science* in 1977. Engel proposed the biopsychosocial model, which could integrate such an early psychosomatic model with the biomedical model. The biopsychosocial model supported the development of mind-body medicine.

Currently, there are several psychological conceptualizations of the mind-body relationship. Each theory maintains its own ideas of contributive factors of psychosomatic illnesses. The psychoanalytic theory suggests that unconscious conflicts are the reason for psychosomatic conditions. The type of unconscious conflict will predict the type of physiological illness that is psychosomatically manifested. The psychodynamic theory suggests that various personality characteristics and traits react to stressful life events differently. Different life stressors interacting with different personality types lead to different physical diseases. In addition, certain personalities are more likely to develop certain physical illnesses. Psychosocial family systems theories state that dysfunctional families create emotional trauma for children and this is the cause for psychosomatic disease. The biological theories of psychosomatic disease suggest that there are genetic predispositions for psychological influence in illness. A more recent psychosomatic viewpoint views human beings as psychosomatic wholes. It integrates mind with body with a more unified view of life that encompasses polarities (opposing but attracting influences). For instance, in the being versus nonbeing polarity, while individuals are continually threatened by illness and nonbeing, they can constantly reasserting their being by engaging in healthy behaviors. Health problems arise when the polarities become unbalanced. Such an understanding appears to avoid mind-body dualism and the overemphasis of the mind over the body in Alexander's viewpoint.

Mind-Body Psychotherapies

Mind-body psychotherapies are forms of psychotherapy that emphasize the interrelations among biological, psychological, sociological, and spiritual factors in the diagnosis, prevention, and treatment of mental disorders.

Definitions

- **Biopsychosocial model** is a way of conceptualizing (thinking about) health and illness in terms of biological, psychological, and social factors rather than purely in biological terms.
- **Consciousness** is the capability for awareness of one's own existence.
- **Evidence-based treatments** are therapeutic interventions (techniques) that scientific research demonstrates to be effective in facilitating therapeutic change. It is also known as empirically supported treatments.
- **Expressive psychotherapy** is a form of therapeutic counseling that emphasizes externalizing to process and understand or increase awareness of impulses, trauma, psychopathology, or unrealized growth potentials.
- **Meditation** is the concentrated focus on a sound, the breath, object, or attention itself to increase awareness of the present moment. Its purpose is reduce stress, promote relaxation, or increase spiritual growth.
- **Mindfulness** is the moment-by-moment awareness of one's thoughts, feelings, sensations, and environment without evaluating or judging them.
- **Psychosomatic** refers to the belief that the mind (psyche) influences diseases affecting the body (soma). Psychosomatic medicine is the branch of medicine that emphasizes the role of psychological factors in causing and treating medical conditions.
- **Somatic psychotherapy** is an alternative form of psychotherapy composed of many approaches, all of which are body centered and emphasize body posture, movement, and the experience of bodily function.
- **Spiritually oriented psychotherapy** is a form of therapeutic counseling informed by spirituality and psychology.

Description

Mind-body psychotherapies are holistic forms of psychotherapy. They are informed by the biopsychosocial model in the diagnosis, prevention, and treatment of mental disorders. Like mind-body medicine, mind-body psychotherapies are informed by the biopsychosocial model. Mind-body psychotherapies, like the biopsychosocial model, emphasize ways in which biological, psychological, sociological, and spiritual factors interact. The biopsychosocial model is suitable for use in various conceptualization of (way of thinking about) a client's presentation. Mind-body psychotherapies utilizes a number of psychotherapeutic interventions that are evidence-based practices which are congruent with client preference, clinician competence, and the goals of treatment.

Mind-body psychotherapies are also akin to but different from somatic or body-centered psychotherapies. Mind-body psychotherapies are larger in scope than somatic psychotherapies and may include their use. Body-centered psychotherapies are focused on intervening in the client's relationship to his or her body, its function and influence on psychological functioning.

Mind-body psychotherapies both include and go beyond somatic interventions. Mind-body psychotherapies emphasize optimal human development in all aspects of human existence, including biological, psychological, sociological, and spiritual dimensions. The clinical practice of mind-body psychotherapies is based on the underlying assumption that human beings are composed of integrated systems. Optimal human functioning is comprised of the healthy functioning of all related systems. Pathology (disease or illness) in one system can compromise the functioning of other interrelated systems. Human consciousness is composed of the sum of its systems functioning.

Mind-body psychotherapies aim to reduce psychopathology through the promotion of health in all mind-body systems. Mind-body psychotherapies often utilize alternative treatments to popular (widely used) therapeutic counseling interventions. Mind-body psychotherapies may include mindfulness, meditation, contemplative prayer, yoga, tai chi, hypnosis, relaxation, nutrition, exercise, dance, art, drama, writing, or play. It may also include culturally sensitive variants of these, such as shamanic healing. An individual's consciousness and awareness of well-being has been scientifically demonstrated to be improved through the use of mind-body psychotherapies.

Development and Current Status

Since the middle ages, Christianity's view of human nature has influenced both the philosophy of mind-body dualism and the practice of Western medicine based on it. Mind-body dualism views illness as either a medical condition caused by biological dysfunction, such as an infection, or a psychological dysfunction caused by trauma or evil spirits. The philosophical distinction between mind and body has been an ongoing discussion beginning with the Greek philosophers. But it was René Descartes (1596–1650), the French philosopher and physiologist, who provided the first systematic account of the mind-body relationship. He proposed that the immaterial mind and the material body are distinct substances (entities) but interact causally with each other. This means that mental events can cause physical events, just as physical events can cause mental events. Unfortunately, Descartes was unable to convincingly explain exactly how the mind can cause changes in the body, and vice versa.

Starting in the 1940s, Franz Alexander (1891–1964), a Hungarian American physician and psychoanalyst, is credited with advocating psychosomatic medicine. His view was largely a psychological explanation that emphasized the power of the mind over the body. This view of psychosomatic model began to wane as research determined that there was, in fact, both biological *and* psychological factors involved. Around this time, psychiatrist George L. Engel (1913–1999) wrote about the need for a new medical model in a landmark article in *Science* in 1977. Engel proposed the biopsychosocial model, which could integrate such an early psychosomatic model with the biomedical model. The biopsychosocial model supported the development of mind-body psychotherapy. Currently, there are many mind-body-based psychotherapeutic interventions. Many of these are based on ancient practices. Each intervention maintains its own emphasis of therapeutic contribution. Different life stressors interacting with an individual's unique biological, psychological, sociological, and spiritual systems lead to different types of disorders or diseases. The following three mind-body psychotherapies are common examples of interventions designed to heal aspects of the integrative human system.

Eye Movement Desensitization and Reprocessing

Eye movement desensitization and reprocessing (EMDR) was conceptualized by Francine Shapiro (1950–). In 1987, Shapiro noticed that moving her eyes from side to side as she walked in a park in San Francisco reduced discomfort associated with negative thoughts and memories. The theory of EMDR concludes that trauma and psychopathology change the neurological structure of the brain. Through the implementation of a structured eight-step EMDR protocol, the brain and the negative experience of trauma and psychopathology may be healed. The eight-step process to EMDR includes history and treatment planning, preparation, assessment, desensitization, installation, body scan, closure, and reevaluation.

Mindfulness-Based Stress Reduction

Mindfulness-based stress reduction (MBSR) was developed by Jon Kabat-Zinn (1944–) at the University of Massachusetts Medical Center for treatment of medical patients. Since then, MBSR has evolved into a common medical and psychological treatment for various health problems. MBSR is a structured group program lasting 2.5 hours and scheduled over 8 to 10 weeks. Each session covers specific exercises and topics that are examined within the context of mindfulness. These include various forms of mindfulness meditation practice, mindful awareness during yoga postures, and mindfulness during stressful situations

and social interactions. Because an individual's development of mindfulness requires regular and repeated practice, participants are expected to practice 45 minutes of homework assignments each day. This involves meditation, mindful yoga, and applying mindfulness to situations in everyday life.

Dialectical Behavior Therapy

Dialectical behavior therapy (DBT) was developed Marsha Linehan (1943–) for the treatment of borderline personality disorder. Recently, it has been modified and extended for use with other personality disorders as well as psychiatric disorders such as mood disorders, anxiety disorders, eating disorders, and substance use disorders. Four primary modes of treatment are noted in DBT: individual therapy, skills training in a group, telephone contact, and therapist consultation. The core strategies in DBT are "validation" and "problem solving." Attempts to facilitate change are surrounded by interventions that validate the client's behavior and responses in relation to the client's current life situation, and demonstrate an understanding of his or her difficulties and suffering. Problem solving focuses on the establishment of necessary skills. Mindfulness is an essential skill set in this approach. Learning to be more aware of feelings and internal states is learned through the core mindfulness "what" and "how" skills. The "what" skills of core mindfulness are to observe, describe, and participate in each moment of our lives. The "how" skills are to be nonjudgmental, one-mindful, and effective. The main objective in learning both sets of mindfulness skills is to develop awareness and insight in order to behave in ways that achieve the individual's treatment goals.

Mindfulness

Mindfulness is the moment-by-moment awareness of one's thoughts, feelings, sensations, and environment without evaluating or judging them.

Definitions

- **Consciousness** is the capability for awareness of one's own existence.
- **Meditation** is the concentrated focus on a sound, the breath, object, or attention itself to increase awareness of the present moment. Its purpose is reduce stress, promote relaxation, or increase spiritual growth.
- **Mindfulness practices** are intentional activities that foster living in the present moment and awareness that is nonjudgmental and accepting.

Description

Mindfulness is a type of consciousness. It is the ability to be aware (conscious) of the present moment with sustained attention. Mindfulness is an experience of awareness. Mindful awareness involves intimately knowing the present experience. As an individual recalls a past event or experience, the memory, or re-experiencing, actually exists in the present moment. That means that it is possible to be mindful of memories as they occur in the present moment. Fantasies and expectations about possible future occurrences are mental projections that occur in the present moment. So, it is possible to be mindful of fantasies and expectations about possible future occurrences. Also,

an individual can be mindful of his or her own patterns of thought and behavior. Mindfulness leads to an acceptance of the experience as it is. It increases the ability to intentionally make choices about one's own actions. Mindfulness itself is passive, but one can be mindful of one's own movement in the world. Such a mindful awareness may include knowledge of taking a deep and relaxing breath, washing dishes, or doing any other activity. Finally, mindfulness is a lifestyle of awareness. It is a way of being.

Mindful practices are the systematic rehearsal of intentionally attending to aspects of the present moment. Mindfulness practices, including mindfulness-based psychotherapies, enhance the awareness of experience. Those practicing mindfulness learn to pay attention to particular aspects of the present moment. Through practice it is possible to develop the capacity to stay mindful longer. Becoming more mindfully aware is a practice of altering the relationship between one's consciousness and the present moment. Mindful practice includes staying present with one's own moment-to-moment experience. As individuals' ability to "stay present" develops, they might learn to relax their concentration and witness the dynamic moment that is always changing in the here and now. Some forms of mindfulness-based practices aim to include positive affect such as love, compassion, or forgiveness into mindful awareness.

Development and Current Status

Mindfulness is commonly associated with Eastern meditative traditions, such as Buddhism or, less frequently, yoga. Yoga documented various mindfulness-based practices over 5,000 years ago. Similarly, Buddhism has a 2,500-year-old tradition of mindfulness-based practices. These Eastern "psychologies" have emphasized the cultivation of attention to one's own subjective experience prior to the formal establishment of modern science. However, mindfulness is a major aspect of almost all religions and spiritual practices. For example, ancient Greek philosophers documented discussions of principles commonly associated with mindfulness today. In other words, mindfulness is an aspect of human experience and does not belong to any particular ideology. Yet many of the most popular and effective mindful practices available today originate in the Buddhist tradition.

Thich Nhat Hanh (1926–), a Zen Buddhist monk and teacher, conducted a retreat on mindfulness in the United States. One of attendees was the American psychologist Jon Kabat-Zinn (1944–). In 1979, Kabat-Zinn adapted Hanh's teachings on mindfulness into his eight-week Mindfulness-Based Stress Reduction course. This course and its emphasis on mindfulness has since spread throughout North America and to other Western countries. Still, there are differences in Eastern and Western views of mindfulness. For example, conventional Western medicine defines health as the absence of pathology. In contrast, Tibetan-Buddhist medicine defines health as the perpetual presence of mindfulness. This tradition teaches that it is most difficult to stay mindful when one is attached to biases, longing for desire, or intensely angry. Many Eastern traditions agree that factors of calmness, tranquility, and balance assist the maintenance of a mindful awareness.

Unfortunately, the term "mindfulness" is misused or too broad in the West. Here, mindfulness can refer to meditation, love, kindness, compassion, or even insight. In Western psychology the term "acceptance" is often used synonymously with mindfulness. "One-pointed concentration" has become another common synonym of mindfulness. Western psychologies often use mindfulness-based practices as interventions designed to disrupt harmful patterns of thinking or behaving. The essence of these interventions is that mindfulness allows the client to witness his or her cognitive and behavioral processes. Such pure witnessing often leads to the insight and motivation required to utilize available resources to promote change.

Mindfulness-Based Psychotherapies

Mindfulness-based psychotherapies are forms of therapeutic counseling whose primary intention is to increase a client's capacity for an awareness or attention that is nonjudgmental, accepting, and engaged in experiencing the present moment.

Definitions

- **Common factors** are the similarities among theories of psychotherapy and the belief that these common factors are the real therapeutic factors.
- **Mindfulness** is an awareness or attention that is nonjudgmental, accepting, and engaged in experiencing the present moment.
- **Psychotherapy** is a psychological method for achieving desired changes in thinking, feeling, and behavior. It is also called therapeutic counseling.

Description

Mindfulness-based psychotherapies are therapeutic interventions centered in consciousness and awareness. Mindfulness-based psychotherapies operate on the theory that the subjective experience of human suffering will be reduced, or become more tolerable, through sustained attention on the present moment. Mindfulness and psychotherapy have different traditions and conceptualizations of the nature of human suffering. They also have different methods of intervening, promoting health, and achieving well-being. Mindfulness and psychotherapy do, however, have much in common. Mindfulness-based psychotherapies are composed of these commonalities. Mindfulness-based psychotherapies assist clients through the utilization of psychoeducational techniques and related interventions that enhance the awareness of experience. Therapists engage clients in mindfulness through instructional processes. Clients learn to pay attention to particular aspects of the present moment. As individuals' ability to "stay present" develops, they learn to relax their concentration and witness the dynamic moment that is always changing in the here and now. This relaxed and mindful witnessing of the present moment optimally occurs without bias or judgment. Some forms of mindfulness-based psychotherapies aim to include positive affects such as love, compassion, or forgiveness in the client's mindful awareness.

Development and Current Status

Mindfulness-based psychotherapies are often discussed in terms of Eastern meditative traditions, such as Buddhism or, less frequently, yoga. Yoga documented various mindfulness-based practices over 5,000 years ago. Similarly, Buddhism has a 2,500-year-old tradition of mindfulness-based practices. In Eastern traditions mental health is defined as a mind that has been cultivated through the practice of mindfulness. In 1979, the American psychologist Jon Kabat-Zinn (1944–) participated in a retreat on mindfulness given by Thich Nhat Hanh (1926–), a Zen Buddhist monk and teacher. Struck by the potential clinical value of mindfulness with medical and psychiatric conditions. Kabat-Zinn adapted Hanh's teachings on mindfulness into what was to become the first mindfulness-based psychotherapies. Four such common mindfulness-based psychotherapies are described here.

Mindfulness-based stress reduction. Mindfulness-based stress reduction (MBSR) was developed by Jon Kabat-Zinn (1944–) at the University of Massachusetts Medical Center for treatment of medical patients. Since then, MBSR has evolved into a common medical and psychological treatment for various health problems. MBSR is a structured group program lasting 2.5 hours and scheduled over 8 to 10 weeks. Each session covers specific exercises and topics that are examined within the context of mindfulness. These include

various forms of mindfulness meditation practice, mindful awareness during yoga postures, and mindfulness during stressful situations and social interactions. Because an individual's development of mindfulness requires regular and repeated practice, participants are expected to practice 45 minutes of homework assignments each day. This involves meditation and mindful yoga, and applying mindfulness to situations in everyday life.

Mindfulness-based cognitive therapy. Mindfulness-based cognitive therapy (MBCT) was developed by psychologists Zindel Segal (n.d.), Mark Williams (n.d.), and John Teasdale (n.d.). It is a form of MBSR that includes information about depression as well as cognitive therapy–based exercises linking thinking and its resulting impact on feeling. MBCT demonstrates how participants can best work with these thoughts and feelings when depression threatens to overwhelm them and how to recognize depressive moods that can bring on negative thought patterns. MBCT is an adjunctive or standalone form of treatment that emphasizes changing the awareness of, and relation to, thoughts, rather than changing thought content. It offers clients a different way of living with and experiencing emotional pain and distress. The assumption is that cultivating a detached attitude toward negative thinking provides one with the skills to prevent escalation of negative thinking at times of potential relapse. Clients engage in various formal meditation practices designed to increase moment-by-moment nonjudgmental awareness of physical sensations, thoughts, and feelings. Assigned homework includes practicing these exercises along with exercises designed to integrate application of awareness skills into daily life. Specific prevention strategies derived from traditional cognitive therapy methods are incorporated in the later weeks of the program.

Dialectical behavior therapy. Dialectical behavior therapy (DBT) was developed by Marsha Linehan (1943–) for the treatment of borderline personality disorder but has recently been modified and extended for use with other personality disorders as well as psychiatric disorders such as mood disorders, anxiety disorders, eating disorders, and substance use disorders. Four primary modes of treatment are noted in DBT: individual therapy, skills training in a group, telephone contact, and therapist consultation. The core strategies in DBT are "validation" and "problem solving." Attempts to facilitate change are surrounded by interventions that validate the client's behavior and responses in relation to the client's current life situation, and demonstrate an understanding of his or her difficulties and suffering. Problem solving focuses on the establishment of necessary skills. Mindfulness is an essential skill set in this approach. Learning to be more aware of feelings and internal states are learned through the core mindfulness "what" and "how" skills. The "what" skills of core mindfulness are to observe, describe, and participate in each moment of life. The "how" skills are to be nonjudgmental, one-mindful, and effective. The main objective in learning both sets of mindfulness skills is to develop awareness and insight in order to behave in ways that achieve the individual's treatment goals.

Acceptance and commitment therapy. Acceptance and commitment therapy (ACT) was developed by psychologist Steven C. Hayes (1948–). It is a form of therapy that uses mindfulness skills to develop psychological flexibility and helps the individual clarify and focus on life-giving behaviors. ACT is a directive and experiential form of therapy that does not view clients as damaged or sick. The aim of ACT is to experience life fully, which includes the full range of human experience, including pain. Acceptance of life as it is, without evaluation or attempts to change it, is a skill that is developed through mindfulness. Mindfulness is taught in a series of exercises in and out of treatment session. Being present means being in direct contact with the present moment and getting in touch with the observing self, the part that is aware of, but separate from, the thinking self. Mindfulness techniques are taught to experience the observing self—firsthand. This means awareness through the five senses, thoughts, and emotions. Opening up is the ability to detach from thoughts and making space for and dropping the struggle with painful feelings, and urges. Acceptance is the ability to allow what is to be as it is instead of fighting or avoiding it.

Mini-Mental State Examination

The mini-mental state examination (MMSE) is a brief psychological test to screen for cognitive impairment. It is also referred to as the Folson Mini-Mental Status Examination and the Folson.

Definitions

- **Alzheimer's disease** is a type of dementia that involves brain disease and progressive degradation of the brain, which involves memory loss and an eventual inability to think and function.
- **Cognitive** refers to mental activities associated with thinking, learning, and memory.
- **Delirium** is a state of mental confusion that develops quickly and can fluctuate in intensity.
- **Delusion** is a belief that is resistant to reason or contrary to actual fact.
- **Dementia** is a medical condition characterized by an overall decline in cognitive (intellectual) functioning, including memory loss, difficulties with language, simple calculations, planning, decision making, and motor skills.
- **Dissociation** is the splitting off of certain mental processes from conscious awareness characterized by feelings of unreality or confusion about one's identity.

Description

The mini-mental state examination is a brief test that screens for cognitive impairment in adults from 18 to 100 years of age. It consists of 11 questions that assess six areas of cognitive functioning: orientation, attention, immediate recall, short-term recall, language, and the capacity to follow simple verbal and written commands. It is particularly useful in identifying delirium and dementia. Besides detecting the severity of cognitive impairment, it can be used to measure decline in cognitive function, to follow the course of the individual's illness, and to monitor responses to treatment. It differs from the mental status exam, which includes questions about the mood and other abnormal experiences such as dissociation. Instead, the MMSE concentrates on the cognitive aspects of mental functioning.

The MMSE is divided into two sections, together taking from 10 to 15 minutes to administer. The first part requires vocal responses to the examiner's questions, which test the individual's orientation, memory, and attention. The second part requires the individual to follow verbal and written instructions, including copying a complex geometric figure. Administration time is approximately 10 minutes. A total score of 30 is possible. Scores greater than or equal to 25 points suggest normal cognitive functioning. Below this, scores can indicate severe (less than 9 points), moderate (10–20 points), or mild (21–24 points) cognitive impairment.

Developments and Current Status

The MMSE appeared in 1975 and was developed by psychiatrist Marshall Folstein and colleagues. It was designed to quickly assess elderly individuals whose capacity to sustain an optimum level of engagement with an examination was limited to a few minutes. While the second edition, MMSE-2, is similar to the first edition, it provides more precise evaluations of individuals with less severe forms of cognitive impairment, such as subcortical dementia. Norms were established from sample of over 1,500 individuals with Alzheimer's disease and subcortical dementia. Reliability and validity were also established. Recently, the MMSE was approved as

a measurement of an individual's ability to complete an advance directive or living will.

Minnesota Multiphasic Personality Inventory (MMPI)

The Minnesota Multiphasic Personality Inventory is a psychological test used to assess personality and psychopathology. It is also known as MMPI.

Definitions

- **Objective personality inventory** is a type of psychological test designed to assess personality traits and behavioral patterns using structured questions. It contrasts with projective personality tests which use unstructured stimuli such as the Rorschach Inkblot Test.
- **Personality** is an individual's unique consistent pattern of thinking, feeling, and acting.
- **Psychopathology** is the study of the conditions and processes of a mental disorder and dysfunctional behavior.
- **Scale** is a subset of test items from a multi-item test.
- **T-scores** are derived scores on a test which have a fixed mean (average) of 50 and a fixed standard deviation (deviation of a set of data from its mean).

Description

The Minnesota Multiphasic Personality Inventory (MMPI) is an objective personality inventory that assesses personality traits and psychopathology. It is primarily intended to test individuals presumed to have mental health or other clinical issues. The MMPI is currently administered in one of two forms. The first is MMPI-2, which has 567 true–false questions. The second is the newer MMPI-2-RF, which is considerably shorter with 338 items. The MMPI-2-RF takes only 30 to 50 minutes to complete. Nevertheless, the MMPI-2 is still the more widely used test because of its existing large research base and familiarity with psychologists. The MMPI-2 is intended for use with adults, 18 and up. A similar test, the MMPI-A, is intended for use with adolescents. The MMPI-2 has English and Spanish versions.

The MMPI-2 is designed with 10 clinical scales, which assess the major categories of abnormal human behavior. It also includes four validity scales, which assess the individuals' general test-taking attitude and truthfulness and accuracy in answering the questions. After the test is taken and scored, an interpretive report is constructed. Scores are converted to "T scores" on a scale ranging from 30 to 120. The normal range of T scores is from 50 to 65. Scores above 65 and those below 50 are considered clinically significant and may result in a psychiatric diagnosis.

A set of standard clinical profiles are used in interpreting the MMPI-2. They are called "codetypes," reflecting two scales where one has a high T score and the other is higher than the other. For example, a 2-3 codetype (both Scales 2 and 3 are significantly elevated) suggests significant depression, lowered activity levels, helplessness, and often physical complaints.

Developments and Current Status

The original MMPI was developed and published in 1939 by psychologist Starke R. Hathaway (1903–1984) and psychiatrist J.C. McKinley. They used the

empirical keying process to develop the MMPI. This involved writing several true–false statements, many of which were not psychiatric (psychological) in nature. These items were given to various groups (college students, medical and psychiatric inpatients, hospital visitors, etc.) and then analyzed to determine which items consistently differentiated psychiatric patients and diagnoses from others. These items were grouped into sets which were named clinical scales.

Several additions and changes to the measure have been made over time, including the addition of supplemental, validity, and other content scales to improve interpretability of the original clinical scales, changes in the number of items in the measure, and other adjustments. The MMPI became the MMPI-2 in 1989 as a result of a major restandardization effort to develop a new set of norms that were more representative of population characteristics 50 years after the original version. In 2003, the Restructured Clinical (RC) scales were added to the MMPI-2. It addressed psychometric flaws in the original clinical scales that complicated their interpretability. The MMPI-2-RF (Restructured Form) was published in 2008. Based on RC scales, it is a streamlined version that retains 338 of the original 567 items. Two new Validity Scales were added as well as new scales for somatic complaints. The MMPI-2-RF's scales now demonstrate increased validity compared to their MMPI-2 counterparts. Overall, the MMPI is the most widely used personality inventory tests in the world and has remained the gold standard in personality testing ever since its inception.

Minuchin, Salvador (1921–)

Salvador Minuchin is an Argentinian psychiatrist best known for his work in creating structural family therapy.

Description

Salvador Minuchin, MD, was born and raised in Argentina. Minuchin's family had emigrated from Russia, and Minuchin was the oldest of three siblings. Minuchin reported being influenced by his large extended family in Argentina as all of his activities growing up included family. As a Jewish male, Minuchin found himself compelled to head to Israel in 1948 after

Israel declared itself a state. Minuchin has long held an interest in social issues and decided to serve as a physician in the Israeli military before moving to the United States to study psychiatry.

During the 1950s, Minuchin went back to Israel where he worked with children from numerous countries. On his return to the United States, he began working with boys who were identified as juvenile delinquents. In his work he started looking into the impact of family dynamics and functioning as he determined that working solely with boys was insufficient. Guided by experience and practice, instead of theory, he learned and developed structural family therapy in the 1960s. Minuchin focused on the structure of the family as he feels the symptoms or dysfunction the boys expressed can be addressed by restructuring the family interactions and patterns.

Minuchin was fascinated by the social world in which families are connected and the impact of the relationships, structures, and boundaries as well as the impact. Because of the experience he had with the boys he was working with, he recognized a need for a focus on doing—as opposed to talking—and utilized techniques such as role playing and enactments. Minuchin felt it was important to study the family and join as a leader challenging their interactions and roles so that they can be modified to use healthier patterns.

Impact (Psychological Influence)

Stanley Minuchin is considered to be a large contributor to the development of family therapy as a whole, as well as helping create the branch of family therapy known as structural family therapy. He also created treatment methods for anorexia nervosa as he felt the eating disorder had its origin in dysfunction within the family unit. Minuchin has authored several books and journal articles focusing on working with families. In 1981, he established the Family Studies Institute in New York City, which was later renamed the Minuchin Center for the Family. This is currently a nonprofit training and consultation organization focused on structural family therapy. Salvador Minuchin retired in 1996.

Mixed Features

Mixed features is a specifier applied to major depression, mania, and hypomania.

Definitions

- **Antidepressants** are prescription drugs that are primarily used to treat depression and depressive disorders.
- **Bipolar disorder** is a mental health disorder characterized by a history of manic episodes (bipolar I disorder), mixed, or hypomanic episodes (bipolar II disorder), usually with one or more depressive episodes.
- **Depression** is an emotional state characterized by feelings of sadness, low self-esteem, guilt, or the reduced ability to enjoy life. It is not considered a disorder unless it significantly disrupts one's daily functioning.
- ***Diagnostic and Statistical Manual of Mental Disorders*** is the handbook mental health

professionals use to diagnose mental disorders. The current edition (fifth) is known as DSM-5, while the previous was known as the DSM-IV-TR.

- **Features** are prominent or conspicuous parts or characteristics. They are considered as an important part, quality, or ability, and something offered as a special attraction.
- **Hypomania** is a mental state similar to mania but less intense.
- **Major depressive disorder** is a mental disorder characterized by a depressed mood and other symptoms that interfere significantly with an individual's daily functioning. It is also referred to as clinical depression.
- **Mania** is a mental state of expansive, elated, or irritable mood with increased energy or activity.
- **Mixed episode** is a distinct period during which an individual experiences nearly daily fluctuations in mood to meet the diagnosis of manic episode and major depressive episode.
- **Specifiers** are extensions to a diagnosis that further clarifies the course, severity, or type of features of a disorder or illness.

Description

Mixed features is a new specifier included for certain diagnoses in *Diagnostic and Statistical Manual of Mental Disorders*, *Fifth Edition* (DSM-5). This specifier replaced "mixed episode" in the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision* (DSM-IV-TR). It can be applied to major depression, mania, or hypomania. The change from mixed episodes to mixed features reflects the way the behaviors intersect and will benefit diagnosis and treatment. There are several reasons this specifier was changed. In *DSM-IV-TR* a diagnosis of mixed episode required an individual to concurrently meet all criteria for an episode of major depression and mania.

Individuals rarely meet the full criteria of both episode types at the same time. The requirements for individuals to be diagnosed with the new specifier in the case of major depression are that individuals will require the presence of at least three hypomanic/manic symptoms. The symptoms cannot overlap with symptoms of major depression. For example, symptoms such as irritability, distractibility, indecisiveness, and insomnia are common to both moods and are not included in the criteria for mixed mood. The requirements for individuals to be diagnosed with the new specifier for hypomania or mania are that the presence of at least three symptoms of depression in combination with the episode of mania/hypomania must be present.

To the contrary, in individuals who are predominantly depressed with some hypomanic and manic symptoms, the mixed features specifier should also be considered. The hypomanic and manic symptoms may include decreased need for sleep, elevated mood, an increase in energy, and an inflated self-esteem. At least three of these symptoms must be present nearly every day during the two most recent weeks of the major depressive episode.

The mixed features specifier allows mental health professionals to more accurately diagnose individuals who may be suffering from concurrent symptoms of depression and hypomania/mania. This will help mental health professionals to provide more effective treatments for the individual's behaviors. This may be particularly important since many patients with mixed features may have a poor response to a particular medication or become less stable when taking other medications, such as antidepressants. As mental health professionals are able to more accurately identify these simultaneous behaviors, this may allow them to recognize individuals with a unipolar disorder who are at an increased risk of progression to another mental health disorder, such as bipolar disorder.

Mixed Receptive-Expressive Language Disorder (MRELD)

Mixed receptive-expressive language disorder (MRELD) is a deficit in the ability to both turn thoughts into speech and understand communication received from others.

Description

Difficulties in both understanding and using language to communicate with others are characteristic of people diagnosed with MRELD. It differs from expressive language disorder because those who are diagnosed with MRELD have difficulty processing verbal instruction from others. MRELD is present when persons have problems both with expressing themselves using verbal language and with understanding what people around them say. Expressive language disorder, MRELD may be either acquired or developmental. MRELD can be acquired, usually the result of an accident or illness that causes brain damage. In the developmental type, deficits are the result of some kind of genetic or neurological problem. Many times it is of unknown origin since the disorder is evident from a very early age. Studies suggest that developmental MRELD may occur in up to 5% of preschool children. It also seems to be more prevalent in boys than in girls.

Those who suffer from MRELD often find it difficult to express themselves in such a way that others can understand. Their meaning is often lost due to limited vocabulary, difficulty in using words they know, wrong use of words, and tense confusion. Visual learning in those with MRELD is often unaffected and can show normal development.

Since children with MRELD find it difficult to communicate as well as their peers, they may feel isolated and exhibit some behavior problems. Add to this the fact that they also have problems understanding what is being said to them by others and it becomes clear why they often do not respond to requests or why they respond inappropriately. Others may assume that they are being stubborn or deliberately uncooperative when they simply do not understand what is being said to them.

Diagnosis

Mixed receptive-expressive language disorder is now classified under the diagnosis of speech sound disorder. Standardized testing can help establish a diagnosis of MRELD. It is important to bear in mind that the ability to communicate may be much more complex for children growing up in bilingual households and testing must take that into account. It has been estimated that 30%–60% of children with MRELD also have attention-deficit disorder.

Prognosis for those with MRELD varies depending on the type. Many children with the developmental type of MRELD will improve substantially over time with help. For those with the acquired type of MRELD, the outcome is entirely dependent on the nature, location, and severity of the injuries.

Treatment

For children diagnosed with the developmental type of MRELD the key to success is early intervention. Speech-language therapy is one of the recommended treatments for children and adults with both types of MRELD. Any treatments should involve all the individual's caregivers and should focus on reading and language skills that can be reinforced during interaction with their peers.

Mobbing

Mobbing is harassment of a coworker by a group of others in a workplace to force the targeted individual out of the workplace.

Definitions

- **Bullying** is an act of repeated aggressive behavior in order to intentionally harm another individual.
- **Target** is the individual who is the recipient or victim of bullying or mobbing.

Description

Mobbing involves a "ganging up" by a coworker, boss, or subordinate who rallies others in a work organization to engage in "mob-like" behavior. The purpose is to cause injury—physical or mental distress or illness, and even expulsion from the organization. Because the organization ignores, condones, or even provokes the behavior, the target may be helpless against this "mob." Instead of understanding mobbing as a reversion to a more primitive aggressive state common to all animals, the individual who has been mobbed most often has received little to no support, has been isolated, and has constructed the meaning of the experience as that of shameful personal failure. The emotional, financial, career, and health consequences of both can be devastating for individual victims and their families. In a 2014 survey by the Workplace Bullying Institute, 27% of Americans have suffered abusive conduct at work, while another 21% have witnessed it. In addition, 72% say they are aware that such workplace abuse happens.

Bullying and mobbing are phenomena that are used interchangeably by many. While both share some similarities, there are some significant differences. In *Mobbing: Causes, Consequence and Solutions*, "mobbing" is defined as the nonsexual harassment of a coworker by a group of other members of an organization for the purpose of removing the targeted individual(s) from the organization or at least a particular unit of the organization. Mobbing involves individual, group, and organizational dynamics. It predictably results in humiliation, devaluation, discrediting, and degradation; loss of professional reputation; and, often, removal of the target from the organization through termination, extended medical leave, or quitting. The results of this typically protracted traumatizing experience are significant financial, career, health, and psychosocial losses or other negative consequences.

In contrast to mobbing, bullying is abusive and harmful behavior directed at a specific target or targets by a single offender. Behaviors may include name calling, verbal or written abuse, exclusion from activities, exclusion from social situations, physical abuse, or coercion. The bully may be a peer or supervisor, but others in the organization are not involved. Unlike mobbing, there is little or no direct organizational involvement in the abusive behavior. As a result, the consequences of bullying tend to be less severe than mobbing.

Workplace mobbing and bullying can be understood on a continuum ranging from health to severe abusiveness. On this continuum, bullying is a less severe and encompassing form of abusiveness than mobbing. In the United States the term "bullying" is used more often than mobbing, whereas in Europe, the term "mobbing" is preferred.

Modeling

Modeling is a form of teaching where individuals learn how to act or perform by observing other individuals.

Definition

- **Behavior** is an observable action demonstrated by a human or animal caused by either internal or external occurrences.

Description

Over time it has become clear that human beings have learned basic and advanced skills by studying and then imitating the behavior of others. Social learning, as modeling is often called, is the foundation of many therapeutic approaches, especially in behavior therapy. In a therapeutic setting, the therapist is often the one modeling desired behavior. More generally parents and peers also play an important role in demonstrating desired skills, behaviors, or activities. There are several important steps of modeling, all of which impact the effectiveness of treatment.

First, there is the observation of the behavior of the person modeling. If the individual is to learn something new, then paying close attention to what is being modeled is essential. Second, the learner must be able to retain a clear sense of what has been modeled. This may be dependent on learners understanding verbal cues and directions that they can turn into mental images and apply to themselves. This includes understanding the results of what has been modeled, which reinforces the motivation to learn. The last step involves the learner's ability to reproduce the modeled behavior, which will often include repetition and practice before it is mastered.

Modeling is used in a variety of situations, from teaching children with developmental disabilities to self-feed to the more complex social skills required for shy or withdrawn adolescents to interact with others effectively. A primary component of modeling is identifying what the learner is motivated by so that he or she can learn effectively. As a behavioral technique, modeling is a well-researched and effective therapeutic tool.

Development

The leading champion of the concept of modeling is the Canadian-born psychologist Albert Bandura. His studies of social learning have shown the process of how skills are learned by children through watching each other. These skills include sharing, aggression, cooperation, social interaction, and delayed gratification. One of his most famous studies involving Bobo dolls is taught in mainstream psychology as a clear example of social learning theory.

Bandura focuses social learning and social cognition theories on motivating factors and self-regulatory mechanisms that contribute to a person's behavior. This focus on cognition is what differentiates social cognitive theory from B.F. Skinner's more purely behavioral viewpoint. Bandura believed that people can control their behavior through a cognitive process of regulation based on awareness, judgment, and self-response.

Current Status

Recently researchers have demonstrated that modeling, like many other therapeutic approaches, is most effective when it is combined with other complementary procedures. For example, it has been found that a combination of modeling and guided participation is generally more effective than modeling alone in reducing fears during covert desensitization. Modeling is also often a major component in assertiveness training. Assertiveness training also includes other components such as learning communication skills, behavioral

rehearsal, feedback, and coaching. Other current areas that integrate modeling through social cognitive theory are neurolinguistic programming and counseling. The idea of self-regulation has been incorporated into social cognitive approaches and has been used with success in dealing with trauma, smoking, drinking, and gambling.

Mood

Mood is an individual's subjective emotional experience and expression.

Definitions

- **Affect** is an observable pattern of behavior that describes an individual's subjective emotional experience and expression.
- **Bipolar and related disorders** is a category of diagnosis characterized by an individual's alternating between states of extremely expansive moods and significant dysphoric moods. This category includes bipolar I and II, cyclothymic disorder, and substance/medication-induced bipolar disorder.
- **Depressive disorders** is a category of diagnosis characterized by significant and enduring dysphoric moods as a central symptom. This category includes disruptive mood dysregulation disorder, major depressive disorder, persistent depressive disorder, and premenstrual dysphoric disorder.
- **DSM-5** stands for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, which is a diagnostic system used by professionals to identify mental disorders with specific diagnostic criteria.
- **Emotion** is a feeling state of consciousness (awareness) in which an emotion like joy, sorrow, or fear is experienced, as distinguished from cognitive (mental) states of consciousness.
- **Subjective** is the description of one's personal and distinct experience of an outer or inner event. It contrasts with an objective or third-party description.

Description

Mood describes an individual's subjective emotional experience and expression. Common examples are anger, elation, anxiousness, and sadness. It contrasts with affect which is an objective description, whereas mood is a subjective experience. This subjective–objective perspective on mood and affect differs somewhat from the DSM-5 perspective. DSM-5 views mood as a sustained and pervasive emotional "climate." In contrast, affect is viewed in DSM-5 as emotional "weather," which fluctuates and is shorter in duration.

From either perspective, mood is an emotional experience. However, mood differs from emotion in that mood can lack an object. For instance, the emotion of anger may be aroused by an insult. But an angry mood can arise even when individuals do not know why or what elicited their anger.

The DSM-5 recognizes five common moods:

- **Dysphoric** describes sad or anxious mood.
- **Elevated** describes an increased perception of well-being or excitement.
- **Euthymic** describes a neutral mood.
- **Expansive** describes a magnified sense of self-importance.

- **Irritable** describes a state whereby an individual is perturbed or easily annoyed or angered.

Disturbances in mood are characteristic of mood disorders. It is important to note that an entire category of DSM-4 (former DSM edition) "mood disorders" has been re-categorized in the DSM-5. These diagnoses have been separated into two distinct categories: depressive disorders and bipolar and related disorders. Mood characteristics remain a central part of the diagnostic criteria for both of these new categories (American Psychiatric Association, 2013).

Mood Disorders

Mood disorders represent a category of mental disorders that all share the main symptom of mood disruptions.

Definitions

- **Affect** is a general and encompassing term that describes emotional experience and expression.
- **Antidepressant medications** are prescription drugs that are primarily used to treat depression and depressive disorders. They are known as antidepressants.
- **Antimanic medications** are prescription drugs that are primarily used to treat bipolar disorder (manic depression). They are also called antimanic and mood stabilizers.
- **Bipolar and related disorders** is a category of diagnosis characterized by an individual's alternating between states of extremely expansive moods and significant dysphoric moods. It includes bipolar I and II, cyclothymic disorder, and substance/medication-induced bipolar disorder.
- **Depressive disorders are** a category of diagnosis characterized by significant and enduring dysphoric moods as a central symptom. It includes disruptive mood dysregulation disorder, major depressive disorder, persistent depressive disorder, and premenstrual dysphoric disorder.
- **DSM** stands for the *Diagnostic and Statistical Manual of Mental Disorders*, which is a diagnostic system used by professionals to identify mental disorders with specific diagnostic criteria. It is currently in its fifth edition (DSM-5).
- **Emotion** is a perceived and brief state of feeling, often in response to a stimulus.
- **Mood** is an individual's subjective emotional experience and expression.
- **Psychotherapy** is a psychological method for achieving desired changes in thinking, feeling, and behavior. It is also called therapeutic counseling.
- **Psychotropic medications** are prescribed drugs that affect thinking, feeling, and behavior. They include antipsychotic, antianxiety, antidepressant, and antimanic drugs.

Description

Mood disorders is a category of mental disorders characterized by significant long-term, frequent, or severe disruptions in mood. This category of disorders includes bipolar disorder, cyclothymic disorder, disruptive mood dysregulation disorder, major depressive disorder, and persistent depressive disorder. Sometimes the mood disruptions are ongoing and long-term, as in the case of persistent depressive disorder. Other

times, mood may swing between extremes, as in the case of the bipolar disorders. Generally, these disorders tend to affect a higher proportion of women than men.

Mood disorders were a separate category in the DSM-4. However, in DSM-5 these disorders have been separated into two distinct categories: depressive disorders and bipolar and related disorders. Despite this change, mood characteristics remain the focus of the diagnostic criteria for both of these new categories. A short description of each of these disorders follows.

Bipolar disorder. Bipolar disorder is a mood disorder characterized by the experience of fluctuations between extremely heightened and lowered mood. Heightened moods are characterized by either hypomanic episodes or a manic episode. During these episodes, individuals feel excessively grand or expansive, experience less sleep, and are abnormally active. Individuals who experience hypomanic episodes are given the diagnosis of bipolar II disorder, while individuals who experience manic episodes are diagnosed with bipolar I disorder. Also, individuals with a bipolar I diagnosis may or may not experience a major depressive (extremely lowered mood) episode. In contrast, individuals with a bipolar II diagnosis have experiences at least one major depressive episode.

The occurrence of this disorder is estimated to be less than 1% of the population in the United States (American Psychiatric Association, 2013). This disorder affects slightly more women than men. The specific cause of this disorder is unknown, but it is believed that genetics, brain functions, and the environment play a role in the manifestation of this disorder. Treatment of this disorder most often includes a combination of psychotherapy and psychotropic medications. These include antimanic drugs like lithium, as well as some antidepressants. It is important to note that there are a number of other disorders listed in the category of bipolar disorders. See the entry Bipolar Disorder for more information.

Cyclothymic disorder. Cyclothymic disorder is a mood disorder characterized by alternating cycles of hypomanic and depressive periods. This disorder is similar to bipolar disorder but is less severe. Similarly, the hypomanic and depressive symptoms are also less pervasive and shorter in duration in cyclothymic disorder. The occurrence of this disorder is also similar to bipolar disorder, affecting less than 1% of the population (American Psychiatric Association, 2013). Also, the cause of the disorder is unknown but believed to be the interaction of genetics, brain function, and the individual's environment. Treatment for this disorder may include both psychotherapy and psychotropic medications similar to those employed in the treatment of bipolar disorder.

Disruptive mood dysregulation disorder. Disruptive mood dysregulation disorder is a mood disorder in children characterized by severe and frequent temper tantrums that interfere with daily functioning. These outbursts exceed the normal outbursts that occur in many children in that they occur more frequently, in more places, and more severe than in normal-functioning children of the same age. This diagnosis was developed in the newest revision of the DSM because it was believed that children were being overdiagnosed with bipolar disorder according to the previous criteria. The occurrence of this disorder is estimated to be between 2% and 5% (American Psychiatric Association, 2013). However, this is a newly formed diagnosis, so very little data is available so far. Treatment for this disorder may include psychotherapy and psychotropic medications.

Major depressive disorder. Also referred to as clinical depression, major depressive disorder is a mood disorder characterized by depressed mood that lasts at least two weeks. Individuals who suffer from major depressive disorder are likely to express one of the principal features of the disorder, feelings of significant sadness, emptiness, or bleakness. They may have lost or may be losing weight and be unable to experience normal sleep. Individuals with this disorder may also experience stunted physical movement and difficulty thinking. Some individuals who experience grief, such as loss of a loved one, will experience these symptoms. However, for this diagnosis to apply, the individual cannot be in the process of grief. The occurrence of this disorder is estimated to be 7% (American Psychiatric Association, 2013). This disorder affects females considerably more than males. The cause of this disorder is still debated. However, it is believed that chemical imbalances in the brain may play a role for many individuals. Also, a person's beliefs or predispositions may also affect manifestation. Treatment for this disorder may include psychotherapy and/or antidepressant

medications. This disorder as well as other depressive disorders commonly co-occur with both anxiety and substance abuse disorders.

Persistent depressive disorder. Persistent depressive disorder is a mood disorder characterized by a chronic depressed mood for at least two years. It contrasts with major depressive disorder, which requires only two weeks to be applicable. The depressed mood is less severe than major depressive disorder but is also characterized by symptoms of sadness, hopelessness, or meaninglessness. The occurrence of this disorder in the United States is estimated to be between .05% and 1.5% of the population (American Psychiatric Association, 2013). Treatment for this disorder may include psychotherapy and/or antidepressant or other psychotropic medications.

Moral Development, Stages of

First studied by psychologist Jean Piaget and then expanded upon in models proposed by Lawrence Kohlberg and Carol Gilligan, the stages of moral development describe a sequence of moral reasoning that people progress through from early childhood on into adulthood.

Definition

- **Heinz dilemma** is a frequently used case example presented to individuals to assess their moral reasoning and stage of moral development; this dilemma was readily used in foundational research on this topic conducted by psychologist Lawrence Kohlberg.

Description

Moral reasoning has been of interest to psychologists, sociologists, philosophers, theologians, and educators for centuries; however, the development of defined stages of moral development can mainly be attributed to the work of psychologists Jean Piaget, Lawrence Kohlberg, and Carol Gilligan. It is believed that moral reasoning provides the basis for ethical behavior. Moral development is not associated with chronological age; rather it unfolds as a result of each person's own thinking, reasoning, and experience. Assessing a person's stage of moral development, therefore, can provide valuable information about how the individual views the world and navigates through the obstacles he or she encounters, though moral thought is not necessarily indicative of moral action.

In order to determine one's present stage of moral development, an individual is proposed a moral dilemma and then asked to answer how he or she would react in that circumstance and to provide a rationale that justifies his or her choice. The assessor, usually a psychologist, then records the answers and categorizes the individual's responses. Kohlberg used a case example known as the "Heinz dilemma" regularly in his research. The story describes a husband's choice to steal an expensive and rare medication needed for his ailing wife from a pharmacist who refuses to sell the drug for less than market price.

Development

Credited as the first psychologist to investigate moral development in children, Swiss psychologist Jean

Piaget extended his research on how young children learn and process information and applied his theory to moral decision making, publishing *The Moral Judgment of the Child* in 1932. He proposed two distinct stages of moral development: *Stage 1: Heteronomous Morality* and *Stage 2: Autonomous Reality*. In Stage 1, younger children, not far along in their cognitive development, are typically obedient to authority, strictly adhere to rules, and are inflexible in their moral reasoning. However, in Stage 2, children progress both in their cognitive and moral development and begin to critically evaluate rules and apply them to varying situations and circumstances. At this stage, respect, cooperation, empathy, and perspective taking are more likely to occur.

Piaget laid the foundation for this research on moral thinking in children, but his follower, American psychologist Lawrence Kohlberg, later expanded on this area. Kohlberg set forth a series of distinct, constructive stages that individuals move through as they develop moral reasoning. Alignment with Piaget's ideas is evident in the first three stages. Progression through Kohlberg's stages is sequential, meaning that one cannot skip stages and it is extremely rare to move backward in them; each is necessary and the moral reasoning skills gained at each level allow for the individual to progress to the next. The six stages can be divided into three levels: *Preconventional, Conventional*, and *Postconventional*. The Preconventional level is comprised of Stage 1—*obedience and punishment*, whereby young children strictly adhere to rules in order to avoid punishment and/or please authority, and Stage 2—*individualism and moral reciprocity*, in which children start to separate their own wants, needs, and viewpoints from those in authority and begin to pursue their own interests. The *Conventional* level contains Stage 3—*mutual interpersonal expectations*, when the person shifts away from himself or herself and begins to value relationships and the interests of others, and Stage 4—*social system and conscience maintenance*, which describes a developmental shift where the individual learns to consider the viewpoint of the larger social system when making decisions. Finally, at the *Postconventional* level, an individual at Stage 5—*social contract and individual rights*, would be concerned with upholding the laws, ethics, and values of society of each and every person and safeguarding those over particular group interests, and at Stage 6—*universal ethical principles*, the individual's moral reasoning is defined by principles that would be agreed upon as just by the majority of people. At every stage in Kohlberg's model, the primary concern is justice.

A later model of moral development was proposed by one of Kohlberg's associates, Carol Gilligan in the 1980s. Gilligan noted that the majority of Kohlberg's study participants were male, essentially resulting in incomplete or biased conclusions. Given the high value they generally place on connections, interpersonal relationships, and caring for others, females may be categorized at a lower stage of moral development (Stage 3) than males when using Kohlberg's model. Gilligan suggested a revised set of stages that more accurately reflected the female orientation in moral development, incorporating what she referred to as the "ethic of caring." Her three-stage model includes Stage 1—*orientation to individual survival*, Stage 2—*goodness of self-sacrifice*, and Stage 3—*morality and nonviolence*. Gilligan's contribution to the assessment of moral reasoning is important in that she offered that moral development might not be a "one-size-fits-all" process.

Current Status and Results

Kohlberg's six-stage model of moral development is the most popular and widely referenced model to date. Proponents offer that these stages are derived from sound studies that produced qualitative and quantitative support, assessed both rater and inter-rater reliability, were extended to include longitudinal data, and resulted in consistent findings across cultures. Evidence suggests that an individual's stage of moral development is usually consistent with his or her behavior, though this is not universal. Piaget, Kohlberg, and Gilligan's work on assessing moral thought has been applied in counseling and educational settings. Parents, teachers, and authority figures can aid youngsters in their moral development by providing them with opportunities to practice problem-solving and conflict resolution skills by engaging in open discussion and role-playing activities.

In doing so, children learn to navigate through life in a democratic and accepting manner.

Moreno, Jacob (1889–1974)

Jacob Levy Moreno was an influential psychiatrist who pioneered the concept of group psychotherapy and the technique of psychodrama.

Description

Jacob Moreno (1889–1974) was born in Bucharest, Romania, but as a young child moved to Vienna, Austria, where he received his education. He graduated from medical school and began to practice psychiatry at the end of World War I. While a student he grew dissatisfied with the strict Freudian approach to the treatment of mental illness because of what he considered Freud's too narrow focus or concentration on a client's history.

He would later tell stories about confronting Freud himself about these limitations. He felt a more open and inclusive approach was needed to include creativity and humor as an important balance to help clients achieve psychological health. He would later assert that he was the psychiatrist who had brought laughter into psychiatry.

While in medical school Moreno had the experience of working in Viennese parks with children on theatrical productions where he learned the field of drama. Then, in 1913 he got the opportunity to facilitate a group session for prostitutes who were seeking to escape their profession. He was impressed that the members of the group seemed able to function as therapists to one another.

From these experiences in the community, Moreno came to feel that group psychotherapy and the use of element from drama could be more powerful and dynamic than individual talk therapy alone. Because of his own love of theater it was natural that he would develop ways to dramatize interpersonal relationships in psychotherapy. He noted that it was important for group work to involve elements of spontaneity and creativity. The group setting seemed to aid in letting clients lower emotional barriers and explore their issues in the context of a supportive environment.

The most famous therapeutic technique Moreno developed was psychodrama. In psychodrama a group of people in therapy concentrate on one person at a time who is called the protagonist. While the protagonist is encouraged to express and act out his or her feelings, the other members of the group respond with spontaneity. They use tools such as mirroring behavior or role reversal to help the protagonist become aware of their behaviors and feelings as well as its effects on them and others.

The Austrian psychiatric community remained closed off to such new and different ideas. In 1925, Moreno immigrated to New York City. The United States was far more accepting of Moreno's ideas and techniques. Moreno always felt that coming to America had given him a golden opportunity to experiment with and develop his ideas.

Soon after setting up his psychiatric practice in New York City, he got the opportunity to use group therapy in diverse settings. He did so in schools and prisons across the country, including in the famous Sing Sing prison in New York State. By 1934, he published his theories and the results he had achieved in a book titled *Who Shall Survive? Foundations of Sociometry, Group Psychotherapy, and Sociodrama*. The psychological community began to accept and use the terms he had coined through his work in group therapy and group psychotherapy. Moreno coined the words "sociatry" and "sociometry." He defined sociatry as healthy social

Jacob Levy Moreno was an influential psychiatrist who pioneered the concept of group psychotherapy and the technique of psychodrama. (Bill Peters/The Denver Post via Getty Images)

relationships. Sociometry meant the scientific study or measurement of relationships between individuals.

He founded a number of psychiatric journals and also taught at several universities. In 1942 his collaborator and wife, Zerka Toeman Moreno, joined Jacob in his work. He was considered the visionary and she became the therapist who showed how his theories could work in practical clinical settings.

Jacob Moreno died in 1974 and since then this wife has continued the work he founded. Zerka Moreno has been called "The Mother of Psychodrama" for her intimate collaboration with him in its development. She has not only continued his work through writing, but she has personally trained people all over the world in the understanding and application of psychodrama.

Impact (Psychological Influence)

Moreno was directly responsible for the American Psychiatric Association's recognition of group

psychotherapy as a credible and viable form of treatment. In addition to group psychotherapy, he is recognized as one of the developers of social network analysis, a branch of sociology that quantifies an individual's role in a group through analysis of connections to others. These are represented in various ways but the sociogram is one of the best known. Today there are still psychodrama certification programs and centers across the United States, and the approach remains popular in both group and individual therapy settings.

Motivation

Motivation is the process or desire that causes one to act on a certain behavior, the reason for the behavior be it biological, social, emotional, or cognitive in nature.

Description

Motivation is the force or drive used to explain the reasoning behind an organism's goal-oriented behavior. It is the underlying cause or stimulus that activates the organism's behavior (biological, emotional, social, or cognitive). The term is commonly used to describe why a person does what he or she does. An individual may be motivated by an impulse to minimize pain or discomfort, maximize pleasure, or optimize his or her well-being. Physical needs such as eating, sleeping, and sex are examples of stimuli that may motivate one to act. Motivation is made up of three major components: activation, persistence, and intensity. Activation refers to what initiates the behavior, persistence refers to maintaining the behavior with effort despite obstacles that may exist, and intensity describes the level of concentration and focus that one puts forth in that behavior.

There are two different types of motivation, extrinsic and intrinsic. "Extrinsic motivation" refers to behavior that is prompted by an outside force, something not within the individual. One may be extrinsically motivated by tangible rewards like food, money, power, awards, recognition, and social status. "Intrinsic motivation" refers to reasons for behavior that are within the person, those that provide internal benefits such as pride, self-worth, a sense of doing what's right, personal accomplishment, or self-satisfaction. A person who is intrinsically motivated acts out of enjoyment or fulfillment of the task itself rather than from external benefits. Motivation can be either conscious or unconscious as well, meaning people may be either aware or unaware of why they engage in certain behaviors.

A number of different theories have been developed to explain motivation, though no one theory is comprehensive. The Instinct Theory of Motivation posits that organisms behave in certain ways due to their evolutionary nature or biological makeup. Several examples of animal behavior can be attributed to instincts, which include hibernation, migration, and predatory reactions. Humans, however, also react instinctively. Attachment, love, anger, fear, protection, modesty, and shame are examples of human instincts. Psychologists William McDougall, Sigmund Freud, and William James wrote extensively about motivation based on human instincts. The principles of behaviorism and the work of B. F. Skinner provide the basis for the next theory, the Incentive Theory of Motivation. This theory suggests that people behave in response to external reinforcers and/or punishers. Drive Theory is another theory of motivation that proposes that people are prompted to act in order to reduce inner tensions derived from unmet needs, primarily physiological. The Arousal Theory maintains that people act in order to maintain an optimal level of arousal. When levels are too low they may engage in activities to increase arousal, and when

levels are too high one may engage in other behaviors meant to decrease arousal states. These states vary from individual to individual and by situation. Lastly, the Humanistic Theory or Motivation, based on Abraham Maslow's hierarchy of needs, suggests that human behavior also has a cognitive component. At lower levels one behaves to meet one's most basic, biological needs including food and shelter, while at higher levels one may act in order to fulfill a sense of love, esteem, or self-actualization. Later theories of motivation have been derived from these core models.

Current Status and Impact (Psychological Influence)

Extensive research has been conducted on motivation attempting to explain why human beings do what they do. Problematic behaviors including procrastination, obesity, substance abuse, and laziness can be explained by lack of motivation. Motivation principles have been applied toward improvements in the areas of education, business, performance, recreation, and relationships. Temporal Motivation Theory, introduced in the *Academy of Management Review* in 2006, is a recent approach at developing an integrative model to explain motivation. The journal article "The Nature of Procrastination," incorporating foundations of Temporal Motivation Theory, received the American Psychological Association's George A. Miller award for outstanding contribution to general science.

Motivational Interviewing

Motivational interviewing is a counseling strategy for helping individuals to discover and resolve their ambivalence to change. It is also referred to as MI.

Definitions

- **Ambivalence** is a form of a conflict between two courses of action (e.g., indulgence versus restraint) in which each course of action has perceived benefits and costs associated with it.
- **Client-centered counseling** is a counseling approach that requires the client to take an active role in his or her treatment while the therapist's role is nondirective and supportive. It is also known as person-centered, nondirective, or Rogerian therapy.
- **Directive counseling** is a counseling approach in which the therapist directs or leads the therapeutic process, while the client's role is to respond to and collaborate with the therapist.
- **Empathy** is the capacity to recognize and respond to another's expression of emotion.
- **Noncompliance** is the degree to which an individual correctly follows medical advice whether it is medication usage, diet, exercises, or therapy sessions. It is also known as nonadherence.
- **Nondirective counseling** is a counseling approach in which the therapist directly influences the course and direction of treatment.
- **Readiness for change** is the degree of preparedness of the conditions, attitudes, and resources needed for change to happen successfully. It is also referred to as stages of change.
- **Resistance** is a form of ambivalence. It is relational behavior that reflects a lack of collaboration. It includes arguing, interrupting, denying, missing or being late to appointments, and talking too much.

- **Self-efficacy** is an individual's self-evaluation of his or her own ability to accomplish a particular task or engage in a particular process.

Description

Motivational interviewing (MI) is a directive, client-centered counseling strategy to promote behavior change. The purpose of MI is to help clients to explore and resolve their ambivalence and to increase their readiness for change. Compared with nondirective counseling, it is more focused and goal directed. The examination and resolution of ambivalence is the main application of MI. Reducing noncompliance is another application of MI. With rates of noncompliance as high as 80%, it is a problem with significant consequences for patients and their families. MI has been found to be an effective strategy treatment in dealing with noncompliance issues.

The basic assumptions of MI—called the spirit of MI—are collaboration (working in partnership with the client), evocation (drawing out ideas and solutions from the client), and autonomy (decision making is left to the client). The essential features of MI are captured in the acronym (word formed from the first letters of other words) OARS. MI begins with a focused use of open-ended questions (O), providing affirmations (A) (favorable comments on a specific trait or strength of the person), listening reflectively (R), and summarizing (S) the client's responses. It also involves the following five strategies: avoid argumentation, express empathy, support self-efficacy, roll with resistance, and develop discrepancies.

Avoid argumentation. MI refrains from using argumentation to confront an individual's denial or minimize his or her substance-related difficulties. The reason is that argumentation and confrontation are counterproductive. They lead to an individual's feeling attacked and less motivated to participate in treatment, and dropout or relapse.

Express empathy. Expression of empathy is critical in MI because it facilitates change. When individuals feel that they are understood, they are more able to open up to their own experiences and share those experiences with others. They become more comfortable fully examining their ambivalence about change and less likely to defend ideas like their denial of problems.

Support self-efficacy. The individual's belief in his or her ability to accomplish a specific change also facilitates the change process. Accordingly, MI encourages individuals to remain motivated and supports their sense of self-efficacy.

Roll with resistance. Resistance is a signal that something is amiss in the relationship between two individuals. Instead of "fighting" against the individual's resistance, MI advocates "rolling with it." That means instead of challenging the individual's resistive comments, the counselor uses the individual's "momentum" to further explore the client's views. The result is that resistance is decreased since the individual is not reinforced for being resistive.

Develop discrepancy. When a discrepancy is perceived between where individuals are and where they want to be, change is fostered. MI helps individuals examine the discrepancies between their current behavior and future goals. When they perceive that their current behaviors are not leading toward some important future goal, individuals become increasingly motivated to make needed changes.

Developments and Current Status

MI was originally developed in the 1980s by the American psychologist William R. Miller (1943–) and Stephen Rollnick (1952–) to help clinicians address client's problematic alcohol and substance use issues. Essentially, MI is a strategy for helping clinicians change what they say so that clients can change what they do. Evidence continues to mount that MI is a clinically effective and economically efficient intervention guiding clients toward change across a wide spectrum of health-related behaviors ranging from substance treatment, diet, medication compliance, and risky sexual practices to self-management of chronic medical conditions.

Since the late 1980s MI was originally taught to those working in substance abuse programs. Since the late 1990s it has been taught and utilized in a variety of medical and psychotherapy settings. Currently, it is being taught to nurses, dieticians, and medical students to increase motivation for change and reduce noncompliance. Research and clinical experience indicate that

intensive training and follow-up supervision or coaching is essential in achieving proficiency in MI skills. For this reason, initial MI training is best learned over two sessions that involve direct coaching. Learners must practice skills between sessions and utilize a learning process that includes reflection, feedback, and additional skill practice. Additional coaching can promote further skill refinement.

Multicultural Counseling

"Multicultural counseling" (MC) refers to the integration of multicultural and culture-specific awareness, knowledge, and skills into counselor interactions, training, and practices.

Description

America is an increasingly diverse nation and is rapidly becoming a multiracial, multicultural, and multilingual society. Race, ethnicity, and culture have a powerful influence on individuals, groups, and communities. Multicultural counseling emphasizes the need for counselors to approach helping from the context of the personal culture of the client and to avoid allowing the counselor's own cultural values and biases to override that of the client.

Development

In 1992 psychologists Derald Wing Sue, Patricia Arredondo, and Roderick J. McDavis published "Multicultural Counseling Competencies and Standards: A Call to the Profession." The competencies set forth in this publication have served as the standard model for multicultural counseling. Multicultural counseling competencies (MCC) include counselor awareness of own assumptions, values, and biases; understanding the worldview of the culturally different client; and developing appropriate intervention strategies and techniques.

Competent multicultural counselors (MCs) are aware of their own cultural beliefs, biases, and values and how these influence their definitions of normality and how they impact the counseling process. Competent counselors are able to recognize the impact of oppression, racism, discrimination, and stereotyping while acknowledging their own racist attitudes, beliefs, and feelings. Competent MCs seek out educational, consultative, and training experiences to increase their MCC, and to actively seek a nonracist identity. They are able to contrast their own beliefs and attitude in a nonjudgmental fashion and are knowledgeable of the culture of their clients and how sociopolitical influences impact them. MCs are respectful of their client's spiritual and religious beliefs, family structures, and other values. They value bilingualism and appreciate cultural differences. Competent MCs are aware of institutional barriers that prevent minorities from using mental health services as well as relevant discriminatory practices in the community that impact the psychological welfare of their clients. Culturally skilled counselors are sensitive to language issues and are willing to have a translator or refer to an outside source. Competent MCs are familiar with relevant cultural research and expand their perspective of minorities by active involvement with minority individuals in their personal life.

Current Status

Since the establishment of MCC standards and practices in the 1990s, the mental health community, scholars, and educators have resoundingly embraced multicultural counseling. More recently multicultural counseling has led to the development of social justice counseling that incorporates social advocacy and activism to assist those impacted by systemic social inequalities and racism.

Multimodal Therapy

Multimodal therapy is a form of psychotherapy that attends to seven modalities of human functioning, whereas other approaches such as rational emotive behavioral therapy attend to only three modalities: cognitions, emotions, and behaviors.

Definitions

- **BASIC ID** is an acronym in multimodal therapy that represents the therapeutic modalities of Behavior, Affect, Sensation, Imagery, Cognition, Interpersonal relationships, and Drugs/Biological processes.
- **Bridging** is a therapeutic procedure in which the therapist identifies issues that the client wants to discuss but then gently guides the discussion into more productive areas.
- **Firing order** is the unique sequence of modalities that are activated when an individual experiences a symptom or conflict.
- **Psychotherapy** is a psychological method for achieving desired changes in thinking, feeling, and behavior. It is also called therapy and therapeutic counseling.
- **Second-Order BASIC ID** is a multimodal therapy technique for focus on a specific problem in the BASIC ID in order to flesh out more information; it can be useful for breaking impasses in therapy.
- **Social learning theory** is a psychological theory that combines classical conditioning, operant conditioning, and cognitive factors to explain the development, maintenance, and modification of behavior.
- **Structural Profile Inventory** is a 35-item questionnaire used in multimodal therapy to assess a client's functioning and concerns.
- **Technical eclecticism** is a type of psychotherapy integration in which techniques from various sources are used without adhering to the approaches from which they came.
- **Tracking** is a method for sequencing treatment procedures based on the firing order of the BASIC ID modalities.

Description

Multimodal therapy is the approach to psychotherapy based on the premise that individuals are biological beings that experience life in several dimensions or modalities. These include thinking, feeling, acting, sensing, imagining, and interacting. Individuals are affected in different ways and to different degrees by each dimension of their personality. Multimodal therapists believe that identifying and addressing these modalities are essential for successful psychotherapy.

In multimodal therapy the acronym "BASIC ID" refers to the seven dimensions of personality. In this form of therapy each dimension is considered. "B" stands for behavior, which is manifest in inappropriate actions, habits, gestures, or deficits. "A" represents affect, which is negative feelings or emotions. "S" stands for sensation, which is negative bodily sensations or symptoms such as pain, tension, sweating, or nausea. "I" represents imagery, which are negative images or mental pictures. "C" stands for cognition, which are negative attitudes, beliefs, or thoughts. The second "I" is for interpersonal relationships, specifically the ability to form and maintain healthy relationships. "D" stands for drugs and other biological

factors, like exercise and diet that affect the individual's health status, physical health, drug use, and other lifestyle choices.

Because of individual differences, some individuals are influenced by some modalities more than others. This means that certain individuals will respond to their problems by themselves, cognitively, some will seek support from others, interpersonally, and others will use drugs and other biological means to deal with problems, like smoking. An individual's response pattern is a combination of how these seven personality dimensions work together. Once the pattern is identified, psychological treatment can be used to focus on those specific dimensions.

The Structural Profile Inventory is a questionnaire helpful in identifying this pattern and dimensions. It is included in the Multimodal Life History Inventory, which is a 15-page survey which is assigned as homework for the client to fill out and bring to the next session. This detailed inventory gives a complete picture of the client's problems and style. It has six sections. They are general information, personal and social history, description of the presenting problems, expectations regarding therapy, modality analysis, and the structural profile. The Second-Order BASIC ID can also be useful in developing a complete multimodal assessment.

Based on this multimodal assessment, a treatment plan is devised and will include interventions in all relevant modalities. These interventions may include effective techniques from other psychotherapeutic approaches. For example, for a client who is able to functioning adequately but is passive and dependent in relating to others, the plan will likely include assertiveness training. For clients who are depressed that they are missing work, their treatment plan may be more detailed. For example, for staying in bed most of the day (B), activity schedule and meeting with friends is prescribed. For feelings of sadness and guilt (A), engaging in positive activities is recommended. For using alcohol to feel better (D), monitoring reducing alcohol use and increasing physical activity are prescribed.

Many therapists find that the interventions called bridging and tracking are very clinically useful. Often, tracking a client's firing order can lead to the abrupt cessation of symptoms. For example, take a client whose firing order is to first experience the sensation of tightness in the chest (S), followed by frightening images (I), to which they attach negative cognitions (C), leading to avoidant behavior (B). This S-I-C-B firing order is likely to require a different treatment strategy than for a client whose firing order is C-I-S-B. A useful intervention for the S-I-C-B sequence may be to instruct the client to override the chest tightness but taking three deep breaths. This simple strategy may be sufficient to deactivate the rest of sequence and reduce or eliminate symptoms.

Developments and Current Status

Arnold Lazarus (1932–2013) was a South African psychologist who immigrated to the United States. In 1958 he was the first to introduce the terms "behavior therapy" and "behavior therapist" into the professional literature. He made several contribution to behavior therapy and cognitive behavior therapy (CBT). Among these was developing multimodal therapy. While Lazarus retained the basic premises of CBT in his multimodal therapy, he believed that since personality is multidimensional, therapy should include these various modalities to be more effective.

Multimodal therapy originated with CBT, which combines cognitive therapy and behavioral therapy. It is also grounded in Social Learning Theory. Because of these theoretical influences, a basic premise of multimodal therapy is that most problems arise from deficient or faulty social learning. Another is that individuals respond to their perceived environment rather than to their actual environment. Lazarus contended that clients cannot change unless they have new experiences. Accordingly, multimodal therapists encourage their clients to "do different things and do things differently."

Lazarus was the one of the first to propose that therapists integrate techniques and methods from various approaches rather than utilize methods from a single approach. He viewed multimodal therapy as an example of this integration, and referred to it as technical eclecticism. In 1990 psychologist Donald Keat (1929–) applied the BASIC ID model to his work with children and adolescents. Because school and other environmental factors were not part of BASIC ID, Keat

expanded the model to BASIC IDEAL. Three letters were added to the acronym to represent education (E), adults in the child's life (A), and learning (L), school, and culture.

Multisystemic Therapy (MST)

Multisystemic therapy (MST) is a community-based treatment model for adolescents presenting with serious clinical problems who are at risk for out-of-home placement.

Description

Multisystemic therapy is a community-based intensive treatment model developed by psychologist Scott Henggeler to decrease crime, violence, and substance use. MST programs focus on youth, aged 12 through 17, who present with serious clinical problems such as violence, drug abuse, and other antisocial behaviors. MST is grounded in the belief that an individual's behavior can best be understood within the context of the multiple systems impacting them, including the person's home and family, school and teachers, neighborhood and friends. In-the-home services are an essential component of MST. Services are also offered at school and in the community.

MST programs are located in communities where juvenile justice, mental health, social welfare, schools, family courts and other service systems work with funders to provide trained MST providers. Two or three teams of three therapists are most often housed within existing mental health services locations. MST programs are primarily funded through Medicaid reimbursement, government sources, and managed care insurance providers.

The organization "MST Services" was established in 1996 and operates through the University of South Carolina. MST Services provides program start-up assistance, initial and ongoing clinical training, and program quality assurance support services. The organization also grants license agreements and program development to ongoing MST programs.

Development

MST was first developed in the 1970s by psychologist Scott Henggeler who found treating juveniles through traditional psychotherapy methods ineffective. Henggeler realized that treating individuals in an office setting far removed from where life was taking place for them would not promote change. He decided to take therapy to the clients in order to see how they lived and began to visit clients' homes, schools, and neighborhoods. He began to view behavior as multi-determined and interactive across these multiple systems. For treatment to be effective, interventions must address a broad range of contributing factors across individual, family, peer, school, and community systems.

Current Status

There are over 500 MST teams operating in 34 states, in 15 countries providing services to more than 23,000 youth a year. Clinical research has been conducted on MST, which has been found to be effective in the treatment of emotional and behavioral problems in juveniles. MST has also been found to improve family relations, increase school attendance, decrease time in out-of-home placements such as residential treatment centers and psychiatric inpatient units, and a decrease in repeat offensives.

Music, Influence of

Music is the artistic combination of vocal and instrumental sounds and rhythms to express and communicate emotion, content, and ideas.

Description

Music has been referred to as the universal language and is a significant part of a shared social experience, especially among adolescents and young adults. Popular music is a way of communicating shared values and meaning; experiencing and expressing emotions; and celebrating events, milestones, and relationships. Technological advances have increased the social nature of music, allowing quick access to shared music files, expressing opinions with others, and watching music videos, all in a cyber community accessed via smart phones.

Impact (Psychological Influence)

Personal identity with music and music video genres, performers, lyrics, and content has been a frequent focus of research. Musicians lead highly desirable lifestyles in the minds of adolescents, and performers communicate attitudes and values, knowingly and unknowingly, through their lyrics and performances.

Music is the artistic combination of vocal and instrumental sounds and rhythms to express and communicate emotion, content, and ideas. Music can be an important component of an individual's self-concept, and music can also be a valuable therapy tool for those dealing with emotional or psychological issues. (Marsia16/Dreamstime.com)

Individuals frequently adopt the clothing and attitudes of performers as a way of expressing personal identity and the kind of image they wish to convey. The influence of music content (lyrics) and musician lifestyle, as portrayed in video performances, on attitudes and behavior has received a great deal of focus. Studies have indicated that music with violent sexual content is associated with acceptance of violence against women. Music genres also have influence: heavy metal is associated with belief in the paranormal, rap music with aggression, and defiant rock music with rebelliousness. Academic success, drug use, aggressiveness, antisocial behaviors, and delinquent behaviors such as vandalism and substance use have all been associated with certain types of music that have violent and antisocial content such as rock, heavy metal, and rap. Although there is general agreement that music has some influence on adolescent attitudes and behavior, there is debate over the magnitude and duration of the impact. Given that music represents just one of a myriad of influences on adolescents, how deeply these behaviors are reinforced in the wider social community impacts the overall effects.

Music can reinforce, change, induce, and express a wide range of emotional states. Perhaps the best examples are found in the movie industry where music is powerfully used to induce fear by foreshadowing the presence of sinister characters (e.g., Darth Vader) or heroes (e.g., Superman), or set emotional tones such as fear (e.g., Jaws), and just about any other emotion.

Music is a powerful medium. It influences attitudes and behaviors, expresses emotion, communicates aspects of personal identity, and provides a means of social connection.

Music Therapy

Music therapy is a therapeutic approach that uses music as a means to accomplish individual treatment goals.

Description

Music therapy is a clinical approach to using music interventions with clients. Music is used as a specific intervention that must be used appropriately in order to offer a therapeutic benefit to the client. Music therapy can be used to explore physical, psychological, cognitive, and social functioning and impairments. The music is utilized as a form of expression and communication, which is important as not every client who comes for therapy is able to express fully using only spoken words.

While music is often enjoyed by many different people in nearly every culture, utilizing it as a therapeutic technique means using it with a distinct purpose to impact positive change for the individual. It consists of five key elements. The first is that it is prescribed and done with purpose and intent. It uses music or music activities such as singing, using instruments, writing music, listening to music, or discussing lyrics. It is provided by a trained professional in the field of music therapy. Music therapy has been well received among clients of all ages—from very young children to the elderly. This form of therapy often is focused on achieving a specific goal.

Music therapists create music with their clients, listen to music, and discuss it to help gain an understanding of the client, as well as to allow the client to express his or her thoughts and feelings. Music therapy can also be used in collaboration with other creative measures such as poetry, dance, movement, storytelling, and play.

Development and Current Status

Music therapy is considered to be beneficial for all ages, genders, ethnicities, and cultures. The key is that it must be individualized to the client. The music is then used to help drive the therapeutic process and provide another opportunity of expression for the client.

Music has long been viewed as having healing properties dating back to ancient times. Early

civilizations found music to help increase health and well-being. The role that music played in nurturing and healing is well documented. Currently, music is used in hospitals to help promote positive health.

Despite music being present throughout history, music as a therapy is still a relatively young field as a profession. Research is continually done to show it as a clinical and evidence-based practice.

Music therapists must pass a national examination after graduating from an approved music therapy program. The exam is given by the Certification Board for Music Therapists. The therapist is then able to become a registered, certified, or advanced certified music therapist. These credentials are required to provide this therapy.

There is a national organization, the American Music Therapy Association. This organization merged two preexisting organizations that were founded in 1950 and 1971. This association is committed to supporting its members and providing continuing education and training to its members.

N

Naltrexone (Naltrexone Hydrochloride)

Naltrexone is a prescription medication used in the treatment of opioid dependence and for alcohol dependence. It is also available under the trade names ReVia and Depade.

Definitions

- **Opiate antagonists** are medications that block opiate receptors, which in turn lead to a blocking of the opiates' effects.
- **Opiates** are a class of naturally derived drugs from opium.
- **Opioids** are synthetically derived drugs and are used as opiate substitutes. The term "opioid" is sometimes used to refer to both opiates and opioids. Both are referred to as narcotics.

Description

Naltrexone belongs to a class of medication known as opiate antagonists. It is used to prevent those who have been addicted to opiates from taking them again. Since it can cause sudden withdrawal symptoms, it should not be given to those who are actively using opiates, including methadone. Naltrexone is thought to work by preventing opiate effects, particularly feelings of well-being and pain relief. It also decreases the desire to take opiates. Naltrexone is also used in the treatment of alcohol dependence. It can help individuals drink less, stop drinking, and decreases the desire for alcohol.

Naltrexone is thought to work by blocking and reversing the physical effects of drugs such as Demerol, morphine, heroin, codeine, oxycodone, and other narcotics. Naltrexone works best when it is an integral part of a comprehensive treatment program that includes behavioral contracts, compliance monitoring, counseling, support, and lifestyle changes When given to those who have been successfully treated for opiate addiction, it helps prevent re-addiction by decreasing cravings and the euphoria associated with opiates. Even though naltrexone is not an alcohol antagonist, it can be an effective treatment for alcohol dependence. When it is an integral part of a comprehensive treatment program that includes behavioral contracts, counseling, support, and lifestyle changes, naltrexone helps decrease cravings, prevent relapse, or decrease the severity of relapse.

Precautions and Side Effects

Because naltrexone can cause liver damage, liver function tests should be done before starting this medication, and then monthly. Individuals should be free of all opiates for 7 to 10 days before starting naltrexone. This reduces the likelihood of opiate withdrawal in those whose bodies are not free from opiates. Individuals should be observed for opiate withdrawal immediately following the first dose of naltrexone. Individuals can mistakenly believe that talking naltrexone makes them immune from the effects of opiates. Actually, these individuals are more sensitive to the effects of opiates. Therefore, those taking naltrexone who continue to use opiates should be monitored for symptoms of opiate overdose. Naltrexone should not be confused with naloxone, which is used for opioid

overdose. Unless there are contraindications, Naltrexone can be used during pregnancy since its benefits outweigh the risks. It is not known whether this medication passes into breast milk.

The most common side effects of naltrexone are cramps, depression, dizziness, diarrhea, headache, irritability, nausea, insomnia, joint and muscle pain, rash, and vomiting. Sudden opiate withdrawal symptoms can occur within minutes after taking naltrexone. Withdrawal symptoms include abdominal cramps, diarrhea, muscle aches, bone pain, nausea and vomiting, anxiety, confusion, extreme sleepiness, visual hallucinations, and a runny nose.

Naltrexone does interact with some medications. Exercise caution in combining naltrexone and Antabuse since it may cause liver damage. Since naltrexone is an opiate antagonist, prescribed and over-the-counter medicines for cough, diarrhea, and pain that are opiate derivatives such as Imodium may no longer be effective.

Len Sperry, MD, PhD

Namenda (Memantine)

Namenda is a prescribed medication used to treat moderate to severe Alzheimer's disease. Its generic name is memantine.

Definitions

- **Alzheimer's disease** is a progressive neurodegenerative disease in which dementia results from the degeneration and death of brain cells because of plaques and neurofibrillary tangles.
- **Dementia** is a group of symptoms (syndrome) associated with a progressive loss of memory and other intellectual functions that interfere with one's ability to perform the tasks of daily life. It impairs memory and reasoning ability, causes disorientation, and alters personality.
- **Glutamate** is a chemical messenger in the brain that promotes learning and memory by binding to N-methyl-D-aspartate (NMDA) receptors. This triggers influx of calcium ions in the brain cells. Calcium ions are important for memory functions, but overstimulation of NMDA receptors by glutamate leads to large influx of calcium ions causing the death of brain cells.

Description

Namenda is used to treat moderate to severe confusion and memory problems associated with Alzheimer's disease. It is believed that high levels of glutamate lead to overstimulation of NMDA receptors, which may be linked to symptoms of Alzheimer's disease. Glutamate also is involved in the development and progression of this disease. Namenda appears to work by blocking these NMDA receptors. While Namenda can improve memory, awareness, and the ability to perform daily functions, it cannot cure Alzheimer's disease. Neither does it prevent or slow the degeneration of brain cells in this progressive neurological disease.

Precautions and Side Effects

Individuals with histories of kidney problems, severe urinary tract infections, and recent dietary change, such as switching from a high-protein diet to a vegetarian diet, should exercise caution in using this medication. Since Namenda can cause dizziness, it is advised to limit driving, using machinery, or engaging in tasks that require alertness until the individual is sure he or she can perform such activities safely. Before having surgery or a dental procedure, inform the surgeon or dentist about Namenda use. Since there may be risks associated with Namenda use during pregnancy and breast-feeding, the risks and benefits should be discussed with the physician.

Namenda is a relatively safe and well-tolerated medication. Side effects with its use are relatively rare. Those reported are body aches, dizziness, constipation, headache, agitation, falling, and accidental injury. Studies on Namenda have relatively few negative interaction with other drugs. Namenda is sometimes combined with Aricept, another Alzheimer's medication. There is some evidence that this "combination therapy" results in greater cognitive, functional, global, and behavioral benefits to those with moderate to severe Alzheimer's disease than in treatment with either medication alone.

Narcissistic Personality Disorder

Narcissistic personality disorder is a mental disorder characterized by a pattern of grandiosity, lack of empathy, and a need to be admired by others.

Definitions

- **Anger management** is a method of increasing temper control and the skill of remaining calm.
- **Cognitive restructuring** is a psychotherapy technique for identifying maladaptive (unhealthy) thoughts and changing them to present a more accurate view of a situation.
- ***Diagnostic and Statistical Manual of Mental Disorders*** is the handbook mental health professionals use to diagnose mental disorders. The current edition (fifth) is known as DSM-5.
- **Empathy** is the capacity to recognize and respond to another's expression of emotion.
- **Empathy training** is a method of increasing skills of recognizing and responding to another's expression of emotion.
- **Narcissistic injury** is the perceived threat to a narcissist's self-esteem or self-worth. It occurs after experiencing a defeat or criticism and results in feelings of emptiness, degradation, or humiliation.
- **Narcissistic rage** is a reaction to narcissistic injury and can range from aloofness to mild irritation or annoyance to serious outbursts, including violent attacks.
- **Personality disorder** is a long-standing pattern of maladaptive (problematic) behavior, thoughts, and emotions that deviates from the accepted norms of an individual's culture.
- **Psychotherapy** is a psychological method for achieving desired changes in thinking, feeling, and behavior. It is also called therapeutic counseling.

Description and Diagnosis

The narcissistic personality disorder is a personality disorder characterized by a pervasive pattern of grandiosity, specialness, unrealistic self-expectations, lack of empathy, and a constant need for admiration. They are the center of their worlds, showoffs, name droppers, and legends in their own minds. They are arrogant, high-handed, and superior, and expect and demand that others will show them deference and admiration. They tend to maintain superficial, and sometimes exploitative, interpersonal relationships. Typically, they are symptom-free and well functioning. But when their impossibly high expectations are not met or they experience narcissistic injury, they become quickly dissatisfied with others and may become depressed, develop somatic symptoms, or manifest narcissistic rage.

Narcissistic personality disorder is increasingly common today. It appears that a number of social trends have fueled this increase. In *The Culture of Narcissism*, historian Christopher Lasch (1932–1994) described some of these trends that he believed showed that Americans were becoming increasingly self-preoccupied and narcissistic. This change reflects a major shift in American values, which was from hard work, a high work ethic, and delayed gratification to pleasure, to a reduced work ethic, and to immediate gratification. More recently, an increasing focus on self-esteem, self-actualization, and entitlement has also fueled this shift to narcissism. Researchers such as Twenge and Campbell (2010) contend that a significant change in parenting has occurred in the past three decades. The shift has been from parents setting firm limits on their children toward letting children get and do whatever they wanted. This change is credited with significantly fueling the narcissism epidemic.

The cause of this disorder is not well understood. However, these individuals tend to have characteristic view of themselves, the world, and others, and a basic life strategy. These individuals tend to view themselves as special and unique, and entitled to rights and privileges whether they have earned them or not. They are likely to view the world as a banquet table to be sampled at will. They view others as owing them admiration and privilege. Their basic life strategy is to expect and demand specialness.

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, individuals can be diagnosed with this disorder if they exhibit a pervasive pattern of self-centeredness and grandiosity. More specifically, they have an exaggerated sense of their own abilities and achievements. They may have a constant need for attention, affirmation, and praise. Typically, they believe they are unique or special and should only associate with others of the same status. They are likely to have persistent fantasies about attaining success and power. These individuals can exploit others for personal gain. A sense of entitlement and the expectation of special treatment is common. They may appear to others as snobbish or arrogant. They appear to be incapable of showing empathy for others. In addition, they can be envious or think that others are envious of them (American Psychiatric Association, 2013).

Treatment

The clinical treatment of this disorder usually involves psychotherapy. In terms of treatment goals, a decision needs to be made as to whether the treatment is short term and crisis oriented or long term. Crisis-oriented psychotherapy usually focuses on reducing symptoms such as anxiety, depression, or somatic symptoms associated with the narcissistic injury. The goal of longer-term therapy involves the restructuring of personality. These goals include increasing empathy, decreasing narcissistic rage and cognitive distortions, and increasing the individual's capacity to mourn losses. Treatment methods and strategies include anger management, cognitive restructuring, and empathy training. When marital issues are involved, couples therapy has been shown to be a useful treatment modality. Medication may also be used when symptoms of depression or anxiety are prominent.

Narcolepsy

Narcolepsy is a sleep disorder involving daytime sleepiness and uncontrollable episodes of falling asleep during the day.

Definitions

- **Cataplexy** is a medical condition characterized by loss of muscle tone, resulting in slurred speech and complete weakness of most muscles. It can last for up to a few minutes.
- **Hypnagogic hallucination** is a vivid, dream-like sensation that occurs at or near the onset of sleep.
- **Hypocretin** is a brain chemical that regulates wakefulness and REM sleep and is associated with some symptoms of narcolepsy.
- **Parasomnias** are a group of sleep disorders characterized by abnormal events that occur during sleep, such as sleepwalking, talking, or limb movement.
- **Polysomnography** is a medical test that records aspects of sleep (REM, NREM, and number of arousals) as well as breathing patterns, heart rhythms, and limb movements.
- **REM sleep** is a stage in the normal sleep cycle characterized by rapid eye movement, dreaming, loss of reflexes, and increased brain activity. REM occurs about 90 minutes after the cycle begins. It is also known as rapid eye movement and REM sleep.
- **Sleep disorders** are a group of mental disorders characterized by disturbance in the amount and quality of sleep and that cause significant emotional distress or interfere with daily functioning.
- **Sleep paralysis** is a condition in which individuals are aware of the surroundings but are unable to move when they awaken from sleep.

Description and Diagnosis

Narcolepsy is a sleep disorder characterized by brief attacks of four symptoms: excessive sleep, cataplexy, sleep paralysis, and hypnagogic hallucinations. This disorder affects the control of sleep and wakefulness with uncontrollable episodes of falling asleep during the day. These episodes can occur at any time of the day. While REM normally occurs about 90 minutes into the sleep cycle, in narcolepsy REM sleep occurs almost immediately. It continues to occur periodically during the waking hours, which leads to the symptoms of narcolepsy.

Individuals experiencing this disorder experience uncontrollable sleepiness during daytime activities. The sudden paralysis associated with narcolepsy can lead to physical harm as they may uncontrollably collapse and fall down resulting in injury. As a result, they may be restricted from driving a car or operating machinery. This disorder commonly involves changes in mood and increased anxiety. Also, individuals with this disorder may engage in unintended eating as well as sudden paralysis or loss of muscle tone when they experience emotions like laughter, sadness, or intense anger. This disorder peaks between the ages of 15 and 25 and then again at 30 to 35. It is also quite rare (American Psychiatric Association, 2013).

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, individuals can be diagnosed with this disorder if they exhibit recurrent episodes of sudden, uncontrollable moments of sleep. These must occur at least three or more times per week over a period of three months. There must also be episodes of cataplexy, or hypocretin deficiency, or polysomnography data showing REM sleep segments are less than 15 minutes. Several specifiers can be made (American Psychiatric Association, 2013).

The cause of narcolepsy is not well understood. Genetics may play a role, and infections can contribute to the development of this disorder. It appears that hypocretin deficiencies may also be a factor. Those with narcolepsy, particularly those who experience cataplexy, can have low levels of it in their spinal fluid. Sleepwalking, teeth-grinding, and bed-wetting are comorbid conditions with narcolepsy. Left untreated, individuals may be at risk for injury to themselves or others as well as the loss of driver's license and ability to work (American Psychiatric Association, 2013).

Treatment

As with other sleep disorders, the treatment of narcolepsy may involve various methods, including lifestyle changes. A formal evaluation study should be

conducted by a sleep medicine specialist, which should include screening for hypocretin deficiency and a polysomnography. While there is no known cure for narcolepsy, the symptoms of narcolepsy can be effectively managed. Avoiding alcohol and heavy meals, while maintaining a regular sleep schedule with regular naps, has proven to be beneficial to many enduring narcolepsy. The National Sleep Foundation recommends counseling or psychotherapy since individuals with this disorder may experience depression and anxiety or feel alienated since the symptoms associated with this disorder are not widely understood. Therapy can also be helpful with the family and social relationship issues that they may also experience.

Narrative Therapy

Narrative therapy is a collaborative treatment approach that looks at the meaning associated with an individual's perception of his or her life and experiences.

Definitions

- **Externalization** is the process of separating an idea from oneself and looking at it from a different view.
- **Modernism** is the view that reasons and science provides accurate and objective knowledge about life and individuals.
- **Postmodern psychotherapy** is the name for psychotherapies that reject modernism and holds that reason and science are ideologies or beliefs that are constructed (created) by people, and that a goal of therapy is to deconstruct such beliefs.

Description

Narrative therapy is a collaborative approach to counseling. It identifies the individual as being the expert of his or her own life. It distinguishes the person's problems as being separate from his or her identity. It looks to understand the person's life from varying points, including his or her socioeconomic status, race, sexual identity, and sexual orientation.

Narrative theory looks at personal narratives or stories that externalize the problem from the person. Narrative therapists believe that the individual creates meaning from his or her own experiences, which in turn creates a person's stories or narratives. They identify how the person perceives himself or herself and his or her problems.

The primary goal of narrative therapy is for the clinician to work collaboratively with the client to rewrite his or her story. As opposed to interpreting events in a client's life, the therapist is more concerned with helping the client to identify new meaning. One way this is done is by having the client tell his or her story from different views. Questions are asked such as if another person is present in the narrative asking how that person viewed the situation and how it differed from the client. Another goal is to assist the client in realizing that he or she is not the problem but rather that the problem is the problem. This is done through externalizing the problem and joining the client in the externalization. To do this, the therapist may ask a client with depression as to how depression has taken over his or her life.

Other key aspects to narrative therapy include inviting significant people in the individual's life to see and hear the new narrative as well as document the

new narrative and knowledge that supports it. This is done through creating a landscape that helps identify the description of the new narrative.

Narrative therapy was developed by Michael White (1948–2008) and David Epston (1944–). They first published on the theory in 1990. The theory originated as a result of White's therapeutic work with young children. He focused on their language to understand their presenting concerns and used this as a tool to explore the problems.

Current Status

Narrative therapy is considered a postmodern psychotherapy. It is one of the more widely used contemporary therapy approaches in English-speaking countries, particularly among family therapists in Australia and the United States. There are criticisms that narrative therapy is based on opinion and lacks scientific or empirical evidence to support its effectiveness with clients.

National Institute of Mental Health (NIMH)

The National Institute of Mental Health (NIMH) is a federal agency whose goal is to prevent and cure mental illness.

Description

The NIMH is one of 27 components of the National Institutes of Health. The mission of the NIMH is to transform the understanding and treatment of mental illness through basic and clinical research and in so doing aims to pave the way for the prevention, recovery, and cure of the mental illness. As a governmental agency, it holds a great deal of authority and credibility on mental health issues.

According to data from the National Comorbidity Survey Replication, during any 12-month period, one in four American adults experience a mental disorder. About 60% of those with a mental disorder suffer moderate to serious symptoms. Despite this high percentage and public education efforts to increase understanding about mental disorders to reduce the stigma associated with them, many people still lack useful knowledge about these conditions. Clearly there is a need to provide reliable and easy-to-understand mental health information online. The NIMH produces such a resource through its website.

In terms of the NIMH's mission, it clearly states that those illnesses that comprise the greatest overall burden of suffering, and those that absorb the greatest amount of human and financial resources in providing care, are its current priorities. These include psychotic disorders, mood and anxiety disorders, and autism spectrum disorders.

Impact (Psychological Influence)

The institute's website contains a wealth of information on mental health disorders and health information by age, gender, and treatment. It is designed to help health consumers find authoritative, reliable information about the most common mental disorders. Highlights of the site include the ability to browse by certain topics and populations, as well as the availability of many publications for online viewing or downloading. Sections include Consumer Health, which offers a mix of educational content about common mental disorders and news based on recent scientific research related to the condition, and Educational Resources, which is targeted toward classroom instruction and provides teachers with lesson plans and manuals for students.

Also available on the website is an outreach program that aims to pave the way toward prevention, recovery, and cure by ensuring interventions, and information can be used by patients, families, health-care providers, and the wider community. Based on the Criteria for Assessing the Quality of Health Information on the Internet of the Health Summit Working Group, the institute's website is listed as one of the top 100 websites for consumer health.

In 2008, the NIMH, for research purposes, implemented a strategic plan to develop new ways of classifying mental disorders based on dimensions of observable behavior and neurobiological measures. It did this because research in psychopathology has increasingly identified problems with the current diagnostic system.

The institute's mission is to reduce the burden of suffering from mental disorders through research and education. One of its challenges is to target its research priorities in the face of budget constraints and cutbacks.

For the NIMH to continue fulfilling its vital public health mission, it fosters innovative thinking and ensures that a full array of novel scientific perspectives are used to further discover the evolving science of brain, behavior, and experience. In this way, it aims for breakthroughs in science to become breakthroughs for all people with mental illness.

"Nature of Love, The"

"The Nature of Love" is the scientific paper written by Harry Harlow about his experiments with monkeys.

Definition

- **Attachment** is the type of connection or relationship that creates a bond.

Description

"The Nature of Love" is a highly celebrated paper that drew a great deal of attention from those in the psychology field. It was written by Harry Harlow (1905–1981) as an interpretation of the research he had been conducting on monkeys. During that time, most experimentation was done with lab rats to help demonstrate the impact of environment. Harlow chose monkeys as he felt it gave a better understanding and connection to humans. This was a time in psychology controlled by the study of behavior, which was viewed to be driven by primary drives of hunger, pain, and sex—whereas love was viewed as secondary. Harlow refused to follow this line of thought and felt that love should not be considered only as a secondary drive. "The Nature of Love" identified and explained the research he conducted and his findings.

In studying the monkeys raised in the lab, he noticed with the lack of contact with a mother, they grew attached to cloth pads that were in their cages. When the pads were removed, even just to put new ones in, the monkeys became very distressed. Harlow

compared this attachment to what a human baby may experience with a specific pillow, blanket or toy. The monkeys who had no pads rarely survived past five days. Harlow began to question the impact of the pads on the monkeys. The traditional behaviorist view was that the monkeys loved mothers because they provided food since it was believed that hunger is a primary need. However, Harlow's experimentation began his questioning of if the love for a mother was based on more than simply meeting the hunger drive but rather also the need for warmth, love, and comfort.

Harlow created surrogate mothers with wood covered in soft cloth and one made of wire that provided milk. His experiment provided results that showed the preference was for the soft cloth mother. When provided with fear or danger, the monkeys also retreated to the soft cloth mother. He determined that the monkey just needed a basic mother figure. However, as adults the monkeys struggled with appropriate behavior and connections due to their lack of community with other monkeys.

"The Nature of Love" and Harlow's experiments provided insight into the intelligence and ability to experience emotions in animals. It also provided a foundation for changing how children's homes were run giving more insight into the need for emotional attachment.

Nature versus Nurture

"Nature versus nurture" describes the ongoing debate among professionals as to which factors contribute most to the variance among individual human traits, biological makeup/genetics or environment/socialization.

Definitions

- **Behaviorism** is a theory developed by psychologists John B. Watson and B.F. Skinner, which is concerned with measureable, observable behavior rather than inner processes such as thoughts and feelings.
- **Determinism** is a philosophical belief that every event that exists is inevitable, predetermined, and established by preceding events.
- **Empiricism** is a theory of thought that posits that human knowledge arises from experiencing and interacting with environmental stimuli.
- **Epigenesis** is a biological term that refers to the development or unfolding of a particular organism.
- **Heritability** is the degree of genetic or biological variation between people on any given trait.
- **Reductionism** is a philosophical and psychological theory that proposes that even the most complex systems can be understood by breaking them down to analyze their simplest parts.
- **Socialization** refers to the process by which an individual becomes acclimated to their current environmental and cultural surroundings by acting in ways that reflect the society's accepted norms, ideals, and behaviors.

Description

The debate over which factor has the largest impact on individual differences, nature (biology) or nurture (environment), is a long-standing one among psychologists, sociologists, biologists, and educators. Nature is viewed from an epigenetic or deterministic perspective, while nurture is based on the principles of behaviorism and empiricism. Those who argue that nature is the most salient factor in determining a person's unique makeup hold that innate qualities are predetermined or imbedded in one's genetic code. From this perspective an individual's physical and

behavioral traits are essentially hardwired and cannot be changed. Arguments in support of the nurture perspective propose that regardless of heredity, one's environment can significantly shape, mold, and change who a person becomes. Environmental factors include child-rearing and care practices, parenting styles, socialization, peer interactions, cultural influences, gender roles, societal norms, and prejudice.

English writer, philosopher, and scientist, Sir Francis Galton was the first to coin the phrase "nature versus nurture" back in the 1860s. A staunch eugenicist, Galton believed that selecting and reproducing the most desirable traits could improve the human race. He was strongly influenced by the work of his half-cousin, Charles Darwin, specifically his 1859 book *On the Origin of Species*, which discussed how the evolution of any organism was reliant on the process of natural selection. Alternatively, Enlightenment philosopher and empiricist John Locke favored the nurture view proposing that every human being enters the world as a "blank slate," or *tabula rasa*, with environmental factors playing the more significant role in the traits, characteristics, and qualities that a person develops. Scientists, theorists, writers, educators, and practitioners have since added to this ongoing debate over salience.

Research has been conducted on the effects of *heritability*, the degree of genetic variation between people on any given trait, by examining differences between siblings, adoptive siblings, and identical/fraternal twins. Studies have been completed on siblings from the same parents and different parents (adoptive situations) as well as situations where the siblings were reared together or apart. Findings were consistent in suggesting that genetics play a substantial role in determining the traits of personality and intelligence; however, much variation is seen among other characteristics, supporting the significance of environmental factors as well. Generalizability of the findings has been questioned however, as these studies were primarily conducted in Western cultures. Making the assumption of "equal environments" is a faulty one in that familial situations cannot be controlled for in a consistent and reliable manner.

Current Status and Impact (Psychological Influence)

Presently, the majority of scientists, researchers, and practitioners agree that the contribution of both nature and nurture factors influences individual differences. Neither nature nor nurture acts independently. Even with traits that are known to be highly heritable, such as personality and IQ, distinctions can vary according to certain environmental factors. Genetics and environment therefore must work together and remain in sync, in order for normal, productive development to occur.

The question of nature or nurture is important for scientists, doctors, mental health professionals, educators, and lay people to understand as most want answers when something goes array in terms of normal human development. The onset of certain diseases, genetic mutations, mental illnesses, learning disabilities, substance abuse issues, antisocial/conduct disorders, and other special needs are topics of continued interest. Whether there is a genetic cause or if socialization is the contributing factor, determining the why is often critical to care providers, loved ones, and the community at large.

Of recent concern is the issue of self-selecting or predetermining genetic characteristics such as sex/gender through medical intervention. Scientific experimentation with cloning raises additional medical and moral dilemmas. Intervening versus allowing nature to take its course remains a highly debated topic.

Neglect

Neglect is a type of harm that is inflicted on a person by another, typically on a child from an adult caregiver.

Description

Neglect involves refusal or failure by those responsible to provide food, shelter, health care, or protection for a vulnerable child or elder. It is the most common form of child maltreatment. Sadly, it often goes unreported and receives less attention than other forms of child maltreatment such as that of physical abuse. The problem is that with physical abuse there is conclusive evidence such as bruises or broken bones that support the claims made by a child.

Neglect is often difficult to prove, leaving the person suffering without help or assistance. The definition of neglect typically varies from state to state, and it is therefore important to check state laws and refer to the child protective agency specific to that state for clear information.

With different definitions across states and trouble proving neglect, it has been troublesome to study it. Neglect is typically broken down to mild, moderate, or severe. Mild neglect may be something such as parents not putting a child in their car seat. This would call for intervention but not necessarily to the level of involving government child welfare agencies. The severity of the neglect is based on how much harm or risk there is, as well as how regularly the neglect occurs.

Along with the severity, there are different types of neglect. Physical neglect tends to be the most recognized as this would include abandoning the child, such as leaving young children unattended in home or even leaving them for extended periods and not arranging reasonable care for them. Expulsion is where the parent or guardian refuses custody of the child without arranging for care. Under the category of physical neglect is also nutritional neglect where the child is undernourished; clothing neglect is where the child lacks seasonal appropriate clothes, such as shoes in the winter, and there is other physical neglect such as driving while intoxicated with the child in the vehicle.

Medical neglect can at times be controversial. This form of neglect includes the denial or delay of health care when the guardian does not allow needed health care or does not seek the care in a timely manner. Another form of neglect is inadequate supervision, where this child is left without an appropriate caregiver for several hours, or environmental neglect, where the child is exposed to potentially hazardous materials.

Emotional neglect tends to be a difficult form to prove as it focuses on the emotional health and nurturing provided to the child. In comparison, educational neglect can be fairly simple to prove since it focuses on the failure of a child being enrolled in school, attention to special education needs, or chronic permitted absence from school.

Despite the physical signs of neglect, the impact is detrimental to a child. The potential longlasting effects of neglect are harmful and can impact health, physical development, intellectual development, emotional development, social development, and behavioral development. The effects can vary based on the child's age, the frequency, duration, type of neglect, and the relationship with the caregiver as well as resiliency or protective factors.

It is important to mention that neglect impacts the elderly as they are considered to be a vulnerable population. The first reports of elder abuse and neglect surfaced in medical literature a little more than 30 years ago, making this a relatively new area of study. The same types of neglect occur, as do the struggles with identification. Those who are neglected tend to die earlier than their peers. Elder neglect often happens in the family home as opposed to in nursing homes as is commonly thought. In the elderly population, neglect may be seen as a lack of medical aid, such as glasses, a lack of assistance in walking, or a lack of adequate food, or confinement to a bed for long periods of time without any assistance.

Neo-Freudian Psychotherapies

Neo-Freudian psychotherapies are psychotherapy approaches that extend the theory and practice of psychoanalysis.

Definitions

- **Ambivalent movement** is when an individual moves in several directions in a social context: moving against others, moving away from others, and moving toward others.
- **Defense mechanisms** are a psychodynamic understanding of behaviors and thoughts that individuals engage in to protect themselves or to reduce anxiety.
- **Feminist psychology** is a psychological treatment that emphasizes social structures and gender. This approach focuses on the principles and values of feminism.
- **Moving against others** is when an individual resists a situation and becomes aggressive, revengeful, and exploitive toward others, to seek power or to seek recognition.
- **Moving away from others** is when an individual withdraws from others to protect himself or herself from perceived harm or criticism.
- **Moving toward others** is when an individual accepts a situation and becomes pleasing and approval seeking from others to feel loved, seek attention, or be helpful.
- **Neopsychoanalyse** is the first psychological approach to depart from Freud's classical psychodynamic approach by including social and cultural factors.
- **Psychoanalysis** is a theory of human behavior and form of psychotherapy that focuses on conflicts and compromises between the unconscious (internal) and the conscious mind. It was developed by Sigmund Freud.
- **Psychodynamic** refers to a way of explaining thoughts, feelings, and behaviors as the manifestation of unconscious (inner) drives and processes.
- **Psychosexual stages** are sexual developmental stages identified by Sigmund Freud that lead to the development of a healthy or unhealthy personality.
- **Psychotherapy** is a psychological method for achieving desired changes in thinking, feeling, and behavior. It is also called therapy and therapeutic counseling.

Description

Neo-Freudian psychotherapy approaches are therapeutic approaches that were originally influenced by Sigmund Freud's theories. These approaches went beyond Freud's biological and unconscious explanation of human behavior, and added sociological and cultural factors. Several examples of Neo-Freudian approaches include Individual Psychology, Jungian psychology, and ego psychology. For example, Alfred Adler (1870–1937) believed that individuals seek belonging and significance in the world. This social and cultural conceptualization of human suffering extended beyond Freud's psychodynamic explanation which emphasized an individual's biology, unconscious mind, libido, and psychosexual development. While Freud's theory provided a foundation for psychology, Neo-Freudian psychotherapy approaches added new explanations and understandings of human behavior, which led to corresponding treatment interventions.

Alfred Adler was the first to explore and develop a comprehensive social theory that went beyond Freud's classical psychodynamic conceptualization. Another Neo-Freudian approach that augmented Freud's theory is called neopsychoanalyse and was created in 1945 by the German psychiatrist Harald Schultz-Hencke (1892–1953). Other known Neo-Freudian theorists include Carl Jung (1875–1961),

Carl Rogers (1902–1987), Erik Erikson (1902–1994), Harry Stack Sullivan (1892–1949), and Karen Horney (1885–1952). After Adler's death, Horney created feminist psychology and also suggested that individuals deal with anxiety in a social context; they move in the various directions: (1) move away from others, (2) move toward others, (3) move against others, and (4) move ambivalently. Horney's conceptualization of movement provided a comprehensive understanding and explanation of human behavior that paved the way for different theoretical explanations of human behavior. Neo-Freudian psychotherapy approaches advanced the field of psychology by furthering the theories of Sigmund Freud.

Neuroleptic Malignant Syndrome (NMS)

Neuroleptic malignant syndrome is a rare but potentially fatal condition in individuals taking neuroleptic medications. It is also known as NMS.

Definitions

- **Antagonist** is a substance that inhibits or interferes with the physiological action of another.
- **Benzodiazepines** are a class of drugs that slow the nervous system and are prescribed to relieve nervousness and tension, induce sleep, and treat other symptoms. They are highly addictive.
- **Delusional disorder** is a mental disorder characterized by delusions, which are fixed or false beliefs that persist despite contrary evidence.
- **Dopamine** is the chemical messenger in the brain responsible for the coordinating of movement of voluntary muscle groups. It also regulates attention, pleasure, and coping with stress.
- **DSM-5** stands for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, which is a diagnostic system used by professionals to identify mental disorders with specific diagnostic criteria.
- **Hypothermia** is a condition in which the body's core temperature falls below what is required for normal body functions.
- **Movement disorders** are a group of neurological conditions that cause an individual to have abnormal involuntary or voluntary movements. These movements may be slow or reduced.
- **Neuroleptic medications** are a class of drugs used to treat schizophrenia, mania, and other types of mental disorders. They are also referred to as antipsychotic medications.
- **Parkinson's disease** is a disease of the nervous system that causes tremor, rigidity, slowness of movement, and unstable posture.
- **Receptor** is a molecule that responds to and receives a neurotransmitter or other substance.
- **Schizophrenia** is a chronic mental disorder that affects behavior, thinking, and emotion, which make distinguishing between real and unreal experiences difficult. Symptoms include hallucinations, delusions, thought and communication disturbances, and withdrawal from others.

Description

Neuroleptic malignant syndrome (NMS) is a complication of therapy for individuals who use antipsychotic (neuroleptic) medications. NMS is associated with dopamine, which is a neurotransmitter that sends messages between nerve cells and the brain, and helps

regulate emotion, mood, motivation, and movement. Antipsychotic medications act as antagonists and prevent dopamine from attaching to receptors. Often, blocking the receptors can result in difficulty regulating body temperature and movement disorders. The onset of symptoms of NMS usually begins within 24 hours to 30 days after an individual has begun taking an antipsychotic medication or when an individual is prescribed a higher dose of the antipsychotic medication (American Psychiatric Association, 2013).

NMS is most commonly associated with the use of first-generation (older) antipsychotic medications such as Haldol and Thorazine. Newer antipsychotic medications such as Risperdal and Clozaril have also been linked to symptoms of NMS, although they pose less of a risk. NMS is easily recognizable due to its onset, presentation, progression, and outcome. For example, hypothermia on at least two occasions with profuse sweating is one recognizable symptom of NMS. This particular feature of NMS sets it apart from other neurological side effects of antipsychotic medications. NMS is characterized by motor dysfunction, changes in consciousness, agitation, exhaustion, dehydration, difficulty breathing, inability to regulate body pressure, muscle rigidity, and fever. It is also associated with symptoms such as tremors; loss or impairment of voluntary activity; uncontrollable and repetitive twisting movements; sudden twitching or jerking of a muscle or group of muscles; weak or non-movement of the muscles of the face, mouth, and respiratory system; and difficulty swallowing. NMS often occurs in individuals who take antipsychotic medications to treat schizophrenia, mania, delusional disorder, and other types of mental illnesses. Individuals with Parkinson's disease who have had their medications abruptly withdrawn also experience symptoms of NMS. NMS has decreased over the years due to changes in prescribing first-generation antipsychotics to individuals. However, NMS is still a danger to individuals who are still being prescribed other antipsychotic medications.

The precise cause of NMS is unknown. One potential risk factor associated with NMS includes genetic factors and is known to run in families. Genetic factors have also been associated with NMS (American Psychiatric Association, 2013). For example, changes in certain genes can affect how antipsychotic medications are absorbed in the liver, and this may result in higher blood concentrations.

Treatment

Treatment for NMS usually begins with discontinuation of the medication that is believed to be causing the problem. Once the medication is stopped, symptoms will usually improve within two weeks. Benzodiazepines and muscle relaxants are usually prescribed during this two-week period to help control symptoms. Typically, after a two-week period, a physician will prescribe a newer (atypical) generation of an antipsychotic medication as it poses a lower risk of NMS. Supportive care and proper nutrition are also helpful forms of treatment.

Neurontin (Gabapentin)

Neurontin is a prescribed medication used to treat seizures and nerve pain caused by the herpes virus. Its generic name is gabapentin.

Definitions

- **Antiseizure medications** are prescription drugs used to treat epilepsy (seizures) as well as burning, stabbing, and shooting pain. It is also called anticonvulsant medications.

- **Diabetic neuropathy** is a medical condition in which the nerve endings, usually in the legs and feet, become less sensitive. This leads to a lack of feeling in the leg or foot and the increased likelihood of infection and other serious problems.
- **Epilepsy** is a medical condition when seizures reoccur. It is also known as seizure disorder.
- **Fibromyalgia** is a medical condition characterized by widespread, unexplained pain and sensitivity to pressure or touch.
- **Multiple sclerosis** is a disease characterized by patches of hardened tissue in the brain or spinal cord, paralysis, and/or muscle tremors.
- **Neuralgia** refers to pain that extends along the course of a nerve.
- **Seizures** are episodes of abnormal electrical activity in the brain that results in changes in the brain and in behavior.
- **Shingles** is a painful skin rash caused by the varicella zoster virus, the same virus that causes chicken pox.

Description

Neurontin is an antiseizure medication that is used for preventing seizures and for treating neuralgia associated with shingles. Neurontin is often used in combination with other anticonvulsants to manage partial seizures with or without generalization in individuals over the age of 12. Sometimes it is used to treat partial seizures in children as young as three years of age. Other uses include treating multiple sclerosis, neuralgia, restless leg syndrome, alcohol withdrawal, cocaine withdrawal, headaches, diabetic neuropathy, and fibromyalgia. The generic version of gabapentin is similar in structure to the chemical messenger (neurotransmitter), gamma aminobutyric acid (GABA). It believed that this similarity is related to Neurontin's mechanism of action, which is to increase GABA in the brain and reduce excited or overstimulated nerve cells which result in seizure activity and pain.

Precautions and Side Effects

Women who are or wish to become pregnant require a careful assessment of the risks and benefits of Neurontin. Women who are breast-feeding and those with kidney problems also need to talk with their physician about the use of this medication. Suddenly discontinuing Neurontin can increase the risk of seizures. If the medication needs to be discontinued, it should be reduced gradually over a week. Using Neurontin can cause problem with driving and operating machinery. The use of alcohol should be avoided while taking Neurontin. The use of this medication has resulted in suicidal thoughts and behavior, so any changes in mood or behavior should be reported to the physician.

A number of side effects can occur when beginning Neurontin. These include blurred or double vision, muscle weakness or pain, trembling or shaking, increased fatigue or weakness, and unsteadiness. Less common side effects include back pain, constipation, decreased sexual drive, diarrhea, dry mouth, frequent urination, headache, indigestion, low blood pressure, nausea, ringing in the ears, runny nose, slurred speech, difficulty thinking and sleeping, weight gain, twitching, nausea and/or vomiting, weakness, depression, irritability, and decreased memory. Rare side effects include pain in the lower back or side, difficulty urinating, fever and/or chills, cough, or hoarseness. Usually, these side effects go away on their own. Antacids can decrease Neurontin levels in the blood and should be used at least two hours before taking Neurontin.

Neuropsychiatry

Neuropsychiatry is the field of medicine that focuses on mental disorders related to the brain and nervous system. It is also called behavioral neurology.

Definitions

- **Brain** is the organ at the center of the nervous system. It is responsible for a wide range of functions, including learning, movement, and regulation of the body.
- **Depressive disorders** are a group of mental disorders characterized by a sad or irritable mood and cognitive and physical changes that significantly disrupt the individual's daily functioning.
- **Neurocognitive disorders** are a group of disorders in DSM-5 that are characterized by a decline from a previous level of neurocognitive (mental) function.
- **Parkinson's disease** is a disease of the nervous system that causes tremor, rigidity, slowness of movement, and unstable posture. When cognitive impairment is also present, this disease can is known as Neurocognitive Disorder Due to Parkinson's Disease in DSM-5.
- **Psychiatry** is the medical specialty that focuses on the diagnosis and treatment of mental and emotional disorders with biological and psychological methods.
- **Psychotherapy** is a psychological method for achieving desired changes in thinking, feeling, and behavior. It is also called therapeutic counseling.
- **Schizophrenia** is a chronic mental disorder that affects behavior, thinking, and emotion, which make distinguishing between real and unreal experiences difficult. Symptoms include hallucinations, delusions, thought and communication disturbances, and withdrawal from others.
- **SSRI** stands for selective serotonin reuptake inhibitors. They are a class of antidepressant medications that work by blocking the reabsorption of serotonin in nerve cells and raising its level in the brain resulting in symptom reduction.
- **Stroke** is damage or death of brain cells due to insufficient blood flow. There are four types of strokes.
- **Traumatic brain injury** is an insult or injury to the brain from an external force. In DSM-5, this disorder is known as Neurocognitive Disorder Due to Traumatic Brain Injury.

Description

Neuropsychiatry is an area of medical practice and a subspecialty of psychiatry. It focuses on mental disorders related to the brain and nervous system and is also called behavioral neurology. This discipline combines neurology (study of the brain and nervous system) and psychiatry. In the past, neurology and psychiatry were seen as distinct areas. This was because most individuals considered the mind and the brain to be two separate entities. Psychiatrists traditionally treated mental disorders such as schizophrenia, anxiety, and depression. These were believed to be problems in the mind (mental). Since they could not be seen or measured, it was assumed that these problems were caused by factors outside of the physical body. These factors included personality traits and unhealthy family environments. Treatments for these disorders involved using psychotherapy to address emotions, thoughts, and behaviors. Neurocognitive disorders related to Parkinson's disease, stroke, and traumatic brain injury were more clearly viewed as physical problems involving the brain. Treatments for these disorders involved medical procedures and medication. They were considered to be different from psychological disorders and were commonly treated by neurologists.

This division changed with advances in neuroscience in the second half of the 20th century. New technologies like magnetic resonance imaging and positron emission tomography revealed a biological (neurological) basis for many mental disorders. This includes those disorders that were previously

considered to be caused by factors outside the individual. For example, research has shown that there are abnormalities in the brain functioning of individuals with schizophrenia. In addition, medications like SSRIs were found to be effective in the treatment of depression. There is also now more focus on the psychological aspects of neurological disorders. For example, Parkinson's disease often results in emotional symptoms like depression. The emerging field of neuropsychiatry is based on the assumption that treatment for mental disorders should include both biological and psychological elements. Mental disorders should not be seen as different from other medical disorders. The American Neuropsychiatric Association is the professional organization for this specialty.

Neuropsychological Tests

Neuropsychological tests are a type of psychological testing for assessing brain functioning.

Definitions

- **Dementia** is the progressive deterioration of intellectual functions, such as memory, within the brain. Alzheimer's disease is a type of dementia.
- **Executive functions** are high-level cognitive abilities that influence more basic abilities such as attention, memory, and motor skills.
- **Neuropsychologists** are psychologists with specialized training and experience in administering, scoring, and interpreting of tests of cognitive abilities and brain functioning.
- **Neuropsychology** is a branch of psychology that studies the structure and function of the brain involving specific psychological processes and behaviors.
- **Psychometric** is a branch of psychology that deals with measurement of mental capacities, processes, and traits.
- **Visual-motor** is the ability to coordinate vision and bodily movements.
- **Visual-spatial** is the ability to manipulate multidimensional figures mentally.

Description

Neuropsychological tests are used to evaluate brain functioning with formal assessment instruments and systematic behavioral observation. These tests are specifically designed to evaluate cognitive abilities, including attention, working memory, short-term and long-term memory, processing speed, reasoning and problem-solving ability, ability to understand and express language, visual-spatial organization, visual-motor coordination, and planning and organizational abilities. By testing a range of cognitive abilities and examining patterns of performance in different cognitive areas, neuropsychologists can make inferences about underlying brain function. Neuropsychological testing is used in the assessment and treatment of traumatic brain injury, attention deficits, dementia, neurological conditions, psychiatric disorders, and drug or alcohol abuse. It is also used in research to determine the effects of toxic substances and medical conditions on brain functioning.

Neuropsychological tests are helpful in identifying syndromes associated with problems in a particular area of the brain. For example, an individual who

performs well on tests of attention, memory, and language but performs poorly on tests that require visual spatial skills, such as making designs with colored blocks, may have dysfunction in the right parietal lobe. That is the region of the brain involved in complex processing of visual information. Following a stroke, an individual may complain of difficulty with pronouncing words. Neuropsychological tests can identify the location of the stroke and help in planning the most appropriate rehabilitation.

In addition, neuropsychological testing of older adults complaining of memory problems can help distinguish those who are at risk for dementia from those experiencing normal age-related memory loss.

Developments and Current Status

Neuropsychology is a branch of psychology with origins in both psychology and neurology. Its primary focus is on brain-behavior relationships. The Russian neuropsychologist Alexander Luria (1902–1977) greatly influenced the development of neuropsychology as it is practiced today. He proposed that the role of neuropsychology was to localize brain lesions and analyze psychological activities arising from brain function through behavioral observation. More recently, American neuropsychologist Ralph M. Reitan (1922–2014) emphasized the value of standardized psychometric tests in evaluating brain-behavior relationships. Along with Ward Halstead, Reitan developed the Halstead-Reitan Battery, which is used to evaluate brain and nervous system function in individuals over the age of 15.

Before the development of brain imaging methods like computed tomography, magnetic resonance imaging, and positron emission tomography, neuropsychological testing was the only method for evaluating brain-behavior functioning. These brain imaging methods provide a direct assessment of brain lesions or structural abnormalities, specifically in localization of brain dysfunction. For a while, it appeared that these imaging methods would eliminate the need for neuropsychological testing. However, neuropsychologists found new uses for their skills and knowledge. They made the case that neuropsychological testing that indirectly assesses brain function complements brain imaging. For instance, neuropsychological testing can clarify if the specific cognitive abilities are impaired or preserved in patients with brain injury. Brain imaging cannot do this. In fact, neuropsychological testing can accurately predict how well individuals will respond to different forms of treatment or rehabilitation. Today, neuropsychological testing and brain imaging methods are used together to determine which part of the brain is affected in a given individual.

Commonly, a neuropsychological evaluation includes tests of sensation and perception, gross and fine motor skills, basic and complex attention, visual spatial skills, receptive and productive language abilities, recall and recognition memory, and cognitive flexibility and abstraction, and other aspects of executive function. Motivation and personality are often assessed as well, particularly in disability evaluations when an individual is seeking monetary compensation for cognitive complaints that may stem from head injuries.

The neuropsychological examination might include a standard test battery such as the Halstead-Reitan Battery or the Luria-Nebraska Battery. These test batteries include tests of a wide range of cognitive functions and are favored by those who believe that all brain functions must be assessed in everyone to avoid diagnostic bias or failure. It is even more likely that the neuropsychological examination will be tailored to the individual being evaluated. That means a customized battery of tests—which may include some subtests from the standard batteries—are chosen based on clinical hunches generated through a clinical interview, observation of the individual, and review of medical records. This more flexible approach to neuropsychological testing has one shortcoming. It is more prone to bias than a standard battery. On the other hand, it has the advantage of preventing unnecessary testing. Because individuals often experience neuropsychological testing as lengthy, stressful, and fatiguing, a flexible battery approach is shorter and less fatiguing. Shorter batteries are also more likely to be reimbursed by insurance companies.

A number of neuropsychological tests are currently available. These include Ammon's Quick Test, Clinical Dementia Rating, Cognitive Assessment Screening Instrument, Continuous Performance Task, Finger Tapping Test, Halstead-Reitan Battery, Kaufman

Assessment Battery for Children, Luria-Nebraska Battery, Repeatable Battery for the Assessment of Neuropsychological Status, Shipley Institute of Living Scale, Test of Memory and Learning, Wechsler Adult Intelligence Scale and Wechsler Intelligence Scale for Children, Wide Range Achievement Test, Wonderlic Personnel Test, and Word Memory Test

Neurosis

Neurosis is an outdated but still used term for various mental disorders characterized by considerable anxiety, irrational fears, depression, or obsessive thoughts. It is also called psychoneurosis.

Definitions

- **Anxiety disorders** are a group of mental disorders characterized by anxiety that tends to be intermittent instead of persistent. It includes panic disorder, phobias, and generalized anxiety disorder.
- **Defense mechanisms** are unconscious strategies for self-protection against anxiety and other negative emotions that accompany stress.
- **DSM** stands for the *Diagnostic and Statistical Manual of Mental Disorders*, which is a diagnostic system used by professionals to identify mental disorders with specific diagnostic criteria.
- **Five Factor Personality Model** is a model of personality in which five factors—extraversion, consciousness, agreeableness, openness, and neuroticism—are viewed as core personality structures.
- **Neuroticism** is a mild condition of neurosis. As one of the dimensions of the Five Factor Personality Model, it is characterized by a chronic level of emotional instability and proneness to psychological distress.
- **Personality** describes an individual's pattern of behaving, thinking, feeling, and relating.
- **Psychoanalytic theory** is a psychological theory that explains behaviors and perceptions as the result of unconscious, sexual, and biological instincts. Sigmund Freud developed this original theory.
- **Psychosis** is a severe mental condition in which individuals lose touch with reality and experience severe disruptions in perceiving, thinking, and acting.
- **Unconscious** is part of the personality that contains emotional conflicts, wishes, memories, and repressed impulses to which one is not aware but that influence thinking and behavior.

Description

"Neurosis" or "neurotic" is an outdated term that is used to describe individuals who experience mental disorders that are not psychotic (loss of touch with reality). Neurosis is characterized by distressing symptoms such as significant anxiety, persistent irrational fears, somatic and depressive reactions, obsessive thoughts, and compulsive acts. Today, the term "disorder" is used instead of the term "neurotic." That means that the once-called psychoneuroses are now classified as anxiety disorders in DSM-5.

Originally, the term "neurosis" was used to describe medical conditions related to the nervous system. However, Sigmund Freud (1856–1939), the developer of psychoanalytic theory, refashioned the

term to describe symptoms that resulted from unconscious conflicts. For example, an individual may experience an unbearable trauma in childhood that he or she does not consciously acknowledge. This is called repression, which is one of the ego defense mechanisms. Repression results in neurosis and neurotic symptoms. This conflict was Freud's definition of anxiety. For Freud, treatment of such conflicts involved helping individuals reexperience these traumas and reduce the unconscious conflicts. If successful, the result was a reduction of neurotic symptoms.

Neurosis and neurotic symptoms can be distinguished from psychotic states and symptoms. Individuals who experience neurotic symptoms do experience an impairment of functioning but maintain full awareness of reality. This differs from the loss of reality, which characterizes psychoses. Whereas both neurosis and psychosis result in distress and impaired functioning, neurosis is much less severe.

"Neuroticism" is also a term used to describe a factor of personality in what is called the Five Factor Personality Model (FFM). Also called the Five Factor Model, this model of personality was created by psychologists Robert McCrae (1949–) and Paul Costa. In FFM, neuroticism is a measure of how likely an individual is to experience negative states such as anger, anxiety, and depression. Individuals who measure high in this dimension are often worrisome, irritable, and/or moody. By contrast, individuals who measure low in neuroticism are considered to be emotionally stable, secure, and relatively untroubled.

Nicotine-Related Disorders

Nicotine-related disorders are mental disorders characterized by the problematic use of tobacco, resulting in considerable distress or disruption of daily life. It is also called tobacco-related disorders.

Definitions

- **Cognitive behavior therapy** is a type of psychotherapy that focuses on maladaptive (problematic) behaviors, emotions, and thoughts. It is also called CBT.
- **Dependence** is the need for a drug to function normally. Dependence can be psychological and/or physical. Psychological dependence is dependence on a psychoactive substance for the reward it provides. "Physical dependence" refers to the unpleasant physiological symptoms if the drug is stopped.
- **Dopamine** is a chemical substance in the brain that influences emotion, mood, thoughts, motivation, and movement.
- **DSM** is the abbreviation for the *Diagnostic and Statistical Manual of Mental Disorders*, which is the handbook mental health professionals use to diagnose mental disorders. The current edition is DSM-5, which was published in 2013, and replaced DSM-IV-TR.
- **Nicotine addiction** is a mental condition characterized by physical dependence on tobacco.
- **Self-help groups** are a group of individuals, sometimes led by a therapist, who provide each other emotional support, information, and advice on problems relating to some shared concern such as an addiction. Alcoholics Anonymous is such a group.

Description

Nicotine-related disorders were a group mental disorders in DSM-IV-TR. Common to these disorders was the use of all forms of tobacco. The main disorder in this group was nicotine dependence. A major change in DSM-5 was eliminating the concept of "dependence" from all categories of substance disorders. Another change involved renaming nicotine-related disorders to "tobacco-related disorders."

Nicotine is a highly addictive chemical substance derived from the tobacco plant. It increases dopamine levels in the brain. High levels of dopamine trigger the reward system in the brain. This leads to feelings of pleasure and relaxation. The reward mechanism in the brain plays a significant role in addiction. Nicotine's effects may also result in various mental disorders like depression and neurological disorders such as migraine headaches.

Nicotine can be inhaled from cigarette smoke. It may also be ingested by chewing tobacco, inhaling smokeless tobacco in powder form, or smoking tobacco in pipes and cigars. Regardless of the route of administration, nicotine is very addictive. It is physically addictive because it creates brain chemical changes that produce cravings. It is also mentally addictive because it creates a persistent desire for the stimulating effects it produces.

Nicotine is found in tobacco products, which are known to cause severe health problems. They contain chemicals that can cause lung cancer, leukemia, heart disease, emphysema, stroke, and diabetes. Other health issues include a compromised immune system, respiratory infections, and gum disease.

Nicotine addiction and related disorders are caused by inhaling the smoke of cigarettes, pipes, or cigars. It is also caused by chewing tobacco or nasally inhaling smokeless tobacco.

Treatment

Treatment for nicotine addiction includes cognitive behavior therapy (CBT), medication, and self-help groups. CBT is useful for helping an individual identify and replace maladaptive thoughts and change behaviors. Antidepressant medications can be used to increase dopamine levels and boost mood. Nicotine replacement patches, gums, lozenges, nasal sprays, and inhalers can help reduce cravings. Self-help groups can provide social support and may reinforce coping skills learned during CBT or other forms of counseling.

Nightmare and Nightmare Disorder

Nightmare is a dream that results in feelings of terror, fear, or extreme anxiety. A nightmare disorder is a sleep disorder that is characterized by recurrent troubling dreams.

Definitions

- **Cognitive behavior therapy** is a type of psychotherapy that focuses on maladaptive (faulty) behaviors, emotions, and thoughts.
- **Mindfulness practices** are techniques for increasing one's capacity to live in the present moment.
- **Parasomnias** are a group of sleep disorders characterized by abnormal events that occur during sleep, such as sleepwalking, talking, or limb movement.
- **REM sleep** is a stage in the normal sleep cycle characterized by rapid eye movement, dreaming, loss of reflexes, and increased brain

activity. It is also known as rapid eye movement and REM sleep.

- **Sleep disorders** are a group of mental disorders characterized by disturbance in the amount and quality of sleep and that cause significant emotional distress or interfere with daily functioning.
- **Stress management** is a set of techniques and intervention to assist individuals to more effectively cope with stress.

Description and Diagnosis

A nightmare involves a dream that occurs during REM sleep and results in feelings of terror, fear, or intense anxiety. Nightmares tend to occur in the latter part of the night and usually awakens the sleeper. Usually, the content of the dream can be recalled. On the other hand, a nightmare disorder is a sleep disorder characterized by troubling dreams that repeatedly occur. These dreams involve threats to survival, security, or self-esteem. On awakening from the frightening dreams, the individual rapidly becomes oriented and alert. The awakenings generally occur during the second half of the sleep period.

Those experiencing this disorder often report recurrent, past, unpleasant events and display unfavorable changes in personality. Changes in typical sleeping schedules and sleep deprivation may contribute to increased risk for experiencing this sleep disorder. While disturbing dreams involve distress, they are less likely to cause social or work-related occupational impairment. However, if the persistence of dreams results in fear of falling asleep, individuals may experience excessive sleepiness during waking hours. This can result in difficulty with concentration, increased anxiousness, sadness, and irritability that affect work and relationships (American Psychiatric Association, 2013). Nightmare is a parasomnia, a sleep disorder that occurs during arousals from REM sleep or partial arousals from non-REM sleep. Other parasomnias include sleep terror disorder, sleepwalking disorder, and restless leg syndrome in addition to nightmare disorder.

Nightmare disorder should be differentiated from sleep terror disorder. While both disorders include being aroused from sleep, individuals who suffer with nightmare disorder can clearly and vividly recall the dream. Nightmares usually occur later in the night than sleep terrors. Also, individuals usually wake up completely once the nightmare has occurred, whereas they do not in sleep terror disorder (American Psychiatric Association, 2013).

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, individuals can be diagnosed with this disorder if they exhibit a pattern of repetitive, discomforting, and frightening dreams which they remember for which they retain full memory of the dream. Content of the disturbing dreams often involves efforts to evade or cope with perceived danger. Individuals who experience a traumatic event may have distressing dreams that possess elements of the event. Clients report feeling increased fear and anxiousness associated with the dream, even after fully awakening from the dream. On awakening from the distressing dream, individuals report rapidly regaining orientation and alertness. To diagnose this disorder, there must also be clinically significant distress or impaired social, work, or relational functioning. In addition, the nightmares are not part of another mental disorder nor are they due to a medication, a drug of abuse, or a medical condition (American Psychiatric Association, 2013).

The cause of nightmare disorder is not well understood. However, it appears that various factors can contribute to it. These include fatigue, sleep loss, eating immediately before bedtime, and irregular sleep. Stressful life events such as divorce, moving, and starting school or a new job can trigger nightmares. Other sleep disorders like sleep apnea and restless legs syndrome and mental conditions like clinical depression and post-traumatic stress disorder can also trigger it. Withdrawal from alcohol and certain medications can also cause nightmares.

Treatment

Treatment for nightmare disorder differs depending on the age of the individual. In adults, treatment usually involves counseling or psychotherapy that addresses the underlying causes of the nightmare such as a traumatic

event. Stress management and mindfulness practices can be helpful in reducing tension and anxiety Medications are generally not used in the treatment of this disorder. Children can also be treated with stress management. It is helpful for parents to be involved in the treatment. The more they understand the disorder and what they can do, the more likely the treatment will be effective. Parents are instructed to ensure that their child gets regular sleep and does not become overly fatigued. They are helped to establish regular bedtime hours and rituals. They are also urged to wake the child during the nightmare and reassure and support their child through the episodes. Gently distracting them from the nightmare will help them relax and fall back asleep.

Nondirective Therapies

Nondirective therapies are a clinical approach to treatment where the therapist allows the client to set the pace and content of therapy. This is also referred to as client-centered treatment.

Definition

- **Nondirective** refers to a clinical approach to treatment where the therapist allows the client to set the pace and content of therapeutic counseling sessions.

Description

Nondirective therapy began with the person-centered or client-centered therapy developed by Carl Rogers (1902–1985). The basis of the nondirective approach is a belief that people have an innate desire to fulfill their own potential, to improve themselves. It takes the power based on educational expertise out of the hands of the therapist and gives it to the client. It is the client's insights, feelings, values, and behaviors that will drive the scope, depth, and timing of therapy.

In nondirective therapies the role of the therapist or counselor is important because the therapist establishes the therapeutic relationship and safe environment. The goal for these therapists is to create an open environment in which the client can feel important, valued, and in control of his or her own mental health. The therapist has the task of listening intently to the client in order to be able to reflect back to the client his or her own expressed anxieties, fears, and actions. Through nondirective therapy, the therapist facilitates the client's concerns and desires so that the client can see himself or herself and his or her behavior more clearly in order to change and improve.

The term "nondirective" has been labeled naïve and misleading since the influential role of the therapist is still key to the success of the therapeutic experience. It is criticized and questioned for its overuse of simply repeating what the client expresses, which by some has been deemed ineffective. In the purest form of nondirective therapy, a counselor would not indicate his or her opinions or preferences to the client. Some have argued that removing the therapist's opinion is nearly impossible and that most end up giving subtle direction in any case. Rogers himself recognized the limitation and he came to use and prefer the terms "client-centered" and "person-centered" to better define his treatment approach.

Development

Nondirective therapy arose mainly due to the inspiration, experience, and teaching of American psychologist Carl Rogers beginning in the 1940s. Because of

this, nondirective therapies are often called Rogerian approaches to counseling and therapy. But Rogers himself had been influenced greatly by the Viennese psychiatrist Otto Rank. Rank was one of Freud's closest coworkers but ended up leaving his work with Freud because of what he considered Freud's single-minded focus on the examination of a patient's past. Rogers credited Rank with inspiring many of his ideas, especially client-centered therapy.

The respect for and influence of Carl Rogers led to the extension of nondirective therapy into many therapeutic specialities. For example, Virginia Axline developed nondirective play therapy for children. Play therapy began to be extended from children to adolescents and later even in formats that were found effective for therapeutic work with adults. The success of the nondirective approach to therapy has influenced many in the psychiatric and psychotherapeutic fields. Another nondirective therapy approach is experiential therapy, an offshoot that was developed by Eugene Gendlin.

Current Status

Today nondirective therapy is widely practiced in a variety of forms. The intent to focus on the client and empower him or her through therapy that is his or her own is very common. As already noted, there are those who suggest that "nondirective" is a misleading word and therefore the term is not used as widely as it had been in the past. Master therapists who believe in respecting a client's strengths and abilities apply nondirective therapies effectively. They do so by allowing the client to identify his or her own treatment goals and are able to work within a client–therapist relationship that encourages insight and growth.

Nonverbal Communication

Nonverbal communication is expressed in ways other than with words, mostly through visual, auditory, and spatial cues.

Definitions

- **Chronemics** describes the study of how one communicates nonverbally using time.
- **Haptics** is the study of nonverbal communication through touch.
- **Kinesics** refers to body language, including posture, gaze, stance, and face/body movements.
- **Oculesics** describes nonverbal communication that is expressed through the eyes, including eye contact, gaze patterns, pupil dilation, and blinking.
- **Paralanguage** refers to the nonverbal elements of the words communicated orally, including a person's voice quality, tone, pitch, volume, rate, and speaking style.
- **Proxemics** is the study of nonverbal communication through personal space and distance (proximity).

Description

"Nonverbal communication," oftentimes mistakenly referred to as body language, refers to the process of communicating information (thoughts, feelings, opinions, mood) through visual, auditory, spatial, body, and timing cues. Simply defined, it is what is relayed and perceived between sender and receiver through the five senses: sight, hearing, smell, touch, and taste. Nonverbal communication encompasses all aspects of communication other than what is expressed in words. Much is communicated between people through the

qualities of voice (paralanguage), eye movements (oculesics), touch (haptics), bodily movements (kinesics), space and distance (proxemics), and time (chronemics). Nonverbal behavior is thus responsible for five primary functions in human communication: expressing emotions, expressing attitudes between people, accompanying what is spoken to manage the cues of the interaction between speaker and listener, helping to relay aspects of an individual's personality, and communicating rituals. Prior to developing the use of language or writing, young children learn to interact with those around them through nonverbal means. A caregiver's facial expressions and body language often relay his or her emotional state, preclude certain actions or reactions, and model expectations he or she holds for the child.

It is estimated that two-thirds of all communication is expressed nonverbally, indicating that what is said or written in word form is not always what is communicated. Clear communication is defined as interaction patterns in which both nonverbal and verbal messages match. Nonverbal messages are meaningless unless there is a person there to interpret those messages; therefore, nonverbal communication is made up of both encoding and decoding processes. "Encoding" refers to the act of generating a message via one's facial expressions, voice quality, gestures, eye movements, distance, spatial relationship, and touch, as well as other cues. The encoding process is generated by the sender. "Decoding" refers to how those messages are interpreted by the receiver. Both encoding and decoding of nonverbal processes are affected by one's personality, innate qualities, and life experiences, opening up the likelihood of misunderstandings and misinterpretations.

Nonverbal communication is of primary importance upon initial encounters, which can take less than one-tenth of a second for someone to make. Often what is expressed through nonverbal means can either increase or decrease the likelihood of future interactions between parties. Situations including potential romantic interests or work-related interviews can be made or broken based on first impressions.

Charles Darwin was the first scientist to write about what was later termed "nonverbal communication." His 1872 book *The Expression of the Emotions in Man and Animals* focused primarily on how humans and animals communicate their emotions through facial expressions. Behaviorists were the next researchers to look at concepts related to nonverbal communication, observing actions such as visual responses, touch, closeness, and other body movements. Formally speaking, the first investigation of nonverbal communication was conducted in 1955 by experimental psychologists and anthropologists Adam Kendon, Robert Scheflen, and Ray Birdwhistell. They used context analysis to code various patterns surrounding common social interactions like greeting rituals and the behavior of people at larger recreational engagements like parties. Research in the 1960s delved deeper into other aspects of nonverbal communication, those related to proxemics and oculesics. Later study investigated the effects of nonverbal behaviors on various relationships, including those with intimate partners, between student and teacher, peer friendships, and among coworkers. The literature on nonverbal communication was abounding by the early 1980s with several books published by various authors on the topic and the founding of the scholarly work the *Journal of Environmental Psychology and Nonverbal Behavior* in 1978. Since that time investigation has continued to further examine the intricacies of nonverbal interactions among various people.

Current Status and Impact (Psychological Influence)

There are commonly agreed-upon behaviors associated with positive and negative nonverbal communication. Positive indicators typically include steady eye contact, confident posture, nodding one's head, smiling, allowing for an appropriate amount of personal space, normal and consistent voice tone and volume, and using acceptable forms of touch. Negative indicators commonly include lack of eye contact, frowning or giving a blank stare, being too close or too far in terms of proximity, using either extremely soft or loud voice tone and/or volume, and engaging in inappropriate or unwelcomed forms of touch. Though these assumptions exist, they are not consistently held across every group or for every individual. Age, gender, power differentials, cultural background, and clothing/dress, as well as emotional, cognitive, or behavioral differences

can further complicate how each individual interprets nonverbal communication. Educating oneself about various subgroups and their accepted cultural/societal norms and expectations is advised. Assumptions, misunderstandings, and/or miscues can lead to resentment, offense, and hurt, which can be prevented.

Nutrition and Mental Health

Nutrition and mental health is an integrative approach that can improve an individual's health and well-being with nutrition.

Definitions

- **Attention-deficit hyperactivity disorder** is a mental health disorder characterized by a pattern of inattention or overly active behavior.
- ***Diagnostic and Statistical Manual of Mental Disorders*** is the handbook mental health professionals use to diagnose mental disorders. The current edition (fifth) is known as DSM-5.
- **Dopamine** is the chemical messenger in the brain responsible for coordinating the movement of voluntary muscle groups. It also regulates attention, pleasure, and coping with stress.
- **Melatonin** is a chemical messenger in the brain, which regulates the sleep–wake cycle and promotes restorative sleep.
- **Nutritional neuroscience** is an emerging discipline that examines the role that nutrition and dietary habits have on an individual's emotions, cognitions, and behaviors.
- **Psychopharmacology** is the study of drugs that affect thinking, feeling, and behavior. It includes antipsychotic, antianxiety, antidepressant, and antimanic medications.
- **Serotonin** is derived from tryptophan and can be found in the gastrointestinal tract and central nervous system and is associated with happiness and feelings of well-being.
- **Tryptophan** is a standard amino acid found in most protein-based foods that also triggers the release of serotonin, a neurotransmitter in the brain.
- **Well-being** is the state of being happy, healthy, prosperous, or successful.

Description

Nutrition and mental health is an approach for improving an individual's health and well-being. It involves holistic (broad) assessment of diet, eating habits, social support networks, physical activity, stressors, family history, medication, and environmental exposure. Based on this assessment, change in diet and eating habits are prescribed.

The relationship between mental health and food is often underestimated. The foods that individuals eat are broken down in the body and influence functions in the brain that regulate mood and overall mental health functioning. Unhealthy, imbalanced, or deficient diets are known to cause long-term physical and mental health issues.

Nutritional neuroscience research continues to examine mental health conditions such as depression that are exacerbated or in some cases are even caused by poor dietary habits. The general population practices dietary habits that are deficient in the amount of vitamins, minerals, and omega-3 fatty acids. Studies have found that vitamin supplements can actually reduce several of the symptoms of some mental health conditions and ultimately improve overall well-being. They

have examined the link between mental health and carbohydrates, protein, omega-3 fatty acids, and vitamins, minerals such as calcium, chromium, iodine, iron, selenium, and zinc.

Healthy dietary habits include the following: fruits, vegetables, whole grains, seafood (if not vegetarian), low-glycemic foods, and non-processed foods. Carbohydrates cause insulin to be released in the body, which then triggers tryptophan to enter the brain. Tryptophan then impacts neurotransmitters in the brain, which also increases serotonin in the brain that is associated with well-being and pleasure. Professionals recommend that individuals should eat foods low in carbohydrates such as vegetables and pasts but avoid foods that are high in sugar.

Various foods contain components that can influence mental health functioning in both positive and negative ways. Proteins are made up of amino acids and are found in dairy products such as milk, meat, and eggs, but they are also found in plant protein such as grains, peas, and beans. While as many as 12 amino acids are produced in the human body, 8 essential amino acids are supplied through specifics foods. The neurotransmitter called dopamine is made from amino acids. Individuals low in certain amino acids can experience low moods or aggression. Omega-3 fatty acids have mood-stabilizing effects and can reduce symptoms among some who are depressed or who experience attention-deficit hyperactivity disorder. Omega-3 fatty acids can be found in walnuts, green leaf vegetables, oily fish such as salmon, and olive oil. Individuals who add vitamins such as B-12 or folate to their diet have enhanced cognitive functioning and experience fewer issues with mood regulation. Minerals such as iodine, iron, and chromium are known to play a role in mental health functioning.

Besides maintaining a balanced diet, it is also recommended that individuals drink enough water, avoid processed foods, seek organic food options when possible, and avoid high-sugar and sodium foods. Although further research needs to be completed in the area of nutrition and mental health, the link between the two is significant.

Obedience Studies

The obedience studies were conducted by social psychologist Stanley Milgram between 1961 and 1962 and sought to determine how far human beings were willing to go when instructed to carry out harmful tasks by an authority figure.

Definition

- "**Milgram's Experiments**" is another term used to describe Stanley Milgram's groundbreaking obedience studies, as they are the research he is most famous for conducting.

Description

Between 1961 and 1962, social psychologist Stanley Milgram conducted a series of experiments on obedience to authority. These have since been referred to collectively as the "obedience studies" or "Milgram's Experiments." Controversy initially surrounded this research as participants were subjected to extremely stressful situations and were not made fully aware of the studies' protocol prior to their consent. Findings suggested that the majority of subjects were willing to administer the most severe level of harm to fellow participants because they were instructed to do so by the experimenter (a perceived person of authority). Milgram published his book *Obedience to Authority* in 1974, which compiled the procedures, results, and implications of these studies. Milgram's Experiments have had a lasting impact being incorporated into most introductory psychology courses and guiding the subsequent practices of research with human subjects.

History

Milgram's obedience studies consisted of inviting several pairs of people into a psychology laboratory to participate in a study about memory and learning. One person was designated the teacher and the other the learner. The experimenter then explained to the pair that the purpose of study was to determine the effects of punishment on learning. A panel of 30 switches was then introduced, ranging from 15 volts to 450 volts. The panel also had written designations, ranging from "SLIGHT SHOCK" to "DANGER-SEVERE SHOCK." The teacher was then instructed by the experimenter to administer a test to the learner, who was placed in an adjacent room where his or her arm was hooked up to an electric shock (the learner was actually an actor and never exposed to any harm). When the learner responded correctly, the teacher was instructed to move on to the next item; however, when an incorrect response was given, the teacher was instructed to give the learner an electric shock. The shocks began at 15 volts, the lowest level, and increased in 15-volt increments, with each incorrect response, all the way to 450 volts. The true purpose of the experiment was to find out how far a person will go in inflicting harm on another if instructed to do so by a perceived authority figure. With each increment increase in voltage, the actor is directed to respond more emotionally, eventually screaming and pleading with the teacher to stop. The results of these experiments indicated that 26 of the 40 participants, or two-thirds, were willing to proceed with the highest level of shock (450 volts). The explanation for these obedient subjects' behavior was that they were able to shift the personal responsibility they felt for their actions to another person,

in this case the experimenter, and blame that person instead. Though the learners were never exposed to any shocks, the experiment and tactics used by Milgram were deemed highly unethical in that they caused stress to the participants.

Current Status

The findings of the studies suggested that under controlled conditions most people would go against their own moral judgment and for no personal gain nor malice harm another human being simply because they were instructed to by an authority figure. These people were able to shift their personal responsibility onto the person in charge of them. It did not occur to most of these participants to go against instructions, refuse, or simply refrain. Milgram related these findings to larger-scale events, including the Holocaust and the Mai Lai Massacre. Those that were executing heinous crimes reported doing so because their superiors told them to. Milgram's groundbreaking obedience experiments are commonly cited by professionals in the field and have been incorporated into most introductory psychology courses. These studies have also been referred to in popular culture, including music, movies, television shows, and publications.

Obedience to Authority: An Experimental View (Book)

Obedience to Authority is the most famous work written by American social psychologist Stanley Milgram, published in 1974, which covers the experimental conditions of his obedience studies as well as possible explanations for his participants' behavior.

Definition

- **Obedience studies** ("Milgram's Experiments"), led by psychologist Stanley Milgram during the early 1960s, articulated the salience of real or perceived authority at influencing a human being's thoughts, values, and actions.

Description

Published in 1974, Stanley Milgram's book *Obedience to Authority* was written compiling the experimental methods, conditions, results, and implications of Milgram's renowned studies on obedience to authority. Milgram conducted a series of studies between 1961 and 1962 to determine to what extent people will obey orders from a person in authority regardless of their consequences. The experiments received harsh criticism from the scientific community because of the tactics employed to mislead participants. Currently, these studies are viewed as a cornerstone of basic psychology courses, and some of the procedures Milgram put in place during his research have since contributed to the creation of internal review boards and the overall practice of engaging in research with human participants.

Milgram became interested in the social phenomenon of obedience to authority early on in his professional career. Born to Jewish immigrants, Milgram was deeply impacted by the effects of the Holocaust and was curious about how human beings rationalize their behavior even when instructed to perform the most heinous acts. He was particularly interested in the 1961 trial of Adolf Eichmann, a high-ranking official in the Nazi party. Milgram's dissertation research examined cross-cultural differences in conformity and he went on to study this topic under Solomon Asch at Princeton. While Asch's research examined low-stakes situations from an academic perspective (having subjects select lines judged to be the same length under the influence of the conflicting opinions of an authority figure), Milgram was more interested

in higher-stakes social situations for the average person. His experiments sought to test the effects of punishment on learning and invited pairs of subjects, one designated the teacher and the other the learner, to participate in a memory test. The two were moved into separate, adjacent rooms and the teacher was instructed to ask a series of questions to the learner. If the learner answered correctly, then the teacher moved onto the next question; if the learner answered incorrectly, then the teacher was to administer an electric shock to the learner in increasing increments of 15 volts, with the highest possible being 450 volts. The learners were never in true danger as they were merely acting, unbeknownst to the teachers. The results of these found that the majority of teachers were obedient subjects in that they were willing to administer the most severe shock to the learners simply because the experimenter instructed them to do so. Even though the consequences of their actions often went against their own personal and moral judgment, most proceeded with inflicting harm to the other participant. Milgram posited from these results that most people rationalized their behavior by displacing their responsibility on the person in authority. Most felt that they were simply doing their job and had no choice but to keep going as they were told. This phenomenon has been used to explain peoples' rationale for compliance even in the most grave of situations. The experiment itself and the tactics used by Milgram came under strict scrutiny from the scientific community and were deemed highly unethical in that they caused stress to the participants. Subsequently, stricter guidelines have been enforced for research practices with human subjects.

Impact (Psychological Influence)

One year after its release (1975), Milgram's *Obedience to Authority* was nominated for a National Book Award after being translated into seven different languages, making it available for international distribution. Milgram went on to make his own film about his experiments, titled *Obedience*. "Milgram's Experiments" have also been referenced in later works, including movies, television shows, and songs. In 2005, the short film *Atrocity* won an award for featuring a reenactment of Milgram's *Obedience to Authority* experiment. The American Association for the Advancement of Science awarded Milgram and in particular his works on obedience the annual social psychology award. The obedience to authority phenomenon has been used to explain the Holocaust, the 1968 Mai Lai Massacre in Vietnam, and other heinous acts of genocide and terrorism. Milgram's experiments have also contributed to the creation of the American Psychological Association's guidelines for conducting research with human participants and the subsequent requirement of an institutional review board.

Obesity

Obesity is a medical condition involving excessive body fat that can lead to an increase in health problems.

Definitions

- **Antidepressants** are prescription drugs that are primarily used to treat depression and depressive disorders.
- **Antipsychotics** are prescription drugs that are primarily used to treat psychotic disorders.
- **Behavioral therapy** is a form of psychotherapy that focuses on identifying and changing maladaptive behaviors.
- **Body mass index** is a medical index for differentiating obesity from non-obesity. The index is calculated from an individual's weight (mass) and height.

- **Calories** are energy that fuels the body. Exceeding the number of calories the body requires leads to weight gain. For example, an excess of 3,500 calories leads to a gain of one pound of fat.
- **Diabetes** is a disease in which there are high levels of sugar in an individual's blood. It is usually a lifelong condition.
- **Dietician** is a professional who promotes good health through proper diet and with the therapeutic use of diet in the treatment of medical conditions like obesity. Registered dieticians are certified by the American Dietetic Association.
- **Prader-Willi syndrome** is a rare genetic disorder that causes constant feelings of hunger, poor muscle tone, and low levels of sex hormones.
- **Thyroid** is a gland in the body that controls how the body uses energy, makes proteins, and controls other hormones.

Description

Obesity is increased body fat in an individual that has built up to the point that it may cause significant health problems. Obesity may also reduce an individual's life expectancy. Obesity, usually, occurs when an individual takes in more calories than he or she burns. Calories are burned through exercise and normal daily activities. The surplus of calories is then saved as fat. Obese individuals have a great risk of developing health problems and diseases (e.g., diabetes, high blood pressure, and heart disease). An individual can calculate body mass index (BMI) to determine if he or she is obese. When an individual has a BMI of 30 or higher, he or she is considered to have obesity.

Obesity increased to a widespread occurrence in the United States. Over two-thirds of adults in the United States are either overweight or obese, and one in three Americans is obese (Haslam and James, 2005). There has been a great increase in obesity among children in the past several years, and nearly 20%–25% of children are either overweight or obese (Haslam and James, 2005). However, it is preventable if an individual seeks help for this condition. It is estimated that in the United States, obesity causes between 111,909 and 365,000 deaths per year (Haslam and James, 2005).

Obesity can be caused by several factors. Some of these factors include inactivity, lack of sleep, family history of obesity (genetics), and an unhealthy diet. For example, diets that are high in calories and lack fruits and vegetables can lead to obesity. Some medications, such as antidepressants and antipsychotics, can lead to weight gain and obesity. In addition, some medical problems, such as Prader-Willi syndrome and low thyroid function, can lead to obesity.

Treatment

The main goal of treatment for obesity is to achieve and maintain a healthy weight. An individual who works with a professional who specialized in behavioral therapy can be an effective form of treatment. The professional (therapist) can assist the individual in addressing behavioral and emotional issues related to eating. In addition, an individual may come to an understanding of why he or she overeats. Working with a dietician and an obesity specialist has been shown to be helpful forms of treatment. The goal is to help the individual understand his or her health condition and alter his or her eating and activity habits. Other forms of treatment include prescription weight loss medications and weight loss surgery.

Object Relations Theory

Object relations theory is a form of psychoanalytic psychology based on the premise that close relationships are the basic human need. This theory emphasizes the central role of mental representations of such relationships.

Definitions

- **Attachment theory** is a concept of developmental psychology which emphasizes the types of bonds developed between parent and child and their effect on future psychosocial interactions.
- **Identification** is the merging of mental representations of self and internal objects.
- **Introjection** is a lack of differentiation between an internal object and an external object.
- **Object** is actual person, place, or thing that an individual has an interest in or emotional reaction to. It is also known as an "external object."
- **Psychoanalysis** is a form of therapy based on psychoanalytic psychology. In psychoanalysis clients are encouraged to talk freely about personal experiences, particularly their early childhood and dreams.
- **Psychoanalytic psychology** is the form of psychology largely developed from the work of Sigmund Freud, which emphasizes the conflicts and compromises between the unconscious and conscious mind.
- **Representation** is an individual's mental construction of a person, place, thing, idea, or fantasy that elicits interest or emotional reactivity. It is also known as an "internal object."
- **Separation-individuation** is the developmental process of learning to differentiate between self, internal objects, and external objects.

Description

Object relations theory is a psychological theory of relationships. It is a psychology of relating to reality or to the mental representations of reality. Specifically, object relations theory explains the influence of early life experiences on present relational dynamics. It is a developmental theory. The capacity for relationships evolves in stages over time as mental representations of self and others are formed. It is important to note that there is a difference between mental representations of self and internal objects. The self has many definitions in the literature; however, it is often referred to as the witness of objects, or the mental representations of one's own consciousness. Object relations theory explains that an infant's representation of self initially is not different than their representation of the other. For example, as the baby gains life experience, it will learn the difference between mother and not-mother. The capacity to differentiate between objects develops over time.

The majority of this developmental process occurs within the first 36 months of life. Later in life, object relations therapies assist individuals to further differentiate between objects and integrate disparate representations of self. The development of mental representations of self and objects is explained through the process of separation-individuation. The first two months are dominated by reflexive living. There is no differentiation between self and other. Between two and six months babies begin to understand that there is a difference between their self and the other that satisfies their needs. The capacity for separation and individuation primarily occurs between 6 and 24 months. In this developmental phase the child will gain a refined understanding of his or her separateness from both internal and external objects. The final stage of development is called object constancy. In this stage a child develops the capacity to maintain a mental representation of an object for extended periods of times. Early experiences related to separation-individuation create pervasive mental representations that influence the individual's pattern of relating to objects. The development of object relations is largely influenced by the predictability of need satisfaction in the formative years.

Development and Current Status

In the early 1900s, Sigmund Freud (1856–1939), the founding father of psychoanalysis, introduced object relations when writing about ways in which individuals identify with others. Freud primarily focused on sex drives and aggression. The Scottish psychoanalyst Ronald Fairbairn (1889–1964) is considered to be the founder of object relations theory and therapy. Instead of the ego and id, Fairbairn described dynamic (relational) structures. Melanie Klein (1882–1960) furthered the work of object relations theory. Fairbairn's major contributions included novel conceptualizations of the self (ego). Other important figures of object relations theory since the 1940s include Wilfred Bion, Otto Kernberg, Margaret Mahler, and Donald Winnicott. The current status of object relations theory is that while the theory has developed considerably, many of its major tenats have remained consistent. John Bowlby's attachment theory is an example of one such developments. Psychoanalytic psychology in general has evolved over the years to offer more pragmatic psychological explanations that are supported by clinical experience and research.

Object Relations Therapies

Object relations therapies are forms of psychoanalytic psychotherapy in which the basic goal is to modify pathological representations of self and others.

Definitions

- **Attachment theory** is a concept of developmental psychology which emphasizes the types of bonds developed between parent and child and their effect on future psychosocial interactions.
- **Identification** is the merging of mental representations of self and internal objects.
- **Introjection** is a lack of differentiation between an internal object and an external object.
- **Object** is actual person, place, or thing that an individual has an interest in or emotional reaction to. It is also known as an "external object."
- **Object relations theory** is a form of psychoanalytic psychology based on the premise that close relationships are the basic human need. Mental representations of self and others determine an individual's motivations and behaviors and fulfill this basic need.
- **Psychoanalysis** is a form of therapy based on psychoanalytic psychology. In psychoanalysis clients are encouraged to talk freely about personal experiences, particularly their early childhood and dreams.
- **Psychoanalytic psychology** is the form of psychology largely developed by the work of Sigmund Freud, which emphasizes the conflicts and compromises between the unconscious and conscious mind.
- **Psychoanalytic psychotherapy** is a psychotherapy approach that assumes dysfunctional behavior is caused by unconscious, internal conflicts and focuses on gaining insight into these conflicts.
- **Psychotherapy** is a psychological method for achieving desired changes in thinking, feeling, and behavior. It is also called therapeutic counseling.
- **Representation** is an individual's mental construction of a person, place, thing, idea, or

fantasy that elicits interest or emotional reactivity. It is also known as an "internal object."

- **Separation-individuation** is the developmental process of learning to differentiate between self, internal objects, and external objects.
- **Transference** is the unconscious redirection of feelings and expectations from one individual in the past to another in the present.
- **Transference enactments** is the acting out of transference with a particular individual in the present.

Description

Object relations therapies are based on the theory of object relations. This theory assumes that that all individuals have a fundamental need to relate. Relationships can be the function of an intimate and honest experiencing of real objects. Alternatively, relationships can be the function of a fictional relationship with self-created internal objects and representations. Object relations therapies assist clients to relate to reality (external objects) through a process of separation and individuation. This alters the influence of mental representations on one's present relational dynamics.

Intervention begins with the development of a therapeutic alliance (bond) between the psychotherapist and the client. The working relationship between psychotherapist and client is important to almost all psychotherapeutic interventions. However, it is of marked importance in object relations therapies. The type of attachment or bond that develops between client and psychotherapist is a real-time example of how mental representations effect client interactions. It is not uncommon that a client will maintain and express completely unreasonable beliefs about his or her psychotherapist. These unwarranted feelings, thoughts, perceptions, and fantasies are primarily based on the mental representations from past experiences. A highly skilled object relations therapist will focus the intervention on the client's distorted experience of reality. The psychotherapist will also manage the interaction through the clear and firm establishment of professional boundaries. The client's distorted experience of the therapist is called transference. A client's transference enactments, and other pervasive mental representations, are key processes in the object relations therapies.

A client seeks therapy to reduce the problems (symptoms) associated with his or her maladaptive relationships. Object relations therapies link the client's presenting problem with the client's internal object dynamics. This means that both the symptoms and the underlying dynamics are focused upon. Object relations therapies have a tendency to explore a client's early development and childhood history to discover the root cause of maladaptive representations. Object relations therapies allow the client to guide the content of psychotherapeutic sessions. Therapists accept and explore client disclosures to identify and alter maladaptive representations and patterns of relating. Object relations therapies utilize nonjudgmental listening. Psychoanalytic therapists are interested in using the content of dreams and fantasies to understand the patterns of the unconscious mind. One goal of object relations therapies is to make a client's unconscious patterns of relating available to his or her conscious mind. This awareness is conceptualized as an entry point to authentic change. Object relations therapies assist clients to witness their pervasive patterns of relating to internal objects. Clients often need assistance from the therapist to gain this insight. The object relations therapeutic technique formulated by Henry Ezriel in the 1950s called "the because clause" can facilitate this awareness. The because clause is a behavioral interpretation a psychotherapist will use to point out a client's internal object dynamics. It is a statement that concisely summarizes the relationship among the client's sense of self, the client's past relationships, and the client's current relationships. Object relations therapies utilize clarification, confrontation, and interpretation in many different forms. Object relations therapies also include forms of couples and family therapies. In object relations couples therapy (ORCT), for example, each individual's representation of the other is directly dealt with and modified in session. The object "couple" is cocreated by the interaction of the two representations of the relationship. ORCT assists each member of the couple to be nurturing and appropriately responsive to the other. It helps couples see each other in terms of

real people instead of in terms of past relationships or internal objects (e.g., fantasies).

Development and Current Status

Sigmund Freud (1856–1939) is considered to be the founding father of psychoanalysis. In the early 1900s, Freud alluded to objects when writing about ways in which individuals identify with others. However, Freud's work focused primarily on instinctual drives and tripartite structural theory (id, ego, and superego). The Scottish psychoanalyst Ronald Fairbairn (1889–1964) is considered to be the founder of object relations theory and therapy. Instead of the ego and id, Fairbairn described dynamic (relational) structures. Melanie Klein (1882–1960) further developed and popularized object relations theory. Other important figures of object relations since the 1940s include Wilfred Bion, Otto Kernberg, Margaret Mahler, and Donald Winnicott.

The current status of object relations is that its theory and practice have continued to develop, while many of its major tenats have remained consistent. John Bowlby's attachment theory is an example of one such developments. Psychoanalytic psychology has evolved over the years to offer more pragmatic psychological explanations that are supported by clinical experience and research. Another example of a therapeutic model informed by empirically supported object relations is Murray Bowen's family systems therapy. Object relations therapies are currently being integrated into novel psychotherapeutic models. For instance, cognitive analytic therapy is the integration of cognitive psychology, cognitive therapy, and object relations therapies.

Obsession

Obsession is a persistent and intrusive, thought, image, or impulse that creates considerable distress or discomfort.

Definitions

- **Compulsions** are habitual behaviors, practices, or rituals that are impulsively engaged in to defend against perceived threats, to reduce fears, or otherwise to minimize distress.
- **Delusions** are fixed, false beliefs that persist despite contrary evidence.
- **Obsessive-compulsive disorder** is a mental disorder that is distressful to the individual and is characterized by unreasonable obsessions or compulsions that are inappropriately time consuming or cause marked distress or impairment.
- **Obsessive-compulsive personality disorder** is a personality disorder that is defined by a pervasive pattern of preoccupation with control, perfectionism, and meticulousness at the expense of flexibility, openness, and efficiency.

Description

An obsession is a persistent and recurrent thought, belief, image, urge, or impulse that is experienced as intrusive or unwanted and that causes marked distress or anxiety. As a result, the individual attempts to suppress or ignore the thought, belief, image, urge, or impulse. Or, the individual attempts to neutralize them with other thought or behaviors, such as a compulsion (American Psychiatric Association, 2013). Obsessions are common in obsessive compulsive disorder. While obsessions can also occur in obsessive-compulsive personality disorder, they are less common. Although

obsessive thoughts seem unnatural to those who have them, they are recognized as originating from within the individual. In contrast to delusions, they are not experienced as originating outside the individual.

It should be noted that obsessions differ from reasonable and legitimate worries about everyday concerns. Reasonable concerns include keeping a job, paying bills, studying for exams, and maintaining personal relationships. Such concerns are not obsessions. Even though they may be carried to obsessive lengths at times, these concerns can change with circumstances and are usually controlled by planning, effort, and action. In contrast, obsessions involve problems or concerns that most consider quite different than normal, everyday concerns.

Here are some examples of obsessions. These might involve thoughts about fear of contamination from doorknobs or handshakes. They may involve the inability to decide whether to keep or to discard things, fear of losing things, doubts about whether the stove was left on, perverse sexual thoughts or images, or scary images of violent acts. They could involve urges to harm someone or to steal something, or fear of blurting out obscenities or insults. Some individuals with such persistent thoughts, images, or impulses often may find themselves acting in compulsive ways in futile attempts to relieve their discomfort. Other individuals with such obsessions will attempt to control them, while others will attempt to ignore them.

Obsessive-Compulsive Disorder (OCD)

Obsessive-compulsive disorder is a mental disorder characterized by persistent thoughts and compulsive actions, such as cleaning, checking, counting, or hoarding. It is also called OCD.

Definitions

- **Cognitive behavior therapy** is a form of counseling and psychotherapy that focuses on changing maladaptive (faulty) behaviors, emotions, and thoughts. It is also known as CBT.
- **Compulsions** are repetitive behaviors or mental acts that an individual feels compelled to perform in response to an obsession or to rules that must be followed rigidly.
- **DSM-5** stands for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, which is a diagnostic system used by professionals to identify mental disorders with specific diagnostic criteria.
- **Exposure and response prevention therapy** is the cognitive behavior therapy method that involves exposure to the anxiety that is provoked by the obsession and then preventing the use of compulsive behaviors to reduce the anxiety. This cycle of exposure and response prevention is repeated until the obsessions are less distressing and compulsions are reduced.
- **Obsessions** are unwanted, repeated, persistent thoughts, images, or urges that the individual cannot ignore and that produce some level of anxiety or distress.
- **Obsessive-compulsive personality disorder** is a type of mental disorder called a personality disorder that is characterized by a preoccupation with perfectionism, orderliness, and control.

Description and Diagnosis

Obsessive-compulsive disorder (OCD) is characterized by persistent thoughts and compulsive actions, such as cleaning, checking, counting, or hoarding. OCD is one of a group of disorders called obsessive-compulsive and related disorders in DSM-5. Common to all these disorders is recurrent and persistent thoughts, mental acts, or behaviors that individuals feel compelled to enact. Basically, these disorders are efforts to reduce anxiety by engaging in repeated thoughts and acts that can then be addressed and controlled. While males are more likely to be affected by this disorder in childhood, females are more affected by this disorder in adulthood (American Psychiatric Association, 2013).

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, individuals can be diagnosed with this disorder if they experience either obsessions or compulsions or both. In addition, the individual must be making an attempt to ignore the obsessions and/or reduce the anxiety, often by enacting the compulsion. The compulsion, however, is not realistically designed to handle or prevent the distress or the compulsive behaviors are clearly excessive. The diagnosis requires that obsessions and compulsions be time consuming, take up more than an hour per day, and cause significant distress or impairment in social, occupational, or other forms of functioning (American Psychiatric Association, 2013). OCD is sometimes confused with obsessive-compulsive personality disorder. While both disorders have some similarities, they have different criteria for diagnosis.

The cause of this disorder is not well understood. However, genetic, psychological, and social factors are associated with it. It may be genetic in origin and tends to run in families where obsessive-compulsive disorder is diagnosed. It is associated with childhood abuse and neglect. Those with the disorder may have not "fit in" within their family, school, or neighborhood peers. As children, they may have developed repetitive patterns of evasion in response to their parent's expectations. Psychologically, obsessions and compulsions tend to reflect negativity and a need for order and control. Both obsessions and compulsion divert an insecure individual from dealing with the responsibilities of friendship, family, and school or work. By engaging in these more manageable processes, the individual retreats from these responsibilities and is instead preoccupied with dealing with his or her symptoms.

Treatment

The clinical treatment of this disorder usually involves counseling or psychotherapy and medication. Depending on the severity of symptoms, treatment could begin with either medication or psychotherapy. For those who are severely affected and are unable to function in a job, in school, or in social situations because of their symptoms, medication usually is tried first before counseling or psychotherapy. Exposure and ritual prevention therapy is an effective CBT intervention for OCD. It is the treatment of choice. Therapists may also combine exposure and response prevention therapy with other cognitive behavior therapy methods which focus on changing faulty beliefs such as fear of contamination. In severe cases of anxiety associated with obsessions or compulsions, medications can also be added. These include antidepressants like Prozac and Luvox.

Obsessive-Compulsive Personality Disorder

Obsessive-compulsive personality disorder is a mental disorder characterized by a pattern of preoccupation with perfectionism, orderliness, and control.

Definitions

- ***Diagnostic and Statistical Manual of Mental Disorders*** is the handbook mental health professionals use to diagnose mental disorders. The current edition (fifth) is known as DSM-5.
- **Obsessive-compulsive disorder** is a mental disorder characterized by unwanted and repeated thoughts and feelings (obsessions), or behaviors that one feel driven to perform (compulsions). It is commonly referred to as OCD.
- **Perfectionism** is the belief that perfection is worth striving for and achieving. In its unhealthy form, it is the belief that it is unacceptable to accept anything less than perfection.
- **Personality disorder** is a long-standing pattern of maladaptive (problematic) behavior, thoughts, and emotions that deviates from the accepted norms of an individual's culture.
- **Psychotherapy** is a psychological method for achieving desired changes in thinking, feeling, and behavior. It is also called therapeutic counseling.

Description and Diagnosis

The obsessive-compulsive personality disorder is a personality disorder characterized by a pervasive pattern of being perfectionistic, controlling, inflexible, judgmental, and overly conscientious. Individuals with this disorder are controlled by rules, schedules, and rigid routines and are seen by others as cold and reserved. They must get every last detail correct and cannot delegate tasks because others cannot be trusted to do things well enough. They also tend to be stingy with money, emotions, and affection. As a result, they avoid intimacy and experience little pleasure from life. While they can be successful in a career, at the same time they can be indecisive and demanding. This disorder is often confused with obsessive-compulsive disorder (OCD). However, compulsions and obsessions do not characterize this personality disorder. Confusing this personality disorder with OCD dates back to one of Freud's most famous cases: the "Rat Man" who presumably would have met DSM-5 criteria for both OCD and obsessive-compulsive personality disorder. Today, relatively few individuals (less than 20%) are diagnosed with both disorders.

The clinical presentation of the obsessive-compulsive personality disorder can be recognized by the following behavior style, interpersonal style, thinking style, and feeling style. The behavior style of this disorder is characterized by perfectionism, and individuals with it are likely to be workaholics. In addition to dependability, these individuals are likely to be stubborn, possessive, indecisive, and procrastinating. Interpersonally, they are overly conscious of social rank and status. As a result, they are likely to be deferential to superiors and autocratic to subordinates and peers. They will insist that others do things their way, without awareness of how others react to their insistence. Yet they are polite and loyal to the organizations to which they belong and ideals they espouse. Their thinking style can be characterized as constricted and rule based. They have difficulty establishing priorities and perspective. Because they focus on details, they tend to lose sight of the larger project. Their indecisiveness and doubts make decision making difficult. In addition to their mental inflexibility, they have a restricted fantasy life. Furthermore, they are continually conflicted between assertiveness and defiance, and pleasing and obedience. Their feeling style is best described as grim and cheerless. While they are more comfortable expressing feelings like anger, frustration, and irritability, they avoid positive and intimate feelings like warmth and tenderness.

The cause of this disorder is not well understood. However, these individuals tend to have a characteristic view of themselves, the world, and others and a basic life strategy. Those with this disorder tend to view themselves as competent, righteous, and responsible. They are likely to view the world as unpredictable and out of control, while viewing others as critical, nonaccepting, and overly demanding. Accordingly, their basic life strategy and pattern is to take control, work hard, strive for perfection, and be right and proper at all times.

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, individuals can be diagnosed with this disorder if they exhibit a pervasive pattern of perfectionism, orderliness, and control instead of flexibility, openness, and efficiency. They are overly preoccupied with details, rules, and schedules. Their perfectionism interferes with completing tasks due to their overly strict standards. They are overly devoted to work and productivity to the exclusion of leisure activities and friendships. When it comes to matters of values, morality, or ethics, these individuals are inflexible, scrupulous, and overconscientious. Often, they are unable to discard worn-out or worthless objects that have no sentimental value. They will not delegate tasks to or work with others unless it can be on their terms. Not surprisingly, these individuals are also rigid and stubborn. Finally, they are misers with money, and it is hoarded in the event of future catastrophes (American Psychiatric Association, 2013).

Treatment

The clinical treatment of this disorder usually involves psychotherapy. The goals of treatment include decreasing perfectionism and constricted thinking while increasing the expression of positive and intimate feeling. The expected treatment outcome is a reasonable balance between thoughts and feelings. Treatment strategies useful with this disorder usually involve long-term psychotherapy. Unlike OCD, where medication and psychotherapy can greatly reduce obsessions and compulsions in a relatively short period of time, the obsessive-compulsive personality disorder does not lend itself to short-term treatment. When both disorders are present together, treatment has been shown to be much more challenging than if only OCD is present.

Occupational Information

The general term, "occupational information," applies to data and facts about vocational areas of interest, necessary skills and abilities, educational and training requirements, and potential salary ranges that people can use to help them determine potential future employment.

Definitions

- **Career assessment** is the process of using tools such as surveys, inventories, and questionnaires to gather information about a person's aptitudes, interests, and abilities to assist in determining his or her potential success in a certain career.
- **Career counseling,** also referred to as career coaching or career guidance, involves working with a professional counselor or trained coach, who assists the client in exploring his or her job interests and potential matches.
- **Career development** defines the lifelong process of how individuals manage and navigate along their vocational paths.
- ***Dictionary of Occupational Titles*** is the former print publication put out during the late 1930s to 1990s by the United States Department of Labor that sought to match job seekers to jobs; it was replaced by an online computer system, the Occupational Information Network, or O*NET.

The general term "occupational information" applies to data and facts about vocational areas of interest, necessary skills and abilities, educational and training requirements, and potential salary ranges that people can use to help them determine potential future employment. (Rawpixelimages/Dreamstime.com)

Description

"Occupational information" refers to facts related to specific jobs that can assist students, job seekers, career counselors, business leaders, and other professionals to understand the current world of work and how to navigate it. Additional information may include descriptors of various occupations, needed skill sets, schooling, licensing, or certification requirements, and projected pay rates. People can seek this information out independently or be assisted by a career counselor or advisor. Career advisors and counselors use occupational information to assist clients in planning for future employment. Several sources are available that provide career-related information, including print publications and other literature, the Internet, computer software and systems, career centers, audio and video tapes, and professional career associations.

Impact (Psychological Influence)

Career counselors should assess their client's comfort level with accessing, discussing, writing about, and following through on the occupational information they gather. Deficient reading, writing, or computer skills may inhibit a client's ability to obtain career information. For instance, the Occupational Information Network, or O*NET, requires both computer access and skills. Career advisors must be practical, knowledgeable, and respectful of their client's aptitudes, interests, and preferences. In addition to adequate advising and counseling skills, counselors must practice cultural competence. A person's gender, ethnicity, race, socioeconomic status, education level, and life experiences can all impact his or her occupational pursuits. Proper career assessment, planning, and advising are all key components in delineating the right work-person-environment fit.

Occupational Stress

Occupational stress is the physical and psychological reaction to stress within the workplace and a worker's job. It is also called job stress.

Definitions

- **Anxiety** is a negative emotional state characterized by feelings of nervousness, worry, and apprehension about imagined danger.
- **Depression** is an emotional state characterized by feelings of sadness, low self-esteem, guilt, or reduced ability to enjoy life. It is not considered a mental disorder unless it significantly disrupts one's daily functioning.
- **DSM-5** stands for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, which is a diagnostic system used by professionals to identify mental disorders with specific diagnostic criteria.
- **Eating disorder** is a class of mental disorders that are characterized by difficulties with too much, too little, or unhealthy food intake, and may include distorted body image.
- **Job strain** is the perception of little control over one's work while facing high job demands. Such strain increases an individual's risk for psychological and medical conditions.
- **Stress** is a state of emotional or mental tension or strain, which results from very unfavorable or demanding circumstances.
- **Substance abuse** is a pattern abuse in which an individual consumes substance(s) in amounts or with methods that are harmful to himself or herself or others.

Description

Occupational stress is the response to demands and pressures that challenge a worker's ability to cope in a normal way. Occupational stress can negatively impact an individual's health when stress in the workplace exceeds an individual's ability to have control over the situation or the ability to cope in an effective way. For example, an individual (employee) may be assigned a very heavy workload and as a result the individual's heart rate may increase and he or she may experience feelings of anxiety. Some other symptoms individuals experience as a result of occupation stress include excessive tiredness, depression, headaches, difficulty sleeping, and stomach problems. Some individuals who experience occupation stress may develop an eating disorder and substance abuse.

Job strain is similar to but different from job stress. While job stress involves job demands at work that are experienced as stressful, job strain involves the negative medical and psychological toll that job stress takes when job demands are high and workers have little decision-making power. Demand and decisional control are two of the main risk factors for various medical conditions such as high blood pressure and heart attacks as well as depression. The key factor in determining negative health consequences is the worker's perceived capacity to control job demands.

Occupational stress is classified in DSM-5 under the section "Other Problem Related to Employment." This category is used when an individual has an occupational problem and is the focal point of attention or has an effect on the individual's prognosis and treatment. Some specific examples that can be classified under this section include threat of job loss, stressful work schedule, sexual harassment on the job, and a hostile work environment.

There can be several causes of occupational stress. Some of them include working long hours, a hostile work environment, increased workloads, and lack of job security within a company. Some other potential causes include working conditions, economic factors, bullying, and workplace conflict.

Treatment

One form of treatment for occupational stress is for an individual to participate in an employee assistance program (EAP). These programs offer ways to assist individuals in stress reduction and offer professional advice. Typically, the EAP will offer suggestions such as reducing work, implementing a program change, and expressing unpleasant feelings about his or her work stress. Some programs may offer individuals vacation time or a leave of absence.

On Becoming a Person (Book)

On Becoming a Person is a book published in 1961 by Carl Rogers, who was the founder of person-centered therapy.

Description

In 1961 Carl R. Rogers (1902–1987) was a professor at the University of Wisconsin, where he completed and published *On Becoming a Person*. This book is a collection of essays, papers, and insights based on his 30-year-long career. Rogers ended up writing a total of 16 books and many articles over the course of his career.

Rogers was an influential psychologist who believed that the aim of life is to be a happy and healthy functioning human being. He also believed that people want to be able to live up to their potential by living in the moment. Rogers was an existentialist. For him this meant that each person's concept of himself or herself should grow out of his or her own experience and that every person should trust his or her own judgment above all else. This kind of freedom of choice is the foundation of a sense of responsibility for someone's own behavior. Such a responsible person will be free to adapt his or her behavior to circumstances without feeling the burden of conforming to false external norms. Awareness of the individual's own needs will lead him or her to seek helpful solutions that balance his or her own conflicted feelings and desires.

In this book, Rogers describes a happy and healthy life as an experience of the full range of emotions and events. This includes joy and pain, love and heartbreak, fear and courage. It involves stretching and growing to meet your own potential. Rogers called it the courage to be, which was living life to the fullest or seizing the day. In this book he wrote about how people are constantly changing and evolving to be their best and achieve happiness.

In therapy Rogers believed that the client should lead treatment. Rogers's approach was *nondirective*, a clinical approach to treatment where the therapist allows the client to set the pace and content of therapeutic counseling sessions. In his essays he documents his belief that therapists should be safe and understanding persons in the life of their clients. He claims that the very presence of such a therapist in another's life is helpful. He also observed that the presenting issue, emotion or problem the client first mentions, is usually a symptom of an underlying struggle of the person to discover who he or she is, or what he or she needs. Therefore, each client is inevitably looking for how to become a better person. It is the job of the therapist to guide the client by mirroring what has been said and gently questioning to open the dialogue further.

Impact (Psychological Influence)

The ideas that appear in *On Becoming a Person* have become a part of mainstream psychology, and therefore, the basic concepts of his work have been fully integrated into the field. Rogers's work has given rise to the creation of organizations, institutes, and journals dedicated to person-centered therapy. Recent research has validated the importance of several of Rogers's core ideas for effective psychotherapy. Chief among the effective elements of psychotherapy are empathy and unconditional and positive regard from the therapist for the client.

A study done in 2002 found that Rogers was the second-most prominent psychological clinician after Sigmund Freud. His client-centered approach to therapy revolutionized psychology and the world of counseling in general. His success leading conflict resolution with groups in both South Africa and Northern Ireland led him to be nominated for the Nobel Peace Prize.

One Flew over the Cuckoo's Nest (Book and Movie)

One Flew over the Cuckoo's Nest was a best-selling book by Ken Kesey (1935–2001) published in 1962 and was later made into a movie in 1975. The movie was nominated for nine Oscars and managed to bring home five Academy Awards, including best picture.

Description

The impact of both the book and the movie was believed to have caused lasting harm to the image of ECT

One Flew over the Cuckoo's Nest was a best-selling book by Ken Kesey published in 1962 and later made into a movie in 1975. Its depictions of the inhumane treatment of the mentally ill led to a strong backlash against electroconvulsive therapy (ECT). (United Artists/Photofest)

(electroconvulsive therapy), ultimately creating a backlash against the entire psychiatric profession. Even decades later, a small resurgence of ECT in the early 1990s had to battle public sentiment that this form of therapy is potentially dangerous and used too often. Unfortunately, it also had the unintended effect of individuals with a mental illness being viewed in a harsher and more negative light. However, the book and movie offer tremendous insights regarding stereotypes of those with mental illness.

The story follows a man named Randle Patrick McMurphy, who is played brilliantly by Jack Nicholson in the film version. McMurphy is a criminal convicted of gambling, who feigns insanity to avoid hard labor in prison. He arrives at the hospital full of bravado and fun-loving swagger. However, in the end, he is unable to avoid ECT, much like many of the patients in the facility. The movie chronicles his interactions with other patients as they face their arch nemesis, Nurse Ratched, a woman who rules the facility with an iron fist. The highlight is the interactions between McMurphy and Nurse Ratched as they engage in a power struggle over his life, which ultimately leads to the climax of the film.

Impact (Psychological Influence)

Even more than 50 years after its initial release, the book, as well as the film, continues to be considered classics. Kesey's novel had a considerable and lasting impact on the field of psychiatry like few other books or movies have done.

Opioid Use Disorder

Opioid use disorder is a mental disorder characterized by a pattern of opioid use, which leads to significant problems for the user.

Definitions

- **Addiction** is a chronic disease of the brain which involves compulsive and uncontrolled pursuit of reward or relief with substance use or other compulsive behaviors.
- **Cognitive behavior therapy** is a type of psychotherapy that focuses on maladaptive (problematic) behaviors, emotions, and thoughts. It is also called CBT.
- **Motivational interviewing** is a counseling strategy for helping individuals to discover and resolve their ambivalence to change. It is also referred to as MI.
- **Opiates** are a class of naturally derived drugs from opium.
- **Opioids** are synthetically derived drugs and are used as opiate substitutes. The term "opioid" is sometimes used to refer to both opiates and opioids and are known as narcotics.
- **Substance-related and addictive disorders** are a group of mental disorders that include substance disorders characterized by physiological dependence, drug-seeking behavior, tolerance, and social withdrawal. This group also includes the non-substance disorder of gambling.
- **Twelve-Step Program** is a self-help group whose members attempt recovery from various addictions and compulsions based on a plan called the Twelve Steps.

Description and Diagnosis

Opioid use disorder is one of the substance-related and addictive disorders. It is characterized by a problematic pattern of opioid use, which leads to significant distress or disrupted daily functioning. Opiates are appealing because they are effective pain killers. In addition to making physical pain manageable, opiates numb psychological pain. Opioid addiction results from prescription drug use or the use of cocaine or heroin. Prescription drugs include Oxycontin, Percocet,

Percodan, and Vicodin. These drugs are prescribed to relieve moderate to severe pain. They are very effective, and a vast majority of those prescribed these drugs do not become addicted. Yet illicit (illegal) use of these prescription drugs is increasing and problematic.

The addiction rate for all opiates, including heroin, is approximately 1% of the adult population of the United States (American Psychiatric Association, 2013). Recently, greater use of prescribed opioids appears to be increasing the addiction rate for opiates. The ratio of heroin users to illicit prescription drug users is 1:6, suggesting that illicit prescription drug use is quite common (SAMHSA, 2006). There are similarities and differences between illicit prescription drug use and heroin use. Heroin is a highly addictive drug, and it is estimated that 23% of those who use heroin, even once, will become addicted to it (American Psychiatric Association, 2013). With heroin there is an initial rush that has been described as so intense that those who experience it spend a lifetime attempting to feel it again. This powerful, initial rush is followed by a euphoric dreamlike state of drowsiness. There is also an increase in self-esteem and decreased concern with problems and concerns. Except for the powerful initial rush, prescription drug use provides many of the same feelings and experience. As a result these drugs have a high potential for addiction. However, chronic use of these prescription drugs often leads to loss of energy, tolerance, physical addiction, and lack of ambition and drive.

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, individuals can be diagnosed with this disorder if they exhibit a problematic pattern of opioid use, leading to significant impairment or distress. This must occur within a 12-month period. This includes taking the substance in larger amounts or for longer than intended. It means wanting to cut down or stop using the substance but not achieving this goal. It involves spending much time getting, using, or recovering from use of the substance. This disorder also involves cravings and urges to use the substance, and continuing to use, even when it causes problems in relationships. It involves failure to meet obligations at home, work, or school because of substance use. It also means reducing or stopping important social, work, or recreational activities because of substance use. This disorder involves repeated substance use even when it is physically dangerous. Despite knowing the risks of the physical and psychological problems that are caused or made worse by the substance, use of it continues. It means develop tolerance (needing more of it to get the desired effect). Finally, it involves withdrawal symptoms, which can be relieved by taking more of the substance (American Psychiatric Association, 2013).

The cause of this disorder is not well understood. However, social and psychological factors may be involved. For instance, heroin users tend to come from families where alcohol or drug use is common. Or, it might be that a family member has a mental disorder like bipolar disorder or antisocial personality disorder. Heroin users may have had health problems or behavioral problems in childhood. Being impulsive and thrill seeking may also be contributing factors. Opioid abuse often begins with a legitimately prescribed medication like Vicodin. The user experiences a desirable psychological feeling that leads to seek more of the drug for this need. Adolescent abuse of this drug often begins by experimenting with unused portion of a prescription found in the home.

Treatment

Treatment of this disorder involves various stages. It begins with physical withdrawal from the opioid. Usually, this takes place in a hospital or treatment center. Over a three- to five-day period of detoxification the drug is withdrawn. Depression is common for several days or weeks after the acute withdrawal. Medications may be given to help individuals cope with withdrawal symptoms. Next, individuals are helped to deal with the problems their addiction has caused and learn to live soberly. Motivational interviewing is useful in identifying reasons to stop using and to increase motivation and readiness for treatment. As treatment begins, these reasons may be as simple as not wanting to experience the negative effects of the drug. As treatment progresses, individuals will usually identify important life goals they would like to achieve. Once these broader goals are identified, they are encouraged to develop short-term and intermediate goals. Then, cognitive behavior therapy can be used to identify the

beliefs, behaviors, and situations that trigger use and cravings. From these they can develop a plan to reduce the likelihood of relapse. Because opioid addiction is considered a chronic condition, long-term treatment to maintain sobriety and prevent relapse is necessary. This often includes continuing in therapy and/or a Twelve-Step Program and possibly methadone.

Opioid Withdrawal Disorder

Opioid withdrawal disorder is a mental disorder characterized by withdrawal symptoms after an individual reduces or completely abstains from heavy and prolonged opioid use.

Definitions

- **Addiction** is a chronic disease of the brain, which involves compulsive and uncontrolled pursuit of reward and relief with substance use or other compulsive behaviors.
- **Alcoholics Anonymous** is a nonprofit fellowship of men and women for whom alcohol has become a significant problem. It was founded by Bill Wilson and Dr. Bob Smith in 1935 to help people struggling with addiction.
- **DSM-5** stands for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, which is a diagnostic system used by professionals to identify mental disorders with specific diagnostic criteria.
- **Narcotics Anonymous** is a nonprofit fellowship of men and women for whom drugs have become a significant problem. It uses the Twelve-Step model and it's the second-largest Twelve-Step Program, next to Alcoholics Anonymous.
- **Opioid antagonist** is a receptor antagonist that acts on opioid receptors preventing the body from responding to opioids.
- **Opioids** are a class of narcotic drugs used to treat moderate to severe pain. The classes include both natural and synthetic substances.
- **Sponsor** is another recovering addict who offers guidance and support in a one-on-one relationship.
- **Substance-related and addictive disorders** are a group of DSM-5 mental disorders characterized by the continued use of addictive substances or behaviors despite significant impairment or distress.
- **Twelve-Step Program** is a self-help group whose members attempt recovery from various addictions and compulsions based on a plan called the Twelve Steps.

Description and Diagnosis

Opioid withdrawal disorder is one of the DSM-5 substance-related and addictive disorders. It is characterized by withdrawal symptoms after the discontinuation or reduction of heavy and prolonged opioid use. Opioids are a type of narcotic pain medication and are prescribed to individuals who have moderate to severe pain. Some examples of opioids include morphine, heroin, codeine, oxycodone, and hydrocodone. The withdrawal symptoms can also be precipitated by the use of an opioid antagonist (e.g., naltrexone), which help prevent the body from responding to opioids. Opioids are often misused (taken in larger amounts)

and over a longer period than intended, and lead to addiction.

Anxiety, restlessness, insomnia, fever, vomiting, negative mood, and muscle aches are some symptoms of opioid withdrawal. An individual's quality of life and the ability to function normally may be severely impacted if he or she is experiencing symptoms of opioid withdrawal. For example, symptoms may be so uncomfortable that an individual may have to miss work, school, social events, or other important engagements. Typically, symptoms of withdrawal from opioids usually begin immediately after discontinuation or reduction and can last anywhere from one week to months. The length of time withdrawal symptoms persist depends on the opioid being used and the amount and duration of use. Withdrawal symptoms can continue even if an individual is in a substance abuse treatment facility, using opioid antagonist therapy, or in a medical management setting.

The occurrence of this disorder is more common in males. The onset of problems related to opioid use usually occurs during adolescence, although it may begin during any period of one's life. Opioid withdrawal occurred in 60% of individuals who had used heroin at least once in the previous 12 months (American Psychiatric Association, 2013).

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, individuals can be diagnosed with this disorder if they have had a reduction in or discontinuation of opioid use that has been prolonged and heavy or has been administered an opioid antagonist. In order to make this diagnosis, individuals must have three or more of the following symptoms. They include nausea or vomiting, diarrhea, muscle aches, dysphoric mood, tearing of the eyes or runny nose, dilated pupils, sweating, yawning, fever, or insomnia. The symptoms must cause significant distress and impairment in occupational, social, or other areas of functioning that are important, and may not be attributed to another medical condition or better explained by another mental disorder (American Psychiatric Association, 2013).

The cause of opioid withdrawal disorder is believed to be the misuse of opioids. The misuse may occur over a short period or more commonly over the course of the individual's lifetime. Individuals often rely on opioids to avoid symptoms of withdrawal. However, over time an individual will need to increase the amount of the drug in order to produce the same effect and not experience symptoms of withdrawal. When an individual stops taking opioids, the body needs time to recover, and the result is withdrawal symptoms.

Treatment

Treatment for this disorder typically involves medications and supportive care from family, friends, and medical providers. Medications are used to reduce withdrawal symptoms. Suboxone is a medication prescribed for relieving symptoms of opioid withdrawal. It can shorten the length of detoxification from opioids. Support groups, such as Narcotics Anonymous and Alcoholics Anonymous, can be very helpful for individuals addicted to opioids. Benefits for recovery are greatest for individuals who participate in a long-term substance abuse treatment program, work a Twelve-Step Program with a sponsor, take part in aftercare sessions, and participate in individual or group counseling.

Oppositional Defiant Disorder (ODD)

Oppositional defiant disorder (ODD) occurs when a child or teen has a persistent pattern of tantrums, arguing, and angry or disruptive behavior toward authority figures.

Definitions

- **Defiant** is an adjective used to describe resistance or objection.
- **Oppositional** is the act of displaying anger or hostility toward a person or group of people.

Description

It may be difficult at times to recognize the difference between a strong-willed or emotional child and one with ODD. It's normal for a child to exhibit oppositional behavior at certain stages of his or her development. But there is a range between the usual independence-seeking behavior of children and that of ODD.

Signs of ODD generally begin before a child is eight years old. Sometimes ODD may develop later but almost always before the early teen years. When ODD behaviors develop, the signs tend to begin gradually and then worsen over months or years. A child may be displaying signs of ODD instead of normal moodiness if the behaviors are persistent for more than six months and disrupt the home or school life.

Causes and Symptoms

There's no known clear cause of ODD. Most scientists and researchers believe that ODD occurs due to inherited and environmental factors. These can include a child's natural disposition and lack of or abusive adult supervision. Physical limitations or developmental delays in a child's ability to process thoughts and feelings could also be a reason that ODD occurs in some children. There has also been research into brain chemicals and differences in serotonin levels.

A child or teen who is diagnosed with ODD exhibits symptoms such as a negative attitude, disobedience, and hostility directed toward authority figures. These behaviors could cause a child to regularly and consistently have temper tantrums or be argumentative with adults in various situations.

In addition to these symptoms, children often refuse to comply with adult requests or rules and annoy other people on purpose. Some children with ODD blame others for mistakes or misbehavior and can be touchy or annoyed when they are accused of wrongdoing. Additional symptoms include feelings of anger and resentment, spite and aggression toward peers. This can cause difficulty performing academically and keeping social friendships, resulting in low self-esteem.

Diagnosis and Prognosis

To be diagnosed with ODD, a child must meet specific criteria. First a child requires a specific pattern of behavior that needs to have lasted at least half a year. During this time period, the child must demonstrate arguments with adults, temper tantrums, disobeying rules, annoying others on purpose, and blaming others. Also important to observe in a child with ODD are the emotional states of anger, resentment, being bothered by others, and often seeking revenge. Finally, it is important that these behaviors must happen more often and more intensively than with other children of the same age. The behaviors also need to cause problems in various places where the child spends time, especially school and home.

It can be difficult for doctors and mental health professionals to sort out and exclude this disorder from others with overlapping symptoms. For example, attention-deficit hyperactivity disorder (ADHD) and disruptive mood dysregulation disorder are sometimes hard to distinguish from ODD. Many times these disorders are provided as multiple diagnoses for one child.

Treatment

Treating ODD generally involves several types of therapy and training for the child and family. Treatment often lasts several months or longer. If a child has coexisting conditions, particularly ADHD, medications may help improve symptoms. However, medications alone generally aren't used for ODD unless another disorder coexists.

There are five cornerstones of treatments for ODD, which usually include individual and family therapy, problem solving, social skills, and parent training. Individual counseling for the child may help him or her to learn better ways of self-expression. Family counseling may help improve communication and relationships, and help members of the family learn how to work together. This can include parent–child interaction therapy (PCIT) which is effective for treating ODD. In PCIT, therapists coach parents while they

interact with their children. This helps parents learn effective parenting techniques and has proven to improve the family relationships and decrease the child's problem behaviors.

Problem solving and social skills training have benefits for children with ODD. During training children learn to identify and alter problematic behaviors that lead to bad decisions and poor relationships with their peers. Finally, parent training gives family members a chance to learn how to encourage positive behaviors while eliminating problem behaviors. Parents learn specific strategies like giving effective timeouts, remaining neutral in times of struggle, and taking care of themselves.

Changes to the environment can help children with ODD and their families. These kinds of changes include having more structure in daily life. One example of this is to create a schedule for the family that includes specific meals that will be eaten at home together. This could also mean that they plan to engage in specific activities where one or both parents can follow the child's lead. With a combination of effective therapy, sometimes with the addition of medication, skills training, and parent involvement, the outcomes for children with ODD can be positive.

Our Inner Conflicts: A Constructive Theory of Neuroses (Book)

Our Inner Conflicts: A Constructive Theory of Neuroses is a book written by Karen Horney about how childhood experiences shape adult neuroses. It was first published in 1945.

Definitions

- **Movement** describes an individual's style of interactions with others, which may be toward, against, or away.
- **Neurosis** is an outdated but still used psychoanalytic term for unconscious anxiety expressed in physical or psychological symptoms.
- **Psychoanalysis** is a theory of human behavior and a form of therapy based on psychoanalytic theory. In psychoanalysis clients are encouraged to talk freely about personal experiences, particularly their early childhood and dreams. It was initially developed by Sigmund Freud.
- **Psychoanalyst** is a practitioner of psychoanalysis.
- **Psychoanalytic theory** is a psychological theory that explains behaviors and perceptions as the result of unconscious, sexual, and biological instincts. It was originally developed by Sigmund Freud.

Description

Karen Horney (pronounced "Horn-eye"), MD, PhD (1885–1952), was a psychoanalyst who made some significant changes to traditional psychoanalytic theory in her work. She disagreed with the idea that individuals are only motivated by their unconscious drives. She also highlighted the role of gender and unrealistic cultural expectations, and is considered to be the first female psychoanalyst. Like other psychoanalysts, she believed that the past was important in explaining the causes of problems. However, Horney also focused on dealing with problems in the present and thought people were capable of solving many issues on their own.

Our Inner Conflicts is a book with broad appeal. The basic theme of this text is that symptoms are caused by unresolved psychological conflicts within a person that developed during childhood. Horney viewed these

conflicts as inconsistencies. An example is a child who wants acceptance from his or her teacher but acts out in class and is always in trouble. He or she may unconsciously doubt his or her ability to be liked or may have feelings of anger toward authority figures. Horney believed that this kind of conflict (called neurosis) occurred when individuals had competing ideas about what they wanted. She viewed neuroses as the result of childhood experiences such as neglect, smothering, instability, and abuse.

According to Horney, these inner conflicts lead people to develop three basic types of "movement" in relation to others: toward, against, and away. One's early childhood experiences lead to the type of movement they develop. Those who experience isolation or fear as children may try to please others in order to feel safe and in control. They learn to move *toward* others. As adults, they can become passive, dependent, and fearful. While they seek to be around people, they are primarily concerned with being taken care of and not with the specific people themselves. Children who experience hostile or abusive family environments learn to see the world and other people as threatening and untrustworthy. They move *against* others with the goal of staying in control. This may be accomplished through open hostility or with subtle charm. In any case, they view relationships as win-or-lose contests. Finally, children who experience too much closeness learn to withdraw into themselves. They move *away from* others in an attempt to achieve separation. These people often feel superior to others and will do anything to avoid being forced to socialize and leave their inner world.

Horney believed that healthy children could display all of these movements at different times. It was only when people are unable to engage in different types of movement and their behaviors become compulsive that problems arise. Horney coined the term "tendency to dependency" to describe the consequence of these neuroses. She believed that people actually became more dependent on others because they are no longer aware of themselves and need validation. According to Horney, modern society encourages this process because of its emphasis on success and competition. In the end, individuals become healthy by integrating the different parts of themselves and achieving wholeness. This leads to meaningful and satisfying self-expression in relationships with others.

Pain and Suffering

Pain is the unpleasant sensory and emotional experience, whereas suffering is the meaning one attributes (gives) to that experience. Suffering is the subjective experience of pain.

Definitions

- **Anxiety** is a negative emotional state characterized by feelings of nervousness, worry, and apprehension about an imagined danger.
- **Biofeedback** is a technique used to help control one's body functions and can enable individuals to focus on making changes, such as relaxing certain muscles to reduce pain.
- **Cognitive behavior therapy** is a form of psychotherapy that focuses on changing maladaptive (faulty) behaviors, emotions, and thoughts. It is also known as CBT.
- **Depression** is an emotional state characterized by feelings of sadness, low self-esteem, guilt, or the reduced ability to enjoy life. It is not characterized as a disorder unless it significantly affects one's daily functioning.
- **Fatigue** is a feeling of tiredness that can have mental or physical causes.
- **Pain behaviors** are things that an individual says or does in response to pain.
- **Psychotherapy** is a psychological method for achieving desired changes in thinking, feeling, and behavior. It is also referred to as therapeutic counseling.
- **Relaxation therapy** is any process, method, or activity that helps an individual to relax in order to attain a state of calmness.

Description

"Pain" and "suffering" are two terms that are often used interchangeably. While they share some similarities, they also are quite different. Pain is an unpleasant sensation and emotional experience of actual or potential bodily damage. Pain can range from mild discomfort to severe agony. Some pain behaviors include moaning, asking for help, taking medications, and seeking medical treatment. Often, pain keeps an individual focused on distress for the purpose of relieving it. It motivates behavior that will help repair, improve, and heal. For example, a blister on the foot will usually motivate an individual to take his or her shoe off and put a bandage on it.

In contrast, suffering reflects the meaning individuals give to their pain. In a sense it is the story they tell themselves and others about their pain. In a very real sense, suffering is the subjective experience of pain. Effective health professionals are usually good at inquiring into an individual's suffering. It may be difficult to resolve pain issues because suffering cannot be found by examining an individual's body alone. Suffering exists only in the mind. It is essential for a physician to listen to an individual's narrative to find out if suffering is occurring. Those who are suffering need help, sometimes even more so than the pain they are experiencing.

Pain behaviors are real and are influenced by environmental consequences. Pain behaviors are triggered either by suffering or by events in the environment that influence an individual. Pain can significantly interfere with the general function of an individual and his or her quality of life. It can limit an individual's ability to concentrate, enjoy social interactions, and participate in physical activities. One common reason individuals seek medical treatment from a physician is for the physical pain and suffering they are experiencing. Pain is a major symptom of several medical conditions. Pain can be classified as either acute or chronic. Acute pain is usually sharp in intensity and begins suddenly. It may be mild and last for just a moment or may persist for months. When the underlying cause of the pain is treated, the pain goes away. Some examples of acute pain include dental problems, broken bones, and cuts and bruises. Chronic pain is pain that persists despite treatment and healing of a medical condition. Chronic pain can last for months or years. Some physical effects of chronic pain include limited mobility, lack of energy, and muscle tension. Emotional effects of chronic pain may include depression, anxiety, frustration, and anger. Some examples of chronic pain include back headaches, back pain, and nerve pain.

The cause of physical pain is from a disease, injury, or something that hurts the body. The cause of physical suffering is the failure to act successfully on the motivation of pain. Continually thinking about pain and how unlucky or unfair it is usually serves to worsen suffering. Suffering usually takes the form of guilt, anxiety, shame, resentment, blame, or anger. Often, an individual who is suffering may expect others to relieve his or her pain, rather than taking action himself or herself.

Treatment

Treatment for pain differs from treatment for suffering. An individual with physical pain usually consults with his or her family physician for a complete assessment and treatment plan. Medications may be prescribed for moderate to severe pain. Biofeedback and relaxation therapy may be effective in reducing physical pain by teaching the individual how to release tension and anxiety that often make painful conditions more intense. Psychotherapy is the usual treatment for suffering. Cognitive behavior therapy is effective in helping individuals focus on changing the meaning individuals have attributed to their pain.

Palliative Care

Palliative care is treatment for symptoms, discomfort, stress, and pain in individuals with medical conditions for which there is no cure.

Definitions

- **Disease** is an objective medical condition that can be acute or chronic.
- **Hospice care** is a form of multidisciplinary treatment that aims to enhance the quality of life and reduce pain of an individual who has been determined to die within six months.
- **Illness** is an individual's subjective experience to a disease.
- **Opioids** are a group of drugs that reduce pain. They are highly addictive and include both prescription drugs like Percocet and illegal drugs like heroin.
- **Psychotropic** medications are prescribed drugs that affect thinking, feeling, and behavior. They include antipsychotic, antianxiety, antidepressant, and antimanic medications.

Description

Palliative care is a kind of medical care used to improve the quality of life among individuals. Usually, it is provided to individuals who are experiencing significant symptoms from medical conditions for which there is no cure. It aims to provide relief from painful symptoms. Some common diseases that are treated in palliative care include congestive heart failure, Alzheimer's, AIDS, kidney failure, various forms of cancer, and renal disease. Symptoms often treated with this type of care include pain, depression, physical discomfort, medication side effects, fatigue, nausea, problems with sleep, and constipation.

Additional goals of palliative care include reducing distressing symptoms, increasing an individual's support system, linking an individual to needed resources, providing spiritual and emotional support, and assistance with rehabilitating an individual back to his or her previous functioning. A palliative care team can consist of a medical doctor, nurse, religious clergy, dietician, occupational therapist, social worker, counselor, and many other health-care workers. Palliative interventions can include pain medication management such as opioids or psychotropic medications, talk therapy, linkage to resources, assistance with daily functions such as bathing, and many more services. Palliative care can also be used with hospice care patients who are near the end of their lives, but palliative care can be used during any stage of an illness.

Palliative care was originally developed in the hospice care setting but is now being used to relieve symptoms and discomfort of individuals among various stages of an illness. Hospice care was originally created out of a hospice care facility in 1967, called St. Christopher's Hospice in the United Kingdom. The founder, Cicely Saunder (1918–2005), is known as the main proponent in the hospice movement.

Panic Attack

A panic attack is an episode of a sudden, intense, and debilitating sense of fear that is short lived.

Definitions

- **Agoraphobia** is extreme fear of public spaces, crowds, or areas from which escape may be difficult and results in intense anxiety.
- **Antianxiety medications** are prescribed drugs that relieve anxiety symptoms. They are also called anxiolytics or tranquilizers.
- **Antidepressant medications** are prescription drugs that are primarily used to treat depression and depressive disorders. They are known as antidepressants.
- **Anxiety** is a negative emotional state characterized by feelings of nervousness, worry, and apprehension about an imagined danger.
- **Fear** is an emotional response to a known danger.
- **Panic** is an intense sense of fear.
- **Panic disorder** is a mental disorder characterized by severe panic attacks that occur frequently and produce significant distress and/or impaired functioning.
- **Psychotherapy** is a psychological method for achieving desired changes in thinking, feeling, and behavior. It is also called therapeutic counseling.

Description

A panic attack is a sudden sense of extreme fear that is associated with both mental and physical symptoms. The experience of these attacks may contain numerous physical symptoms that may include heart

palpitations (pounding heart), sweaty palms, narrowing of vision, shortness of breath, and tingling in the fingers. Because of these symptoms, individuals may conclude that they are having a heart attack. They may feel detached from their experience (called derealization). In addition, they may sense that that are dying or going crazy. It should be noted that a panic attack is just one of the criteria necessary for the diagnosis of panic disorder.

The physical experience of panic (e.g., tightness in chest, shortness of breath, trembling) is associated with the human fear response. In normal functioning, a fearful stimulus registers and the body responds with the fight or flight response. The response is considered to be an evolutionary development that allows us to fight threats or escape from them (flight). The body does this by shutting down nonessential functions such as digestion and directs physiological resources to more necessary systems such as muscles. It is this redirection of resources in preparation for fighting or fleeing that results in the physical symptoms associated with panic attack. Individuals who suffer from recurrent panic attack are thought to have an overly sensitive fear response and therefore experience the fight or flight response as a result of mental activity as opposed to a truly dangerous stimulus.

The prevalence of panic attacks is relatively common in the United Sates, affecting approximately 11% of the population. Panic attacks affect more women than men. Typically, no treatment is needed for isolated episodes of panic. However, treatment is warranted for those who experience panic attacks as part of panic disorder.

- **Panic attack** is an episode of a sudden, intense, and debilitating fear that is short lived.
- **Psychotherapy** is a psychological method for achieving desired changes in thinking, feeling, and behavior. It is also called therapeutic counseling.

- **Psychotropic medications** are prescribed drugs that affect thinking, feeling, and behavior. They include antipsychotic, antianxiety, antidepressant, and antimanic drugs.

Description and Diagnosis

Individuals with panic disorder experience recurring panic attacks that cause significant levels of distress. It is one of the anxiety disorders in the DSM-5. These attacks can include numerous physical symptoms such as heart palpitations (pounding heart), sweaty palms, narrowing of vision, shortness of breath, trembling, and tingling in the fingers. Because of these symptoms, those with this disorder may fear that they are having a heart attack. They may also sense that they are detached from their experience (called derealization). In addition, they may have a sense that that are dying or going crazy. An important component of panic attack is that there is usually no obvious, plausible cause of their acute fear. For example, an individual experiencing a panic attack may think he or she will choke while having no physical obstruction of his or her airway. The duration of a panic attack is usually only a few minutes but in extreme cases may last an hour. Not only do individuals experience distress during the attacks, but they may also experience distress between attacks. This is called anticipatory anxiety as they anticipate experiencing another episode at any time. The experience of this disorder may be so severe that it is completely debilitating and may result in varying levels of disability.

Panic disorder is one of the less common anxiety disorder. Approximately 2.5% of the population is diagnosed with panic disorder (American Psychiatric Association, 2013). Also unlike the other anxiety disorders, it seems that panic disorder occurs in similar proportions to both sexes. This disorder may be accompanied by other anxiety symptoms or disorders, particularly agoraphobia. However, agoraphobia that occurs without panic attacks is a distinctly different presentation than agoraphobia that follows the onset of panic disorders. Those with only agoraphobia tend to fear public spaces because the environment is somehow dangerous to them. Individuals who develop agoraphobia following panic disorder often fear public spaces because they fear suffering a panic attack without a secure environment to readily escape to. Some also fear the embarrassment of being observed by others as having a panic attack.

To be diagnosed with this disorder, individuals must meet a number of specific criteria. They must experience recurring panic attacks, including various physical symptoms. They must also experience significant concern about future attacks or have changed their behavior so as to actively avoid situations that may result in future panic attacks (e.g., avoiding public spaces). In addition, this diagnosis can only be made when other mental disorders or physiological causes have been ruled out (eliminated) (American Psychiatric Association, 2013).

The precise cause of this disorder is not known and may vary from individual to individual. However, certain aspects of this disorder are known. The physical experience of panic (e.g., tightness in chest, shortness of breath, trembling) is associated with the human fear response. In normal functioning, a fearful stimulus is registered and the body responds with the fight or flight response. The response is thought to be an evolutionary response that allows one to fight threats or escape from them (flight). The body does this by shutting down nonessential functions such as digestion while directing the majority of resources to more useful systems such as muscles. It is this redirection of resources in preparation for fighting or fleeing that causes the majority of physical symptoms associated with panic attack. Individuals who suffer from panic attack are thought to have an overly sensitive fear response and therefore experience the fight or flight as a result of mental activity as opposed to a truly dangerous stimulus. Also, this disorder occurs more frequently in individuals who have other mental conditions, have been abused, have a family history of anxiety or panic, or have recently experienced extreme stress.

Treatment

Treatment for this disorder may include psychotropic medications, psychotherapy, or both. Both antidepressant medication and antianxiety medication may be utilized but serve fundamentally different purposes. Antidepressants such as Lexapro are typically

prescribed to reduce the frequency and severity of panic attacks. Antianxiety medication such as Ativan and Klonopin are prescribed to reduce the acute symptoms of an anxiety attack. These medications may be used together where the antidepressant reduces the frequency of the panic attacks and the antianxiety drug is taken at the onset of a panic attack to reduce the symptoms. Although the medications are useful, they are not the preferred long-term solutions. This is because antidepressants are often accompanied by unwanted side effects and because individuals often build a tolerance to the antianxiety medications and can be addictive.

Psychotherapy is the treatment of choice for this disorder. The most commonly utilized and most effective therapy for panic disorder is cognitive behavior therapy. The aim of this therapy is to help the individual understand his or her faulty beliefs, especially those concerning his or her physical symptoms. Also, individuals are taught relaxation and coping techniques to help them experience their physical symptoms in a more calm state. Often, both medications and cognitive behavior therapy are used in conjunction. The medications reduce frequency and intensity of attacks in the short term while the individual's maladaptive beliefs and behaviors are altered in therapy. This disorder is not likely to resolve without intervention. Self-help books and workbooks can be used along or in conjunction with psychotherapy.

Paradoxical Intention

Paradoxical intention is a psychotherapy technique developed by psychiatrist Viktor Frankl, where the client is instructed to deliberately focus on a negative state, habit, or thought in order to identify it and alleviate its effects.

Definition

- **Logotherapy** is a directive type of therapy developed by Frankl aimed at helping clients who are lacking purpose or exhibiting problem behaviors find meaning; it literally means "therapy through meaning."

Description

Paradoxical intention is a therapeutic method used by practitioners wherein they instruct clients to intentionally exacerbate their aversive emotional states in order to alleviate negative symptomatology. The purpose is to have the client recognize the irrationality of his or her reaction and relinquish control over it, thereby relieving oneself of unpleasantness. Austrian psychiatrist, Viktor Frankl, developed the technique while he was imprisoned in the Nazi concentration camps during World War II. He wrote about this and other methods at the end of his book *Man's Search for Meaning*, where he discussed how humans are able to overcome dire circumstances. Frankl refers to his therapeutic approach as logotherapy, which helps people find meaning and direction in their lives.

Therapists use paradoxical intention to counteract a variety of conditions. It is considered a cognitive behavioral strategy in that it focuses the client on both the intellectual (mental/cognitive) and the behavioral (feelings/actions) aspects of the problem. In practice, the client is directed to turn on or engage in the negative symptom and even to intensify it. This process allows the client to

realize he or she is in control of the worry, fear, or discomfort he or she is experiencing. Engaging in an anxious state does not help the client solve the problem, and therefore, it serves no purpose. By letting go of this, the client is then able to tackle the issue head-on.

Current Status and Impact (Psychological Influence)

Over the past decade, therapists have incorporated paradoxical intention more readily into their clinical practice. It has been used as an effective treatment for certain emotional, behavioral, and psychological disorders. Specifically, paradoxical intention has been used to treat generalized anxiety disorder and obsessive-compulsive disorder. It can help alleviate symptoms associated with insomnia, migraines, eating disorders, and phobic behaviors. Though paradoxical intention has proven effective in addressing conditions such as these, it should not be used to treat people suffering from more severe issues, including suicidal ideation and schizophrenia.

Paranoia

Paranoia is a mental condition involving suspicion or distrust that is unfounded or exaggerated.

Definitions

- **Alzheimer's disease** is a medical and mental disorder that causes dementia particularly late in life. It is also referred to as Neurocognitive Disorder Due to Alzheimer's Disease.
- **Behavior therapy** is a form of psychotherapy that focuses on identifying and changing maladaptive behaviors.
- **Cognitive behavior therapy** is a form of psychotherapy that focuses on changing maladaptive behaviors, emotions, and thoughts. It is also known as CBT.
- **Delusions** are fixed false beliefs that persist despite contrary evidence.
- **Dementia** is a group of symptoms including loss of memory, judgment, language, and other intellectual (mental) function caused by the death of nerve cells in the brain.
- **Huntington's disease** is a neurodegenerative disorder that affects the nerve cells in the brain to degenerate. It is characterized by muscle coordination where individuals have uncontrolled movements; clumsiness; and inability to walk, talk, and swallow.
- **Multiple sclerosis** is an inflammatory disease, which involves an immune-mediated process of abnormal response of the body's immune system and is directed against the central nervous system. The central nervous system is made up of the brain, spinal cord, and optic nerves.
- **Parkinson's disease** is a disease of the nervous system that causes tremor, rigidity, slowness of movement, and unstable posture.
- **Social skills training** is a treatment method that assists individuals to learn specific skills that are missing or those that will compensate for the missing ones.
- **Thought broadcasting** is the delusional belief that individuals can hear or are aware of another individual's thoughts and these thoughts are being broadcast to the environment.

Description

Paranoia is a mental condition characterized by an unfounded or exaggerated distrust or suspiciousness of others. Sometimes, paranoid individuals exhibit

feelings of persecution and an exaggerated sense of self-importance. Those who are often paranoid may believe that others are out to get them or are talking behind their backs. As a result, they respond defensively to what they view as personally threatening (e.g., a relationship, a job, the world). Paranoia can lead to intense feelings of distrust and hostility.

While minor feelings of paranoia are common, severe paranoia can cause significant fear and anxiety and noticeably effect social functioning. In fact, paranoia is a feature of several mental health disorders. It is often a symptom of schizophrenia. Individuals with schizophrenia are often preoccupied with delusions where the individual holds the belief that the world is against him or her. Paranoia also occurs as a symptom of other neurological diseases (e.g., Alzheimer's disease, brain injuries, strokes, Huntington's disease, Parkinson's disease, as well as various types of dementia). Another symptom of a paranoid individual includes the sense that others can read his or her mind. This is referred to as thought broadcasting. Individuals with paranoia also believe that they have the capability to use their thoughts to impact others' thoughts and actions. Paranoid individuals may believe that others are putting thoughts into their minds. They may be convinced that programs on television or radio are specifically talking to them. Other symptoms of paranoia include rage, hatred, and betrayal as a result of their intense and irrational suspicion of others, difficulty with forgiveness, taking offense easily, inability to relax, argumentative, stubborn, and self-righteousness.

In Greek the term "paranoia" means "madness beside or by the mind." The term was used to describe a mental illness in which a delusion was the only and most important feature. The delusion did not have to be oppressive to be classified as paranoia. Historically, any delusional belief could be classified as paranoia. Currently, there are several delusions besides paranoia.

The cause of paranoia is not fully understood. It may result from physical or chemical changes in the brain. The use of certain medications can cause symptoms of paranoia in an otherwise normal individual. Psychological factors also appear to be involved. For example, paranoia may result from the breakdown of several mental and emotional functions. Symptoms of paranoia may arise from denied, repressed, or projected feelings. For example, an individual with paranoid thoughts and feelings can become a part of a delusion because of a misunderstanding, an accident, or minor injustice.

Treatment

Treatment for individuals with paranoia may be quite challenging due to the distrust of individuals' motivations toward them. Psychotherapy is one option for individuals willing to participate in treatment. Cognitive behavior therapy (CBT) and other forms of therapy may be beneficial for certain individuals with paranoia. CBT attempts to make an individual more aware of his or her actions and motivations. CBT also attempts to help the individual learn more accurately how to interpret cues around him or her in an effort to help the individual change the dysfunctional behavior. Behavior therapy can help reduce sensitivity to the criticism and improve upon his or her social skills through training. Therapy also attempts to break the cycle of suspicion and isolation by using relaxation techniques and anxiety management by helping the individual to change his or her behaviors. Support groups can also be helpful for individuals experiencing paranoia as well as for their family members. Support groups can be very helpful in assisting individuals (e.g., family, friends, caretakers) who must learn to care for and live with a paranoid individual.

Paranoid Personality Disorder

Paranoid personality disorder is a mental disorder characterized by a pattern of a high level of distrust and suspiciousness of the motives of others.

Definitions

- ***Diagnostic and Statistical Manual of Mental Disorders*** is the handbook mental health professionals use to diagnose mental disorders. The current edition (fifth) is known as DSM-5.
- **Personality disorder** is a long-standing pattern of maladaptive (problematic) behaviors, thoughts, and emotions that deviates from the accepted norms of an individual's culture.
- **Psychotherapy** is a psychological method for achieving desired changes in thinking, feeling, and behavior. It is also called therapeutic counseling.
- **Social skills training** is treatment method that assists individuals to learn specific skills that are missing or those that will compensate for the missing ones.

Description and Diagnosis

The paranoid personality disorder is a personality disorder characterized by a pervasive pattern of aloofness, emotion coldness, unjustified suspiciousness, jealousy, and hypersensitivity. Individuals with this disorder can also be rigid, contentious, and litigious. Because of their tendency to project blame on others, they are often disliked by others. Anticipating that others will take advantage of them, make fun of them, or plot against them, they remain alert and vigilant and never share what they are thinking or feeling. They never forget a slight but hold grudges and collect injustices. As a result, they lead isolated lives and are disliked by others.

The clinical presentation of the paranoid personality disorder can be described in terms of behavioral and interpersonal style, thinking style, and feeling style. Individuals' behavioral style is characterized by being chronically tense, guarded, defensive, argumentative, and litigious. Interpersonally, they tend to be distrustful and secretive, and avoid intimacy. Their thinking style is characterized by careful scrutiny and scanning the environment for "clues" or "evidence" to confirm their preconceptions. While their perception may be accurate, their judgments often are not because their prejudices influence what they see and hear to fit their preconceptions. Therefore, they will disregard evidence that does not fit their preconceptions. When under stress their thinking can take on a conspiratorial or even delusional tone. Their hypervigilance and need to seek evidence to confirm their beliefs result in their mistrustful outlook on life. Their feeling style tends to be cold, aloof, unemotional, and angry. They seem to lack a deep sense of affection, warmth, and sentimentality. Because of their hypersensitivity to real or imagined slights, and their resulting anger at what they believe to be deceptions and betrayals, they tend to have few, if any, friends. Anger and jealousy are the two emotions they commonly experience and express.

The cause of this disorder is not well understood. However, these individuals tend to have characteristic view of themselves, the world, and others and a basic life strategy. They tend to view themselves as special but different from others but consider themselves better than others. Life and the world tend to be viewed as unfair, unpredictable, and demanding. They anticipate that life will sneak up and harm them when they least expect it. Accordingly, their basic life strategy is to be wary, counterattack, trust no one, and excuse themselves from failure by blaming others.

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, individuals can be diagnosed with this disorder if they exhibit a pervasive pattern of distrust and suspicion and interpret others' motives as harmful. Without sufficient basis, they suspect that others are exploiting, harming, or deceiving them. They are obsessed with unfounded doubts about the loyalty of friends and associates. Because of their unfounded fears, they are reluctant to confide in others. They are likely to interpret otherwise benign remarks and situations as threatening and dangerous. Not surprisingly, they are unforgiving of slights, insults, and injuries. These individuals are quick to react angrily or to counterattack when they believe that

their character or reputation is being attacked. They are likely to continually suspect, without justification, that their spouse or sexual partner is unfaithful.

Treatment

The clinical treatment of this disorder usually involves psychotherapy. Until recently, the prognosis for treatment of this disorder was considered guarded. Today, there is more optimism about achieving the basic goals of treatment. These include increasing benign perceptions and interpretations of situations, and increasing trusting behavior. Social skills training is used to change the way they process information. Paranoid individuals are taught how to reduce their perceptual scanning and attention to inappropriate cues and to attend to more appropriate cues. They learn to use logic and make more benign interpretation of cues. In so doing they can learn to interpret feedback, including criticism, as constructive. This social skills intervention approach is usually combined with psychotherapy to achieve positive therapeutic outcomes.

Paraphilic Disorders

Paraphilic disorders are mental disorders characterized by fantasizing about and engaging in sexual behaviors that are unusual and extreme.

Definitions

- **Cognitive behavior therapy** is a psychotherapy approach that focuses on maladaptive (faulty) behaviors, emotions, and thoughts.
- **DSM-5** stands for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, which is a diagnostic system used by professionals to identify mental disorders with specific diagnostic criteria.
- **Noncompliance** is the failure, in whole or part, to follow a prescribed treatment regimen.
- **Paraphilia** is a mental condition in which individuals can only become sexually aroused by inappropriate object, actions, or fantasies.

Description and Diagnosis

Paraphilic disorders are a group of DSM-5 sexual disorders in which an individual's sexual arousal and gratification depend on fantasizing about and engaging in sexual behavior that is unusual and extreme. It involves a particular object, such as underwear, or a particular action, such as exposing oneself. Paraphilias involve a preoccupation on the object or action to the point of being dependent on it for sexual gratification. They are common in men than in women.

According to the American Psychiatric Association (2013), atypical sexual behavior is not in and of itself a mental disorder. Rather, most individuals with atypical sexual interests do not have a mental disorder. To be diagnosed with a paraphilia, an individual must meet one of two criteria. The first criteria is that the individual must experience distress about his or her atypical sexual interest, and not just society's disapproval of his or her sexual behavior. The second criteria is that the atypical sexual interest or behavior must cause psychological distress or injury to another person and is not consensual or illegal.

The DSM-5 includes the following as paraphilic disorders. Symptoms for all these disorders include chronic and extreme sexual arousal.

Voyeuristic disorder. In this disorder sexual arousal is achieved by observing an unsuspecting and non-consenting person who is undressing engaged in

sexual activity. It may involve masturbation by the voyeur. The voyeur does not seek sexual contact with the person he or she is observing. This disorder is also known as "peeping" or "peeping Tom."

Exhibitionistic disorder. In this disorder sexual arousal is achieved with intense, sexually arousing fantasies, urges, or behaviors that result from exposure of one's genitals to an unsuspecting stranger. The condition usually is limited to the act of exposure, and actual sexual contact with the victim is rare. However, it may involve masturbation during the exposure. This disorder is also known as "flashing."

Frotteuristic disorder. In this disorder sexual arousal is achieved with intense touching or rubbing one's genitals against the body of a non-consenting, unfamiliar person. Most commonly, this behavior involves a male rubbing his genital area against a female, often in a crowded public location.

Sexual masochism disorder. In this disorder sexual excitement and climax are achieved through sexual fantasies, urges, or behaviors that involve being humiliated, beaten, or suffering. These acts can be self-inflicted and include cutting, piercing, or burning the skin, themselves. They may involve a partner who enjoys inflicting pain or humiliation and include bondage, spanking, or simulated rape.

Sexual sadism disorder. In this disorder sexual excitement and climax are achieved by inflicting psychological or physical suffering on a sexual partner. It differs from minor acts of aggression in normal sexual activity, for example, rough sex. Sometimes, sexual sadists are able to find willing partners to participate in the sadistic activities.

Pedophilic disorder. In this disorder sexual arousal is achieved with fantasies, urges, or behaviors that involve illegal sexual activity with a child 13 years of age or younger). Such behavior includes undressing the child, making the child watch the abuser masturbate, touching or fondling the child's genitals, or forcefully performing sexual acts on the child.

Fetishistic disorder. In this disorder sexual arousal is achieved by wearing or touching nonliving objects (fetish). The object of a fetish is often underwear, shoes, or lingerie. The fetish may replace sexual activity with a partner or may be integrated into sexual activity with a willing partner.

Transvestic disorder. In this disorder sexual arousal is achieved in heterosexual males by dressing in female clothes. This disorder differs from cross-dressing where the purpose is not to become sexually aroused or experience sexual climax.

The cause of this disorder is not well understood. It may be these disorders are caused or predisposed by childhood trauma. If there is a history of such trauma, it is often sexual abuse. Or, it may be that specific objects or situations have become sexually arousing if they are often and repeatedly associated with a pleasurable sexual activity. In general, individuals diagnosed with a paraphilic disorder have difficulty developing normal intimate and sexual relationships with others. Often, these disorders begin in adolescence and continue into adulthood. The intensity and occurrence of the fantasies associated with these disorders tend to decrease as the individual ages.

Treatment

Most individuals diagnosed with these disorder can be treated with cognitive behavior therapy aimed at modifying their sexual behavior. Medications may help to decrease the compulsiveness associated with paraphilias and reduce the number of deviant sexual fantasies and behaviors. Antidepressant medications and hormone medications like Depo-Provera, Androcur, and Lupron can also be used to lower the sex drive in pedophiles. These medications work by reducing their testosterone levels, which then lowers sex drive. Effective treatment for paraphilias is long term, and unwillingness to comply with treatment can hinder its success. Unfortunately, noncompliance is a problem and, as a result, treatment is less likely to be effective.

Parent, Loss of

The loss or death of a parent can be a life-changing experience for which few are prepared, especially children. This experience can extend beyond death to include abandonment.

Definition

- **Incomplete grief** is grief that persists and is chronic with no resolution that may include a lack of satisfaction regarding the end of relationship with the deceased parent.

Description

Losing a parent at any age can have a tremendous impact on an individual, whether the person is a child, an adolescent, or an adult. For a child, the loss of a parent can negatively impact his or her emotional development, which may in turn have impact on the individual's adult life. Some studies have suggested that the loss of a parent can make a child susceptible to substance abuse, higher rates of depression, increased likelihood of criminal behavior, underachievement in school, and lower employment rates.

One form of grief referred to as acute grief is considered to be a part of healthy bereavement. With acute grief, there may be some distress related to one's own physical health, goals the person was unable to attain, or there may be a disruption in the daily routine and regular behavior. In addition, there may be feelings of sadness or guilt in regard to the status of the relationship when the parent passed, meaning there could have been unresolved issues between the parent and child.

One area of concern is that the individual may experience incomplete grief. With this there may be persistence to the feelings experienced by the individual. This may include exaggerated and continued depression, denial, and impacts on aspect of daily living such as eating and sleeping. Accompanying this are major changes in behavior and intensified feelings with an excessive focus on the loss.

It is important to recognize that children and adults who lose their parents may have and display different dynamics. For instance, if a child is experiencing incomplete grief, he or she may identify with the deceased parent in what is considered a socially inappropriate way with adopting the parent's attitude and mannerisms. This can lead to social isolation from other children as they reject the child's change. The child's identity is connected to his or her parent–child interactions. Early loss of a parent can have grave impacts on relationships and interactions moving forward.

An important part of loss is constructing the narrative of that loss. A common way of coping with life stress, which includes the loss of a parent, includes sharing parts of the parent's narratives with others. Sharing of feelings is considered to be an essential part of coping and adapting to life after loss.

There are numerous variables that impact the process of grieving, such as personality, the perceived relationship with the lost parent, conflicting memories or experiences with that person, and the way in which the parent died, as well as the preparation time the person had leading up to the death. For instance, suicide tends to be one of the most difficult types of death for children to grieve and process.

It is also important to recognize that loss of a parent is experienced not just through death but also through abandonment of a child. This experience is likely to lead to emotional and behavioral difficulties and distress as an adult. Children who are orphaned or abandoned are more likely to experience additional stressors such as relocation from their home, separation from family or siblings, and movement from unstable living conditions.

Parental Alienation Syndrome

Parental alienation syndrome (PAS) is a condition that occurs when one parent consciously or unconsciously attempts to negatively affect a child's relationship with the other parent.

Definitions

- **Alienating parent** is the parent who criticizes and belittles the other parent in order to undermine and interfere with the child's relationship.
- **Child–parent relationship problem** is when a child perceives an alienated parent to have negative attribution, hostility, and feelings of estrangement toward the other parent.
- ***Diagnostic and Statistical Manual of Mental Disorders*** is the handbook mental health professionals use to diagnose mental disorders. The current edition (fifth) is known as DSM-5.
- **Target parent** is the parent who is slandered by the other parent in order to undermine and interfere with the child's relationship.

Description

Parental alienation syndrome is a condition in which there is a preoccupation with a child or children by one parent (the alienating parent), who engages in criticism and slandering of the other parent (the target parent). PAS primarily arises in the context of child-custody disputes. Often times during a divorce with children there are situations where one parent will attempt to damage the relationship between the child and the other parent. Parents can get so involved in conflict with each other during a divorce that they focus more on "winning" than on what is in the best interest of the child or children involved. This may include brainwashing (controlling another's thoughts and beliefs) the child. This may lead to the child's own contributions of making vicious or defamatory statements against the target parent. When a child unites himself or herself with the alienating parent and becomes hateful toward the target parent, parental alienation syndrome has developed. Some signs of parental alienation include the sudden rejection from the child/children without cause or specific event, or a child who refuses to communicate or spend time with the target (rejected) parent. A child with PAS becomes an alienator in his or her own right and actively participates in belittling the target parent in some of the following ways: (1) the child uses foul language and exhibits disobedient and hostile behavior; (2) the child feels the need to support and protect the alienating parent; (3) the child displays anger and hatred toward the target parent; and (4) the child does not show remorse or guilt over the cruelty toward the target parent.

Parental alienation syndrome was first described by Richard A. Gardner (1931–2003) in the 1900s. Gardner was an American child psychiatrist known for researching parental alienation in separated and divorced parents. He stated that one parent (usually the custodial parent) intentionally alienates the child or children form the noncustodial parent. The alienating parent (usually the custodial parent) attempts to damage or sever the child's relationship with the noncustodial parent. During Gardner's observations in private practice, he explained what he considered to be an epidemic of false accusations, particularly child abuse.

To date, the American Psychological Association has yet to formally include parental alienation syndrome in its *Diagnostic and Statistical Manual of Mental Disorders*. Some have suggested that the general concept is included under Parent–Child Relational Problem. Under this diagnosis, the child's perception of the target parent may include negative attributions of the other's intentions, hostility toward the target parent, excessive parental pressure, and inadequate

parental control, supervision, and involvement with the child.

Parenting Skills Training

Parenting skills training, also referred to as parent training or parent education, is a support service targeted at improving communication, teaching positive discipline styles, and reducing negative interactions between parents and their children.

Definitions

- **Parent education programs** are classes or workshops geared toward informing and teaching parents about child/adolescent development, strategies for effective communication, and alternative approaches to discipline.
- **Positive reinforcement** is an operant conditioning technique used to increase the occurrence of desirable behaviors by providing some reward for those and reducing the likelihood of undesirable ones by ignoring them.

Description

Parenting is considered one of the most difficult jobs, and yet it comes without any formal preparation, training, or instruction. When children display academic, behavioral, psychological, emotional, or social concerns, parents are often the first to be blamed though many lack the education, means, and skills to provide adequate guidance and care. Those parents in need of additional support may seek it out through parenting skills classes or parent education programs. Child welfare services may also order certain parents to participate in education or skills training as a consequence of child/adolescent maltreatment. Courts can require these caregivers to complete skills training courses as a prerequisite to reunification with their children. Education-based programs are meant to impart factual, applicable content, while training-based programs focus on skill building and practice. Both services aim to provide adults with the knowledge and strategies needed to become competent, effective, and caring parents. The goal of parental intervention is to reduce the risk of child abuse, neglect, and dysfunction and increase a family's strength, stability, and sense of connectedness.

A variety of professionals from educators and health-care workers to counselors and therapists can lead parent skills training sessions. Parental interventions can be offered at agencies, clinics, and schools as a supplement to existing programs, though availability can vary from one geographical area to another. Services are provided to individual parents or groups of parents face-to-face, via the Internet, and through recorded or print media. Participants actively acquire new knowledge and skills by engaging in open discussion, modeling, skills practice, and homework.

Development (History and Application)

Clinical psychologist Thomas Gordon developed one of the first parent skills training programs *Parent Effectiveness Training* (PET), in Pasadena, California, in the early 1960s. PET remains a widely used program and has been studied, practiced, and proven effective worldwide. Several additional programs also exist, each with its own guiding principles, approach, and format. These include *Parent Management Training* also founded in the 1960s by the Oregon Social Learning Group; *Systematic Training for Effective Parenting* published by psychologists Don Dinkmeyer and Gary D. McKay in the mid-1970s; *Love and Logic*, also developed around this time; and the *Active Parenting* curriculum released in 1983. These founding programs have since been added, revised, and updated

to incorporate "best practices" in terms of parental intervention. Research investigating programs such as these have sought to link participation with positive outcomes for both parents and children.

Current Status

A meta-analytic review conducted in 2008 indicated that the most effective parent skills training programs not only assisted caregivers in acquiring new skills and behaviors but were also impactful at reducing negative, externalizing behaviors in children. Programs that fared best taught emotional communication skills and positive parent–child interaction skills, and required participants to practice these skills with their own child within the program sessions. These key components encourage empathy, patience, and respect, which in turn foster healthy relational bonds among family members. In addition, by expecting caregivers to demonstrate skills in sessions with their children, mistakes can be corrected and proper skill use reinforced. Practice, repetition, feedback, and consistency allow for growth to occur.

Parenting Styles or Disciplinary Styles

There are four types of parenting or disciplinary styles, authoritarian, authoritative, permissive, and uninvolved, each offering a unique approach to discipline and perspective on how the relationship between parent and child should best be maintained.

Definitions

- **Authoritarian parenting** describes a disciplinary style that is highly structured, rule-oriented, rigid, and demanding with a low level of responsiveness.
- **Authoritative parenting,** also known as democratic parenting, characterizes parenting that is both demanding and responsive; authoritative parents provide the proper balance of expectations, limits, and support.
- **Permissive parenting,** or indulgent parenting, describes those who are highly responsive to their children but do so with little to no demands, expectations, or boundaries.
- **Uninvolved/unengaged parenting** characterizes a disciplinary style that is low in both responsiveness and demands; parents who operate from this style may be rejecting and neglectful.

Description

Four distinct parenting or disciplinary styles characterize the relationship between parents and their children. Each describes a variation on the relationship dynamic, approach to punishment and rewards, and resulting effect on the child's development. Though one's parenting style may vary depending on the situation, or the child's or parent's current circumstance, a preferred style usually surfaces. Psychologist Diana Blumberg Baumrind conducted 30 years of research, beginning in the 1960s, on child development, socialization, and parenting. She was the first to identify and describe the four major parenting styles, authoritarian, authoritative, permissive/indulgent, and unengaged/uninvolved, that parents use to manage their children's behavior. It is important to note that the various styles, though different, are all characteristic of "normal," non-abusive, non-neglectful parents. Baumrind's research is considered the gold standard on this topic and has been cited and expanded upon by many others in the psychological community. The Baumrind Model proposes that both love and discipline fill the child's need for support and guidance; thus, each of the four styles reflects a different balance between responsiveness (warmth,

responsiveness, reciprocity, attachment) and demandingness (confrontation, monitoring, consistency, discipline strategies). For one, authoritarian parents place high demands on their children but are low in responsiveness. Interactions between this type of parent and their child may be described as overly structured, rigid, strict, and punitive. Therefore, children with authoritarian parents may display anxiety, fear, moodiness, and low self-esteem. Alternatively, the authoritative, or the democratic parenting, style is characterized by high responsiveness and high demandingness. Experts endorse this perspective as optimal in terms of fostering a healthy, balanced relationship between parent and child. Adults who operate from this orientation are described as assertive, communicative, and respectful. They have high, yet realistic, expectations, establish healthy boundaries, but are able to provide an environment of positivity, love, care, and support which allows for the child to explore, discover, and thrive. Next, the permissive parenting style is low on demandingness yet high on responsiveness. Parents who operate from this disciplinary style do not believe in stringent rules, and are more open, accepting, and perhaps indulgent. Children of permissive parents appear friendly, pleasant, social, creative, and confident but may also react in aggressive, controlling, and impulsive ways. Lastly, the unengaged or uninvolved parenting style describes adults who are low in demandingness and low in responsiveness toward their children. On the extreme, unengaged parents may be rejecting and neglectful. Children whose parents are uninvolved have difficulty forming secure attachments. They are also likely to engage in deviant or risky behaviors.

Impact (Psychological Influence)

The professional literature abounds with studies correlating parenting style with positive and negative outcomes. Findings indicate that a parent's disciplinary style can have a dramatic effect on a child's development, impacting not only the parent–child relationship but future relationships, in addition to the child's mood and overall temperament into adulthood, and the manner in which he or she eventually parents his or her own children. Research suggests that children from authoritarian households exhibit lower levels of frustration tolerance and experience anger and aggression more readily. Studies have also found that children with uninvolved parents tend to experience at-risk behaviors, such as substance abuse, dropping out, and teen pregnancy at increased rates. As previously mentioned, the authoritative parenting style has been endorsed by parenting experts as it allows for an appropriate balance between demandingness and responsiveness. A large review investigating the relationship between parenting styles and at-risk behaviors in adolescent health found that youth from authoritative families consistently demonstrate higher protective factors and fewer problem behaviors than those from non-authoritative families. A guardian's ability to relay warmth and care and to communicate effectively while still commanding respect has been associated with gains in academic achievement as well as with positive psychosocial adjustment. More research is needed to address parenting styles with diverse populations as assumptions should not be made across cultures. Programs, services, and interventions that support parental development and growth are needed so that families can learn the skills necessary to function in healthy ways.

Parents, Overinvolved

Overinvolved parents, commonly referred to as overprotective, invasive, or helicopter, exhibit overly

controlling, stimulating, or hovering behaviors, considered excessive or extreme to the average parent.

Definitions

- **Helicopter parenting,** also referred to as intensive parenting, refers to the actions of parents or guardians who overtly infuse themselves into every aspect of the child's life, not allowing the child to deal, cope, grow, or mature properly on his or her own.
- **Invasive parenting**, also known as hyperparenting or "hothouse parenting," describes a parent–child relationship characterized by pressure, smothering, preoccupation, and excessive attention on the child, his or her relationships, activities, successes, and accomplishments.
- **Overparenting,** or overprotective parenting, is defined by intense worrying, hovering, and protectiveness whereby the parent seeks to shelter his or her child from any source of possible stress, harm, worry, or fear.
- **Snowplow/bulldozer parent,** considered a step up from helicopter parent, is an extreme form of parent who intervenes and interferes in the child's life by attacking, threatening, or eliminating any obstacle that may be in the child's way.

Description

Parents who excessively or intensively attempt to control their child's lives may be characterized as "overinvolved." "Invasive," "overprotective," "hyperparenting," and "overparenting" are also terms used to describe this dysfunctional parenting style. Overinvolved parents wish to insert themselves into every situation involving their child. Subsequently, the child never learns to properly cope, problem solve, navigate, or mature on his or her own. Helicopter parents are known for hovering behavior, paying close attention to their child's safety, well-being, and success. This pejorative term first appeared in psychologist Haim Ginott's 1969 book *Between Parent and Teenager*, quoting a teenager who used the metaphor to describe his mother's smothering nature. More recently, the words "snowplow" or "bulldozer" have been added to the vernacular to define even more extreme parenting styles. As their names denote, these types of parents attempt to extinguish whatever or whomever gets in their child's way.

Impact (Psychological Influence)

Though overinvolved parents may have good intentions and truly care about their child's success, they often do not understand how their excessive involvement deters proper maturation and development. Thus, many children remain dependent on parental supervision in order to complete daily tasks. However, happiness, self-esteem, and personal autonomy result from accomplishing tasks, learning to solve conflicts, and persevere through hardships. By not permitting a youngster to weigh pros and cons, manage disagreements, and make decisions for himself or herself, progression into adulthood is delayed. Psychologists describe this as "extended adolescence," a trend that has been noted in the millennial generation (those born roughly between 1981 and 2000), who consistently report significant levels of stress, anxiety, and apprehension about growing up. Increased rates of depression and suicide have also been noted in this subgroup over the past decade. Researchers attribute this rise in part to parenting as many adolescents have been too sheltered, protected, and managed by their parents. Lack of experience with disappointment, realistic expectations, and constructive criticism has left many young adults ill-prepared to navigate through life's stressors. In contrast to overinvolvement, experts recommend an authoritative parenting style, characterized by balanced expectations and support, collaboration, and responsibility, in promoting healthy, confident, and competent children.

Parkinson's Disease

Parkinson's disease is a disease of the nervous system that causes tremor, rigidity, slowness of movement, and unstable posture. When cognitive impairment is also present, this disease is known as Neurocognitive Disorder Due to Parkinson's Disease in DSM-5.

Definitions

- **Dopamine** is the chemical messenger in the brain responsible for coordinating the movement of voluntary muscle groups. It also regulates attention, pleasure, and coping with stress.
- **DSM-5** stands for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, which is a diagnostic system used by professionals to identify mental disorders with specific diagnostic criteria.
- **Neurodegenerative disease** is a medical condition in which the nervous system progressively and irreversibly deteriorates.

Description and Diagnosis

Parkinson's disease is a progressive, neurodegenerative disease that occurs when the neurons within the brain that produce dopamine become impaired or dies. When most of the brain's dopamine-producing cells no longer function, the symptoms of Parkinson's disease begin to appear. Common symptoms include tremor or shaking, stiff muscles and achiness, slurred speech, limited movement, continuous "pill-rolling" movement of the thumb and forefinger, shuffling gait, and difficulty with balance. As the Parkinson's disease progresses, individuals begin to shake, tremble, and exhibit severe movement disturbances.

When there is also a decline in cognitive functioning, DSM-5 designates it as Neurocognitive Disorder Due to Parkinson's Disease. This decline comes on unexpectedly and progresses gradually. Symptoms include apathy, anxious and depressed mood, hallucinations, personality changes, and excessive daytime sleepiness.

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, individuals can be diagnosed with this disorder when they begin exhibiting the cognitive decline associated with the onset of Parkinson's disease. Also required is an insidious beginning and a slow, steady progression of impairment. The disorder cannot be caused by another medical condition, nor can there be evidence of mixed etiology, and Parkinson's disease must precede the onset of the neurocognitive disorder. Criteria must also be met for either major or mild neurocognitive disorder. This disorder can be coded with or without behavioral disturbance (American Psychiatric Association, 2013).

The cause of this disorder has been established as decreased levels of dopamine. This occurs when neurons (nerve cells) in a part of the brain called the substantia nigra deteriorate and no longer produce dopamine. Other factors that may be causative are genetics, aging, inflammation, and toxins in the environment.

Treatment Considerations

Because there is an obvious biological basis for Parkinson's, treatment is largely biological. Currently, there is no known treatment that can stop or reverse this disease. However, certain medications can relieve many of its symptoms. The goal is to correct the shortage of dopamine. Sinemet (L-dopa) is the most commonly prescribed and most effective drug for controlling the symptoms of Parkinson's disease by increasing dopamine. Surgery can also be an effective treatment for some individuals.

Partial Hospitalization Program

Partial hospitalization programs are intensive mental health or substance treatment programs for individuals who would otherwise require inpatient treatment. It is also called PHP and intensive outpatient treatment.

Definitions

- **Addiction** is a chronic disease of the brain that involves compulsive and uncontrolled pursuit of reward or relief with substance use or other compulsive behaviors.
- **Alcohol use disorder** is a mental disorder involving a pattern of alcohol use that leads to significant problems for the user.
- **Cannabis use disorder** is a mental disorder characterized by cannabis (marijuana) use, which leads to significant problems for the user.
- **Case management** is a collaborative process between a health professional and an individual and family to assess, plan, coordinate, evaluate, and advocate for the individual's health needs.
- **Drug dependence** is a mental condition characterized by physical dependence. It is similar to but different from addiction.
- **Inpatient treatment** is a mental health or substance treatment provided in a hospital setting.
- **Intensive outpatient treatment** is a mental health or substance treatment group and individual services of that allow individuals to participate in both daily affairs and treatment at an appropriate facility in the early morning or in the evening. It is also called intensive outpatient program or IOP.
- **Substance-related and addictive disorders** are a group of mental disorders that include substance disorders characterized by physiological dependence, drug-seeking behavior, tolerance, and social withdrawal. This group also includes the non-substance disorder of gambling.

Description

Partial hospitalization programs are intensive mental health or substance treatment centers that treat individuals with mental conditions. These programs allow individuals who would otherwise require inpatient treatment to reside in their own homes. They are also known as intensive outpatient treatment. Such treatment allows individuals to remain with their families and maintain employment while receiving intensive outpatient care. The goal of partial hospitalization programs is to reduce inpatient hospitalization cost and ultimately reduce the cost of long-term care. In the United States, partial hospitalization programs can be housed in a hospital setting or in an individual community mental health center. Programs are often required to pass significant inspection and review from state, national, and insurance bodies. Funding for services can often be covered by insurance companies, private pay, Medicaid, and Medicare.

Treatment administered in such programs includes individual and group counseling, case management, and medication. Examples of substance-related and addictive disorders conditions treated in this setting include alcohol use disorder or cannabis use disorder. Mental health conditions treated in this setting include depression, eating disorders, and many other forms of mental illness. Treatment is typically delivered by psychologists, psychiatrists, mental health counselors, social workers, nutritionists, case manager, physicians, and other health-care workers.

Albert E. Moll, MD (1938–2007), a Canadian psychiatrist, pioneered partial hospitalization programs which he called day hospital treatment. He believed that individuals could be successfully treated while still remaining at home and also remaining employed. This form of substance abuse and mental health care is designed to reduce cost to society and to the individual receiving treatment.

Passionflower

Passionflower is an herbal remedy used to treat anxiety and sleep problems.

Definitions

- **Alkaloids** are plant compounds composed of carbon, hydrogen, and nitrogen, which are pharmacologically active. Examples are caffeine, morphine, nicotine, and Yohimbine.
- **Antispasmodic** is a medication or preparation used to relieve muscle or digestive cramps.
- **Flavonoids** are plant compounds that have anti-inflammatory, anticancer, or antioxidant effects.

Description

Passionflower is a plant (*Passiflora incarnata*) whose leaves and flowers are used to make an herbal remedy for anxiety, sleep problems (insomnia), stomach upset related to anxiety or nervousness, and generalized anxiety disorder. It has been used to reduce symptoms related to narcotic drug withdrawal. Other uses include seizures, asthma, symptoms of menopause, attention-deficit hyperactivity disorder, palpitations, irregular heartbeat, high blood pressure, pain relief, hemorrhoids, and fibromyalgia.

Although some studies have shown passionflower to have sedative and antispasmodic effects, it is not clear which compounds in the plant have these properties. Passionflower is known to contain flavonoids and a group of alkaloid compounds that include harman, harmine, harmaline, and harmalol. It is thought that the medicinal effects of passionflower derive from a combination of these substances rather than from any of them in isolation.

Precautions and Side Effects

It should be noted that passionflower had been approved as an over-the-counter sedative and sleep aid in the United States. However, in 1978 it was taken off the market because its safety and effectiveness had not been proven. Passionflower should not be used in doses higher than the recommended levels. Because it has a sedative effect, it should not be combined with alcohol or prescription sedatives. Passionflower should not be used by pregnant or lactating women or for children under six months old. It can increase the effects of anesthesia and other medications during and after surgery. So, those planning major surgery should stop using passionflower at least two weeks before their procedure.

The alkaloids found in passionflower, especially harman and harmaline, may increase the effects of a class of prescription antidepressants called monoamine oxidase inhibitors such as Nardil and Parnate. Passionflower may also increase the effects of sedative medications and should not be used in conjunction with either of these medications. Because passionflower can cause sleepiness and drowsiness, it should not be used with sedative medications. These sedative medications include Nembutal, Luminal, Seconal, Klonopin (Clonazepam), Ativan, and Ambien.

Passive-Aggressive Personality Disorder

Passive-aggressive personality disorder is a mental disorder characterized by an enduring pattern of negative attitudes and passive-aggressive behaviors. It is also known as negativistic personality disorders.

Definitions

- **Dependent personality disorder** is a mental disorder characterized by pervasive pattern of submissiveness, a lack of self-confidence, and an excessive need to be taken care of by others.
- ***Diagnostic and Statistical Manual of Mental Disorders*** is the handbook mental health professionals use to diagnose mental disorders. The current edition (fifth) is known as DSM-5.
- **Passive-aggressive behavior** is the indirect expression of hostility characterized by procrastination, stubbornness, forgetfulness, sarcasm, inconsistency, stubbornness, resentment, and repeated failure to accomplish requested tasks for which an individual is responsible.
- **Personality disorder** is a mental disorder characterized by a long-standing pattern of maladaptive (problematic) behaviors, thoughts, and emotions that deviates from the accepted norms of an individual's culture.

Description and Diagnosis

The passive-aggressive personality disorder is a personality disorder characterized by an enduring pattern of negative attitudes and passive resistance in complying with reasonable expectations for adequate performance in school, work, or social settings. It includes passive-aggressive behaviors such as forgetfulness, procrastination, inconsistency, and underachievement. This disorder begins by early adulthood and presents in various situations and contexts. Basically, individuals with this disorder accept others' needs and desires but passively resist them. Instead of asserting their own needs and desires, they become increasingly hostile and angry. Because they identify themselves in opposition to others' goals, it is very difficult for them to pursue their own identity and goals.

Passive-aggressive personality disorder was listed among the other personality disorders in the *Diagnostic and Statistical Manual of Mental Disorders, Third Edition Revised* (DSM-III-R). However, it was moved to an appendix in the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition* (DSM-IV) as a diagnosis needing further research support. This disorder is also listed in the *Psychodynamic Diagnostic Manual* (PDM) as a variant of the dependent personality disorder.

The DSM-IV provides research criteria for the passive-aggressive personality disorder. According to the DSM-IV individuals can be diagnosed with this disorder if they passively resist completing routine social and occupational tasks. They tend to complain of being misunderstood and unappreciated by others. They are likely to be sullen and argumentative, and unreasonably criticize and scorn authority. They may also express envy and resentment toward those who appear to be more fortunate than them. They also tend to persist in exaggerating and complaining about their personal misfortunes. In addition, they characteristically alternate between hostile defiance and contrition or submission.

The PDM describes individuals with this disorder as having a characteristic view of others and themselves. They tend to view others as wanting them to conform to their rules. At the same time, they view themselves as only able to achieve a sense of worth and dignity when they sabotage the achievement of others. Accordingly, their basic preoccupation is to get revenge and tolerate misfortune. Their basis affects or feelings are anger, resentment, and taking pleasure in their passive-aggressive behaviors. In short, individuals with this disorder are reactive to others' agendas and goals rather than active in achieving their own goals and agendas.

Treatment

The clinical treatment of this disorder usually involves psychotherapy. The PDM indicates that the main task of therapy is to increase individuals' self-acceptance and identity as agents of their own destinies instead of simply being reactors to others' demands. These individuals need help in naming their negative feelings and distinguishing verbal from behavioral expressions of their anger. In response to the oppositional attitude of these individuals, therapists need to take their inconsistencies and provocations in stride. Effective therapists continually focus therapy on the price these individuals pay for their passive-aggressive behaviors.

Pastoral Counseling and Psychotherapy

Pastoral counseling and psychotherapy is a form of counseling that integrates theological, spiritual, and psychological concepts in order to provide faith-based counseling interventions.

Description

Pastoral counseling is a psycho-spiritual approach to helping and is most commonly provided by clergy. Clergy are individuals who are trained and endorsed by their religious organization to provide spiritual leadership and services on behalf of the religious organization. Clergy representing Christianity, Judaism, Islam, and other faith traditions can become pastoral counselors. Many pastoral counselors have also received specialized mental health training, certification, or licensure as mental health practitioners, marriage and family therapists, clinical social workers, or psychologists.

As of 2013 only six states (Arkansas, Kentucky, Maine, New Hampshire, North Carolina, and Tennessee) license the title of "pastoral counselor." In states where there are no licensing requirements, pastoral counseling is unregulated. Although pastoral counseling is largely unregulated in the United States, the American Association of Pastoral Counselors (AAPC) provides certification, sets training standards, and defines ethical practice for pastoral counselors. In unregulated states, pastoral counselors can be legally limited in the counseling or psychotherapeutic services they provide and any fees associated with those services. Pastoral counselors in unregulated states may choose to meet state requirements to become licensed professional counselors or licensed marriage and family therapist.

Development

Throughout human history religious communities have provided social structure, support, comfort, and care to its religiously oriented members. Clergy have traditionally served in a helping role in the lives of individuals and families. Before the development of modern psychology, clergy were one of the few helping relationships people could turn to outside of family.

By the early 1900s the need to integrate psychological concepts into pastoral training began to be recognized by clergy and a new form of training, referred to as Clinical Pastoral Education (CPE), was developed. CPE included training in which theological students were placed in psychiatric hospitals and provided supervised care to patients. Influenced by the rise and popularity of Freudian psychology, a variety of CPE organizations were formed with a focus on the integration of psychology in pastoral training. In the 1930s the Council for Clinical Training of Theological Students and the American Foundation of Religion and Psychiatry were both independently formed. By the 1950s some church denominations began to form their own training certification. The Southern Baptist Association of Clinical Pastoral Education was founded in 1957 and in 1967 merged with other pastoral groups to form the Association for Clinical Pastoral Education. CPE does not provide training in counseling or psychotherapy but focuses on educating and training seminary

students, clergy, chaplains, and laypeople (non-ordained) in the provision of care in hospitals, hospice settings, retirement homes, and other direct care settings.

The American Association of Pastoral Counselors was formed in 1963 with a focus on the establishment of educational training, standards, and professional ethics in pastoral counseling and psychotherapy. Founded as a membership and certification organization, the AAPC has over 2,000 members and sets practice standards for certification as pastoral counselors. The AAPC has 75 pastoral counseling centers. The purpose of the AAPC is to provide spiritually informed and integrated counseling, collaborative community-based services, training, and education in order to enhance the well-being of individuals, families, and communities. The mission of the AAPC is to bring healing, hope, and wholeness to individuals, families, and communities by expanding and equipping spiritually grounded and psychologically informed care, counseling, and psychotherapy.

Certification as a pastoral counselor by the AAPC requires an undergraduate degree, and a graduate masters or doctoral degree in theological/spiritual studies or in pastoral counseling from schools accredited by agencies recognized by the U.S. Department of Education. Additional requirements include endorsement for ministry from a religious organization, active relationship in a religious community, completion of a supervised self-reflective pastoral experience, three years of ministry experience, 375 hours of pastoral counseling, and 125 hours of supervision.

Pastoral counseling and psychotherapy is a unique form of helping provided by clergy from diverse religious perspectives and traditions. The integration of specific theologies and spiritual traditions are essential components of professional practice provided by certified pastoral counselors.

Pastoral Counselor

Pastoral counselors are professional counselors with specialized training in theology, pastoral care, and psychology.

Description

Clergy were providing care to people needing help with their personal and mental health problems long before counselors, psychologists, social workers, psychiatrists, or other mental health professionals existed. Recognizing that many congregants suffer from mental health conditions pastors began to seek and receive specialized training in psychology in order to better serve their congregations and communities. In 1963, the American Association of Pastoral Counselors (AAPC) was formed in order to establish standards of educational, training, and ethical practices. The AAPC has approximately 4,000 members and is the largest certification organization for pastoral counselors. In order to become AAPC certified, pastoral counselors must meet the educational and training standards set by the organization. Many clergy choose to integrate a graduate clinical degree in a mental health discipline, such as counseling, marriage and family therapy, social work, or psychology, into their pastoral duties.

The primary goal and function of pastoral counselors is to assist individuals cope with physical, emotional, and moral difficulties. Secondary goals include symptom reduction and problem resolution. Addressing spiritual and religious needs is a fundamental component of pastoral counseling, especially for those needing help in coping with crises and personal problems. There are three forms of pastoral counseling that are practiced. A pastoral counselor may choose to provide a brief, situational focused, single session, for those individuals needing help dealing with a specific

issue. A time-limited form of treatment may be offered to those needing one to five sessions. Pastoral psychotherapy may be provided to those needing long-term treatment relating to personality change. Only clergy who have formal supervised clinical training and who are certified or licensed to practice psychotherapy may provide pastoral psychotherapy.

Pastoral counselors provide care with a unique blend of spiritual, religious, and psychological concepts with therapeutic knowledge and clinical competencies. Pastoral counselors help individuals resolve difficulties, restore their psychological health, and promote positive growth and change. Clients are most often individuals struggling with emotional or relational problems; with life transitions; or because of guilt, addictions, abuse, or low self-esteem.

The process of pastoral counseling is similar to other forms of psychotherapy. A positive therapeutic alliance and relationship between the client and the pastor is an important component that can maximize client change. As with most psychotherapies, maintaining some degree of therapeutic distance can aid in accurate diagnosis and client change. In addition to examining client circumstances, the pastor may assess the client's awareness of God, the role God plays in a client's life, client understanding of repentance and grace, and other spiritual dynamics related to the specific religious affiliation. A client's relationship and involvement in the faith community may also be assessed.

Pastoral counselors engage in a wide variety of therapeutic interventions associated with problem solving or solution-focused counseling models. Interventions include active listening and advice giving regarding spiritual and religious matters. Pastoral counselors who maintain clinical licensure can choose from a wide array of therapies to promote client change. Most pastoral counseling models resemble traditional counseling sessions, with clients being seen individually, with their spouse, or as a family, in an office setting during appointed times. Sessions may or may not be conducted at the church or faith facility.

Current Status

Pastoral counselors are actively engaged in establishing their identity as recognized professionals. Pastoral counseling is largely unregulated and only six states (Arkansas, Kentucky, Maine, New Hampshire, North Carolina, and Tennessee) license the title of "pastoral counselor." The AAPC is a strong member organization that will continue to have the strongest voice on behalf of pastoral counselors. Pastoral counselors provide meaningful and effective mental health services to countless faith communities throughout the United States and the world.

Pattern-Focused Psychotherapy

Pattern-focused psychotherapy is a form of psychotherapy for quickly and effectively identifying and replacing maladaptive patterns with more adaptive ones.

Definitions

- **Biopsychosocial therapy** is an integrative approach that incorporates biological, psychological, and sociocultural factors in planning and implementing psychological treatment. It emphasizes pattern identification, pattern change, and pattern maintenance.
- **Cognitive behavior analysis system of psychotherapy** is a psychotherapy approach that focuses on identifying and changing hurtful thoughts and behaviors with more helpful ones. It is also referred to as CBASP.
- **Evidence-based practice** is the integration of the best research evidence with clinical experience and client values to inform clinical decision making.

- **Motivational interviewing** is a counseling strategy for helping individuals discover and resolve their ambivalence to change. It is also referred to as MI.
- **Pattern** is the predictable, consistent, and self-perpetuating style and manner in which individuals think, feel, act, cope, and defend themselves.
- **Psychotherapy** is a psychological method for achieving desired changes in thinking, feeling, and behavior. It is also called therapeutic counseling.

Description

This form of psychotherapy emphasizes patterns. Patterns can either be maladaptive or adaptive. Maladaptive patterns tend to be inflexible, ineffective, and inappropriate, and cause symptoms, impairment in personal and relational functioning, and chronic dissatisfaction. If such a pattern is sufficiently distressing or impairing, it can be diagnosed as a personality disorder. In contrast, an adaptive pattern reflects a personality style that is flexible, effective, and appropriate.

Pattern-focused psychotherapy is based on four premises. The first is that individuals unwittingly develop a self-perpetuating, maladaptive pattern of functioning and relating to others. Subsequently, this pattern underlies a client's presenting issues. The second premise is that pattern change is an essential component of evidence-based practice. The third premise is that effective treatment involves a change process in which the client and practitioner collaborate to identify the maladaptive pattern, break it, and replace it with a more adaptive pattern. At least two outcomes result from this change process: increased well-being and resolution of the client's presenting issue. The fourth premise is that "replacing" non-productive thinking and behaviors with more productive ones is likely to effectively and quickly lead to therapeutic change than might otherwise occur with directly "restructuring" cognitions or "modifying" behavior.

Pattern-focused psychotherapy begins with establishing a collaborative relationship and educating the client in the basic premises of this approach. Central to it is the case conceptualization process in which maladaptive pattern is identified, and treatment is planned that focuses on pattern change. Key factors considered in treatment planning are level of readiness for change, severity, skill deficits, and strengths and protective factors.

The basic therapeutic strategy of this approach is to analyze problematic situations that clients report in terms of their maladaptive pattern. Clients are first asked to describe the situation and their resulting interpretations (thoughts) and behaviors. Then, they are queried about their expected outcome in contrast to the actual one that resulted. Clients inevitably report that they did not achieve their expected outcome. They are then asked about their interpretation and if each "helped "or "hurt" them in getting what they expected. If not, they are asked what alternative interpretations would have helped them achieve. Their reported behaviors are also analyzed as to whether they helped or hurt in achieving their expected outcome. If not, the focus is on identifying alternative behavior which could achieve that end. Finally, the client's "level of importance" of changing the maladaptive pattern and "level of confidence" in doing so are assessed and therapeutically processed.

Development and Current Status

Pattern-focused psychotherapy was developed by Len Sperry (Sperry, 2016). It is derived from biopsychosocial therapy, the cognitive behavioral analysis system of psychotherapy, and motivational interviewing. Pattern-focused psychotherapy is a focused therapeutic strategy that is effective in identifying and changing a maladaptive pattern to a more adaptive one. It accomplishes this by replacing the non-productive interpretations and behaviors that underlie the maladaptive pattern with more adaptive ones. Other modalities such as cognitive restructuring, exposure, skill training, reframing, and interpretation can be employed as adjunctive treatments. In the current era of accountability in health care, pattern-focused psychotherapy has considerable promise as an evidenced-based practice.

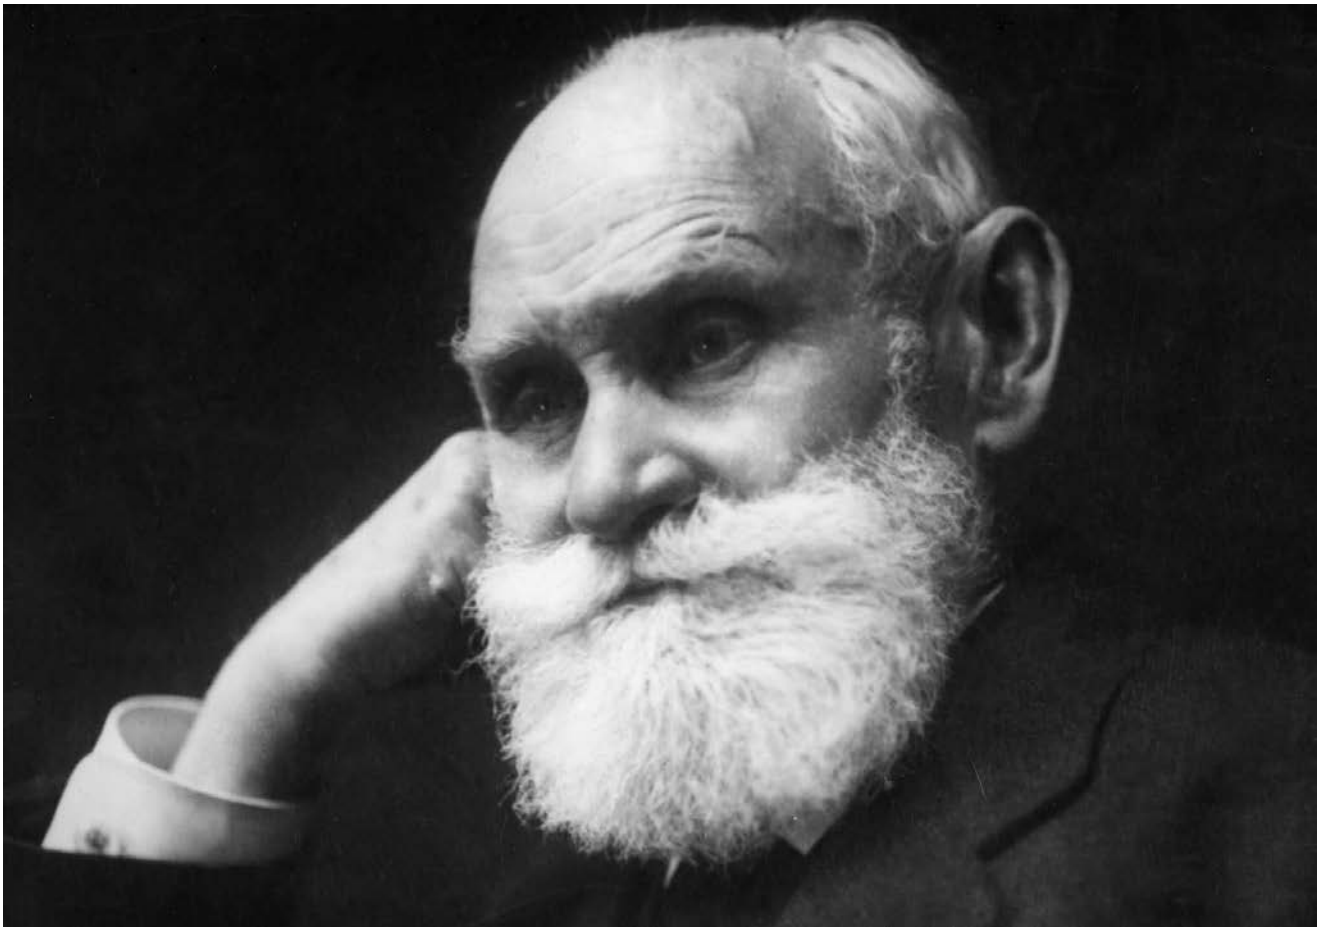
Pavlov, Ivan (1849–1936)

Ivan Petrovich Pavlov was a researcher and psychologist who developed the concept of reflex conditioning based on his experiments with dogs and feeding. Pavlov was able to have dogs associate feeding with the sound of a bell, at which they would begin salivating, even when there was no food present.

Description

Ivan Pavlov is one of the most famous physiologists in history. He lived and worked in Russia for his entire life and career. Pavlov and his studies of classical conditioning became famous from the time of his early work between 1890 and 1930. But he is best known for his discovery of conditioned or learned response. Pavlov established the existence of unconditioned responses by presenting a dog with a bowl of food and measuring its saliva. He did this through a technique he developed to directly observe the salivary glands. Pavlov observed that any object or event that dogs learned to associate with food, such as the entrance of



Ivan Petrovich Pavlov was a researcher and psychologist who developed the concept of reflex conditioning based on his experiments with dogs and feeding. (Sovfoto/UIG via Getty Images)

his lab assistant or the ringing of a bell, would cause the dogs to begin to salivate. At this point he realized that he had made an important scientific discovery. In behavioral terms, the lab assistant was originally a neutral stimulus, which produced no saliva. But after the dogs learned to associate either the assistant entering the room or the bell with the arrival of food, the dogs salivated. Because this response was learned, or conditioned, he termed it a conditioned response.

Impact (Psychological Influence)

By 1905, Pavlov was able to show that almost any external factor could become the conditioned or learned signal, which could initiate the natural response. Classical conditioning involves learning to associate an unconditioned stimulus that already brings about a response, or reflex, with a new or conditioned stimulus. The purpose of classical conditioning is that the new stimulus brings about the same response as the original stimulus.

With his research, Pavlov opened the way for new advances in the theory and practice of psychology and medicine. With extreme clarity he showed that the nervous system played the dominant part in regulating the digestive process. This discovery is in fact the basis of the modern physiology of digestion. He was awarded the Nobel Prize in 1904 for his work in the field of digestive physiology.

But his experiments in the field of conditioned responses or reflexes revolutionized the study of the relationship between learning and responses. This had major implications for the field of human behavior and for the development of behavior therapy, especially because it means not only increasing positive responses but decreasing negative behaviors. The work Pavlov did was the basis for the use of aversion therapy as applied, for example, to smoking cessation.

Paxil (Paroxetine)

Paxil is a prescribed medication used to treat depression and anxiety disorders. Its generic name is paroxetine.

Definitions

- **Antidepressant medications** are prescription drugs that are primarily used to treat depression and depressive disorders. They are known as antidepressants.
- **Anxiety disorders** are a group of mental disorders characterized by anxiety. These include obsessive-compulsive disorder (OCD) and post-traumatic stress disorder (PTSD).
- **Selective serotonin reuptake inhibitors (SSRI)** are medications that act on and increase the levels of serotonin in the brain that influences mood.
- **Serotonin discontinuation syndrome** results from the abrupt discontinuation of an SSRI medication. It is characterized by withdrawal symptoms such as anxiety, agitation, insomnia, nausea, vomiting, diarrhea, fatigue, vivid or bizarre dream, dizziness, and other sensory disturbances.

Description

Paxil is in the class of antidepressant medications known as selective serotonin reuptake inhibitors (SSRIs). Its primary use is in the treatment of clinical depression and for anxiety disorders: generalized anxiety disorder, obsessive-compulsive disorder, panic disorder, post-traumatic stress disorder, and social anxiety disorder. Depression and anxiety disorders are believed to be caused by low levels of serotonin, a chemical messenger (neurotransmitter) that is released and transmitted in the brain. Like other SSRI

medications such as Luvox, Zoloft, and Prozac, Paxil is believed to work by increasing the level of serotonin in the brain. Increased levels can benefit those with depression and anxiety disorders.

Precautions and Side Effects

Those taking Paxil should be monitored closely for insomnia, anxiety, mania, significant weight loss, and seizures. Like other SSRIs, Paxil carries a warning regarding use in children and adults up to the age of 24. They appear to have an increased risk of developing suicidal thoughts or behaviors while using these medications. Paxil should never be taken with monoamine oxidase inhibitors such as Nardil or Parnate. Caution should also be exercised when prescribing Paxil to those with impaired liver or kidney function, children, those over the age of 60, those with known bipolar disorder or a history of seizures, and those with diabetes. The risks and benefits of Prozac should be considered by women who are or might become pregnant, and those who are breast-feeding. Alcohol should not be used while taking Paxil. Care must be taken in driving, operating machinery, or participating in hazardous activities when taking this medication. Paxil use should not be stopped abruptly since it can cause serotonin discontinuation syndrome.

Common side effects associated with Paxil include headache, weakness, chills, malaise, nausea, and sleepiness. Other complaints included dry mouth, dizziness, tremors, constipation, diarrhea, and problems with ejaculation. Side effects with Paxil use have been reported for all organ systems of the body, but all of these side effects are uncommon. In general, the incidence of side effects increases as the dosage of Paxil increases.

Paxil interacts with a number of medications. Combining Paxil with Mellaril (an antipsychotic) has the potential to cause fatal cardiac arrhythmias (irregular heartbeat). The use of Paxil in combination with tryptophan (a nutrition supplement) may result in unwanted reactions, including agitation, restlessness, and gastrointestinal distress. Paxil may also increase the chance of having a seizure in those with a history of seizure disorders. Those taking anticonvulsants to control seizures should have close medical monitoring. No interactions between Paxil and lithium have been reported, nor are there any reported interactions with the antianxiety medication, Valium. Phenobarbital can decreases the efficacy of Paxil.

Pedophilic Disorder

Pedophilic disorder is a sexual disorder in which sexual arousal is achieved with fantasies, urges, or behaviors that involve sexual activity with prepubescent children (13 years of age or younger). It is also referred to as pedophilia.

Definitions

- **Paraphilic disorders** are a group of sexual disorders in which an individual can only become sexually aroused by inappropriate objects, actions, or fantasies. Pedophilic disorder is one of these disorders.
- **Pedophile** is the term given to those who engage in pedophilia.

Description and Diagnosis

Pedophilia is a type of paraphilic disorder in which an individual engages in sexual fantasy or actual sexual behavior with a prepubescent child. It is the individual's preferred or exclusive way of achieving sexual arousal and gratification. It may be directed toward children of the same sex, children of the other sex, or both boys and girls. Some pedophiles are attracted only

to children, while others are attracted to adults as well as to children. In addition to being a mental disorder, pedophilia is a criminal act.

This disorder is more common in males than females, and 3%–5% of the male population meet the criteria for the disorder (American Psychiatric Association, 2013). Pedophiles likely become aware of their sexual interest in children around the time of puberty but may not be diagnosed until they are adults. Many males with this disorder report they were sexually abused as a child. Individuals with this disorder also often present with antisocial personality disorder (American Psychiatric Association, 2013) and as a result may not admit to their sexual behavior harming children.

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (DSM-5), individuals can be diagnosed with this disorder if they exhibit intense, reoccurring sexual fantasies, urges, or behaviors toward a prepubescent child (age 13 or younger). The individual must experience significant distress or interpersonal problems as a result of these fantasies, urges, or sexual behaviors. Individuals can only be diagnosed with this disorder if their self-report, legal history, or objective assessment shows they have acted on their sexual impulses with children. If the individual does not express guilt or shame, and it can be proven he has never acted on his fantasies, then the individual has pedophilic sexual orientation but not pedophilic disorder. In contrast, if an individual does not admit to pedophilic urges or sexual behaviors, but it is proven the individual has engaged in these behaviors, he meets criteria for the diagnosis (American Psychiatric Association, 2013).

The cause of this disorder is not well understood. However, there is some evidence that prenatal (before birth) influences increase the probability of development of this disorder. While there is relatively little published research on the biologic basis for pedophilic disorder, there is considerable research focusing on the psychological and sociological factors that contribute to the disorder.

Those diagnosed with this disorder often have a history of sexual abuse and/or a concurrent diagnosis of antisocial personality disorder. It may be that individuals with both were exposed to an environment and family system that they perceived as unsafe or hostile and offered them little modeling of respect, caring, and cooperation. As a result, such children are likely to develop safeguarding behaviors, which means they learn to hurt others before they are hurt themselves.

Treatment

Because this disorder so negatively impacts children and their families, prevention rather than treatment should be the focus of this disorder. That means working with high-risk parents, that is, those who are abusive and neglectful since their children are at greater risk for developing this disorder. The main treatment intervention for this disorder are incarceration (prison) during which mental health treatment is also provided. Medications can also be used to lower the sex drive in pedophiles by reducing their testosterone levels. In reducing these levels, medications like Depo-Provera, Androcur, and Lupron are referred to as chemical castration. Treating pedophiles is a highly specialized field, with most clinicians needing additional training and supervision in working with such individuals.

Peer Counseling

Peer counseling is a form of counseling provided by an individual who has the same status as the client. An example is a high school student who is trained to counsel fellow students. It is also known as peer helping or peer support.

Definitions

- **Peer facilitator,** peer leader or peer educator, is an individual who either is a volunteer or is

selected and then trained to lead a small group of peers.

- **Peer mediation** is a helping process in which a peer leader facilitates two opposing parties through a conflict resolution or problem-solving model.
- **Peer mentoring** typically occurs in school or work settings and is described as when older, more experienced, or knowledgeable individuals assist younger or struggling individuals by tutoring them and helping them to feel welcome, or to acclimate more easily to their new environment.
- **Self-help group,** or support group, refers to a small network of peers from similar backgrounds and experiences who come together on a regular basis to share issues, concerns, and successes with one another.

Description

Peer counseling is a means of social support provided to individuals struggling with issues commonly experienced in everyday life. The difference between this helping process and others is that the support, or "counseling," is provided by a peer, or equal, rather than by a professional such as a counselor, therapist, or other health practitioner. This model of support has been proven effective as research indicates that people may feel more comfortable, open, and willing to share their problems with peers, those who have experienced similar issues, than with professionals. Being able to relate to a particular situation because one has "been there" is valuable. Thus, peers can provide a distinct level of empathy, understanding, and practical advice. In contrast to working with a mental health professional, peer counseling does not focus on assessment, diagnosis, evaluation, or deficits. Group facilitators and members work to empower, relate to, and uplift their peers. Peer counseling is also a cost- and time-conscious approach to offering help and support. People of any age can participate in peer counseling. Peer counseling can be offered in a variety of settings, including workplaces, churches, and community centers, but is most common in schools. In the school setting this may be referred to as a *peer helper program, peer mentoring, peer tutoring, peer mediation, peer facilitation*, or simply as *peer support*.

Peer counselors usually receive some level of training in order to be considered qualified to lead or facilitate their peers. Levels of training vary and depend on the intervention or program being used. Some training models are specific and manualized, while others may be more open and flexible. Regardless, some core aspects of peer counseling are typically presented. First, participation in peer counseling is voluntary. In addition, the peer counseling environment should be nonjudgmental, empathic, and respectful. Lastly, peer counseling requires honest and direct communication from all parties, both the leader and the participants.

Development (History and Application)

Though people have been helping one another since the beginning of time, the history of the peer counseling dates back to the 1930s with the emergence of the Twelve-Step Model and onset of peer support and self-help groups. Organizations such as Alcoholics Anonymous, Narcotics Anonymous, and Gamblers Anonymous are some of the most common self-help groups still active today. However, the past several decades have given rise to other support groups that address particular issues related to dealing with friends or family members with physical impairments, learning disabilities, behavioral problems, and psychological disorders. Peer counseling in schools soon followed in the 1960s–1970s with the inception of peer tutoring, peer helper programs, and peer mentoring, which took place during the regular school day. Facilitators were trained by teachers or counselors to work with their peers on common student problems. Therefore, the peer counseling movement responded to the shortage of helping professionals in relation to a growing number of people with needs.

Current Status

Peer counseling is a viable intervention for people suffering from a wide range of problems, particularly in times of financial constraint. Research indicates that school-based peer counseling programs provide many benefits to students, schools, and communities.

Programs that are evidence based are more likely to impact student behavior and achievement. Further, it has been documented that both participants and peer leaders report positive outcomes from peer counseling involvement. However, prior to implementing a peer counseling program, one must (1) consider the possible liability of the organization or entity providing the peer counselors, (2) ensure that the proper level of training and supervision is provided, and (3) properly address matters pertaining to confidentiality.

Peer Groups

Peer groups are informal associations of people of like age, background, social status, and interests.

Definitions

- **Cliques** are small groups of people (typically the term refers to groups of adolescents) who have similar characteristics and common interests, and who generally socialize exclusively with one another.
- **Peer pressure** describes the positive or negative influence one's peer group, or clique, has on one's attitudes, values, and behaviors.
- **Socialization** refers to the process by which an individual becomes acclimated to his or her current environmental and cultural surroundings by acting in ways that reflect the society's accepted norms, ideals, and behaviors.

Description

One's peer group, or the group of people that an individual associates with, can have a significant impact on his or her development. The term "peer group" refers to a social group as well as the primary group that one is affiliated with. Members of peer groups are typically similar in age, ethnicity, background, views, interests, financial state, and/or social status. Albert Bandura, founder of Social Learning Theory, proposed that the social group one belongs to helps determine what that person views as appropriate behavioral norms. Socialization also contributes to self-concept formation as most people compare themselves to peers whom they have things in common with. A peer group can influence what a person thinks, knows, learns, does, wears, and eats. However, peer groups can also foster one's ability to negotiate, problem solve, prevent conflict, and cope. This is particularly true for adolescents who struggle to find out who they are and what their place is in the world. Renowned psychologist and theorist, Erik Erikson, referred to the adolescent stage of conflict as *Identity vs. Role Confusion* and emphasized the importance of societal influences and peer pressure. The majority of adolescents rely primarily on the feedback they receive from their peers to reflect how they should feel about themselves, whether these judgments/opinions are accurate or not. Therefore, individuation and self-acceptance are ongoing processes that evolve over the course of a person's lifetime.

Peer groups usually have established hierarchies and members have some sense of understanding as to what behavior patterns are considered acceptable or unacceptable. A peer group where the leadership or rules are viewed as excessive or unreasonable may be referred to as a "clique." "Cliques," a word that usually has a negative connotation, are small groups of people who think, act, and dress in similar ways and socialize primarily with one another. Gangs, or groups of youth involved in crime and delinquent behavior, are another example of a negative type of peer group.

Impact (Psychological Influence)

Evidence suggests that an individual's peer group can have a profound effect on his or her likelihood to engage in future destructive behaviors, including committing acts of aggression, dropping out of school, and engaging in criminal activity and substance abuse, and sexual promiscuity. However, there is also data to support that positive peer groups can have the opposite effect. Displaying pro-social behaviors, encouraging others' academic success, making pacts to abstain from drug/alcohol use and risky sexual behavior, and developing healthy relationships with others are examples of these.

Perfectionism

Perfectionism is the belief that striving for perfection is important because one's self-worth is measured by one's productivity and accomplishments.

Definitions

- **Anorexia nervosa** is an eating disorder characterized by refusal to maintain minimal normal body weight along with a fear of weight gain and a distorted body image.
- **Cognitive behavior therapy** is a type of psychotherapy that focuses on maladaptive (faulty) beliefs, behaviors, and emotions.
- **DSM-5** is the abbreviation for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, which is the handbook mental health professionals use to diagnose mental disorders.
- **Five-Factor Personality Model** is a model of personality in which five factors—extraversion, consciousness, agreeableness, openness, and neuroticism—are viewed as core personality structures.
- **Mindfulness practices** are intentional activities that foster living in the present moment and awareness that is nonjudgmental and accepting.
- **Obsessive-compulsive personality disorder** is a mental disorder characterized by a pattern of preoccupation with extreme perfectionism, orderliness, and control.
- **Personality** is the enduring pattern of perceiving, feeling, relating, and thinking about one's environment and oneself.
- **Personality trait** is an enduring interior characteristic inferred from an individual's trend of actions, feelings, and habits.
- **Psychotherapy** is a psychological method for achieving desired changes in thinking, feeling, and behavior. It is also called therapy or therapeutic counseling.

Description

Perfectionism is the belief that perfection is worth striving for and achieving. In its unhealthy form, it is the belief that it is unacceptable to accept anything less than perfection. It is a personality trait that is characterized by the belief that achieving very high performance standards is all important. It also involves overly critical self-evaluations and concerns regarding others' evaluations of the extent to which those standards are achieved. Besides very high performance standards, some perfectionists adhere to highly structured routines and make very detailed plans. They may also apply excessive control to the environment in an effort to achieve their expected performance. Some believe their accomplishments are never good enough

despite exceeding what most consider above-average performance.

The term "perfectionism" is best understood on a continuum or range of possible descriptions. On one end of the continuum, there is maladaptive (unhealthy) view of perfectionism. It is characterized by the belief that everything must be completely perfect all the time and it is shameful not to achieve it. On the other end of this continuum is a more adaptive (healthy) view of perfectionism. It is characterized by the belief that pleasure can be derived from one's striving for perfection even if the result it less than perfect.

Those with an unhealthy view of perfectionism may avoid completing a task, anticipating that the results will be less than perfect. Procrastination is not uncommon in those with such a view of perfectionism. Those with this view tend to avoid doing new activities, taking new jobs, or meeting new people for fear of less-than-perfect outcomes. They may also be overly critical of others as a consequence of their perfectionist expectations. In contrast, life tends to be different for those with a healthier view of perfectionism. These individuals are also highly goal oriented and conscientious, but they are able to accomplish tasks. Their drive for perfection serves as a motivator to achieve significant success in a given field such as business, art, and university teaching. However, they can accept less-than-perfect outcomes and they are able to enjoy their accomplishments. They seldom procrastinate or be overly critical of others.

Researchers have identified perfectionism as an aspect of conscientiousness as measured by the five-factor model of personality (McCrae and Costa, 2006). According to the five-factor model, conscientious is a measure of the tendency of an individual to be orderly, structured, disciplined, and goal oriented. Conscientiousness is measured on a continuum ranging from healthy to unhealthy. By identifying this continuum of conscientious and perfectionism, it is clear that perfectionism can be healthy or unhealthy.

There are a number of DSM-5 mental disorders that involve unhealthy perfectionism. Of these, obsessive-compulsive personality disorder is the most common. Individuals with this disorder are more likely to engage in perfectionistic behavior because they believe it is beneficial and necessary. Anorexia nervosa is also associated with perfectionism. Individuals with this disorder often have unreasonable expectation about physical perfections combined with skewed body image.

Although perfectionism is not a standalone diagnosis, it can be very distressing. It follows that perfectionism can be and is treated. For individuals who simply find themselves stressed by their overly perfectionistic strivings, psychotherapy is the preferred treatment. Of the various psychotherapy approaches, cognitive behavior therapy (CBT) is the often used treatment of perfectionism. CBT can be helpful in reducing unreasonable expectations of performance. It accomplishes this by helping the individual identify and modify belief about being perfect. This is combined with behavioral exercises. Such exercises expose the individual to tasks he or she has avoided and to setting more appropriate goals and expectations. Mindfulness practices may be also be a part of treatment.

Performance-Enhancing Drugs

Performance-enhancing drugs (PEDs) are substances that professional or amateur athletes use to enhance, sustain, or improve their normal performance.

Definitions

- **Doping** is a slang term that describes the act of using substances that enhance athletic performance, endurance, or ability; the word "doping" was derived from the Dutch word "doop," which is an opium concoction that was favored by the Greeks.
- **Steroids,** also known as anabolic androgen or anabolic steroids, is an illegal drug injected into the body usually via syringe that contains a synthetic form of testosterone that aids in quickly increasing muscle mass in a body but has several negative physical and psychological side effects.

Description

People use substances known as performance-enhancing drugs to improve their normal athletic ability. This is also referred to as "doping." PEDs come in several forms, including pills, powders, liquid injections, and topical creams. The use of PEDs has become increasingly prevalent over the past few decades, resulting in a negative impact on sports as a whole. World-doping organizations have therefore imposed stricter regulations to discourage the use of these enhancing substances and to penalize those discovered to have used in their athletic careers. However, PEDs are still used at alarmingly high rates as some athletes, both professional and amateur, believe that their benefits outweigh the costs.

A broad set of substances are deemed performance-enhancing drugs. Categories of PEDs range from prototype performance enhancers like anabolic steroids (synthetic hormones) all the way to substances such as lean muscle builders, diuretics, painkillers, and masking drugs. Proteins and vitamins, though several have been proven to enhance performance and reduce recovery time, are rarely considered PEDs as most are produced naturally by the body. Enforcing standards and laws on the use of performance-enhancing drugs has been difficult to regulate given this wide range.

Professional or personal competition can influence one to begin using performance-enhancing drugs. The yearning to make a team, to prevent being cut from a current position, or to excel to the top of a chosen sport can drive one to use. Several world record holders and/or chasers as well as distinguished professional athletes across a variety of sports have been exposed for using PEDs. Lyle Alzado, Ben Johnson, Marian Jones, Jose Canseco, Lance Armstrong, Mark McGwire, Barry Bonds, and Alex Rodriguez are some of the most recognized names. Some have indicated that the pressure to attain certain goals or a level of ranking in the sport influenced their decision to begin using. However, in addition to damaging their own reputations, these athletes' associations with PED use have resulted in tarnishing the value of awards, trophies, and other sports-related accomplishments. Another reason both professional and amateur athletes report for using performance-enhancing drugs are personal and health-related gains. As cited, PEDs can enhance muscle mass, burn fat, eliminate excess water, and relieve pain. Though there are benefits, the use of performance enhancers can result in serious short-term and long-term physical, psychological, and personal consequences for users. Physical symptoms may include acne, changes in primary and secondary sex characteristics, and hair growth. Physiologically, one can also experience increased heart rates, fluctuations in blood pressure, rapid weight loss, and mood swings. Several other side effects are commonly reported. Prolonged use can damage internal organs and eventually lead to death.

Dating back to the Ancient Greeks and the first Olympic Games (776–339 BC), performance-enhancing substances have been used in sport. The Greeks used herbal medications, wine potions, hallucinogens, and other concoctions to improve their performance. Roman gladiators were also known to ingest a hallucinogenic solution containing strychnine and fed enhancers to their horses. The first documented use of PEDs in the Olympic Games occurred in 1904, with athletes using strychnine, cocaine, heroin, and caffeine combinations to boost their ability. In 1928, the International Association of Athletics Federation became the first international sports federation to ban doping. An increase in performance-enhancer use then came after the Federal Drug Administration approved the sale of anabolic steroids in the United States in 1958. A decade later (1968), the International Olympic

Committee (IOC) instituted compulsory drug testing at the Winter Olympic Games. The IOC added steroids to the list of banned substances in 1975. On September 27, 1988, Canadian runner Ben Johnson was stripped of his Olympic medal after testing positive for the anabolic steroid stanozolol. President Reagan then signed the Anti-Drug Abuse Act of 1988 banning the sale of steroids for nonmedical purposes. On October 5, 1990, Congress passed the Anabolic Steroids Control Act classifying these synthetics as Schedule III narcotics. Former NFL player Lyle Alzedo died of brain cancer in May 1992; Abuse of steroid and human growth hormone for decades was linked to his death.

Impact (Psychological Influence)

On November 10, 1999, the World Anti-Doping Agency was officially established to combat doping in international sports arenas. President Bush signed the Anabolic Steroid Control Act on October 22, 2004, and went on to sign a law banning gene doping in sports in December 2006. A litany of professional athlete names soon came under public scrutiny for their use. Cyclist Floyd Landis was stripped of his Tour de France title on September 20, 2007, as speculation surrounding his sport increased. On December 12, 2007, Marion Jones was stripped of her three gold and two bronze medals from the 2000 Olympics and her world record holding for her use. On January 11, 2009, she was also sentenced to six months in prison for lying. Barry Bonds was then indicted before a grand jury on November 15, 2007, for lying about his steroid use. He was also found guilty on March 21, 2011. Documented use of PEDs in other sports such as soccer, tennis, and swimming was also made public. On May 2, 2009, the winner of Kentucky Derby tested for steroid use for the first time. Former MLB player and home run record holder Mark McGwire admitted to using performance enhancers for nearly a decade on January 11, 2010. On May 19 of the same year, Floyd Landis admitted to using most of his career and went on to accuse other riders, including Lance Armstrong. On August 23, 2012, Armstrong was stripped of his seven Tour de France titles after growing speculation. Finally, on January 17, 2013, after repeated denials of involvement, Armstrong admitted to his using performance-enhancing drugs in an interview with Oprah Winfrey. On August 5, 2013, MLB player Alex Rodriguez was suspended after evidence mounted surrounding his use.

Perls, Fritz (1893–1970)

Fritz Perls was a German-born American psychiatrist of Jewish descent best known for the development of gestalt therapy, the empty chair technique, and his controversial style of therapy.

Description

Friedrich (Fritz) Salomon Perls was born in Berlin, Germany, on July 8, 1893. Perls grew up in Berlin during the bohemian avant-garde years leading up to World War I. As a teenager he enjoyed poetry and existential philosophy, and was highly involved in theater. He served in the German army and fought in the trenches of World War I. His war experiences were horrific. After the war he studied medicine and began working with veterans who had suffered brain injuries. Being drawn to the work of Sigmund Freud he studied at the Berlin Institute of Psychoanalysis. In 1930, Perls married Lore Posner, later to be known as Laura Perls, and had two children together. Laura Perls, a psychotherapist, was heavily involved in the development of gestalt therapy along with her husband.

Soon after Hitler came to power in 1933, the Perls fled to the Netherlands before immigrating to Johannesburg, South Africa. In South Africa Fritz established

a psychoanalytic training institute. In 1942, during World War II, Fritz became a captain in the South African army, serving as a psychiatrist until 1946. Perls's first book *Ego, Hunger, and Aggression* was published in 1942.

In 1946 the Perls moved to the United States and eventually settled in Manhattan, New York, where he incorporated ideas garnered from psychodrama, posture and movement, and modern dance. Working with American sociologist, poet, and intellectual Paul Goodman, Perls wrote his second book *Gestalt Therapy*, published in 1951. Fritz and Laura Perls founded the Gestalt Institute and began seeing clients in their Manhattan apartment.

Fritz Perls began conducting workshops and seminars on gestalt therapy and traveled throughout the United States. In 1960, Fritz Perls left Laura Perls and moved to California where he further developed his ideas on gestalt. Influenced by humanistic, existential, and Zen philosophies he conducted workshops, and eventually lived, at Esalen Institute in Big Sur, California. Esalen is a residential community, retreat center, and alternative educational institute, which focuses on personal growth, meditation, yoga, spirituality, and other humanistic-oriented practices. Perls lived on Esalen property until 1969 before moving to Vancouver Island, Canada, where he started a gestalt community. Fritz Perls died in 1970 after undergoing heart surgery in Chicago.

Impact (Psychological Influence)

Frits Perls was instrumental in the development of gestalt therapy, a term he coined. The word "gestalt" is defined as something that is made of many parts and is greater than the sum of those parts. Gestalt therapy is an insight-oriented psychotherapy that focuses on the present moment using what is taking place between the therapist and client to develop insight and promote change. Perls believed that as clients increased their awareness and understanding of their perceptions, feelings, and behaviors in the here and now as they interact with the therapist, change automatically occurs.

Perls was known for being a dramatic showman with a confrontational and sometimes hostile style. During the development of gestalt therapy many of Fritz's students emulated his style and this remains a criticism of Perls. Perls was also considered arrogant and dismissive to his family. Laura Perls made significant contributions to the development and establishment of gestalt therapy and is credited with correcting many of the excesses exhibited by Fritz.

Fritz Perls was a controversial pioneer in the development of gestalt therapy. He published three books in his lifetime: *Ego, Hunger and Aggression* (1942), *Gestalt Therapy Verbatim* (1969), and *In and Out the Garbage Pail* (1969).

Persistent Depressive Disorder

Persistent depressive disorder is a mental disorder characterized by a long-standing depressed mood. Previously it was called dysthymic disorder or chronic depression.

Definitions

- **Acceptance and commitment therapy** is a form of therapy that focuses on helping individuals accept their negative experiences without being critical or judgmental. This is combined with a commitment to set goals. It is also referred to as ACT.
- **Cognitive behavior therapy** is a form of psychotherapy that focuses on changing maladaptive (faulty) behaviors, emotions, and thoughts. It is also known as CBT.

- **Depressive disorders** are a group of mental disorders characterized by a sad or irritable mood. It includes major depressive disorder, disruptive mood dysregulation, and persistent depressive disorder.
- **Dialectical behavior therapy** is a psychotherapy approach that focuses on coping with stress, regulating emotions, and improving relationships.
- **DSM-5** stands for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, which is a diagnostic system used by professionals to identify mental disorders with specific diagnostic criteria.
- **Major depressive disorder** is a mental illness characterized by depressed mood or loss of interest in formerly pleasurable activities that lasts the most days for two weeks or more.
- **Mood** is an individual's subjective emotional experience and expression.
- **Neurotic** is an outdated but still used term to describe an individual who is somewhat more emotionally unstable than others or is more prone to psychological distress.
- **Psychotherapy** is a psychological method for achieving desired changes in thinking, feeling, and behavior. It is also called therapeutic counseling.
- **Psychotropic medications** are prescribed drugs that affect thinking, feeling, and behavior. They include antipsychotic, antianxiety, antidepressant, and antimanic drugs.

Description and Diagnosis

Persistent depressive disorder is one of the group of depressive disorders that is characterized by chronic depression lasting at least two years. Those with persistent depressive disorder experience symptoms similar to those of major depressive disorder. The main difference is that depressive symptoms in persistent depressive disorder tend to be less severe and last for two years or more.

Estimates of the prevalence of this disorder range from .05% to 1.5% in the United States. This contrasts with major depressive disorder that affects approximately 7% of adults (American Psychiatric Association, 2013). This disorder, as well as other depressive disorders, commonly co-occurs with both anxiety and substance abuse disorders.

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, to be diagnosed with this disorder, the individual must meet certain criteria. As stated earlier, the most important criterion is that the depressed mood has been present for at least two years in adults. In children and adolescents, the symptoms need be present only for one year to be considered. In addition, the individual must experience a depressed mood for the majority of days. Also, the individual may experience fluctuations in appetite, inability to sleep or sleep excessively, fatigue, reduced self-esteem, difficulty thinking, or a sense of hopelessness. Individuals may experience any of the symptoms with differing levels of severity. That is to say that some may have a mild form of this disorder while others may have a far more severe form. Like all disorders, it is important to rule out other disorders that may share certain attributes or symptoms (American Psychiatric Association, 2013).

The specific cause of this disorder is unknown, but it is believed that genetics, brain functions, and the environment play a role in the manifestation of this disorder. Specific factors may include a family history of depressive disorders, loss of a parent in childhood, and the existence of other mental disorders.

Treatment

Treatment for this disorder is likely to include psychotherapy and psychotropic medications. Effective forms of psychotherapy include cognitive behavior therapy, dialectical behavior therapy, and acceptance and commitment therapy. Common to these approaches is an emphasis on helping the individual increase coping skills, better understand symptoms, and modify maladaptive (unhealthy) beliefs. Unlike other mental illness, those with persistent depressive disorder are more likely to come to the attention of their primary care physician. Ideally, those physicians would refer

them to a mental health professional for further assessment and possible treatment, as many physicians are not adequately trained to address mental illness.

Personality Change Due to Another Medical Condition

Personality change due to another medical condition is a mental disorder characterized a persistent personality change caused by a medical condition.

Definitions

- **Delirium** is sudden and severe confusion due to changes in brain function that occur in mental and physical illness.
- **DSM-5** stands for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, which is a diagnostic system used by professionals to identify mental disorders with specific diagnostic criteria.
- **Epilepsy** is a medical condition when seizures reoccur. It is also known as seizure disorder.
- **Huntington's disease** is an inherited disease that causes degeneration of nerve cells in the brain.
- **Opioids** are a class of narcotic drugs used to treat moderate to severe pain. The classes include both natural and synthetic substances.
- **Personality** is a set of enduring mental and behavioral traits that distinguish individuals.
- **Personality disorders** are a group of DSM-5 mental disorders characterized by a long-standing pattern of maladaptive (problematic) behaviors, thoughts, and emotions that deviates from the norms of an individual's culture.
- **Psychotherapy** is a psychological method for achieving desired changes in thinking, feeling, and behavior. Psychotherapy is also called therapeutic counseling.
- **Selective serotonin reuptake inhibitors** are the most commonly prescribed antidepressant medication because they generally have few side effects. They are also referred to as SSRIs.
- **Specifiers** are extensions to a diagnosis that further clarifies the course, severity, or type of features of a disorder or illness.
- **Stimulant** is a drug that increases brain activity and produces a sense of alertness, euphoria, endurance, and productivity.
- **Stroke** is a medical condition when there is deprivation of oxygen to the brain due to a lack of blood flow.

Description and Diagnosis

Personality change due to another medical condition is one of the DSM-5 personality disorders. It is characterized by symptoms that include poor impulse control, affective instability (e.g., emotions, feelings, perceptions), outbursts of aggression and rage, paranoid thoughts, and suspiciousness. Often, others will notice that an individual is just not himself or herself.

The presentation of an individual with this diagnosis may depend on the features of the disease process. For example, injuries to the frontal lobe (front part) of the brain may cause symptoms of impulsiveness, lack of judgment, and intense feelings of excitement. Strokes have been shown to cause personality changes in individuals. Some of these changes include an individual not being able to perform simple voluntary acts (e.g., keeping eyes closed). In addition, the individual may have the inability to remember things. For example, an individual may be asked to recall a memory of a particular object and draw a picture of it. The individual may only draw half of the object or draw nothing at all.

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, individuals can be diagnosed with this disorder if an individual exhibits a personality change that is persistent and a change from an individual's previous personality pattern. Children with a personality disturbance must have a noticeable diversion from normal development or exhibit a remarkable change in the child's usual behavior patterns, and must last for at least one year. The personality change must be the direct result of a medical condition. The disturbance cannot be better explained by another mental disorder and cannot occur solely during the course of a delirium. The personality disturbance must cause clinically significant distress in occupational, social, or other important areas of an individual's life. Specifiers must be included when making this diagnosis. According to the DSM-5 manual, these specifiers include the aggressive type, apathetic type, labile type, paranoid type, disinhibited type, combined type, other type, and unspecified type. The aggressive type is a kind of specifier that mainly reveals aggressive behavior. The apathetic type primarily displays disinterested and indifferent behavior. The labile type is a specifier where the main feature is affective lability (e.g., outward emotional expressions). The paranoid type is a kind of specifier where the primary feature is an individual having paranoid thoughts or suspicions. The disinhibited (lack of restraint) type is characterized by poor impulse control (e.g., shopping sprees and sexual indiscretions). The combined type is a kind of specifier that is assigned if more than one feature is present (e.g., apathetic type and aggressive type). The other type is a kind of specifier that is assigned when it is not characteristic of any other subtypes (e.g., paranoid type, labile type). The unspecified type is a kind of specifier that is assigned to this diagnosis when the characteristic feature is unidentified (American Psychiatric Association, 2013).

The occurrence of this disorder includes several medical and neurological conditions. These conditions have been known to cause personality changes in individuals as a result of the symptoms. Some other conditions that cause this disorder include epilepsy, Huntington's disease, and head trauma. Some chronic (long-term) medical conditions are also associated with changes in personality (e.g., pain and disability). This diagnosis can be assigned only if the medical condition is established from the process of examining abnormal conditions.

Treatment

Psychotherapy and medication management have been shown to be effective forms of treatment for individuals diagnosed with this disorder. Some medications prescribed for this disorder include selective serotonin reuptake inhibitor (SSRI) antidepressants. SSRI antidepressants have been shown to be effective in helping individuals with lability (readily undergoing a change). Low-dose stimulants have been shown to be helpful for individuals with impulsivity. Managing environmental factors can also be helpful for managing fatigue and pain. Healthy sleep patterns and avoiding alcohol, caffeine, illicit substances, and opioids for pain can be effective for this disorder. Implementing and maintaining a healthy exercise routine has also been shown to be helpful. Families should participate in the process of therapy. This may help educate families about the disorder and develop an understanding of an individual's inappropriate behaviors.

Personality Disorders

Personality disorders are mental disorders characterized by long-standing pattern of problematic behaviors, thoughts, and emotions that deviates from the accepted norms of an individual's culture.

Definitions

- **Cognitive behavior therapy** is a type of psychotherapy that focuses on maladaptive (faulty) behaviors, emotions, and thoughts.
- **DSM-5** stands for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, which is a diagnostic system used by professionals to identify mental disorders with specific diagnostic criteria.
- **Psychotherapy** is a psychological method for achieving desired changes in thinking, feeling, and behavior. It is also called therapeutic counseling.

Description and Diagnosis

DSM-5 defines a personality disorder as a persisting pattern of inner experience and behavior that differs markedly from the expectations of the individual's culture. The disorder is pervasive and inflexible, and is stable over time. This pattern leads to significant problems and limitations in relationships, work and school, and social situations. Personality disorders have their onset in adolescence or early adulthood (American Psychiatric Association, 2013). Basically, personality disorders are a group of behavioral disorders that are distinct and different from the anxiety, mood, and psychotic disorders.

The majority of those with a personality disorder do not seek or receive mental health services. Those who receive treatment do so in the context of another mental disorder. Or, they may receive services because of a personal crisis such as harming themselves or committing a crime. Still, recognition and diagnosis of personality disorders is important since these disorders predispose individuals to other mental disorders and affect the way these other disorders present and are treated. However, since personality disorders can cause considerable distress and impairment (problems), they can and should also be treated.

Personality disorders are believed to be caused by a combination of genetic and environmental influences. That means that an individual may have a genetic vulnerability to developing a personality disorder and his or her life situation may trigger the development of the disorder. Following is a brief description of the 10 personality disorders described in DSM-5.

Antisocial personality disorder. Antisocial personality disorder is characterized by a callous unconcern for the feelings of others. The individual with this disorder disregards social rules and obligations, is irritable and aggressive, acts impulsively, lacks guilt, and fails to learn from experience. The individual often has no difficulty finding relationships, but they are usually turbulent and short lived. Those with this disorder often have a criminal record or even a history of being in and out of prison. It is more common in men than in women.

Avoidant personality disorder. Individuals with this disorder tend to be persistently tense because they believe that they are socially inept, unappealing, or inferior. They often have a history of actual or perceived rejection by parents or peers during childhood. As a result, they fear being embarrassed, criticized, or rejected. They are likely to avoid meeting others unless they are certain of being liked. They also avoid taking risks. It is not uncommon for those with this disorder to also be afflicted with an anxiety disorder.

Borderline personality disorder. Those with this disorder often lack a cohesive sense of self. As a result, they experience feelings of emptiness and fears of abandonment. This shows in intense, unstable relationships, emotional instability, angry outbursts, and impulsive behavior. Suicidal threats and acts of

self-harm are also common. Many with this disorder have a history of childhood sexual abuse. The disorder is so named because it lies on the "borderline" between the neurotic (anxiety) disorders and psychotic disorders like schizophrenia.

Dependent personality disorder. This disorder is characterized by a lack of self-confidence and an excessive need to be taken care of. These individuals often need others to help them make everyday decisions as well as important life decisions. They greatly fear abandonment and may go to great lengths to secure and maintain relationships. These individuals view themselves as inadequate and helpless. As a result, they tend to shun personal responsibility and put their fate in the hands of others to protect and care for them.

Histrionic personality disorder. Those with this disorder usually lack a sense of self-worth, and so they depend on the attention and approval of others. They can be quite dramatic in their efforts to attract and manipulate attention. They are also very concerned about their physical appearance and behave in a manner that is overly charming or seductive. Because they crave excitement and act on impulse or suggestion, they put themselves at risk of being harmed or exploited. Their relationships with others often seem insincere or superficial. They also tend to be sensitive to criticism and rejection and react badly to failure or loss.

Narcissistic personality disorder. Those with this disorder typically have a grandiose sense of self-importance, a need to be admired, and a sense of entitlement. They lack empathy and readily exploit others to achieve their own needs. To others, they seem to be self-absorbed, controlling, intolerant, insensitive, and selfish. They also tend to be envious of others. If they feel slighted or ridiculed, they will respond with rage and may seek revenge. Their anger and rage can have disastrous consequences for all involved.

Obsessive-compulsive personality disorder. Those with this disorder are characterized by excessive preoccupation with details, rules, lists, order, and schedules. Their perfectionism is so extreme that it prevents them from completing tasks. Their devotion to work and productivity is at the expense of relationships and their well-being. They also tend to be doubting, cautious, humorless, rigid, controlling, and miserly. Their underlying anxiousness is rooted in their perceived lack of control of the individuals and situations. The result is that they have little tolerance for ambiguity and view everything in absolutes (all right or all wrong). Their relationships with friends, colleagues, and family tend to be strained by their unreasonable and inflexible demands. This disorder is not to be confused with obsessive-compulsive disorder.

Paranoid personality disorder. This disorder is characterized by a pervasive pattern of distrust of others. Individuals with this order are often guarded and suspicious. They constantly look for clues to confirm their worst fears. Typically, they have a strong sense of self-importance and personal rights. They are also overly sensitive to setbacks and criticism, and are easily humiliated. They also bear grudges and will lash out when they feel threatened. As a result, they have a tendency to withdraw from others and have difficulty engaging in close relationships.

Schizoid personality disorder. Individuals with this disorder are often detached and aloof, and are prone to introspection and fantasy. Many have little desire for social or sexual relationships. They tend to be indifferent to social norms and conventions, and lack emotional responsiveness. In some situations, they may appear cold and callous. Nevertheless, they are generally able to function well despite their pattern. For those who might desire some level of intimacy, they may find initiating and maintaining relationships are sufficiently difficult or distressing that they give up trying.

Schizotypal personality disorder. This disorder is characterized by a pervasive pattern of oddness or eccentricity in appearance, thinking, speech, and behavior. Their thinking and thought process may include odd or unusual beliefs, magical thinking, suspiciousness, obsessions, and unusual perceptual experiences. They typically view others as potentially harmful and as a result fear relating to those they do not know. On the other hand, they may involve themselves with others or groups who have similar odd or unusual beliefs.

Treatment

Effective treatment depends on the particular personality disorder and its severity. Some personality

disorders are easier to treat (avoidant personality disorder), while others are less responsive to treatment (antisocial personality disorder). Usually, psychotherapy is the mainstay of treatment for these disorders, and its goal is to decrease distress or symptoms and to improve functioning in relationships, work or school, and social situations. Cognitive behavior therapy is a common psychotherapy approach for the various personality disorders. It is often useful in identifying unhealthy and negative beliefs and behaviors and replacing them with more healthy and positive ones. Currently, no medications have been specifically approved by the Food and Drug Administration to treat personality disorders. But various types of medications are used to treat specific personality disorder symptoms. These include antidepressants, antipsychotics, and antianxiety medications.

Personality Tests

Personality tests are psychological measures used to assess various personality characteristics.

Definitions

- **Five-factor model** is a model for describing personality in terms of conscientiousness, extroversion, agreeableness, emotional stability or neuroticism, and intellect or openness to experience.
- **Norms** are standard or range of test scores that represent the typical score of a group and used to determine the relative standing of an individual's test score compared to others in the group.
- **Objective personality test** is a psychological test that usually has a multiple-choice format and yields scores that are independent of the opinion or judgment of the examiner.
- **Projective personality test** is a psychological test where the test-taker responds to ambiguous stimuli that reveal his or her unconscious (hidden) emotions and personality characteristics.
- **Psychometric** refers to the characteristics of a psychological test, particularly its reliability (consistency) and validity (accuracy).

Description

A personality test is a procedure for assessing personality characteristics in a variety of contexts ranging from individual and couples therapy to employee selection and career planning. In a therapy context, personality tests are used for diagnosing, treatment planning, and structuring the therapeutic relations with clients. There are different types of personality tests. The most common uses are the self-report inventory tests. Self-report inventories consist of questions or items to which the test-taker responds by rating the degree to which each item or question reflects his or her behavior or attitude. Because these tests can be scored objectively, they are also known as objective personality tests. An example of an item on a personality test is, "I talk to a lot of different people at parties." Test-takers rate the degree to which they agree with the statement by using a scale of 1 ("strongly disagree") to 5 ("strongly agree"). In contrast, the Minnesota Multiphasic Personality Inventory has a True–False format. In addition to these self-report inventories, there are many other methods for assessing personality, including observational measures, peer-report studies, and projective tests such as the Thematic Apperception Test and the Rorschach Inkblot Test. Today, personality tests have become a

multimillion-dollar industry and are used in a several contexts: individual therapy, couples counseling, employee selection, and career planning.

Developments and Current Status

The first personality tests were developed in the 1920s and were intended to ease the process of personnel selection, particularly in the military during World War I and World War II. The Rorschach Inkblot Test was published in 1921, the Minnesota Multiphasic Personality Inventory appeared in 1939, and the Rotter Sentence Completion Test appeared in 1950. Since then, a wide variety of personality tests have been published. There are two main categories of personality tests: structured or objective personality tests and projective personality tests. The most common are briefly described here.

Objective Personality Tests

Objective personality tests are administered and scored in a standardized fashion. These tests consist of the administration of a designated set of items that are marked and compared against exacting scoring mechanisms that are fully standardized. They are scored and interpreted in a manner that is independent of the examiner's own beliefs and subjective biases. Typically, these tests have norms.

Minnesota Multiphasic Personality Inventory (MMPI). This personality inventory that assesses personality traits and psychopathology used to assess individuals presumed to have mental health or other clinical issues. There are two current forms: the MMPI-2 with 567 true–false items and the lesser used but shorter MMPI-2-RF with 338 items The MMPI-2 is designed with 10 clinical scales that assess the major categories of abnormal human behavior. It also includes four validity scales that assess the individuals' general test-taking attitude and truthfulness and accuracy in answering the questions. After the test is taken and scored, an interpretive report is constructed based on a set of standard clinical profiles called "codetype." For example, a 2–3 codetype (both Scales 2 and 3 are significantly elevated) suggests significant depression, lowered activity levels, helplessness, and often physical complaints.

Millon Clinical Multiaxial Inventory (MCMI). This personality inventory assesses personality traits and psychopathology. Its fourth edition, MCMI-IV, provides a measure of personality disorders and clinical syndromes of adults undergoing psychological assessment or treatment. It is helpful in developing a treatment plan based on the test-taker's personality style and coping behavior. The MCMI-IV is composed of 175 true–false questions and takes about 25 to 30 minutes to complete. It can be hand scored or computer scored and produces 24 personality and clinical scales and 5 correction scales that verify how the test was approached and taken. An interpretive report includes a treatment guide for focusing treatment interventions.

Myers–Briggs Type Indicator (MBTI). This personality inventory test designed to identify an individual's personality type, strengths, and preferences. The test was developed by Isabel Myers and Katherine Briggs and is based on Carl Jung's theory of personality types. It includes 93 forced-choice questions, which means that the test-taker chooses only one of two possible answers to each question. It can be hand scored or computer scored. Based on the response to the MBTI questions, test-takers are identified as having one of 16 personality types. Its purpose is to increase the test-takers' understanding of their likes, dislikes, strengths, weaknesses, possible career preferences, and compatibility with others. Unlike other objective personality tests, the MBTI is not normed. It is commonly used in career counseling, team building, personal and professional development, leadership training, executive coaching, life coaching, and couples counseling.

NEO Personality Inventory-Revised (NEO PI-R). This personality test is based on the five-factor model of personality. It concisely measures five basic domains of personality and the six facets that define each domain. The NEO PI-R provides a detailed assessment of normal personality, for use in human resource development, industrial and organizational psychology, and vocational counseling as well as in clinical practice. It has 240 items and 3 validity items and takes 35 to 45 minutes to complete. It can be hand scored or computer scored. Two report options are available: an individual report for professional development planning and a professional development for management planning. Both identify an individual's strength and limitations in four major areas: problem-solving skills; planning, organizing, and implementation skills; style of relating to others; and personality style.

Projective Personality Tests

The use of projective personality tests is based on the premise that when individuals are exposed to vague or ambiguous stimuli, their interpretation of the stimuli will reflect their motivations, thought processes, and conflicts. Because of their subjective nature of the interpretation of the test-taker's responses, projective tests tend to have poorer psychometric properties than objective personality tests. Most projective personality tests have intricate scoring criteria and guidelines which require extensive training in the proper administration, scoring, and interpretation of these measures.

Rorschach Inkblot Test. The Rorschach is the most widely used and well known of all the projective personality tests. It consists of 10 inkblots present to the test-taker in two phases. In the first or association phase, the examiner holds out one card at a time and asks the test-taker what each might be. The examiner records these responses. In the second or inquiry phase, the examiner goes through each card and asks the test-taker to explain what he saw in each card.

The examiner records these responses verbatim. Scoring is based on the responses and explanations. Over the years, a number of scoring systems have been developed for interpretation. Currently, the most widely used is the Exner Comprehensive System.

Thematic Apperception Test. This test differs from other projective personality tests in that the test-taker is asked to construct a story from a picture shown by the examiner. The story is recorded verbatim and then interpreted using specific scoring criteria. Examples of elements considered in the interpretation are the hero, motives (needs) such as affiliation (belonging), power, and achievement, as well as environmental presses (factors), family relations, and recurring themes.

Rotter Sentence Completion Test. This test presents the test-taker with 40 sentence stems (first part of a sentence) and asked to complete the sentence in writing. Examples of these stems are "Other people _____." and "The happiest time_____." By grouping and evaluating the responses the examiner can postulate and make judgments about the test-taker's personality dynamics. Originally developed by psychologist Julian Rotter in 1950, this test is widely used in a variety of evaluations. Since the original Rotter test was first introduced several, variations on this kind of test format have been developed. This includes versions for children, adolescents, and older adults. Some are specifically geared toward testing sex offenders and other behaviorally disordered individuals.

Expressive Tests

These tests ask the test-taker to engage in drawing. The test-taker is given paper and drawing items (crayons or markers) and given specific directions. For example, in the Draw-A-Person test, the instruction is to draw a person of their choosing. In the House-Tree-Person test, the test-taker is asked to draw a house, a tree, and a person in that order. In the Kinetic-Family-Drawing, the test-taker is asked to draw a picture of their family including themselves engaged in some activity (doing something). The drawings are interpreted through specified guidelines. Conscious and unconscious (hidden) dimensions of personality as well as relational dynamics can be assessed using such expressive tests of personality. For instance, a child's Kinetic-Family-Drawing picture is presumed to elicit the child's attitudes toward his family and the overall family dynamics.

Personalized Medicine

Personalized medicine is medical practice that uses information about an individual's unique genetic makeup and environment to customize medical care to the individual's unique needs.

Definitions

- **Gene expression** is the process by which information from a gene is used to make proteins.
- **Genes** are the carriers of the genetic code present in each cell.
- **Genetic code** is the sequence of genes that reflect biochemical basis of heredity (inherited traits).
- **Genotype** is one's genetic makeup and the potential for unique traits or characteristics to develop.

Description

Personalized medicine is a model of medical practice based on the tailoring treatment to the causes and the unique characteristics of each individual. The basic premise is that treatment is based on causes. This means that all medical decisions and interventions are based on information about an individual's unique genotype and environment. The result of this customized approach is that most individuals get well. This contrasts with the conventional model of medical practice where treatment is based on a diagnosis that is based on symptoms. The basic premise is that treatment is based on symptoms and all individuals who have the same symptoms receive essentially the same treatment. With this "trial-and-error" approach, some get well, while others do not.

Personalized medicine is the use of detailed information about an individual's genotype or level of gene expression and unique and environmental circumstances such as levels of stress, diet, activity level, and exposure to toxins. Such data is considered in selecting a medication, therapy, or preventative measure that is uniquely suited to that individual. The benefits of this approach are its accuracy, efficacy, safety, and speed. The term "personalized medicine" emerged in the late 1990s with progress in the Human Genome Project.

Developments and Current Status

In the past decade, a predictive science has emerged from biomedical research. It is recognized by the shared terminology of "omics." These include genomics, proteomics, metabolomics, cytomics, and nutrigenomics. This new approach focuses on how individuals' unique molecular and genetic profile and environment makes them susceptible to certain diseases. This focus on causes over symptoms increases the level of prediction about which treatments will be safe and effective for an individual and which will not. Because of the increasing precision of diagnostic methods, health-care providers can more confidently select a treatment protocol that will maximize therapeutic effects and minimize harmful side effects. Also, there is mounting evidence that personalized medicine is more cost effective than the "trial-and-error" conventional medical practice. Personalized medicine is changing the way health-care professionals think about, diagnose, and manage health problems. Increasingly, it is already impacting the delivery of medical care. Besides medical conditions, personalized medicine also has applicability to neuropsychiatric and psychiatric conditions.

Person-Centered Therapy

Person-centered therapy is a name for the client-centered, nondirective approach to counseling and psychotherapy developed by psychologist Carl R. Rogers.

Definition

- **Nondirective** refers to a clinical approach to treatment where the therapist allows the client to set the pace and content of therapeutic counseling sessions.

Description

Person-centered therapy is characterized by two main ideas. The first is that human beings have the power to identify and find answers to their psychological problems. The second idea is that the role of the therapist is to help guide and not to direct the treatment process. Hence, person-centered therapy is often also called client-centered and nondirective therapy.

Carl Rogers (1902–1985) was influenced by the revolt of Otto Rank, one of Freud's colleagues, who came to oppose the traditional psychotherapeutic model of the time. In this model, the role of the therapist was to act as an emotionless but critical observer as the client shared his or her feelings and behaviors. According to this model, the therapist would provide superior knowledge and insight into a client's issues and offer an analysis of the meaning of his or her life. In this environment, it is easy to see how many clients would come to depend on their therapists. This was based on the belief that the therapist was the only person who could provide understanding and answers for a client. In this model, it was the therapists who made recommendations for changes and were responsible for the clients making improvements or getting better.

Rogers's firmly rejected Freud's paradigm of psychotherapy and challenged the notion that the therapist was responsible for the success of the treatment. He realized that it was actually the client's needs, feelings, and experiences which should determine the direction and pace of psychotherapy. From this concept Rogers developed person-centered or Rogerian therapy.

Rogers saw the therapist as a kind of supportive facilitator of the process, a knowledgeable and emotionally available guide. But this doesn't mean that he underestimated the role of the therapist. On the contrary he believed that an emotionally open, honest, and nonjudgmental approach on the part of the therapist was the foundation for effective analysis and treatment. The person-centered therapist's goal is to support his or her client who should be the source of the answers that will allow for healing.

This person-centered approach is based on a clear vision about the importance of the client and the secondary role of the therapist. A positive relational climate is the most important factor in creating successful treatment outcomes in this model. This is because it creates a positive clinical environment where the client can explore and discover his or her own truth.

Rogers repeatedly emphasized that the client discovers the truth based on his or her own experience. Person-centered therapists believe that the clients themselves hold the answers to their own questions and that it's the therapist's job to help them in the process of discovering what these answers are based on the clients' reality and experiences. Rogers expressed it this way in one of his most famous books *On Becoming a Person*: "Experience is, for me, the highest authority. The touchstone of validity is my own experience. No other person's ideas, and none of my own ideas, are as authoritative as my experience. It is to experience that I must return again and again, to discover a closer approximation to truth as it is in the process of becoming in me."

Development

Rogers had studied with the influential psychiatrist Alfred Adler in the late 1920s. From Adler, Rogers learned the value of simple and direct communication with his clients. He used this when he began his own formal work in the 1930s where much of his therapeutic work was conducted in a clinical setting with children. In 1939 his first book *Clinical Treatment of the Problem Child* was published. During these years he began to formulate his ideas and recommendations for person-centered therapy.

At the University of Chicago in 1945, Rogers got the chance to put his ideas into practice in a clinical setting attached to the university. He summarized his insights and results in the influential book *Client-Centered Therapy*, published in 1951. The book title is indicative of Rogers's preference to use the word "client" instead of "patient." This signifies a more equal relationship between therapist and the person seeking therapy than the illness-based word "patient."

Rogers never identified one guiding teacher or mentor, but he did admit that Søren Kierkegaard and Martin Buber were enormous influences on his approach to psychotherapy. In Kierkegaard's work he saw the primacy of experience reinforced or of being in the here and now rather than spending time in the past. There was no longer any need for the client to look outside himself or herself for validation,

especially not from the therapist. Instead the client can become his or her best person in and outside of therapy. Buber's work strongly reinforced Rogers's commitment to the person-to-person relationship that should exist between client and therapist. The therapist was more genuinely present and served as a facilitator who showed emotion. Rogers learned through Buber about how communication and language could create intimacy in the therapeutic relationship.

Current Status

Outcome studies over many years have validated the principles and approach that Rogers used by the fact that it demonstrates stable changes in clients' lives. As a result, Rogers's work became so influential that the adjective Rogerian was often applied to any client-centered, nondirective approach to psychotherapy. His prominence was recognized when he was elected president of the American Psychological Association in 1956. In 1961 he published his most famous book *On Becoming a Person*.

Although there will always be those who dislike nondirective therapeutic approaches, the person or client-centered methods that Rogers used continue to be popular not just with therapeutic professionals but with clients as well. Rogers's ideas and person-centered therapy are commonly taught to therapists in training. Client-centered therapy was the inspiration for at least two other variants of nondirective therapies: experiential therapy and process-experiential therapy.

Person–Environment Fit

The concept of *person–environment fit* describes the degree of overlap or compatibility between an individual's intrinsic characteristics and his or her extrinsic environment.

Definitions

- **Congruence Model,** developed by Nadler and Tushman in the early 1980s, suggests that organizations thrive when the degree of compatibility between four elements, task, people, structure, and culture, is high.
- **Organizational psychology** is the study of how humans behave in occupational or workplace settings.

Description

Person–environment fit describes how well an individual's characteristics (biological, psychological, emotional, and relational makeup) match up with his or her social and/or work setting. Alignment between these two entities has been an area of interest in organizational psychology and career counseling/assessment for decades. David A. Nadler and M. L. Tushman's Congruence Model, developed in the early 1980s, suggests a link between worker performance and degree of compatibility between the individual's values and those of his or her work environment. A correlation has also been noted regarding degree of compatibility and one's happiness and success.

The concept of person–environment fit can further be broken down into various domains, including person–organization fit, person–job fit, person–group fit, and person–person fit, each of which has been studied by researchers. Person–organization fit is the most commonly investigated, with research indicating that higher levels of congruence between a person's values and the organization in which he or she works result in higher levels of trust, satisfaction, a greater sense of community, connectedness, increased investment, and more productivity.

Current Status and Impact (Psychological Influence)

Determining person–environment fit is a critical element of career counseling and assessment practice. Those entering the workforce, seeking employment, or moving into new fields may undergo a series of assessments, typically in the form of questionnaires/surveys, to help determine the best fit for their individual aptitudes, personality, and characteristics. Organizations themselves have also seen the value of conducting these assessments during interview processes in order to determine if the potential candidate is an appropriate fit and will acclimate well in the company. Research suggests that organizations that invest in training and professional development opportunities can impact the degree of fit between themselves and their employees. Investment in such things increases worker buy-in subsequently resulting in better performance.

Pervasive Developmental Disorders

Pervasive developmental disorders (PDD) are group of diagnoses that describe impairments in the areas of communication, socialization, and behavior.

Description

Medical professionals often use the term "pervasive developmental disorders" as a synonym for autism spectrum disorders (ASD). PDD is a category of childhood diagnoses that included autistic disorder and Asperger's disorder in former classification systems. The diagnostic category of PDD differs from specific developmental disorders such as language impaired or specific learning disorders. PDD has encompassed a group of five disorders, all of which have in common delays in the development of basic functions around behavior, socialization, and communication. The diagnoses included under the category of PDD are pervasive developmental disorder-not otherwise specified, autistic disorder, Asperger's disorder, Rett syndrome, and childhood disintegrative disorder.

Each of these is explained in further detail in the encyclopedia entry for them. It is important to note that the first three of these disorders are also usually called autism spectrum disorders. However, the last two disorders are regressive in nature and rare. It is estimated that PDD or ASD may affect as many as 1 in 68 children.

Causes and Symptoms

Although medical professionals feel confident that the causes of PDD or ASD arise from deficits in brain functioning, there has been no clear identification of specific origins. The exception is Rett syndrome where it seems almost certain that a defect in the X chromosome is responsible, hence its restriction to girls. Researchers have identified some genetic abnormalities among certain groups of people with PDD or ASD but not one generalizable cause. Some suggest that a combination of genetics or biology and environmental influences during fetal development creates a predisposition to developing PDD or ASD.

Because of misconceptions in the past, it is important to note that parenting behaviors are not the cause of PDD or ASD. In the 1950s and 1960s, when the understanding about PDD or ASD was limited, many parents were informed by their physicians that their child's condition was a result of faulty bonding. This

group of parents were referred to as "refrigerator mothers." Since that time many advancements have been made, and although no one or even a group of causes have been identified, it is clear that parenting methods do not cause PDD or ASD.

The symptoms of PDD can be varied. Among the most commonly cited are difficulty using and understanding language and difficulty relating to people socially. Limited use of facial responses and unusual ways of playing with toys and other objects is often observed. It is common to see difficulty coping with changes in routine or familiar surroundings for people diagnosed with PDD or ASD. Many of them demonstrate repetitive body movements or behavior patterns, such as hand flapping or body rocking. Several symptoms need to be present in order for a child or adult to receive a diagnosis of PDD or ASD.

Diagnosis and Prognosis

In the current diagnostic system, PDD has been replaced with ASD. Both the previous PDD and the current ASD diagnosis depend on the involvement of several physicians. Families who are seeking a diagnosis for their child are usually referred to a neurologist to rule out any physical brain damage that may be causing problems with development. In addition to that a psychologist, psychiatrist, or other mental health professional can conduct standardized behavioral observations to determine if a child or adult meets the criteria for one of the ASD or former PDD diagnoses.

Some medical professions use the diagnosis global developmental disorder or social communication disorder for very young children when they are not yet sure that they are truly suffering from ASD. Since very young children tend to exhibit limited social interaction and communication skills simply because of their age, this makes it more difficult to diagnose milder cases of autism in toddlers.

PDD and ASD are lifelong conditions that do not have a cure. Many individuals with a PDD or ASD diagnosis who receive early intervention therapies make progress and are able to learn skills that they have not naturally acquired. The potential of each person with a PDD varies, and therefore, it is hard to make a prognosis for the population as a whole.

Treatment

As with so many other disorders, effective treatment will be based on the individual, on when they receive help or intervention, and on all of the factors in the child's environment. Once a sufficient diagnosis is reached, it is possible to plan for specific and tailored behavioral therapies and educational programs that can help alleviate some of the symptoms of PDD. Some of the evidence-based therapies approved for treating PDD include speech-language therapy, applied behavior analysis, occupational therapy, and social skills training. All these will help the child to behave and communicate with others in various ways that it is hoped will benefit them.

Education is an important component of treatment for those with PDD. There are programs to teach parents how to help their children through positive reinforcement and the enforcement of limits applied with consistency at home. Most physicians recommend 25 to 40 hours a week of therapy or some kind of active engagement with others. This can be done with family members at home as well as through school programs. Some children with PDD will need special education, while others with less severe symptoms may be able to be in mainstream education. It is not uncommon for individuals with PDD to be under psychiatric care because the use of medications can help treat many of the more severe symptoms of aggression and co-occurring mental health conditions.

Phantoms in the Brain: Probing the Mysteries of the Human Mind (Book)

Phantoms in the Brain: Probing the Mysteries of the Human Mind is a best-selling book written in 1998 by V. S. Ramachandran and Sandra Blakeslee about Ramachandran's work with patients who have neurological disorders.

Definitions

- **Anomalies** are something that is different from what is considered normal or expected.
- **Neuroscience** is the scientific study of the nervous system and the brain.
- **Phantom limbs** is the sensation or feeling that a part of the body that is physically missing or has been removed is still present. The feelings are generally painful.

Description

Phantoms in the Brain is a best-selling book exploring the mysteries of the mind. The main author V. S. Ramachandran (1951–) is a prominent neurosurgeon, considered to be one of the best in the world. He has taken on the challenge of exploring medical anomalies. This book explores his cases of rare client disorders that could easily be mistaken for psychological disorders, yet the root of the problem lies within the brain.

Ramachandran is no stereotypical scientist. His work uses influence from the English playwright William Shakespeare and Holistic guru Deepak Chopra, as well as psychologists and references to religion. He takes an approach like that of Sherlock Holmes, thinking outside of the box and questioning everything. The book has some informality to it where Ramachandran's curiosity and wonder can be truly experienced by the reader.

Ramachandran is best known for his work with individuals who experience phantom limbs, meaning the sensation that people who have had limbs or other parts of the body removed feel. This book explains where some of these sensations originate, as well as the impact of damage to different parts of the brain on an individual. The author begins the conversation of hoping to connect an understanding of the brain and the impact and relationship with that of the individual who houses it.

Each of the patients written about suffers from damage of some sort to specific parts of the brain that results in bizarre changes in behavior. Traditionally, when someone was seen to experience behavior changes such as hearing or seeing things that were not present or feeling missing limbs, the assumption was that the person was mentally ill. *Phantoms in the Brain* finds these kinds of behavior changes to be the guide allowing for exploration of the human brain. The book explores the way these disorders are viewed from a psychological standpoint, as well as from a medical view. This leads to the possibility of exploring cases previously viewed as insanity as possibly simply being malfunctions in the brain.

Phencyclidine-Related Disorders

Phencyclidine-related disorders are mental disorders characterized by the persistent use of phencyclidine or similar drugs (e.g., ketamine).

Definitions

- **Auditory and visual hallucinations** are severely distorted perceptions of what is real.
- **DSM** is the abbreviation for the *Diagnostic and Statistical Manual of Mental Disorders*,

which is the handbook mental health professionals use to diagnose mental disorders. The current edition is DSM-5.

- **Hallucinogen-related disorders** are DSM-5 mental disorders characterized by the use of mind-altering drugs that cause changes in mood, thoughts, perceptions, and consciousness. Unlike other drugs, they cause auditory and visual hallucinations.
- **Ketamine** is a drug that is used in both individuals and animals to treat pain or for sedation.
- **Substance-related and addictive disorders** are a group of DSM-5 mental disorders characterized by maladaptive thoughts, excessive and repetitive behaviors, and physical symptoms. It includes cannabis use disorder and hallucinogen disorders.

Description and Diagnosis

Phencyclidine-related disorders are one group of the DSM-5 substance-related and addictive disorders. They are further subcategorized under the hallucinogen-related disorders. Phencyclidine is also known as PCP (or by the street name "angel dust"). It is primarily used by veterinarians and less often by physicians. However, it is also illegally used by individuals as a recreational substance. Phencyclidine and similar substances may be used for their pain-reducing, numbing, and/or hallucinogenic effects. They may be ingested orally, injected intravenously, or smoked. These substances affect dopamine and serotonin levels in the brain. Small amounts of phencyclidine drugs may result in euphoric feelings, while larger quantities may lead to aggressive behaviors. Physical side effects may include high blood pressure, increased heart rate, or lack of muscle coordination.

The occurrence of this disorder is not known. Use of phencyclidine and similar substances appears to increase with age. About 0.3% of individuals between the ages of 12 and 17 have taken phencyclidine. Approximately 1.3% of young adults aged 18 to 25 and 2.9% of adults aged 26 and older have used the drug. Males are more likely than females to use phencyclidine (American Psychiatric Association, 2013). African Americans and Hispanics are more likely to use phencyclidine and Caucasians are more likely to use ketamine (phencyclidine-like substance).

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, individuals can be diagnosed with this disorder if, over a 12-month period, they need higher doses of the drug to achieve the desired effect. They have not been able to reduce usage or stop using. They have strong cravings and spend a lot of time finding, buying, and using the drug. Continued drug use leads to occupational, social, and interpersonal problems. The drug is used during situations that could potentially be dangerous, such as when driving. Phencyclidine-related disorders are not characterized by withdrawal symptoms (American Psychiatric Association, 2013).

The cause of this disorder may be attributed to genetic, biological, and environmental factors. An individual with a first-degree relative with a phencyclidine-related disorder has a higher chance of developing the disorder. Individuals with brain chemical imbalances may use phencyclidine substances to improve mood. Environmental stressors may also contribute to substance use.

Treatment

Treatment can include medication, psychotherapy, psychoeducation, and self-help groups. Once drug usage ceases, antipsychotic drugs may be necessary to manage phencyclidine-induced hallucinations. Antidepressant drugs may be necessary to treat symptoms of depression often associated with cessation of phencyclidine use. At this time, it is important to conduct a suicide assessment and refer individuals who require psychiatric hospitalization. Cognitive behavior therapy is the psychotherapy of choice in the treatment of phencyclidine-related disorders. The individual learns how to identify maladaptive thoughts, feelings, and behaviors and replace them with adaptive thoughts, feelings, and behaviors. Education on addiction, recovery, and coping skills can be very helpful in maintaining sobriety. Self-help groups founded on the Twelve-Step principles may provide a sober social network and support.

Phobic Disorders

Phobic disorders are mental disorders characterized by intense and unreasonable fears of a situation or an object that cause little danger but produce anxiety and avoidance.

Definitions

- **Antidepressant medications** are prescription drugs that are primarily used to treat depression and depressive disorders.
- **Anxiety** is a negative emotional state characterized by feelings of nervousness, worry, and apprehension about an imagined danger. It is the anticipation of future threat.
- **Anxiety disorders** are a group of DSM-5 mental disorders characterized by excessive fear and anxiety and associated behavioral problems. These include panic disorder, generalized anxiety disorder, and phobic disorder.
- **Benzodiazepines** are a class of drugs that slow the nervous system and are prescribed to relieve nervousness and tension, to induce sleep, and to treat other symptoms.
- **Cognitive behavior therapy** is a form of psychotherapy that focuses on changing faulty behaviors, emotions, and thoughts. It is also known as CBT and cognitive behavioral therapy.
- **DSM-5** stands for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, which is a diagnostic system used by professionals to identify mental disorders with specific diagnostic criteria.
- **Exposure therapy** is a behavioral therapy method in which an individual is exposed to a feared object or situation.
- **Fear** is an emotional response to a known danger.
- **Panic attack** is an episode of sudden, intense, and debilitating sense of fear that is short lived.
- **Psychotherapy** is a psychological method for achieving desired changes in thinking, feeling, and behavior.

Description and Diagnosis

Phobic disorders are one of the group of DSM-5 anxiety disorders. They are characterized by a feeling of panic or terror when exposed to the source of an individual's fear. Individuals with a specific fear may do everything possible to avoid what they fear. Often, they are not able to function normally because they experience severe anxiety as a result of the fear. Symptoms of phobic disorders include rapid heartbeat, difficulty breathing, sweating, and a feeling of panic and extreme anxiety. Very often, an individual acknowledges that his or her fears are unreasonable but feels powerless to control them. In some cases, just thinking about a fear (e.g., snakes, spider, elevators) leads to intense anxiety in an individual. Phobias are generally long lasting and cause intense physical and psychological reactions. Phobias can affect an individual's ability to function normally at work, in social settings, and in other important areas of his or her life.

There are three separate disorders that fall under the classification of phobic disorders. They include

agoraphobia, social anxiety disorder (social phobia), and specific phobia. A brief description of each follows and is more fully described in their own entries in this encyclopedia.

Agoraphobia. Agoraphobia is a fear of an actual or anticipated situation, such as being in open or enclosed spaces (e.g., elevators), being in a crowded area (e.g., mall), or being outside of one's home alone. Anxiety usually develops because the individual feels there is not means to escape. Most individuals who have agoraphobia develop panic attacks. Agoraphobia may be so severe that these individuals refuse to leave their home.

Social anxiety disorder. Social anxiety disorder (social phobia) involves a combination of excessive self-consciousness and a fear of humiliation in social situations. Individuals in social situations have a fear of being rejected by others or have a fear of offending others. This disorder was previously called social phobia.

Specific phobia. Specific phobia involves continuous and irrational fears of a specific situation or object that is out of balance to the actual risk. For example, an individual may have a fear of elevators because he or she may think the elevator may malfunction. Some other examples of specific phobias include a fear of animals, thunderstorms, heights, and loud noises. There are several types of specific phobias.

Treatment

If a phobia is affecting individuals' daily life, there are several therapies and medications available that can help them overcome their fears. Psychotherapy has been shown to be effective for individuals with phobic disorders. In particular, desensitization or exposure therapy and cognitive behavior therapy can greatly help individuals overcome phobias. Antidepressant medications and benzodiazepines are commonly used to treat phobias to reduce anxiety.

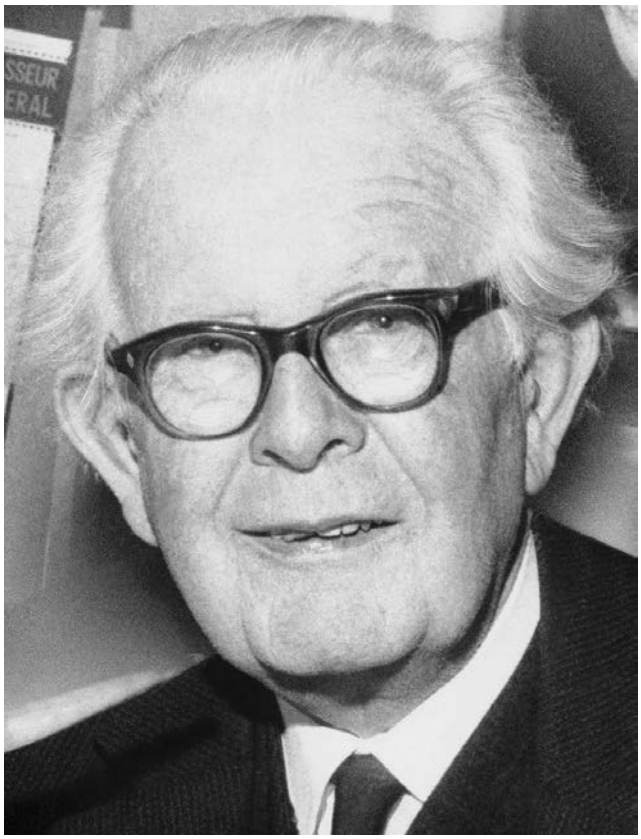
Piaget, Jean (1896–1980)

Jean Piaget was a Swiss-born developmental psychologist best known for his studies on the cognitive development of children.

Description

Jean Piaget, PhD, was born and raised in Switzerland. Piaget was the oldest of three children. His father Arthur was considered to be a highly influential figure



Jean Piaget was a Swiss-born developmental psychologist best known for his studies on the cognitive development of children. (AP Photo)

in science and education in Switzerland. This influence led to an early interest in the sciences and by age 11, Piaget had begun to write educational papers. He had a strong desire to understand how things worked. Piaget found his father's expectations and way of connecting with him a large motivator in his own accomplishments. Piaget was married and had three children of his own. His children would become focus points for his area of study and the basis for his writing and theories.

Early in his career, Piaget worked with Alfred Binet using Binet's intelligence tests. Using these tests he started to notice that children think differently than adults do. This understanding led him to begin studying the development of thought process and intelligence in his own children. Throughout his life, Piaget was invested in revising his theories and staying focused in the fields of psychology, philosophy, sociology, and epistemology (the study of knowledge and understanding, grounded in philosophy). Piaget's theory was influenced by philosophy, specifically that of Jean-Jacques Rousseau who had argued that reasoning and understanding in children happens in stages.

Piaget's theory of cognitive development identified four stages: (1) the sensorimotor stage, (2) the preoperational stage, (3) the concrete operational stage, and (4) the formal operation stage. The sensorimotor stage is identified from birth to about age 2 where babies are taking in sensations but cannot symbolize their experiences. The preoperational stage is from about ages 2 to 7 when thinking is not yet logical and children can focus only on one piece of information. The concrete operational stage is from about ages 7 to 12 where thinking is becoming quicker and more efficient. Logical thinking can be connected to concrete material. The final stage of formal operations is from about age 12 to adulthood and is evidenced when logical thinking is connected to abstract information.

When Piaget was in his 50s, he founded the International Center for Genetic Epistemology in Geneva. He was the director of the center until his passing in 1980. His hope in creating this center was to unify scientists and researchers from various disciplines and connect them to doctoral students or new developmental psychologists.

Impact (Psychological Influence)

Piaget became a key figure in both European and American psychology. His theories are still widely studied and used, especially when looking at human growth and development. His work has been a large contributor to understanding the thinking development of children as opposed to simply thinking of them in terms of adult intelligence. He had an impactful career filled will numerous publications. His theories have been and continue to be a leading presence in the field of development.

Pica

Pica is the persistent craving and compulsive eating of nonfood substances, like dirt, paint chips, or ice. It is considered an eating disorder in DSM-5.

Definitions

- **Behavior therapy** is a form of psychotherapy that focuses on identifying and changing maladaptive behaviors. It is also referred to as behavioral therapy.
- **Behavioral analysis** is a type of assessment that focuses on the observable and quantifiable aspects of behavior and excludes subjective phenomena such as emotions and motives.

- **DSM-5** stands for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, which is a diagnostic system used by professionals to identify mental disorders with specific diagnostic criteria.
- **Eating disorder** is a class of mental disorders that are characterized by difficulties with too much, too little, or unhealthy food intake, and may include distorted body image.

Description and Diagnosis

Pica is an eating disorder that is characterized by the persistent craving and compulsive eating of nonfood substances. It is most common among children over the age of two years who have developmental or intellectual delays. Those with this disorder consume various substances, including sand, clay, starch, ice, cigarette butts and ashes, hair, paint chips, soap, wood, coal, chalk, and paper. Although pica can occur in individuals of various backgrounds, it is more likely to be associated with pregnancy, early childhood, mental retardation, autism, anorexia nervosa, poor nutrition, and low blood levels of iron and other minerals. Consuming nonfood substances is seldom done publicly. The reason is that most are embarrassed to admit to this unusual habits and so they hide it from their family and doctors. Or, they may not report the pica to their doctor because of a lack of knowledge of pica's potential medical significance. Pica can lead to health problems such as intestinal obstructions, nutritional deficiency, and parasites.

Pica is also associated with certain religious and cultural traditions. For example, in some cultures, nonfood substances are believed to have positive spiritual and health effects. Among some African Americans eating a particular kind of white clay is believed to promote health and reduce morning sickness during pregnancy. In some cultures eating certain substances is believed to bring good luck or increase fertility.

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, individuals can be diagnosed with this disorder if they exhibit a persistent pattern of eating nonnutritive, nonfood substances. It requires that the eating of these substances must be developmentally inappropriate and not culturally supported. When pica appears in individuals with autism, schizophrenia or Kleine-Levin syndrome, it is not an additional diagnosis unless the condition is severe (American Psychiatric Association, 2013).

The cause of this disorder is not well understood. Iron deficiency is most commonly associated with pica. While individuals with documented iron deficiency engage in pica, it is not clear whether the iron deficiency was a cause of pica or a result of it. It has been observed that pica cravings in individuals with iron deficiency stop once iron supplements are given. Low blood levels of iron are common in pregnant women and those with poor nutrition. Pica is also common in those diagnosed with hookworm infections. Pica has a higher incidence in populations with mental disorders like autism and conditions such as mental retardation. Because these conditions do not involve iron deficiency, it may well be that psychological factor are involved as a cause. Pica may be the result of a desire for attention, or the avoidance of some task, or a desire for sensory feedback.

Treatment

An examination by a medical practitioner is warranted as a starting point for treatment of pica and/or rumination disorder. Ruling out and then supplying treatment for medical causes and complications is the first step in the treatment of both diseases. When pica presents in infants and toddlers, it may be normal oral exploration unless the presentation is severe; however, the presentation of moderate to severe rumination disorder in infancy can pose a threat to development and even lead to lethal medical conditions. Making sure that a medical team is alert to the presence of these disorders is extremely important.

The second consideration in treatment for pica is the use of psychological interventions. Both school psychologists and special educators provide the first line of diagnosis in children with developmental disorders who may engage in pica. Psychological interventions that have been effective in treating pica include behavioral analysis and behavior therapy. However, identification of the purpose of the behavior is often key to the development of an effective treatment plan. Once a purpose is identified (desire for attention, avoidance of task, desire for sensory feedback), behavioral

interventions can be utilized to extinguish the behavior or substitute more positive oral stimulation for it.

Pick's Disease

Pick's disease is a rare form of dementia that causes a slow shrinking of cells in specific areas of the brain.

Definitions

- **Alzheimer's disease** is a medical and mental disorder that causes dementia particularly late in life. It is also referred to as Neurocognitive Disorder Due to Alzheimer's Disease.
- **Dementia** is a group of symptoms, including loss of memory, judgment, language, and other intellectual (mental) function caused by the death of neurons (nerve cells) in the brain.
- **Dementia praecox** refers to a chronic, deteriorating psychotic disorder characterized by cognitive disintegration, usually beginning in the late teens or early adulthood.
- **Depression** is an emotional state characterized by feelings of sadness, low self-esteem, guilt, or the reduced ability to enjoy life. It is not considered a disorder unless it significantly disrupts one's daily functioning.
- **Frontotemporal dementia** is a group of disorders caused by cell degeneration in the brain's frontal lobes (the area behind the forehead) or its temporal lobes (the area behind the ears). It is also referred to as FTD.
- **Paramnesia** is a distortion of memory in which fact and fantasy are confused.
- **Primary progressive aphasia** is a form of cognitive impairment that involves a progressive loss of language function. It is also referred to as PPA.
- **Semantic dementia** is a progressive neurological disorder characterized by loss of semantic memory (general knowledge) where individuals can speak easily but their words convey limited meaning.

Description

Pick's disease is a type of dementia distinguished by progressive degeneration in the frontal and temporal areas of the brain. Pick's disease is similar to Alzheimer's disease; however, it affects only certain areas of the brain, whereas Alzheimer's disease affects all areas of the brain. Pick's disease is also referred to as frontotemporal dementia (FTD). Pick's disease, primary progressive aphasia, and semantic dementia are grouped together and classified as FTD. It is usually diagnosed in individuals under the age of 65 years. Individuals with Pick's disease initially exhibit behavioral and personality changes before they lose the inability to speak coherently. The early stages of Pick's disease are often misdiagnosed as depression or Alzheimer's disease. Some behavioral signs and symptoms of Pick's disease include extreme restlessness, impulsivity and poor judgment, poor personal hygiene, withdrawal or decreased interest in activities, repetitive or obsessive behavior, promiscuity, and a decline in function at work and home. Some emotional signs and symptoms of Pick's disease include apathy, rudeness, impatience, aggression, poor attention span, abrupt changes in mood, and a lack of empathy, warmth, and concern for others. Some language signs and symptoms of Pick's disease include trouble finding the right word, difficulty speaking, loss of vocabulary, decreased ability to write or read, uncoordinated speech sounds, and a complete loss of speech. Some physical signs and

symptoms of Pick's disease include loss of memory, general weakness, difficulty moving around, increased muscle rigidity, lack of coordination, and urinary incontinence.

Arnold Pick (1851–1924) was the psychiatrist who first discovered and described the disease. He is known for identifying the clinical syndrome and the characteristic of this disorder, which are Pick bodies. In 1892, Pick examined brain tissue of several deceased individuals with histories of dementia. The characteristic feature is a protein tangle that appears as a large body in the tissue of neurons, known as a Pick body. Pick headed the Prague neuropathological school which is one of the two neuropathological schools in Europe, which framed Alzheimer's disease through several studies.

The cause of Pick's disease is the result of a buildup of protein in the affected areas of the brain. The accumulation of Pick bodies eventually leads to socially inappropriate behavior, changes in character, and poor decision making. The progression of Pick's disease eventually leads to severe intellectual, memory, and speech impairment. Pick's disease is slightly more common in women than in men and usually affects adults between the ages of 50 and 60 years. Unfortunately, the cause of this buildup of protein is unknown.

Currently, there is no cure for Pick's disease. However, by understanding the unique symptoms, an individual with Pick's disease can better manage the disease and his or her quality of life. Treatment for Pick's disease is similar to that for Alzheimer's disease. The goal of treatment is symptom management that maximizes the quality of life. This may include medications to manage specific symptoms. Treatment should also include emotional support for the caregiver. The prognosis for individuals with Pick's disease is poor. The disease progresses rapidly, ranging from 2 to 10 years for life expectancy. Eventually, some individuals with Pick's disease will need around-the-clock care, whether it be at home or in an institutionalized care setting.

Placebo Effect

The placebo effect is any genuine psychological or physiological response to an inert substance or procedure.

Description

Historically a placebo is an inert substance, such as a sugar pill, which contains no medication, and is given to subjects of controlled medical studies. In these studies one group of patients is given an experimental treatment and the control group is given a placebo and no treatment. Neither group would know if they were receiving the treatment or the placebo. Researchers have consistently found that both groups, in spite of the fact that only one group received a placebo, would benefit. This phenomenon is known as the placebo effect.

The placebo effect, sometimes referred to as the placebo response, has been a topic of interest in the scientific and medical communities for many years. Originating out of the medical field, the placebo effect has also resulted in both philosophical and psychological inquiry. How something inert, or a fake treatment as some have described certain types of placebo, can have a real effect has been the focus of much inquiry. Research has shown that placebos mimic many characteristics of actual medications. For instance, two placebo pills are more effective than one, and larger pills have a stronger effect than small pills. Placebo injections produce stronger effects than placebo pills. In one study a placebo anesthetic was applied to one index finger of participants. When pain stimulation was applied to both index fingers, the pain was perceived as less on the finger with the placebo anesthetic. Placebos have been shown to improve health but have also been

shown to mimic side effects. Attempts to understand, or explain away, the placebo effect have resulted in a large body of research that indicates the placebo effect is a genuine phenomenon.

Current Status and Impact (Psychological Influence)

Research indicates that placebo effect is related to expectancy and conditioning. Expectancy is related to the belief one has about the positive benefits of the medication or procedure. The stronger the belief, the stronger the effect. Expectancy develops through personal experience, receiving verbal information or suggestion, and observational learning. For instance, positive counseling outcomes have been shown to be related to expectancy. Common factors in counseling such as the quality of the therapeutic relationship (personal experience), normalizing symptoms (verbal information), and provider reputation (observational learning) are associated with positive counseling outcomes separate from technique or expertise.

Placebo effect is also related to conditioning. Classical conditioning teaches that if you experience two events simultaneously and repeatedly you come to expect the same result when only one of the conditions is met. This is called conditioned stimulus-response. For instance, people consistently go to the doctor when they are sick and then get better after the visit. We take pills when we feel ill and then we feel better. These repeated stimulus-response (go to the doctor, feel better; take a pill, feel better) results in positive health outcomes regardless of what the doctor does or what the pill contains.

Placebo effect is considered a pervasive phenomenon, meaning that the response is part of any and all medical intervention. Placebo effect is also known to have an effect on positive counseling and psychotherapeutic outcomes. Placebo effect is a powerful phenomenon that demonstrates the brain's role in physical and psychological health outcomes.

Play Therapy

Play therapy is a therapeutic method used by a play therapist who provides carefully selected play materials in a safe setting for the child to express his or her feelings, emotions, fears, and beliefs.

Description

Play therapy is formally defined (Association for Play Therapy, 2015) as "the systematic use of a theoretical model to establish an interpersonal process wherein trained play therapists use the therapeutic powers of play to help clients prevent or resolve psychosocial difficulties and achieve optimal growth and development."

This important relationship offers a way for the child to explore his or her inner self using the familiar and often symbolic medium of play. Play therapy can include the use of therapeutic games, puppets, role playing, a wide variety of toys, dress-up clothes, bop bags, play doh, dollhouses, musical instruments, or even sand tray, which is an experiential form of play therapy. There are many different theoretical approaches to play therapy, including filial therapy, client-centered play therapy, Adlerian play therapy, and nondirective play therapy.

Development and Current Status

At the beginning of the 20th century, well-known psychoanalysts, including Sigmund Freud, Anna Feud, and Melanie Klein, began advocating play as an important therapeutic approach for children. Play can be therapeutic for individuals, including children, adolescents, adults, and even the elderly. Interestingly, although play therapy is most commonly associated with children, there is a growing demand to use play therapy with adults and geriatric clients. Case studies have shown that using play therapy with elderly clients

can lead to less isolation, reduced stress, more socialization, higher self-esteem, less forgetfulness, lower levels of depression, and increased mental sharpness.

For children, this form of therapy is considered highly effective, especially since they have a limited emotional vocabulary and have yet to master abstract concepts that are necessary for traditional talk therapy. Experts in the field of play therapy believe that play helps to bridge the gap between concrete experience and abstract thought by giving the child (or adult) a familiar medium to express his or her thoughts and feelings. This can be particularly beneficial for individuals who are experiencing emotional or behavioral challenges.

There are many reasons that the use of play therapy has been so effective across a variety of populations and presenting issues. Some of the unique characteristics of play include its voluntary nature in a world of rules and requirements; it is free from evaluation and judgment so it's safe to make mistakes without it being seen as failure; it encourages the use of the imagination; it increases involvement and interest, which can increase social interest and reduce social isolation; and it also promotes self-development. A client who is engaged in play therapy often feels a sense of being able to be in control of his or her world, particularly in ways that are impossible in the real world. Whether child or adult, play therapy offers a medium to symbolically express what is going on in his or her inner world. As with any form of therapy, it is advised to be used with purpose and intent as part of a professional treatment plan.

Much of the basic tenets of play therapy in use today are based on the work of Virginia Axline, whose 1964 book *Dibs: In Search of Self* was considered groundbreaking and still is a must-read for today's play therapists. Axline, who developed nondirective play therapy, was influenced by the person-centered approach of Carl Rogers. Axline, in turn, influenced Violet Oaklander, whose seminal book *Windows to Our Children* on gestalt play therapy is among the most highly read on play therapy and has been translated into 14 different languages. In addition to Axline and Oaklander, many play therapists have contributed to the growth of this form of therapy. Among today's most influential play therapists and play therapist researchers are Garry Landreth, Eliana Gil, Rise VanFleet, Terry Kottman, and Paris Goodyear-Brown.

There are several different theoretical approaches that can be used for play therapy. Filial therapy is also referred to as family play therapy or child relationship enhancement therapy. The basic premise is to teach the parents to play the role of the therapist. The goal with this approach is to create a better relationship between parents and their children. There is also the client-centered or child-centered play therapy model, which is based on the principles of Virginia Axline's work. Adlerian play therapy was developed by Terry Kottman and is led by the child through a supportive and accepting environment that helps target misbehavior and is especially helpful for children who have suffered abuse or trauma. Another modality is nondirective play therapy, which is often used to help children develop their verbal language skills.

Polysomnography

Polysomnography is a set of medical tests used to diagnose and evaluate sleep disorders.

Definitions

- **Dyssomnias** are disorders involved in falling asleep or staying asleep.
- **Hypopnea** is breathing that is too shallow to maintain adequate levels of oxygen in the blood.
- **Narcolepsy** is a disorder characterized by frequent and uncontrollable attacks of deep sleep.
- **Parasomnia** is a type of sleep disorder characterized by abnormal changes in behavior or body functions during sleep, specific stages of sleep, or the transition between sleeping and waking.
- **Restless leg syndrome** is a medical condition characterized by unpleasant sensations in the legs that occur at rest or before sleep and is relieved by walking.
- **Sleep apnea** is a brief suspension or interruption of breathing.
- **Sleep disorders** are chronic disturbances in the quantity or quality of sleep that interfere with an individual's ability to function normally.
- **Sleep latency** is the amount of time it takes to fall asleep.

Description

Polysomnography is a set of medical tests performed while an individual sleeps. It examines brain wave patterns, eye movements, and muscle tone. Polysomnography is used to diagnose and evaluate many types of sleep disorders, including dyssomnias, parasomnias, and other medical, psychiatric, and dental disorders that produce symptoms during sleep. Sleep apnea is a dyssomnia that is common in middle-aged and elderly obese men. In sleep apnea the muscles of the soft palate in the back of the throat relax and close off the airway during sleep. This causes the individual to snore loudly and gasp for air at night. This results in the individual becoming excessively sleepy during the day. Narcolepsy is another dyssomnia, which results in excessive daytime sleepiness, sudden attacks of muscle weakness, and hallucinations at sleep onset. Some parasomnias detected using polysomnography include disorders of arousal or rapid-eye-movement (REM) sleep problems, such as nightmares. Medical conditions that can be evaluated by polysomnography include sleep-related asthma, restless leg syndrome, depression, and panic disorder. It is also used to evaluate seizures of sleep-related epilepsy that occur during sleep.

Developments and Current Status

Polysomnography is performed during an overnight stay in a sleep laboratory. While the individual sleeps, a wide variety of tests can be performed. One form of monitoring is electroencephalography (EEG), in which electrodes are attached to the individual's scalp to record his or her brain wave activity. The EEG monitors brain wave activity from different parts of the brain and records them on a graph. It identifies the stage of sleep as well as detects seizures. Another form of monitoring is continuous electrooculography (EOG), which records eye movement and is useful in determining when the patient is going through a stage of REM sleep. Both EEG and EOG are helpful in determining sleep latency, total sleep time, the time spent in each sleep stage, and the number of arousals from sleep. The electrical activity of the patient's heart is also measured using electrocardiography. Electrodes are placed on to the individual's chest to record electrical activity from various areas of the heart. They help detect cardiac arrhythmias (abnormal heart rhythms), which may occur during periods of sleep apnea. Blood pressure is also measured as episodes of sleep apnea sometimes dangerously elevate blood pressure. A final

standard measurement is muscle tone. This is done using electromyography, which involves placing an electrode on the muscle to record its contractions. Depending on the suspected disorder, polysomnography can also include sound monitoring to record snoring, video monitoring to document body positions, core body temperature readings, incident light intensities, penile swelling (tumescence), and pressure at various levels of the esophagus.

Positive Psychology

Positive psychology is an approach to psychology that emphasizes strengths and health rather than deficits and illness.

Definitions

- **Values** are principles that govern virtuous behavior. When values are lived or put in action, they are known as virtues.
- **Values in action inventory of strengths** is a psychological inventory that assesses positive psychological traits, strengths, and virtues. It is also called VIA-IS.
- **Well-being** is the state of being happy, healthy, prosperous, or successful.

Description

Positive psychology is the scientific study of strengths and virtues that influence individuals to live meaningful and fulfilling lives. It is a reaction to most other psychological approaches that view human nature in terms of pathology and deficiencies. Instead, positive psychology views human nature in terms of health and strengths. It assists individuals to utilize their strengths and to live meaningful and fulfilling lives. Positive psychology seeks to understand what makes people well rather than what makes them ill. Another basic premise is that human beings are drawn by the future rather than being driven by the past. Mental health is not viewed by the absence of symptoms but by the presence of purpose, happiness, and acceptance.

Positive psychology has a significant research basis. Comprehensive research has explored and continues to examine the nature of human happiness and well-being. This scientific endeavor will lead to a greater understanding of human behavior and corresponding methods of psychological treatment. Positive psychology is considered one of the most recent psychological efforts to study and understand the nature of well-being and happiness. This approach has gained significant international attention in a short amount of time. The International Positive Psychology Association (IPPA) has expanded to over 80 countries with thousands of members. The mission of IPPA is to further the scientific study of positive psychology around the world in various contexts.

Developments and Current Status

As a field of study, positive psychology was developed by psychologist Martin Seligman (1942–) in 1998. However, the term "positive psychology" was used by Abraham Maslow (1908–1970) in 1954. This approach is influenced by the humanistic psychology perspective, which was influenced by the work of Abraham Maslow, Carl Rogers, and Alfred Adler. These approaches focus on promoting mental health rather than the treatment of mental illness. Positive psychology is the basis for positive psychotherapy, which is the psychological treatment of individuals using the principles of positive psychology.

Positive Psychotherapy

Positive psychotherapy is a form of psychotherapy that assists individuals to build on their strengths and virtues so they can lead more meaningful and fulfilling lives.

Definitions

- **Positive psychology** is an approach to psychology that emphasizes strengths and health rather than deficits and illness.
- **Psychotherapy** is a psychological method for achieving desired changes in thinking, feeling, and behavior. It is also called therapy and therapeutic counseling.
- **Values** are principles that govern virtuous behavior. When values are lived or put in action, they are known as virtues.
- **Values in action inventory of strengths** is a psychological inventory that assesses positive psychological traits, strengths, and virtues. It is also called VIA-IS.
- **Well-being** is the state of being happy, healthy, prosperous, or successful.

Description

Positive psychotherapy is a form of psychotherapy based on positive psychology. It emphasizes the individual's strengths and virtues to ultimately influence living a life of meaning and fulfillment. Instead of targeting symptoms like the majority of other psychological approaches, the goal of positive psychotherapy is to increase positive emotions through various strategies and interventions. Positive psychotherapy was originally developed to treat individuals suffering from depression, but further research and clinical application suggest that this approach can treat a variety of presenting issues.

Positive psychotherapy can be used among individuals, couples, families, groups, and organization settings. Individuals are trained to focus their attention to what is going well in their lives and to focus their attention and memory on positive encounters and experiences. For example, the "three good things" exercise is a daily activity done in the evening in which individuals write down what went well in the day and what they did to make it go well. Another therapeutic strategy includes individuals taking the values in action inventory of strengths (VIA-IS) and to journal about how they can implement their signature strengths in their daily lives.

Developments and Current Status

Positive psychology and psychotherapy was developed by psychologist Martin Seligman (1942–) in 1998. This approach was influenced by the humanistic psychology perspective, which was influenced by the work of Abraham Maslow, Carl Rogers, and Alfred Adler. These approaches focus on promoting mental health rather than the treatment of mental illness. Positive psychotherapy is considered one of the most recent psychological efforts to study and understand the nature of well-being and happiness.

Positron Emission Tomography (PET)

Positron emission tomography is a diagnostic imaging technique that uses radioactive substances to produce three-dimensional colored images within the body. It is also called the PET scan and PET/CT scan.

Definitions

- **Computed tomography** is a diagnostic imaging device that uses x-rays to produce cross-sectional images (tomographs) of the body.
- **Magnetic resonance imaging** is a diagnostic imaging device that uses electromagnetic radiation and a strong magnetic field to produce images of soft tissues.
- **Positron** is a positively charged particle, which is the antimatter counterpart of the electron.
- **Radioactive** refers to radiation emitted by certain substances.
- **Radiopharmaceutical** is a radioactive drug.

Description

Positron emission tomography (PET) is a medical imaging device that uses short-lived radioactive substances to produce three-dimensional colored images of those substances functioning within the body. These images are called PET scans and the technique is termed PET scanning. Three-dimensional imaging is achieved with a CT x-ray scan performed on the patient during the same session, in the same machine. PET is a highly specialized scanning method that provides information about the body's chemistry not available through other procedures. Unlike CT (computerized tomography) or MRI (magnetic resonance imaging) scans that identify anatomy or body structure, PET studies metabolic activity or body function.

PET uses small amounts of radioactive positrons. These radiopharmaceuticals have a short half-life, which means that the amount of radiation exposure is similar to that of two chest x-rays. The PET scanner uses a special camera and a tracer (glucose and a radioactive chemical) to take images of organs and tissues within the body. The camera records the position of the tracer, and the resulting data is then sent to a computer for analysis. In areas where higher levels of chemical activity occur, the radioactive chemical within the tracer accumulates. These areas show up as brighter spots on a PET scan and aid in diagnosis. The resulting image is used to evaluate for cancer, neurological problems, and heart disease.

The PET scan has been used to assess the benefit of coronary artery bypass surgery, identify causes of childhood seizures and adult dementia, and detect active tumor tissue. It is useful in the diagnosis, staging, and treatment of cancer because it provides information that cannot be obtained by other techniques, such as CT and MRI. It is becoming the scan of choice for head and neck, brain, lymphoma, melanoma, lung, colorectal, breast, prostate, and esophageal cancers. PET scans are also valuable in studying brain activity and how mental illness changes brain activity.

Developments and Current Status

Since the 1950s there have been several developments in imaging which led to the development of PET. One of the most recent of these was the introduction of the PET/CT scanner in 2000. David Townsend, a physicist, and Ronald Nutt, an electrical engineer, are credited with this device, which *Time* magazine named as the medical invention of the year in 2000.

Physicians first used PET to obtain information about brain function and to study brain activity in various neurological diseases and disorders, including stroke, epilepsy, Alzheimer's disease, Parkinson's disease, and Huntington's disease, and in psychiatric disorders such

as schizophrenia, depression, obsessive-compulsive disorder, attention-deficit hyperactivity disorder, and Tourette's syndrome.

PET scans are to differentiate between brains of individuals with and without mental disorders. For instance, because PET detects metabolic activity in the brain activity, PET scans of the brains of depressed and nondepressed individuals, it can localize decreased brain activity in those who are clinically depressed. Similarly, such data has been collected in schizophrenia and Alzheimer's disease. PET scans are also used for individuals suspected of having transient ischemic attack (mini strokes), multiple sclerosis, and other nervous system disorders. Such research can help scientists discover new ways to treat these disorders. PET scans are also used for monitoring the results of treatment. At the present time, PET scans are primarily used in research studies rather than as aids to treatment in psychiatric settings.

PET scans do not show as much detail as CT scans or MRI scans. However, PET scans provide an advantage over CT and MRI because they can determine whether a lesion is malignant. CT and MRI provide images of anatomical structures but are not particularly used in determining malignancy. That is because CT and MRI show structure, while PET shows function. PET has been used in combination with CT (called PET/CT) to identify abnormalities with more precision and indicate areas of most active metabolism. This additional information permits more accurate evaluation of cancer treatment and management.

Postpartum Depression

Postpartum depression is a mental condition that can affect women after childbirth. It is also known as peripartum depression.

Definitions

- **Cognitive behavior therapy** is a form of psychotherapy that focuses on changing maladaptive (faulty) behaviors, emotions, and thoughts. It is also known as CBT.
- **Depression** is an emotional state characterized by feelings of sadness, low self-esteem, guilt, or the reduced ability to enjoy life. It is not considered a disorder unless it significantly disrupts one's daily functioning.
- **Depressive disorders** are a group of DSM-5 mental disorders characterized by sad, irritable, or empty moods along with somatic (bodily) and cognitive (mental) changes that greatly affect everyday functioning.
- **DSM-5** stands for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, which is a diagnostic system used by professionals to identify mental disorders with specific diagnostic criteria.
- **Major depressive episode** is a period characterized by symptoms of a major depressive disorder.
- **Peripartum onset** is the depressive disorder specifier given for depressive symptoms that occur during pregnancy or in the four weeks following delivery. "Peri" means around the time of, whereas "postpartum" means after.
- **Selective serotonin reuptake inhibitors** are the most commonly prescribed antidepressant

medication because they generally have few side effects. They are also referred to as SSRIs.

- **Specifiers** are extensions to a diagnosis that further clarifies the course, severity, or type of features of a disorder or illness.
- **Unspecified depressive disorder** is one of the DSM-5 depressive disorders. It is characterized by depressive symptoms that cause significant distress or disrupt daily life but do not meet the full criteria for any disorder in the depressive disorders group.

Description

Depressive symptoms occur in some females who are about to give or have already given birth. "Peri-" means around the time of and includes "before" and "after," whereas "post-" means "after." When depressive symptoms occur in a female after giving birth, the term "postpartum depression" has been used. However, because research shows that at least 50% of the so-called postpartum depressions actually begin before giving birth, the term "postpartum" is not an accurate designation (American Psychiatric Association, 2013).

The DSM-5 does list postpartum depression as a separate diagnosis (American Psychiatric Association, 2013). However, it does recognize unspecified depressive disorder with the peripartum-onset specifier. About 3%–6% of women will likely experience the onset of a major depressive episode during pregnancy or in the weeks to months postpartum. Since most so-called postpartum depressions begin before delivery, the term "peripartum" has become the preferred designation (American Psychiatric Association, 2013).

The cause of peripartum depression is unknown. However, there are some characteristics that are associated risk factors. These include low self-esteem, increased stress, and past or current emotional difficulties. They can also include a family history of depression, a lack of good-quality medical care during pregnancy, or a lack of support from one's partner, friends, and family.

Treatment

There are several treatment options available for women with this type of depression. The combination of medication and psychotherapy is one form of effective treatment. Commonly prescribed medications are SSRIs like Prozac and Lexapro, and other antidepressants. Cognitive behavior therapy (CBT) has been found to be effective for this condition. CBT helps an individual with PPD focus on changing faulty behaviors, emotions, and thoughts.

Post-Traumatic Stress Disorder (PTSD)

Post-traumatic stress disorder is a mental disorder characterized by nightmares, irritability, anxiety, emotional numbing, and recurrent flashbacks of a traumatic event that an individual experienced or witnessed. It is also referred to as PTSD.

Definitions

- **Cognitive behavior therapy** is a type of psychotherapy that focuses on maladaptive (faulty) behaviors, emotions, and thoughts. It is also called CBT.
- **Cognitive processing therapy** is a form of CBT specifically designed for treating PTSD, which teaches skills for recovery from

traumatic events by changings one's view of self, world, and others.

- **Cognitive therapy** is a type of cognitive behavior therapy that focuses on identifying and changing automatic thoughts and maladaptive beliefs.
- **DSM-5** stands for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, which is a diagnostic system used by professionals to identify mental disorders with specific diagnostic criteria.
- **Exposure therapy** is a behavior therapy intervention (method) in which a client is exposed to a feared object or situation. It is also referred to as flooding.
- **Eye movement desensitization and reprocessing** is a treatment method to reduce trauma-based symptoms by visualization of the traumatic event while concentrating on the rapid lateral movements of the therapist's finger. It is also known as EMDR.

Description and Diagnosis

Post-traumatic stress disorder (PTSD) is one of a group of trauma- and stress-related disorders in DSM-5. PTSD can develop after an individual experiences or witnesses a traumatic or terrifying event in which serious physical harm occurred or was threatened. Symptoms can include recurrent flashbacks of the event, nightmares, irritability, anxiety, emotional numbing, fatigue, forgetfulness, and social withdrawal. Most who experience a traumatic event will react with nervousness, fear, shock, or anger. These reactions are common, and in time, they decrease and go away. However, for those with PTSD, these reactions continue and increase to such an extent that the individual can no longer live a normal life.

Individuals with this disorder are prone to angry outbursts. They may be easily startled when surprised and have difficulty initiating and maintaining sleep. They often feel uncomfortable in social situations, which may lead to social isolation. They may experience depression, shame, and guilt, as well as anger and aggression. They can become enraged with little provocation. Emotional detachment and withdrawal from loved ones is common. Interpersonal conflict is common, which can lead to divorce and separation. In their efforts to avoid reminders of the traumatic event, these individuals tend to avoid those associated with event. They are unlikely to make as they increasingly withdraw from social activities.

Approximately 3.5% of adult Americans suffer from PTSD during the course of a year, and 8.7% of Americans experience PTSD at some point in their lives (American Psychiatric Association, 2013). PTSD can develop at any age, and women are more likely to develop it than men. This difference is probably because women are more likely to be victims of abuse, rape, and domestic violence than men. Rates of PTSD and anxiety are disproportionately high among military veterans, as compared with the civilian population.

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, individuals can be diagnosed with this disorder if they experience specific symptoms as a result of direct or indirect exposure to traumatic events that could result in death or serious injury. The symptoms can present in one of four categories; reexperiencing, avoidance, negative mood, and arousal. Reexperiencing symptoms include nightmares, intrusive thoughts, flashbacks, and general psychological and physiological distress when confronted with thoughts or experiences associated with the original traumatic event. Avoidance symptoms include attempts at avoiding external and internal reminders of the event. The negative mood symptom cluster includes inability to recall portions of the trauma, distorted cognitions, loss of interest in activities, emotional detachment, unremitting negative emotions, and the inability to experience happiness or joy. They may also show irritable behavior, angry outbursts, recklessness, excessive vigilance, and problems with attention and concentration. The heightened arousal also includes an exaggerated startle response and sleep problems (American Psychiatric Association, 2013).

While the immediate cause of PTSD is exposure to a traumatic event, only a small number of those experiencing trauma actually develop PTSD. Several factors can predispose an individual to developing this disorder. These include a previous experience of trauma,

childhood abuse or neglect, or having other mental health problems, such as anxiety or depression. Other risk or predisposing factors include having a family history of PTSD, alcoholism, anxiety, or depression, having low cortisol levels, or lacking an adequate support system of family and friends.

Treatment

Effective treatment of PTSD usually involves psychotherapy. Some medication may also be useful. The goal of treatment is to decrease symptoms, to better control feelings, and to improve functioning in relationships, work or school, and social situations. Cognitive behavior therapy is the general therapy approach used. There are three specific forms of it that are effective with PTSD. They include cognitive therapy, exposure therapy, and eye movement desensitization and reprocessing (EMDR). Cognitive therapy is useful in changing one's thoughts about the trauma that are not true or that cause stress. Exposure therapy is useful in talking about and reexperiencing the traumatic event safely while the fear of it lessens. EMDR is also useful in lessening the experience of the trauma. A newer approach is called cognitive processing therapy, which is now being used with military personnel to reduce distressing thoughts and foster trauma recovery. Various medications can help reduce the symptoms of PTSD. Chief among these are antidepressants like Zoloft and Paxil.

Post-Traumatic Stress Disorder (PTSD) in Youth

Post-traumatic stress disorder (PTSD) in youth is about the specific way in which the diagnosis of PTSD is seen within that population.

Definitions

- ***Diagnostic and Statistical Manual of Mental Disorders*** is the handbook mental health professionals use to diagnose mental disorders. The current edition (fifth) is known as DSM-5.
- **Post-traumatic stress disorder** is a mental disorder characterized by nightmares, irritability, anxiety, emotional numbing, and recurrent flashbacks of a traumatic event that an individual experienced or witnessed. It is also referred to as PTSD.
- **Trauma** is a singular or recurrent event that is both extraordinary and severely distressing. It is also called traumatic event. This can include abuse, domestic violence, medical trauma, accidents, acts of terror, war experiences, and natural and man-made disasters.

Description

Post-traumatic stress disorder is a diagnosis in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (DSM-5). However, as a mental health disorder, it is seen differently in children and adults and can have some varying impact. It is important to look at how PTSD is a unique experience for youth. Over the past decade there has been an increasing interest in the role that trauma, and specifically post-traumatic stress, has in regard to at-risk behaviors and the mental health of youth. In fact with the increasing interest, Alan Kazdin, PhD, president of the American Psychological Association (APA) in 2008, put together a task force to specifically look at PTSD in children and adolescents. This was the result of the majority of knowledge about PTSD being based on adult studies.

What applies to adults may not necessarily be true to that of youth in regard to symptoms, experience, and presentation of PTSD. Community samples in a study done by APA found that more than two-thirds of children report experiencing a traumatic event by the time they are 16 years. The three main categories of symptoms include reexperiencing the trauma, avoiding reminders, and hyperarousal, which may include being jumpy and quickly reacting to loud noises or overalert to potential dangers, as well as seeming increasingly agitated. However, it is important to note that youth will vary in their responses to trauma with influence from their developmental level, family life, cultural factors, and past trauma experience and exposure. Youth who experience PTSD may develop new fears, have trouble sleeping, experience separation anxiety, have a decline in their school or athletic performances, increase in anger, and increase in physical health complaints.

Unless the caregiver is supportive, the chances of the youth receiving effective treatment are reduced. In fact, most children with trauma-related distress receive little or no mental health treatment. When treatment is provided it may be suboptimal, because of the therapist's lack of expertise in trauma focused methods. In short, youth need to be offered support from the caregiver and expert treatment from professionals.

Poverty and Mental Illness

Poverty and mental illness looks at the connection between these two areas and the impact that poverty can have on an individual's mental health.

Description

There is a complicated relationship between mental illness and poverty. This is an area that needs continued research. Poverty has great impact on physical health, as well as mental health. Studies have shown that those who experience poverty or are negatively impacted by unemployment or the lack of affordable housing are far more susceptible to developing a mental health disorder. The exception to this is in the case of those diagnosed with schizophrenia. With patients diagnosed with this disorder typically, the mental illness comes first and as a result leads to a lack of ability to maintain work and/or housing.

Some research has indicated that those with the lowest socioeconomic status have greater likelihood of developing or suffering from a mental health disorder. Despite having the greatest need for mental health services, quality services are not often received. This is due in part to multiple reasons, including access to care and being able to afford mental health services.

A groundbreaking study in the 1950s conducted by psychologist August B. Hollingshead (1907–1980) and psychiatrist Frederick Redlich (1910–2004) looked at the mentally ill population in New Haven, Connecticut. They studied the treatments provided to those who were mentally ill. They compared the types of treatments with social class. They found that those in poverty received treatment typically from institutions. The methods used were also highly intrusive, such as electroshock and lobotomies. This was greatly different from those of higher classes who received far less invasive treatments such as talk therapy. A big difference from this study to current day is that those in poverty instead of receiving treatment in institutions are more likely to receive no treatment at all. The study from Redlich and Hollingshead as well as studies that have come since indict the direct relationship between poverty and prevalence of mental illness.

The lack of mental health services then leads to a vicious cycle preventing those in poverty from moving forward and obtaining employment and affordable housing. Poverty is viewed as a great cause of suffering. It has impacts on social, emotional, behavioral, and psychological development, and problems. With a lack of ability to maintain basic needs of safety and hunger, it makes it even more complicated to attempt to maintain positive mental health.

Prayer

Prayer, the act of communicating with a deity in word or thought, is an intervention utilized in spiritually oriented psychotherapy.

Description

Prayer has been an essential spiritual practice for thousands of years and has long been associated with various benefits to psychological well-being. Mental health researchers have investigated how people utilize prayer for personal growth, healing, coping, recovery from life-limiting behavioral patterns, forgiveness of wrongs, and increasing hope. Prayer has been associated with quality of life, lower levels of psychological distress, and more rapid recovery from health-related problems. Prayer allows people to ask for help and guidance; offer praise and thanks; and find comfort, hope, and support.

Survey research indicates that approximately 90% of Americans believe in God or a universal spirit. Experts in the mental health fields have recognized the centrality of spirituality and religion in the lives of most people. Spiritually oriented psychotherapy has become an important way to help the spiritually oriented cope with life's difficulties. Spiritually oriented interventions include prayer. Types of prayer include petitioning or asking God or a higher power for help and resources; meditative prayer that focuses on the nature of God, connecting to God, or finding peace in God's presence; and intercessory prayer, which is praying for, or on behalf of, someone else. Centering and contemplative prayer are types of mindfulness meditation that can be encouraged to strengthen self-esteem and reduce symptoms related to stress, anxiety, and depression.

Prayer can serve as a useful tool for counselors helping those who are spiritually or religiously oriented. Prayer can serve as a way to measure the spiritual and psychosocial functioning of clients; as a way to foster cognitive and behavioral change; or as a tool of reflection, among others. There are several types of prayers utilized by counselors. Clinicians may pray with clients, pray for client healing outside of treatment sessions, pray for guidance regarding treatment issues, and allow clients to pray during psychotherapy sessions. Therapeutic benefits to prayer include extending a sense of comfort beyond the counseling session, expressing clinician care, enhancing client–therapist trust, and decreasing a client's sense of isolation and loneliness.

Prayer must be used with caution in therapeutic settings. Praying with clients can have an unpredictable impact on the therapeutic relationship, and boundary issues can occur as shared prayer can be an unintentionally intimate experience. Prayer can also be upsetting to people who are emotionally unstable.

Current Status

There are currently no studies, professional standards, or professional consensus in the use of prayer in

therapeutic settings. The use of intercessory prayer is classified by the American Psychological Association to be an experimental intervention. Prayer is considered by many professionals to be a controversial practice.

Prejudice

Prejudice is the preconceived judgment or opinion about a group or class of people based on limited, inaccurate, or assumed information.

Definitions

- **Discrimination** is the unjust treatment of others based on racist beliefs.
- **Genocide** is the large-scale murder of people belonging to a particular racial, political, or social group.
- **Hate crimes** are hostile criminal acts such as assault or vandalism motivated by racial, sexual, or other group prejudices.
- **Oppression** is the unjust exercise of authority or power.
- **Racism** is a socially shared belief that all members of a particular race possess characteristics that are inferior to another race resulting in oppression.

Description

Prejudice involves negative attitudes and beliefs about people that are not based on actual experiences. Feelings of dislike, fearfulness, anxiety, or contempt are often associated with the person or group. The people in question are often thought of, or referred to, as "them" or "they" and represent a group of people who have some kind of feature in common. Prejudices can be based on race, social class, sexuality, gender, age, religion, physical features, or just about any other shared group element.

Prejudices are based on oversimplified stereotypes, for instance, the notion that women with blond hair are less intelligent than women with dark hair; that is, "dumb blonds" is a stereotype without basis. Discrimination occurs when others are treated in a manner based on stereotype. Discrimination can be thought of as the behaviors driven by prejudice. Hiring women with dark hair over women with blond hair, because they have blond hair, would be a discriminatory practice.

Racism occurs when prejudicial beliefs and attitudes permeate the dominant social group so completely that minority groups are perceived as inferior with little thought as to the veracity of the belief. Racism is a pervasive majority group attitude that accepts and reinforces oppression and racial inequalities. The consequences of prejudice are racial inequality that impacts all facets of life, including job availability, hiring practices, wages, education, housing, and access to services. Hate crimes are the ultimate consequences of prejudice and have resulted in vandalism, murder, and genocide.

Impact (Psychological Influence)

Prejudice, discrimination, and racism have been a significant source of social conflict in America, and multiple efforts across diverse fields continue to move toward positive change. Extensive social research continues to explore ways to eliminate racism, and all of the mental health professions have adopted significant multicultural professional competencies and standards. Social justice counseling is a developing method that actively addresses issue of oppression and social inequalities. In addition to the helping professions, lawmakers are actively pursuing ways of eliminating the impact of prejudice through legislation aimed at reducing social inequalities and hate crimes.

Premature Ejaculation

Premature ejaculation is a mental disorder in males characterized by ejaculation just before or within one minute of sexual activity.

Definitions

- **Antidepressant medications** are prescription drugs that are primarily used to treat depression and depressive disorders. They are known as antidepressants.
- **DSM-5** stands for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, which is a diagnostic system used by professionals to identify mental disorders with specific diagnostic criteria.
- **Psychotherapy** is a psychological method for achieving desired changes in thinking, feeling, and behavior. It is also called therapeutic counseling.
- **Sexual dysfunctions** are a group of mental disorders characterized by significant difficulty in the ability to respond sexually or to experience sexual pleasure. These include premature ejaculation and delayed ejaculation.
- **SSRI** stands for selective serotonin reuptake inhibitors. They are a class of antidepressant medications that raise serotonin levels in the brain. The result is a reduction of symptoms.

Description and Diagnosis

Premature ejaculation is a mental disorder whereby a male lacks control of the climax of his sexual response during sexual activity with a partner. Specifically, it refers to the experience of premature (less than one minute) ejaculation during vaginal intercourse or non-vaginal sexual activity. Most individuals with this disorder have experienced symptoms since they began sexual activity. However, some acquire this disorder after experiencing a pattern of normal sexual response. It may be experienced during all sexual activities, while others may experience symptoms in certain situations. Approximately 25% of men in the United States report dissatisfaction with ejaculation. However, if only those individuals who ejaculate in less than one minute are included, only 1%–3% of individuals qualify for this diagnosis (American Psychiatric Association, 2013).

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, for an individual to be diagnosed with this disorder, specific symptoms must be present. The primary symptom is uncontrollable ejaculation that occurs before the individual wants to, typically less than one minute following penetration. This response must occur more often than not and for a minimum of six months. The symptoms must cause the individual distress and cannot be better explained by another mental disorder or medical condition (American Psychiatric Association, 2013).

There are a number of factors that can cause this disorder. Certain medical conditions commonly cause such inflammation of the prostate. Individuals may have a history of sexual or emotional abuse that may contribute to the onset of the disorder. Also, some individuals may experience anxiety about sex, which may contribute to the manifestation of this disorder. As with other sexual dysfunctions, cultural issues are especially important to consider in the diagnosis of this disorder.

Treatment

Treatment for this disorder varies depending on both the type of clinician seen and the willingness of the individual and partner to engage in certain therapies. For example, if an individual reports these symptoms to a medical doctor, the doctor may prescribe an SSRI (selective serotonin reuptake inhibitor). While commonly used to treat depression, SSRIs are also effective in

the treatment of premature ejaculation. Psychotherapy is also used to treat underlying psychological causes, or to help the couple adapt to the disorder. A clinician may also suggest specific exercises designed to learn how to control sexual response and prolong ejaculations. However, these exercises are not always effective because they require regular practice and patience on the part of both partners. Sometimes, a combination of medication, psychotherapy, and exercises is used.

Premenstrual Dysphoric Disorder

Premenstrual dysphoric disorder is a mental disorder characterized by a severe form of premenstrual syndrome in which depression, mood swings, irritability, and anxiety disrupt daily functioning.

Definitions

- **Depression** is a sad mood or emotional state that is characterized by feelings of low self-worth or guilt and a reduced ability to enjoy life. It is not considered a mental disorder unless it significantly disrupts the individual's daily functioning.
- **Depressive disorders** are a group of mental disorders characterized by a sad or irritable mood and cognitive and physical changes that significantly disrupt the individual's daily functioning. These disorders include major depressive disorder, persistent depressive disorder, disruptive mood dysregulation, and premenstrual dysphoric disorder.
- **Mindfulness practices** are intentional activities that foster living in the present moment and awareness that is nonjudgmental and accepting.
- **Premenstrual syndrome** is a medical condition in which cramps, breast tenderness, bloating, irritability, and depression occur prior to a woman's menstrual period and subsides after it.
- **SSRIs** stands for selective serotonin reuptake inhibitors. They are a class of antidepressant medications that work by blocking the reabsorption of serotonin in nerve cells and raising its level in the brain.
- **Stress management** is a set of psychological techniques for increasing the capacity to better cope with psychological stress. It usually includes relaxation methods.

Description and Diagnosis

Premenstrual dysphoric disorder is one of a group of depressive disorders. It is characterized by a severe form of premenstrual syndrome in which mood swings, depression, irritability, or anxiety significantly impair everyday functioning. Both premenstrual syndrome and premenstrual dysphoric disorder have physical and emotional symptoms. However, premenstrual dysphoric disorder causes extreme mood shifts that can disrupt the individual's work and relationships. In both the syndrome and disorder, symptoms typically begin 7 to 10 days before the menstrual period starts and continue for the first few days of the period. Both can cause fatigue, bloating, breast tenderness, and changes in sleep and eating patterns. However, in the disorder at least one of the following emotional or behavioral symptoms stands out: extreme moodiness, marked irritability or anger, overwhelming sadness or hopelessness, or extreme anxiety or tension.

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, women can be diagnosed with this disorder if they exhibit a pattern of symptoms during the final week before the onset of their menstrual cycle, which starts to improve within a

few days after it, and are minimal or absent in the following week. These symptoms include marked mood swings, irritability, anger, or increased interpersonal conflicts. They also include depressed mood, feelings of hopelessness, anxiety, feelings of being "on edge," or decreased interest in usual activities. Other symptoms may include difficulty in concentration, a lack of energy, a change in appetite or sleep patterns, breast tenderness, food cravings, weight gain, or a sense of being overwhelmed. These symptoms must be significantly distressing and impair the individual's ability to function in important areas of life. Finally, this condition cannot have been caused by substance use or a medical condition or other mental disorder (American Psychiatric Association, 2013).

Just as with premenstrual syndrome, the cause of premenstrual dysphoric disorder is not well understood. As with other mental disorders several factors appear to be involved. First among these are hormones. Hormonal changes in the menstrual cycle can trigger some of the symptoms of this disorder. In addition, changes in levels of serotonin, a neurotransmitter (brain chemical) thought to regulate mood, could trigger these symptoms. For instance, low levels of serotonin can cause premenstrual depression, fatigue, and sleep problems. Other factors include stress, which can increase symptom intensity, and poor nutrition. Eating highly salted foods can cause fluid retention, while using alcohol and caffeine can cause moodiness and fatigue. Low levels of vitamins and minerals and a previous history of depression may also increase the likelihood of having this disorder.

Treatment

Medications and counseling or psychotherapy have a place in treating this disorder. Commonly prescribed medications include the SSRIs such as Prozac, Paxil, and Zoloft. They can help with the symptoms of depression, fatigue, sleep problems, and food cravings. Over-the-counter medications like Advil, Motrin, and Aleve can ease cramping and breast tenderness. Diuretics (water pills) can reduce swelling and bloating. Oral contraceptives (the Pill) can stabilize hormonal swings, and Depo-Provera, an injectable hormone, can temporarily stop menstruation and the accompanying pain. Psychotherapy can also help those with this disorder to develop more effective coping strategies. The use of stress management and mindfulness practices can reduce stress and increase relaxation, acceptance, and living in the present.

Prescription Drug Abuse

Prescription drug abuse occurs when medications are taken in greater amounts or for different reasons than what was prescribed by a physician.

Definitions

- **Benzodiazepines** are tranquillizers used in the treatment of anxiety, panic attacks, depression, and insomnia and other disorders.
- **Central nervous system depressants** are drugs that slow down the normal functions of the brain.
- **Central nervous system stimulants** are drugs that enhance attention.
- **Cognitive behavior therapy** is a type of psychotherapy that focuses on maladaptive (problematic) behaviors, emotions, and thoughts. It is also called CBT.

- **Detoxification** is a process of purging the body of the toxic effects of a drug or substance. During this process the symptoms of withdrawal are also treated. Also called detox, it is often the first step in drug treatment.
- **Dopamine** is a chemical substance in the brain that influences emotion, mood, thoughts, motivation, and movement.
- **Epinephrine** is a hormone that is also known as adrenaline.
- **Neurotransmitters** are chemicals in the brain that send messages across synapses from one neuron to another neuron.
- **Norepinephrine** is a chemical produced by the adrenal gland. It takes on the role of both a hormone and a neurotransmitter.
- **Opioids** are drugs that are primarily used to relieve pain.
- **Psychotherapy** is a psychological method for achieving desired changes in thinking, feeling, and behavior. It is also called therapy and therapeutic counseling.
- **Self-help groups** are a group of individuals, sometimes led by a therapist, who provide each other emotional support, information, and advice on problems relating to some shared concern such as an addiction. Alcoholics Anonymous is such a group.

Description

Prescription drug abuse is the misuse of medications prescribed by a physician. The medications are not taken for the intended effects but for the feelings that the drug produces. Prescription drug abuse is the use of prescription medications for their mind-altering effects. The most commonly abused prescription drugs are opioids (painkillers), central nervous system depressants (e.g., benzodiazepines), and central nervous system stimulants (e.g., amphetamine). Opioids are typically misused for their euphoric effects. Individuals may abuse central nervous system depressants to reduce anxiety and inhibitions and promote relaxation. Central nervous system stimulants elevate dopamine, norepinephrine, and epinephrine levels and increase alertness and attentiveness. Stimulants may be abused by students to improve focus while studying or simply to get high. Even some over-the-counter cold and cough medicines made with dextromethorphan can be taken in greater doses than recommended to achieve a euphoric effect.

Prescription drug abuse can be caused by using medications that have been prescribed for a family member or friend. It can also be caused by increasing the dosage (without physician approval) of one's own prescription medications. Altering the form of prescribed medications and snorting or injecting them is also considered drug abuse. The misuse of prescription medications may lead to increased tolerance. This means that higher doses of the drug are necessary to achieve the desired effect. Drug dosage is also increased to avoid feeling the negative effects of withdrawal symptoms. Abuse of prescription drugs can lead to addiction.

Treatment

Treatment may consist of detoxification, psychotherapy, self-help groups, and medication. During detoxification, individuals may require medication to decrease the severity of withdrawal symptoms. Cognitive behavior therapy can assist individuals with reframing negative thoughts and beliefs and modifying maladaptive behaviors. Group therapy and self-help groups can provide support and social network opportunities. Family therapy can provide information to family members and help them understand prescription drug abuse. It can also be a great source of support. Medications may also be necessary to reduce drug cravings and long-term withdrawal symptoms.

Prevention of Mental Illness and Substance Abuse

Prevention of mental health and substance abuse is a strategy implemented to prevent the onset of a mental or substance abuse condition.

Definitions

- **Competence** is the ability to do something efficiently or successfully.
- **Mental disorder** is a bodily or mental condition due to sufficient disorganization of personality, emotions, and mind that seriously impair the normal psychological functioning in an individual.
- **Protective factors** are conditions in individuals, families, and communities that help individuals cope more effectively when stressful events occur and eliminate risk in communities and families.
- **Resilience** is the ability to recover quickly from difficulties.
- **Risk factors** refer to any characteristic, attribute, or exposure of an individual that increases the likelihood of developing an injury or disease.
- **Substance use disorder** is a disorder in which one or more mind-altering substances lead to clinically significant distress or impairment in an individual.
- **Well-being** is the state of being happy, healthy, prosperous, or successful.

Description

Preventing mental illness and substance abuse has been a long-standing concern. Over the past several years, many ideas have been created on how to generate possible strategies to prevent behavioral problems and mental disorders in children and adults. However, it wasn't until 1980 that a multidisciplinary field began focusing on prevention of mental health. This development was facilitated by increasing knowledge on risk and protective factors. Research centers, practitioners, and prevention research centers have been focusing on preventive interventions and mental health promotion that can impact risk and protective factors that reduce the occurrence of some mental disorders. Some examples of risk factors include stressful life conditions, being neglected or abused as a child, and having few healthy relationships. Some examples of protective factors include social participation, self-esteem, resiliency, the ability to cope with stress, parental involvement, and limited availability of illegal drugs. Mental health promotion needs to be an integral part of public health at local and national levels. Promotion and prevention of mental health should be integrated within a public policy approach that embraces action through the environment, different public sectors, housing, social welfare, employment, and education. Mental health promotion intends to promote positive mental health by increasing psychological well-being, resilience, and competence, and creating supportive environments and living conditions. Positive mental health serves as a strong protective factor against mental illness.

Prevention of substance abuse is a process used to deter the onset of substance abuse and to restrict the development of problems associated with using substances of abuse. Prevention from substance abuse attempts to stop the abuse before it begins, by increasing protective factors and reducing risk factors. Some substance abuse risk factors include stress, family problems, health problems, social pressures, and feelings of grief or loss. Some substance abuse protective factors include learning how to solve problems, staying positive, and developing an emotional bond with family and friends. Some other protective factors include parents setting rules for their children and having a belief that the community is important in substance abuse prevention. The process of prevention begins by providing all individuals with skills and information necessary to prevent the problem. Substance abuse

prevention is an effective way to reduce the burden associated with substance use disorders. Promoting mental health and preventing mental health disorders and substance use disorders are fundamental in order to decrease the effects of behavioral health conditions in America.

Principles of Psychology, The (Book)

The Principles of Psychology is an influential psychology textbook written by William James and first published in 1890.

Definitions

- **Nervous system** is the structure inside an animal that performs voluntary and involuntary actions. It sends messages throughout the entire body. It includes the brain, spinal cord, sensory organs, and connecting nerves.
- **Neural pathways** connect different parts of the nervous system with each other. They determine how signals are sent through the nervous system.
- **Physiology** is the scientific study of the normal functioning of all living things. It is how a living organism's various parts work.

Description

The Principles of Psychology is a two-volume book originally published in 1890. The author, William James (1842–1910), was a philosopher and psychologist. He is considered to be the greatest American philosopher and a founding figure of modern psychology. William Wundt (1832–1920) is the other father of modern psychology. James also established the first experimental psychology lab in the United States in 1875. *The Principles of Psychology* emphasizes the individual mind or the personal self. It illustrates how the thoughts, feelings, wants, reasoning, and decisions of an individual are shaped by the physical world in which he or she lives. It is written in technical and philosophical language and includes many difficult concepts. Passages in the book are very long and include physiology of the brain and nervous system.

It took James 12 years to write the 1,400 pages contained in the original two volumes. James also wrote a shorter version called the "Jimmy" for college students. The shorter version has influenced several generations of students. Before the late 1950s, it was used as the core textbook in psychology courses for students in business, science, and liberal arts as well as psychology programs.

Furthermore, individuals are creatures of habit. They have a multitude of needs and wants and must deliberately develop new habits in order to obtain a desired outcome. Individuals have the ability to form positive habits through deliberate and repeated productive responses. Repetitive actions create neural pathways in the brain, thus making it easier for subsequent nerve signals to journey down the same pathway. James stated that each individual's mind is divided into two parts: (1) me and (2) the remaining world and the people in it. Most individuals take interest in the "me" part. James stated that an individual who wants to learn about psychology does so in order to better understand his or her own thoughts and feelings, not necessarily to learn about the general topic of thoughts and emotions.

The book explains that conscious thoughts fluctuate frequently. Physical needs or wants (i.e., hunger or exhaustion) and environmental changes (i.e., nighttime or cold weather) continually impinge on thoughts, constantly changing them. This leads to a continuous

flow or stream of thought. James compared conscious thought to a flowing stream. Individuals never have the same thought twice. One may look at the same thing many times and have differing thoughts on every occasion. The continuous flow of thoughts and feelings is what constitutes consciousness.

Since it was first published, *The Principles of Psychology* is considered the most important book in the history of modern psychology. Generations of leaders in all spheres of life were likely to be influenced by this book in a college psychology course. Since James's book was usually the text for this course, his influences on how these future leaders would come to think about human behavior were profoundly influenced by this book.

Pristiq (Desvenlafaxine)

Pristiq is a prescribed medication used to treat depression. Its generic name is desvenlafaxine.

Definitions

- **Antidepressant medications** are prescription drugs that are primarily used to treat depression and depressive disorders. They are known as antidepressants.
- **Metabolite** is chemical compound that results from the breakdown or metabolism of a parent drug.
- **Neurotransmitter** is a chemical messenger secreted by a nerve cell (neuron) that transmits a nerve impulse to another nerve cell. Common neurotransmitters are serotonin and norepinephrine.
- **Selective serotonin norepinephrine reuptake inhibitors (SNRI**) are antidepressant medications that act on and increase the levels of serotonin and norepinephrine in the brain that influences mood. They differ from selective serotonin reuptake inhibitors, which act only on serotonin.
- **SNRI discontinuation syndrome** is a condition caused by abrupt discontinuation of an SNRI resulting in withdrawal symptoms. These include flu-like symptoms, anxiety, agitation, vivid or bizarre dreams, insomnia, nausea, diarrhea, dizziness, headache, numbness, and tingling of the extremities. This syndrome can be avoided by dose reduction over time.

Description

Pristiq is an antidepressant medication and is a selective serotonin norepinephrine reuptake inhibitors (SNRIs). It affect the neurotransmitters serotonin and norepinephrine and is used to treat depression. It is believed that a decrease in serotonin and norepinephrine contributes to depression and anxiety disorders. SNRIs works by counteracting this by increasing the actions of both neurotransmitters, although Pristiq increases serotonin more than norepinephrine. Pristiq is a metabolite of Effexor, an SNRI that was developed to have fewer side effects and drug interactions than Effexor.

Precautions and Side Effects

Antidepressant drugs, including Pristiq, have been associated with an increased risk of suicidal thoughts and behaviors in children and adults up to age 24. Any patient taking an antidepressant drug should be monitored for changes in behavior and worsening depression. If treatment with Pristiq is ceased, it should be slowly discontinued to avoid the development of SNRI discontinuation syndrome. Close medical monitoring

is needed if Pristiq is used by those with liver or kidney function impairment, seizure disorder, bleeding disorders, glaucoma, dehydration, and history of alcohol abuse, and in patients younger than 25 years of age or the elderly. Pristiq should be used only for a short time and with careful monitoring in those with bipolar disorder as it can induce mania. Since the safety of Pristiq use during pregnancy and breast-feeding is unknown, its use is not recommended.

In general, SNRIs tend to have fewer side effects than SSRIs and tricyclic antidepressants, but side effects may still occur. Dry mouth, dizziness, and nausea are the most common side effects reported with Pristiq. Side effects that are less common include hot flashes, nosebleeds, and yawning. Most side effects are minor and easily treated. Serious, but rare, side effects include mania, hallucinations, panic attacks, suicidality, seizures, serotonin syndrome, liver damage, and glaucoma. Drug interactions may occur when alcohol, Haldol, or nonsteroidal anti-inflammatory drugs are taken with Pristiq. Other medications that can cause drug interactions with Pristiq include Tagamet, lithium, anticoagulant medicines like aspirin or Aleve, and herbal remedies like Yohimbine, ginkgo biloba, and St. John's wort.

Privilege and Privileged Communication

"Privilege and privileged communication" refer to the legal rule safeguarding the communication that occurs within certain "protected relationships," including that of patient/health-care professional, attorney/client, clergy/laity, and spouse/spouse.

Definition

- **Confidentiality** defines the keeping private of information that is disclosed by a patient, client, or other protected party within the context of a safe, trusting relationship.

Description

"Privilege," in terms of communication, refers to the legal statute establishing that information discussed between certain protected parties is safeguarded from forced disclosure, except as specified by law. This precedent was set forth in the 1996 U.S. Supreme Court case of *Jaffee v. Redmond* that recognized the evidentiary privilege of mental health-care professionals. Mary Lu Redmond, a police officer who shot and killed Ricky Allen whom she discovered wielding a knife and attempting to harm another man, was sued by Carrie Jaffee, the representative of Allen's estate. Jaffee was seeking damages, arguing that Redmond had used excessive force. After learning that Redmond sought counseling to deal with the situation, Allen wanted access to the case notes recounting the details of her therapy sessions. Both Allen and the social worker she worked with refused to provide these documents citing privileged communication. This resulted in the Federal Court's ruling that information discussed among certain parties be kept confidential and remain safeguarded from disclosure to third parties. State jurisdictions, however, can vary in how they interpret and apply privileged communication in cases.

The words "privileged" and "confidentiality" are sometimes used interchangeably to describe the context of communications among qualified parties. Protected relationships include that of doctor/patient, counselor/counselee, attorney/client, clergy/laity, and spouse/spouse. Patients/clients are granted control over whom their private information is released to, with certain exceptions. In order to qualify as "privileged," there must be the understanding, at the onset of the relationship, that the communication exchanged

between the parties is confidential. This would not be the case if any third party or parties are present at the time. There are exceptions to privileged communication that occur when the patient or client provides his or her consent for disclosure, either verbally or in writing, and other circumstances that do not require consent. Situations involving the abuse or suspected abuse of minors, the elderly, and the disabled, as well as situations involving a duty to warn third parties whose welfare may be threatened, are such exceptions. In addition, privilege may be limited and consent may not be required in cases where a patient's sanity is being called into question.

Impact (Psychological Influence)

The prevalence of technology in today's digital age presents particular challenges to professionals charged with safeguarding client information. Unlike times past where communications were limited to phone calls, paper documents, and faxes, professionals are now afforded multiple means with which to communicate with their clients. However, these professionals must now be even more vigilant to protect privileged communications with their clients. Likewise, patients/clients should be informed, be cautious, and remain thorough in their review of paperwork, policies, and practices, which involve patients' personal information.

Problem-Solving Therapy

Problem-solving therapy is a brief treatment approach that focuses on helping clients to effectively cope with life's stressors. Problem-solving therapy helps clients to find their own solutions to their current problems, as well as bolster self-efficacy.

Definition

- **Cognitive behavior therapy**, which is also known as CBT, is a type of psychotherapy that focuses on maladaptive (problematic) behaviors, emotions, and thoughts.

Problem-solving therapy is considered to be an intervention under the umbrella of cognitive behavioral approaches. It is a brief therapy that can be completed in approximately four to eight sessions. It is considered to be beneficial for both minor and major stressors and mental health problems.

The goal of problem-solving therapy is to increase the individual's planning in problem solving and minimize his or her negative problem-solving skills, such as avoidance or impulsive reactions. There are two major components that look at the person's general beliefs or attitudes to problems and his or her style in which to solve problems.

Clinical assessment looks at the abilities and attitudes in relation to problem solving, the way in which the individual currently solves problems, and what the problem he or she is experiencing. Problem solving is divided into either five or seven stages depending on the model. The seven-stage model includes the steps of the orientation of the problem or the client's attitude, recognizing and identifying the problem, and selecting and defining the problem where one specific thing is chosen to work on in therapy; solutions are then compiled followed by making decisions as to what to do. This is followed by creating an action plan and finally reviewing the progress made by the individual.

Clients are asked questions such as describing the situation and why it is a problem for them. Clients are also asked to identify their emotional reactions to the problems both at onset and throughout the situation. The clients are then asked how they specifically handled the

problem and what the outcome was. This allows for the clinician to gain insight into the client patterns to help generate potential alternatives going forward.

Problem-solving therapy was explored by Thomas D'Zurilla and Marvin Goldfriend in 1971 when they published a review related to problem solving in real life which was later called social problem solving. Based on this review they developed a model that consisted of problem orientation and problem-solving skills. Their model included four problem-solving skills: problem definition and formulation, creation of alternatives, decision making, and solution implementation.

Contemporary problem-solving therapy was developed by Thomas D'Zurilla, Christine Maguth Nezu, and Arthur Nezu. It is considered a form of brief therapy due to the limited number of sessions that are needed. In the original treatment, clients were encouraged to stop and think to assist in coping with something stressful. However, in the contemporary model, clients are encouraged to use the "SSTA" method, which stands for Stop, Slow Down, Think, and Act.

Process Addiction

Process addiction is a compulsive behavior pattern, not involving substances or chemicals, which interferes with daily living.

Definition

- **Addiction** is a chronic disease of the brain, which involves compulsive and uncontrolled pursuit of reward or relief with substance use or other compulsive behaviors.

Description

Process addiction, different from substance addiction, has received a lot of publicity due to the unusual compulsive behaviors of public figures. Common process addictions include engaging in compulsive work, sex, spending money, exercise, shopping, gambling activities, and eating disorders. In the addiction counseling field there is some question about whether or not food can be considered a chemical addiction. While many process addictions are not officially diagnosed, the American Psychological Association has otherwise recognized them as valid disorders.

Many process addictions are connected to lifestyle and access, which suggest an environmental influence on the development of such addictions. Process addictions are less researched and can be harder to recognize than substance addictions. However, these compulsive and maladaptive behaviors can be equally destructive to individual well-being and happiness.

Some researchers estimate that almost half of the population in the United States has some kind of addictive behavior. While others suggest that about 53 million people, or about 17%, of the United States are addicts of some kind. In terms of each process addiction, the estimates range from a low of 2% of the population for gambling and as high as 10% estimated to be addicted to work.

Causes and Symptoms

It is nearly impossible to identify a single cause of process addiction. Many factors come into play, including genetics, social status, mental state, and individual experience. What is well established is that certain activities stimulate the brain's reward center in the person, which causes the production of chemicals, such as serotonin, that make the person feel good while engaging in the activity. When something feels good, people want more of it and in the addict's case the obsession can have negative impacts.

The most telling symptom of a process addiction is the fact that the person loses control and no longer has the ability to choose freely whether to stop the behavior. There are many other symptoms as well, including increased tolerance of the activity, withdrawing from

others when the person is not able to pursue the activity, excessive time spent in the activity, and secrecy around the activity. For reasons that are also not clearly identifiable, some people might display one addiction while others seem prone to multiple addictions.

Diagnosis and Prognosis

One of the difficulties in diagnosing process addiction is that the behaviors can, in part, be in the normal range of activities. What is important to identify in diagnosis is when the activity becomes obsessive. A major sign of addiction is when personal health and social relationships suffer. In addition to that when finances are negatively affected and when obvious behavior problems surface, it becomes more clear that the behavior is addictive.

It is important to note that the application of the word "addiction" can have a negative connotation. Individuals with process addictions are likely to be invested in particular behaviors such as exercise or work. Many will strongly deny any suffering or unpleasant consequences or symptoms from the activities they are addicted to.

Many people with process addictions can be helped by learning how to identify all the aspects of a behavior which feed the addiction. This can be difficult due to denial and the secret keeping that many addicts display. The most important factors are that the addict recognizes and then is willing to commit to changing or stopping the behavior.

Treatment

Treatment methods for process addictions vary, but the most effective include long-term behavioral modification therapies. In combination with behavioral techniques, many use medication intervention. But without the individual's own desire to stop the behavior, it will be hard to accomplish any change.

A holistic approach with multiple therapies, both psychological and physical, seems to be helpful in changing the patterns of tension and release, which mark the behaviors of people with addictions. Group therapy including family and friends is a successful option when possible. Addictions tend to be social, and building healthy relationships during treatment can be a powerful tool in helping the person with a process addiction.

Profanity

Profanity is a verbal activity involving the use of taboo words.

Description

Profanity, also known as swearing, cursing, and cussing, is a verbal behavior that involves the use of taboo words. The most common taboo word categories include bodily functions, body parts, sex, and religion. Swearing can be broadly grouped into annoyance swearing and social swearing.

Impact (Psychological Influence)

Using profanity as an expression of both positive and negative emotions is one of the most characteristic elements of swearing. Research into profanity has shown that the most frequently expressed emotion is anger and frustration followed by humor, pain, and sarcasm. Expressing negative emotions through swearing can reduce tension and is the most mentioned reason for swearing among students. Swearing has been found to increase pain tolerance, but the effect diminishes for those who cuss frequently.

Because swearing uses taboo language, profanity can be shocking and offensive to others. This behavior can have a negative impact on an individual's social standing and reputation. Swearing can be an indication that a person is unable to manage his or her emotions and can evoke feelings of fear or hostility in others. This can result in others distancing themselves, which may lead to a sense of rejection and social isolation. Swearing intensifies the offensiveness of emotionally abusive language and increases the level of hostility perception. People who engage in out-of-control profanity are often perceived as unstable and dangerous.

The impact of profanity is associated with the social context of the behavior and can serve to strengthen social connectedness and solidarity in different settings. For instance, collective swearing out of shared job frustration or dissatisfaction increases group connectedness and becomes part of a group identity. Nonmembers are usually not accepted into the group culture without conforming to the norms, including the use of profanity. Swearing as a means to group membership holds true across a variety of social groups including athletes, soldiers, sailors, laborers, police, and emergency workers. Swearing is a very common sign of solidarity and belonging among adolescent groups.

Use of profanity may be related to social status and is widespread among lower socioeconomic classes, students, and adolescents. This may be due to these groups having little risk of falling in social status and are thus relatively resistant to the negative reactions of others. Swearing has most often been identified as a masculine behavior. Boys begin swearing at an earlier age than girls, and men know and use more swear words than women. More recent research indicates that gender differences in swearing are decreasing.

Profanity has existed for as long as there has been language. It uses taboo words to express emotion, to gain entry into social groups, or as a warning of hostility. Controlling the use of profanity is an important consideration in all social contexts.

Professional Identity

"Professional identity" refers to the unique growth process through which an individual defines himself or herself in terms of his or her role, philosophy, and approach to others both within and outside the chosen profession.

Definitions

- **Competency** defines one's ability to demonstrate skill in an efficient and successful manner.
- **Constructivism** is a philosophy that posits that meaning is continually and actively constructed based on the experiences one encounters and the value he or she attributes to his or her experiences.
- **Person–environment fit** is the degree of compatibility between an individual's characteristics and the characteristics of his or her environment.
- **Self-concept,** or self-identity, refers to how individuals perceive themselves or the image they have of themselves.
- **Social identity theory** holds that individuals gain a sense of who they are from the membership and status they hold in certain groups, both personal and professional.

Description

"Professional identity" refers to the sets of beliefs, attitudes, and understanding of roles a person holds about himself or herself related to his or her work. It is both a cognitive/psychological and social process whereby individuals come to integrate their personal attributes,

education, and training into the context of a professional community. The way in which one views oneself professionally is based on one's self-concept and interactions with others both within and outside the work environment; it describes interpersonal and intrapersonal experiences.

One's professional identity is thus one aspect of a one's self-concept, which is continually being constructed and altered. Professional identity consists of the individual's present view of himself or herself (who the person is) and his or her current performance (what the person does) as well as his or her future goals and aspirations (what the person wants to do or hopes to attain). A positive self-concept is typically reflected in a positive professional identity, with the person behaving as competent, able, and successful. Positive professional identity is associated with high levels of collaboration, tenacity, and flexibility. A negative self-concept rather typically results in a negative professional identity as evidenced by inadequate performance, self-doubt, non-assertiveness, and lack of drive. Professional identity can therefore play a large role in predicting success.

Professional identity is a concept grounded in constructivism and social identity theory. From a constructivist perspective, professional identity is based on how individuals attribute meaning to the situations they encounter at work or related to their work environment as well as how they view themselves as professionals. How one constructs meaning is a personal process that varies from person to person. Professional identity is further supported by social identity theory, proposed by psychologist Henri Tajfel in the late 1970s, which holds that people gain a sense of who they are based on their group membership, both personal and professional. One's self-concept can thus be enhanced or diminished by the feedback one receives from others in terms of recognition, rewards, punishment, and status. Researcher Herminia Ibarra's work revealed three basic tasks when transitioning from one role to the next in the professional hierarchy: (1) observing role models that display possible professional identities; (2) experimenting with these possible identities in professional practice; and (3) evaluating experiences in these new roles, weighing them against internal standards and external feedback, and determining which identity to adopt.

Impact (Psychological Influence)

The foundation of one's professional identity is based on one's personal and professional philosophy, moral judgment, ethical decision making, responsible behavior, and internal and external standards. Alignment between one's personal attributes and the environment in which one works is referred to as *person–environment fit*. When the two are matched, job success and satisfaction are more probable than when the two are at odds. Future research is needed to address personal and environmental characteristics that moderate successful alignment between the two. The study of organizational dynamics seeks to determine ways to improve this fit. Career assessment practices also work to match individual characteristics to proper professions to increase levels of personal and professional success.

Project MATCH

Project MATCH was a major research study that attempted to identify the best alcoholism treatment for each individual involved.

Definitions

- **Addiction** is a chronic disease of the brain, which involves compulsive and uncontrolled pursuit of reward or relief with substance use or other compulsive behaviors.

- **Alcoholics Anonymous** is a mutual aid or self-help fellowship that was founded by Bill Wilson and Dr. Bob Smith in 1935 to help people struggling with alcoholism.
- **Alcoholism** is a general term for the compulsive and uncontrolled consumption of alcohol to the detriment of the drinker's health, relationships, and social standing.
- **Psychotherapist** is a trained professional who uses a psychological method for achieving desired changes in thinking, feeling, and behavior with individuals.
- **Twelve Steps** refer to the 12 guiding principles on which Alcoholics Anonymous is based.

Description

The basic premise of Project MATCH was that the most effective treatment for those with alcoholism was the one that was best matched to the individual. It has been acknowledged and observed by addiction professionals for a long time that no single treatment plan has worked for all individuals with alcoholism. Many have suggested that different treatment approaches for specific types of patients struggling with alcoholism might be more effective than others. During the investigation of Project MATCH, psychotherapists administered three types of treatments. Although Alcoholics Anonymous (AA) meetings were not included in the investigation, Twelve-Step methods were incorporated into the treatment. In order to examine the essence and strength of commonality between the treatment approaches, Project MATCH was financed and supported by the National Institute on Alcohol Abuse and Alcoholism. This project was initiated in 1989 and took over eight years to implement. The cost of the investigation was over $27 million.

Three specific types of treatment were evaluated. They were cognitive behavioral coping skills therapy, motivational enhancement therapy, and twelve-step facilitation therapy. Cognitive behavioral coping skills therapy focuses on correcting low self-esteem, and negative and self-defeated thinking. Motivational enhancement therapy assists individuals in becoming aware of and building on their personal strengths, which can help to encourage an individual to stop drinking alcohol. The twelve-step facilitation therapy was introduced as an independent form of treatment to familiarize individuals with the AA philosophy and encourage participation. The outcome of the study concluded that individual treatment matching is not necessary because all three forms of treatment were equally effective.

There were several criticisms in the methods used in Project MATCH. One in particular is that there was no control group (e.g., a group who did not receive treatment) used in the investigation. Therefore, the investigation could not determine whether any of the treatments was effective versus the natural recovery process. In addition, the psychotherapists who were part of Project MATCH had more training than other addiction counselors in the field. Another criticism was that the main outcome measure was reduced alcohol use. Critics maintain that the outcome measure should have been complete abstinence (no alcohol use).

Prostitution

Prostitution, also referred to as commercial sex, defines the act or practice of engaging in sexual relations in exchange for monetary gain or any other benefit.

Definitions

- **Commercial sex** is a sexual act in which something of value is given to or received by any of the involved parties.
- **Human trafficking** describes the illegal buying, selling, and trading of human beings for the purpose of sexual slavery, exploitation, or forced labor.
- **Sex tourism** is defined as when a person travels nationally or internationally to procure prostitution services.

Description

The word "prostitution," a variation of the word "prostitute," is derived from the Latin word *prostituta*, meaning "to put forward for sale." Prostitution is deemed "the world's oldest profession" and has a long-standing history dating back to the 18th century BC where it was referred to in the Code of Hammurabi. Nearly every civilization has some account of prostitution on record, including Mesopotamia, Greece, Italy, Spain, Japan, Australia, France, India, Sweden, and Norway.

"Prostitution," or commercial sex, refers to the business, activity, or practice of exchanging sexual relations for money or another desired benefit. Terms used to describe a person who works in this field are prostitute, sex worker, hooker, call girl, whore, escort, gigolo, hustler, and streetwalker. Commercial sex is offered in various ways, at specified establishments known as "brothels" (in slang terms "whore houses"), call-out services, and most commonly through street prostitution. The majority of sex workers are female who typically service male clients (called "johns" or "tricks"). However, males may also work as prostitutes. Gay, lesbian, prostitution, though less prevalent, exists as well.

Pricing for prostitution services depends on different factors, including the type of sex act performed, current economic conditions, the location, and simple supply and demand. High-end prostitutes can earn significant amounts of money, thousands of dollars, for acts rendered, while lower-end street workers may make only a few dollars. A portion, often a significant amount, of the sex worker's earnings goes to a pimp, madam, or other procurer/procuress. Prostitutes can be found in both urban and rural communities, though larger cities experience the most problems. Like other criminal activities, prostitution is associated with lower socioeconomic status, higher dropout rates, and increased substance abuse. Clients who engage in sex tourism travel to various locations to seek out prostitution services. Victims of human trafficking are also recruited, coerced, or forced into lives of prostitution against their will. Criminal traffickers demand large sums for young girls and those who are virgins in particular.

The average age of someone who enters into prostitution is 14 years; most sex workers are between the ages of 18 and 29. Many who begin this lifestyle have been victims of physical or sexual abuse and are seeking a way out of their current living situation. The majority of prostitutes end up becoming addicted to alcohol or drugs, a factor that contributes to the cycle. Studies indicate that most prostitutes are aware that their actions are illegal and they desire to leave the sex worker industry; however, most report feeling trapped for one reason or another. Pimps, madams, and procurers/procuresses provide money, shelter, clothing, food, and protection.

Impact (Psychological Influence)

Laws and regulations on prostitution vary from country to country. Presently, prostitution is illegal in every U.S. state except for some parts of Nevada. Traditional law enforcement approaches to combating prostitution consists of arresting the prostitute, incarcerating them for a brief period of time, and subjecting them to a fine. However, further analysis has weighed the effectiveness of this approach as the majority of prostitutes return to the lifestyle almost immediately. Alternative suggestions include rescuing prostitutes from these situations and offering them shelter, support, and a new direction. Regardless, the long-term effects of prostitution are also well documented. Victims are more likely to experience lower self-esteem, adjustment issues, difficulty forming and maintaining relationships, suicidal thoughts and attempts, and substance abuse issues.

Current estimates suggest that the prostitution industry generates over $100 billion per year. There is now ongoing debate as to the pros and cons of legalizing prostitution. Proponents suggest that decriminalizing and regulating commercial sex would reduce the allure, deter the punishment of victims, enforce age and health guidelines, and establish proper monitoring and testing standards to reduce the risk of sexually transmitted diseases.

Prozac (Fluoxetine)

Prozac is a prescribed medication used to treat depression and other medical and mental conditions. Its generic name is fluoxetine.

Definitions

- **Antidepressant medications** are prescription drugs that are primarily used to treat depression and depressive disorders. They are known as antidepressants.
- **Food and Drug Administration** is the federal agency responsible for monitoring safety standards for food and prescription medications.
- **Selective serotonin reuptake inhibitors (SSRIs)** are a class of antidepressant medications that work by blocking the reabsorption of serotonin in nerve cells and raising its level in the brain.

Description

Prozac was the first of antidepressant medication to be known as selective serotonin reuptake inhibitors (SSRIs). It was the first such drug approved by the FDA for the treatment of depression. Depression and some other mental disorders appear to be caused by low levels of serotonin, a chemical messenger (neurotransmitter) that is released and transmitted in the brain. Like other SSRI medications such as Luvox, Zoloft, and Paxil, Prozac is believed to work by increasing the level of serotonin in the brain. Increased levels can benefit those with major depression, obsessive-compulsive disorder, panic disorder, post-traumatic stress disorder, mood swings, premenstrual tension, alcoholism, and certain kinds of headaches.

Precautions and Side Effects

Those taking Prozac should be monitored closely for insomnia, anxiety, mania, significant weight loss, and seizures. Its use should be also be monitored in children and adults up to age 24 because they are at an increased risk of developing suicidal thoughts. Caution should also be exercised when prescribing Prozac to those with impaired liver or kidney function, those over age 60 years, children, individuals with known bipolar disorder or a history of seizures, and those with diabetes. The risks and benefits of Prozac should be considered by women who are or might become pregnant and those who are breast-feeding. Those with diabetes should monitor their blood or urine sugar carefully, since Prozac can affect blood sugar. Alcohol should not be used while taking Prozac. Care must be taken in driving, operating machinery, or participating in hazardous activities when taking this medication. Prozac use should not be stopped abruptly since it can cause withdrawal symptoms.

Common side effects include decreased sexual drive, restlessness, skin rash, hives, and itching. Less common side effects include fever, chills, and joint or muscle pain. Prozac interacts with many other medications. Those considering taking this medication should review the other medications they are taking with their physician for possible interactions. Also, those who

are taking Prozac should inform all their health providers including dentists.

Pseudocyesis

Pseudocyesis is the false belief of being pregnant. It is also known as false pregnancy, hysterical pregnancy, and phantom pregnancy.

Definitions

- **Anxiety disorders** are a group of mental disorders characterized by anxiety, which tends to be intermittent instead of persistent. The group includes panic disorder, phobias, and generalized anxiety disorder.
- **Depressive disorders** are a group of mental disorders characterized by sad or irritable mood and cognitive and physical changes that significantly disrupt an individual's daily functioning.
- **DSM-5** stands for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, which is a diagnostic system used by professionals to identify mental disorders with specific diagnostic criteria.
- **Endocrine system** is a group of glands that produce hormones to regulate the body's growth and sexual development.
- **Psychotherapy** is a psychological method for achieving desired changes in thinking, feeling, and behavior. It is also called therapy and therapeutic counseling.
- **Somatic symptom disorder** is a mental disorder characterized by bodily symptoms that are very distressing or result in disrupted life functioning.

Description

Pseudocyesis is a condition in which signs and symptoms associated with pregnancy occur when an individual is not pregnant. Symptoms of it are very similar to those of a real pregnancy. They can include morning sickness, missing a menstrual period, weight gain, and tenderness in the breasts. The abdomen may be swollen and expands so much that the individual looks pregnant. The swollen abdomen may be due to feces, gas buildup, urine, or fat. Another common physical sign of pseudocyesis is irregularity with menstrual cycles. Also, most women also report feeling the fetus move even though there is no fetus present. The main distinction between a true pregnancy and pseudocyesis is the lack of a fetus. No matter what the symptoms, the unquestioned belief that one is pregnant is necessary to make the diagnosis.

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, individuals can be diagnosed with "Other Specific Somatic Symptom and Related Disorder" if they have pseudocyesis. This category is one of the DSM-5 somatic symptoms and related disorders. This category applies to the appearance of symptoms that are typical of a somatic symptom and related disorder. This condition must cause major impairment and distress in an individual's work, social life, or other important areas of life. However, individuals do not meet the full criteria necessary for any of the other disorders in the somatic symptom and related disorders classifications. Other presentations that are identified under this diagnosis include brief somatic symptom disorder, brief illness anxiety disorder, and illness anxiety disorder without excessive health-related behaviors (American Psychiatric Association, 2013).

There is no known cause for pseudocyesis. One theory is that this condition is due to emotional

conflict. For example, many women have a strong desire to become pregnant or a strong fear of becoming pregnant. This can create changes and internal conflict in the body, particularly within the endocrine system. The endocrine system is responsible for the release of hormones, and this may explain why women experience symptoms related to pregnancy. A second theory is that if a woman desires to become pregnant badly enough, she may perceive that any small change in her body is due to pregnancy. Another theory is that pseudocyesis may be due to chemical changes in the body related to some depressive disorders, which triggers symptoms associated with this condition.

Treatment

Since there is not any underlying medical cause of pseudocyesis, medications are generally not prescribed. However, in some situations an individual may be prescribed a medication for terminating menstruation. Individuals who have underlying psychological problems may benefit from psychotherapy. The use of an ultrasound to reveal to the individual that she is not pregnant may be the best form of treatment.

Psychedelic Drugs

Psychedelic drugs are a class of mood-altering substances, natural and manufactured, that can cause hallucinations or altered sensory experiences in those who ingest them.

Definition

- **Psychoactive** is a drug or substance that has a significant effect on mental processes. There are five groups of psychoactive drugs: opioids, stimulants, depressants, hallucinogens, and cannabis.

Description

Psychedelic drugs were originally intended to enhance the experience of people going through psychotherapy. British psychiatrist Humphry Osmond first coined the adjective "psychedelic" in the 1950s. There is a wide range of psychedelic or hallucination-causing substances. The most common class of psychedelic drugs is those that affect serotonin or dopamine levels in the brain. The best known of these psychedelic drugs are LSD (lysergic acid diethylamide), and psilocybin, mushrooms or magic mushrooms. The second most widely known drugs associated with psychedelics are cannabis, marijuana, and mescaline. Other examples of psychedelic drugs are DMT (dimethyltryptamine) and MDMA (ecstasy). The list of natural and derived, or synthetic, psychedelic drugs is long, and new drugs continue to be developed every year.

Originally psychedelics were valued therapeutically because they could reduce patients' resistance to accessing painful thoughts and memories. In addition, they enhanced the visual or sensory reality of images and feelings experienced during psychotherapeutic sessions. They also seemed to cause little physical harm, especially in a controlled setting. Their initial use in therapy resulted in mild physical and psychological dependency and were not viewed as harmful.

Although other existing drugs, such as alcohol, heroin, and cocaine, also have the potential to induce hallucinations and powerful disconnections, they have not been used for psychological treatment. This is because they are highly addictive and have strong adverse physical effects on the people ingesting them. For these reasons, they are not generally included in the classification of psychedelic drugs.

Development

For all of recorded history, humans have been using various substances to relieve pain or induce ecstatic experiences. These experiences were used to alter perceptions often in the context of religious or celebratory occasions. Some groups of people have used and continue to use these drugs to get experiences or responses to questions not otherwise accessible to the mind. For example, Native Americans have used peyote as part of their religious practices.

As opposed to traditional drugs, the class of hallucinogens called psychedelics is a modern innovation and arose as a way to aid patients with psychological problems. It was intended to improve the quality and content of their thoughts and feelings during extended therapeutic sessions with the guidance of a professional. The intent was to free patients to explore their inner psychological states without self-judgment and with greater creativity than talk therapy alone could provide. The recreational use, or abuse, of these drugs came after their use in treatment. Eventually their use was classified as a criminal offense since many of these drugs are restricted to be used only under strict medical supervision.

In the 1960s, Harvard psychology professor Timothy Leary became the most famous person to use and advocate that others use LSD. His intent was to create a path to personal fulfillment through expanded or changed consciousness. Leary also believed you could administer psychedelics in treatment only if you yourself had ingested them and experienced the results. Leary's increasing advocacy and use of LSD was an instrument to raise political awareness and activism. But his approach and the use of these drugs in therapy provoked opposition, and his ideas were ultimately discredited. Government support of scientific investigations into psychedelics was halted during the 1970s.

Current Status

Many people assume that all psychedelic drugs are illegal, while in actuality, medical and religious use of psychedelics regulated by law is allowed in the United States. It's legal in other countries as well. It is estimated that about 10% of the U.S. population, an estimated 32 million people, has used LSD, mushrooms, or mescaline. Men are reported to be using these drugs at a higher rate than women. The use of perception and mood-altering drugs is a staple of modern medicine and psychotherapy but not widely in the form of psychedelics.

Use of these psychedelic drugs outside of accepted medical treatments continues to be socially and legally controversial. Nevertheless, it does seem that the voting public feels that there is a false distinction between legally approved traditional mood-altering substances, like alcohol, and previously banned products, such as marijuana. Thus, although currently only two states in the United States (Colorado and Washington) have made the psychedelic drug marijuana legal for public consumption, 23 states have approved the medical use of marijuana. The trend toward legalization of some drugs continues. Beneficial as some of these psychedelic drugs may be, controversy remains as it pertains to preventing them being made available to young people or to people who exhibit mental disorders.

Psychiatrist

A psychiatrist is a physician who specializes in the diagnosis and treatment of mental disorders; a psychiatrist is also referred to as shrinks.

Definitions

- **Clinical psychologist** is a graduate trained and licensed psychologist who can provide clinical assessment, diagnosis, psychotherapy and other interventions, and consultation.

- **Clinical psychology** is a form of psychology that integrates science, theory, and practice to increase the knowledge of the psyche and its function. It is also concerned with predicting, assessing, diagnosing, and alleviating psychological problems and related disability.
- **Cosmetic psychopharmacology** is the use of psychotropic medications to optimize mood and cognitive functioning in individuals with no diagnosable mental disorder.
- **Health Maintenance Organization** is an organization that provides or manages health-care delivery to control costs (managed care).
- **Neurotransmitters** are chemical messengers that carry signals between neurons (nerve cells) and other cells. Deficits or excesses result in anxiety, depression, and other disorders.
- **Psychotropic medications** are prescribed drugs that are capable of affecting the mind, emotions, and behavior. These include antidepressants such as Prozac and antianxiety medications like Xanax. They are also called psychoactive medications.

Description

Psychiatrists are medical doctors who specialize in the diagnosis and treatment of mental disorders. They treat patients in outpatient settings (clinics or private offices) and in hospital settings through a combination of psychotherapy and medication. The training of a psychiatrist consists of four years of medical school, followed by one year of internship and at least three years of psychiatric residency. Psychiatrists may receive board certification from the American Board of Psychiatry and Neurology. Certification requires two years of clinical experience beyond residency and passing a written and an oral examination. While a medical license is required in order to practice psychiatry, board certification is not required. The general public often confuses clinical psychologists and psychiatrists. Although both treat individuals with mental disorders, clinical psychologists are licensed as psychologists and not as physicians.

Psychiatrists can practice general psychiatry or choose a specialty. These specialties include child and adolescent psychiatry, geriatric (older adults) psychiatry, forensic (legal) psychiatry, emergency psychiatry, and community psychiatry. Those whose work primarily involves the use of psychotropic medication are known as psychopharmacologists. Psychiatrists treat the biological, psychological, and social aspects of mental disorders. Because they are licensed physicians, psychiatrists can prescribe medication; they are also able to admit patients to the hospital. They can also diagnose whether symptoms are due to physical causes, such as a thyroid imbalance, or whether psychological symptoms are contributing to physical conditions, such as high blood pressure.

In addition to their clinical work, psychiatrists can be involved in related professional activities such as teaching, research, and administration. The American Psychiatric Association supports the profession by offering continuing education and research opportunities, keeping members informed about new research and public policy issues, helping to educate the public about mental health issues, and serving as an advocate for people affected by mental illness. It reports a membership of 33,000 psychiatrists.

Developments and Current Status

The history of psychiatry begins about 400 BC, with Hippocrates distinguishing mental from physical disorders. The early practice of psychiatry took place largely in psychiatric hospitals until the end of World War II. Since then, outpatient treatment has displaced the central role of the psychiatric hospital in the practice of psychiatry. Several factors account for this change. These include the inability of state governments to remedy the deteriorating condition of many public psychiatric hospitals. The Community Mental Health Centers Act of 1963 provided federal funds to establish a network of community mental health centers (CMHC), which would provide a variety of services, including outpatient treatment and partial hospitalization. These CMHCs contributed to the growing trend toward the deinstitutionalization (discharging patients to the community) of mental patients. Another key factor was the development of more effective psychotropic

medications that allowed patients to live in the community. Today, the majority of psychiatric patients are treated without hospitalization.

Controversy has surrounded psychiatry, particularly the anti-psychiatry movement. Advocates of this movement insist that psychiatric treatments are more damaging than helpful to patients. Anti-psychiatry advocates point to treatments like electroconvulsive therapy as dangerous. In the 1960s and 1970s radical critics within the profession, such as psychiatrists Thomas Szasz (1920–2012) and R.D. Laing (1927–1989), challenged the medical model of mental illness itself. Psychiatry also came under fire from the feminist movement, which saw it as a vehicle for controlling women. Feminist authors have portrayed psychoanalysis as instrumental in suppressing the original feminist movement of the late 19th and early 20th centuries by labeling women's legitimate dissatisfaction and agitation as hysteria and providing an intellectual theory that aided in legitimizing society's continuing subordination of women. Published in 1972, Phyllis Chesler's (1940–) *Women and Madness* was a landmark in feminist criticism.

Advances in neurobiology, endocrinology, and immunology have greatly impacted the way psychiatry is practiced today. Research on neurotransmitters has led to the development of new medications and in the way psychiatrists think about mood, personality, and behavior. Many of these new drugs have fewer side effects than drugs previously used to treat anxiety and depression. Some have become controversial because of their potential use for cosmetic psychopharmacology. The medical and psychiatric professions, as well as ethicists, must deal with the issue of using drugs as mood enhancers to make already healthy individuals more assertive, energetic, and resilient.

Another issue with wide-ranging implications for psychiatry is the policies of insurance companies and health maintenance organizations (HMOs), whose cost-containment policies have already had a significant effect on the way psychiatry is practiced. Insurers and HMOs generally favor psychiatrists using medication management (use of medication only) over psychotherapy with their patients. So, they are more likely to reimburse for medication management and therefore discourage the practice of therapy by psychiatrists. They also tend to promote the use of generic (cheaper) medications over more expensive brand name medication, even when the brand name offers greater benefits.

Psychoanalysis

Psychoanalysis is a theory of human behavior and form of psychotherapy that focuses on conflicts and compromises between the unconscious (internal) and the conscious mind. It was developed by Sigmund Freud (1856–1939).

Definitions

- **Psychoanalytic psychotherapy** is a form of psychoanalysis that assumes that dysfunctional or unwanted behavior is caused by unconscious, internal conflicts and focuses on gaining insight into these conflicts.
- **Psychoanalytic theory** reflects a psychodynamic view of human behavior which emphasizes the conflicts and compromises between the unconscious (internal) and conscious mind.
- **Psychodynamic** refers to a way of explaining thoughts, feelings, and behaviors as the manifestation of unconscious (inner) drives and processes.
- **Psychodynamic psychotherapies** are a group of psychodynamic approaches that assume that dysfunctional or unwanted behavior is caused by unconscious conflicts, and therapy focuses on resolving conflicts through insight and/or corrective experiences.

Description

Psychoanalysis is both a theory of human behavior and a form of psychotherapy developed by Sigmund Freud. In psychoanalysis, the analysand (patient) is encouraged to talk freely about personal experiences, particularly early childhood experiences and dreams. It is based on psychodynamic theory. Freud viewed personality as having three parts: the id, the ego, and the superego. He developed a model of personality and psychopathology (abnormality) based on it. The id is comprised of instinctual drives for food, sex, and aggression, and these drives are unconscious. The id seeks immediate gratification and anxiety results when it is frustrated. Linked to the id is the ego, which has been socialized. As a result the ego recognizes that gratification of the id's urges cannot always be achieved. The superego acts as an arbiter of right and wrong and moderates the id's urges in terms of a moral code. Freud used this model to demonstrate how instinctual drives are frustrated with social codes (by the ego) and by morality (by the superego). The inevitable conflicts between these three components are the basis of psychoanalytic theory.

In dealing with these conflicts, psychoanalytic theory contends that the human mind constructs three different forms of adaptive mechanisms: defense mechanisms, neurotic symptoms, and dreams. Freud identified several defense mechanisms, such as repression, displacement, denial, rationalization, projection, and identification. Each has its own unique role, but all work to distance an individual from a conflict that is too difficult to confront realistically. Neurotic symptoms are understood to be symbolic actions that represent the repressed longings of the id.

Freud believed dreams were vivid representations of repressed urges. Some neurotic symptoms have both physical and psychological components. For example, a severe headache can result from unfulfilled longings that the individual is unable to confront on a conscious level. Because of this inability, individuals may develop an acceptable symptom (headaches) for which they can seek medical attention. Dreams have two parts, the manifest (obvious) content, the narrative that one is able to remember on waking, and the latent (hidden) content, the underlying, largely symbolic message. Since dreams are understood as representing unfulfilled longings of the id, psychoanalysis deals heavily with dream interpretation.

Such conflicts are believed to originate during one of the four developmental stages. Freud believed that adult neuroses could be traced to frustrated sexual gratification during one of these stages. Four stages were identified: the oral stage (birth to one year), the anal stage (one to three years), the phallic stage (three to five years), and the latency stage (five years to puberty). Each of these stages is in turn divided into substages. In each of the major stages, the infant has sexual needs which, because of social mores, are left largely unfulfilled, causing neuroses to originate. It is during the phallic stage that the Oedipus complex develops. During this stage, the child begins to associate his genitals with sexual pleasure and becomes erotically attracted to the parent of the opposite sex while at the same time developing an intense jealousy of the same-sex parent. Later, Carl Jung (1875–1961) described the Electra complex for women in which the same dynamics of erotic attraction and jealousy is played out from the girl's perspective.

Developments and Current Status

Sigmund Freud noted that many of his patients were suffering from physical symptoms for which he could find no cause. At first he sought to uncover the psychological cause through hypnosis. Because of limited success with it, he instructed patients to talk freely about their problems. This led individuals to reveal the unconscious heart of the problem. Continuing his research of the mind and the unconscious, Freud published *The Interpretation of Dreams* in 1900. This was followed by *The Psychopathology of Everyday Life* in 1904 and *A Case of Hysteria* and *Three Essays on the Theory of Sexuality*, both in 1905. By 1920, Freud had become internationally recognized, and psychoanalysis emerged as a significant intellectual and social development. As a result, entering psychoanalytic treatment became fashionable among the elite.

Classical psychoanalysis is the version of psychoanalysis practiced by Freud and his early followers. It often required years of therapy, sometimes on a daily basis. Not surprisingly, it was criticized for being

time consuming and costly. More recently, a number of modern approaches have been developed that are briefer and more effective. These are broadly labeled psychodynamic psychotherapies. They include psychoanalytic psychotherapy, ego psychology, object relations therapy, self-psychology, and the interpersonal psychoanalysis.

Psychodrama

Psychodrama is a therapy technique that explores psychological issues through guided and creative reenactments.

Description

The developer of psychodrama was Dr. Jacob Moreno (1889–1974), who believed that each person is impacted by the roles that he or she plays. These roles include cultural, social, and psychological expectations. From his perspective, a person is mentally healthy when he or she is able to flexibly act and react with a variety of responses or roles, depending on circumstances. For example, one person could play the role of a father in some circumstances and an employee in others. Conversely, issues and problems are indicated by restrictions in emotional responses and spontaneity when asked to take on certain roles.

Psychodrama is an active and involved method of group and individual psychotherapy. In this technique, people are helped to explore their psychosocial issues by enacting scenes from their lives, their dreams, or their fantasies. This is done in a facilitated setting so that each individual may gain new insights into his or her thoughts and behaviors and be able to access previously unspoken emotions. The power of acting out and getting immediate emotional response from other group members is accomplished through psychodrama. Psychodrama can help to reduce inhibitions and provide the opportunity for surprising breakthroughs in awareness. The goal is that these opportunities fuel their courage to try new roles and new behaviors outside of therapy.

Development

From 1918 to 1925, Dr. Moreno practiced psychiatry and psychodrama in Vienna. His work was an effort to depart from the typical Freudian approach to psychotherapy and its exclusive concentration on individual talk therapy. From theatrical work that he had done with children in the parks of Vienna, he came to realize the healing impact and importance of creativity and spontaneity. Moreno had also worked with a group of prostitutes seeking rehabilitation. During this experience he became aware that working with them together as a group had positive results, in fact results that were greater than might have been achieved with individual one-on-one work because each person was able to function as a kind of therapist and support for the others. This led him to expand on the idea of incorporating group therapy and psychodrama into treatment to effect change. Psychodrama was popularized during the 1930s in New York City by Moreno. He accomplished this through the extensive use of psychodrama in the context of group therapy. The United States proved to be fertile ground for further development and the spread of both group therapy and psychodrama.

Current Status

Psychodrama has become a standard tool that is used in group therapy. Moreno's work has continued for the half century after his death through his wife Zenka Toeman Moreno. Today there are psychodrama certification programs and centers across the United States and the concept of psychodrama is widespread in creative group therapy settings.

Psychodynamic

"Psychodynamic" refers to a way of explaining thoughts, feelings, and behaviors as the manifestation of unconscious (internal) drives and processes.

Definitions

- **Ego psychology** is a form of psychoanalysis that emphasizes the role of the ego in managing competing demands.
- **Object relations theory** is a variant of psychoanalytic theory which emphasizes the essential need for close relationships. The attempted fulfillment of this need through mental representations of self and others is believed to determine one's motivations and behaviors.
- **Psychoanalysis** is a form of therapy based on psychoanalytic theory. In psychoanalysis, clients are encouraged to talk freely about personal experiences, particularly their early childhood and dreams.
- **Psychodynamic psychotherapies** are a group of psychodynamic approaches that assume that maladaptive or unwanted behavior is caused by unconscious drives and processes, and therapy focuses on fostering insight and/or corrective experiences.
- **Self-psychology** is a form of psychoanalysis that assumes that dysfunctional or unwanted behavior results from unmet or disrupted developmental needs.

Description

The origin of the term "psychodynamic" is from the Greek words "psyche," meaning mind, and "dynamis," meaning power or force in motion. In other words, the mind is made up of powerful forces in motion. Sigmund Freud (1856–1939) used the word "psychodynamic" to describe the mind as an energetic moving system of parts. We are aware of the conscious parts of the mind and unaware of the unconscious parts. From a psychodynamic perspective, maladaptive behaviors are the result of unconscious processes and develop early in life.

The unconscious consists of feelings, memories, self-perceptions, ways of relating to others, conflicts, and beliefs that we are not aware of. All of these processes develop during childhood and are a unique combination of an individual's early experiences, family environment, biological factors, and genetic predispositions. Psychodynamic theory posits that certain thoughts, feelings, and fantasies are forced into the unconscious because they are overwhelming or would give us a sense of disgust or shame.

Psychodynamic theory states that unconscious mental processes affect conscious thoughts, feelings, and behaviors. Becoming aware of how past experiences impact present behavior is a central goal of the psychodynamic psychotherapies. Similar to psychodynamic theory is psychoanalytic theory. While it reflects the psychodynamic view of human behavior, psychoanalytic theory emphasizes the conflicts and compromises between the unconscious and conscious mind. In other words, the psychoanalytic theory holds that individuals' unwanted or maladaptive (problematic) behaviors are the result of internal conflicts and experiences being locked up in the unconscious by way of psychological defense mechanisms such as regression and repression. Once the experiences and internal conflicts are brought into the consciousness of the client, the maladaptive behaviors cease.

Development and Current Status

Psychodynamic theory has its roots in psychoanalysis, being the oldest of the psychodynamic psychotherapies. Freud's ideas about personality, the ego, unconscious

processes, defense mechanisms, and the importance of early childhood experiences have all been further developed by numerous other psychiatrists, psychologists, and theorists over the past century.

Other psychodynamic theories and approaches include ego psychology (Anna Freud), psychosocial development (Erik Erikson), object-relations theory (Otto Rank and Melanie Klein), Individual Psychology (Alfred Adler), Jungian/analytical psychology (Carl Jung), and self-psychology (Heinz Kohut). A more recent theory that has made considerable contributions to psychodynamic psychotherapy is that of attachment theory (John Bowlby), which recognizes the central role of the primary caregiver, most often the mother, in the emotional development of a person.

Psychodynamic Diagnostic Manual (PDM)

The *Psychodynamic Diagnostic Manual* (PDM) is a diagnostic framework that characterizes individuals in terms of their psychodynamics.

Definitions

- **Psychiatric diagnosis** is a form of diagnosis based on comparing symptoms and impaired functioning with diagnostic criteria for a specific disorder.
- **Psychoanalysis** is a form of psychodynamics therapy in which patients are encouraged to talk freely about personal experiences, particularly about their early childhood and dreams.
- **Psychoanalysts** are therapists who practice therapy from the perspective of psychoanalysis.
- **Psychodynamic** refers to interaction of conscious and unconscious processes as they influence personality, behavior, and attitudes.
- **Psychodynamic diagnosis** is a form of diagnosis that involves an investigation into how individuals acquire their symptoms and the meaning they attribute to their symptoms.

Description

The *Psychodynamic Diagnostic Manual* is a diagnostic framework that characterizes individuals in terms of both their psychodynamics and their emotional, cognitive, and social functioning. The purpose of the PDM is to complement the *Diagnostic and Statistical Manual of Mental Disorders* (DSM) with psychodynamically based descriptions of patterns of personality, global functioning, and symptom formation. The PDM emphasizes motivational factors that commonly underlie the emergence of particular personality disorders and symptom disorders (depressive disorders) and the ways individuals with these disorders are likely to experience them.

Psychodynamic diagnosis differs from psychiatric diagnosis. Whereas a psychiatric diagnosis focuses on symptoms and impairment, the psychodynamic diagnosis focuses on the individual who is experiencing those symptoms and impairment. While a psychiatric diagnosis is a DSM diagnosis that is primarily descriptive (describes a group of symptoms), the psychodynamics diagnosis identifies the causes or etiology of the individual's behavior and feelings.

The PDM provides a diagnostic framework that describes both the deeper and surface levels of an individual's personality, emotional and social functioning, and symptom patterns. A psychodynamics evaluation explores how and why those influences are emerging in the present and causing symptoms, including the

role of early environment, developmental factors, current stressors, and internal psychological factors.

The PDM can complement the more descriptive approach of the DSM diagnosis with an individualized, dimensional, and motivationally based classification system. It accomplishes this by describing individuals in terms of their personality characteristics, the adequacy of their mental functioning, operative patterns of symptom formation, and their experience of these symptoms. Accordingly, each person being evaluated with the PDM is diagnosed on three axes that are labeled S (Symptom Patterns), P (Personality Patterns and Disorders), and M (Profile of Mental Functioning). The PDM diagnosis begins with the P axis, considers next the M axis, and concludes with the S axis. This sequence reflects the belief that symptom disorders are embedded in an individual's personality structure and manifest in ways that vary with the individual's functioning capacities.

The PDM is divided into two parts. Part 1 focuses on adult disorders and closes with three case illustrations of how the P, M, and S codes can be applied. The three individuals in these cases have the same PDM S axis diagnosis of depressive disorder (S304.1), but their P axis and M axis diagnoses differ in ways that have implications for their uniqueness as people and for treatment strategies tailored to their individual needs. Part 2 focuses on child and adolescent disorders. It is organized around the same P, M, and S axes as are used with adults, but in a different sequence. The PDM diagnosis of children and adolescents begins with attention to the adequacy of basic functioning capacities, in the form of an MCA axis that provides guidelines for classifying mental functioning and coping.

Developments and Current Status

The PDM was published in 2006. It was a collaborative effort of five psychoanalytic organizations: the American Psychoanalytic Association, the International Psychoanalytic Association, the Division of Psychoanalysis of the American Psychological Association, the American Academy of Psychoanalysis and Dynamic Psychiatry, and the National Membership Committee on Psychoanalysis in Clinical Social Work. It was authored by a task force consisting of Stanley Greenspan, Nancy McWilliams, Robert Wallenstein, and an interdisciplinary group of 37 other task force members and consultants.

Despite the considerable clinical value of the PDM, it seems unlikely that the PDM will replace the DSM. There are many reasons for this, not the least of which is that the PDM does not yet have the established reliability necessary to warrant its widespread adoption. Overall, the PDM complements DSM by providing a valuable framework for planning and implementing clinical treatment.

Psychodynamic Psychotherapies

Psychodynamic psychotherapies are a group of psychodynamic approaches that assume that dysfunctional or unwanted behavior is caused by unconscious (internal) conflicts, and therapy focuses on resolving conflicts through insight and/or corrective experiences.

Definitions

- **Object relations theory** is a variant of psychoanalytic theory which emphasizes the essential need for close relationships. The attempted fulfillment of this need through mental representations of self and others is believed to determine one's motivations and behaviors.
- **Object relations therapies** are forms of psychoanalytic psychotherapy in which the basic

goal is to modify pathological representations of self and others.

- **Psychoanalysis** is a form of therapy based on psychoanalytic psychology. In psychoanalysis, clients are encouraged to talk freely about personal experiences, particularly their early childhood and dreams.
- **Psychoanalytic psychotherapy** is a form of psychoanalysis that assumes that dysfunctional or unwanted behavior is caused by unconscious, internal conflicts and focuses on gaining insight into these conflicts.
- **Psychoanalytic theory** reflects a psychodynamic view of human behavior which emphasizes the conflicts and compromises between the unconscious (internal) and conscious mind.
- **Psychodynamic** refers to a way of explaining thoughts, feelings, and behaviors as the manifestation of unconscious drives and processes.
- **Relational psychoanalysis** is a form of psychoanalysis that emphasizes the role of real and imagined relationships with others in mental disorder and psychotherapy.
- **Self-psychology** is a form of psychoanalysis that assumes that dysfunctional or unwanted behavior results from unmet or disrupted developmental needs.

Description

Psychodynamic psychotherapies represent a broad category of psychotherapeutic approaches that are based on the principles of psychodynamics and psychoanalytic psychology. Generally, dynamic therapies endeavor to bring unconscious material and processes into full consciousness so individuals can gain more control over their lives. These therapies have their origins in psychoanalysis and stem from the work of Sigmund Freud (1856–1939) and others who have made major contributions and reformulations (variants) to Freud's original theory and therapeutic approach, which is called classic psychoanalysis. These reformulations include psychoanalytic psychotherapy, ego psychology, object relations theory, self-psychology, and the interpersonal psychoanalysis. While there are important differences in both theory and practice among these different approaches, they share certain common principles. These include (1) the unconscious and the belief that much of mental life involves and is influenced by unconscious processes; (2) resistance and the exploration of resistance to change, and defenses as a focus of therapy; (3) transference (reenacting past feelings and expectations) and the exploration of such reenactment of the past in response to the therapist; (4) symptoms and behavior which are determined by complex and usually unconscious forces; and (5) exploration of basic assumptions about self and the world or maladaptive interpersonal patterns rather than simply focusing on symptom relief.

Developments and Current Status

Sigmund Freud (1856–1939) is considered to be the father of psychoanalysis. Freud's work focused primarily on instinctual drives and structural theory (id, ego, and superego). However, psychoanalysis has evolved considerably since Sigmund Freud. Five different phases of this evolution can be identified. Each is briefly described.

Classical psychoanalysis. Classical psychoanalysis is the approach developed and practiced by Freud. In this approach, the analysand (client) verbalizes thoughts, free associations, fantasies, and dreams, from which the analyst (therapist) identifies the unconscious conflicts causing the client's symptoms and related characterological (personality) issues, which includes unconscious aspects of the therapeutic alliance (relationship with the analyst). The analyst's interventions include confrontation, clarification, interpretation, and working through (process of generalizing new awareness to the client's life). Typically, the analyst sits behind the analysand who lies on a couch during sessions.

Psychoanalytic psychotherapy. Another drive-based dynamic approach is psychoanalytic psychotherapy. It is a modified form of classical psychoanalysis, which is more widely practiced than classical psychoanalysis today. It is less intense and less concerned with major changes in the client's personality structure and

focuses on the client's current concerns and the way these concerns relate to early conflicts. Typically, therapist and client face each other in this approach.

Ego psychology. Ego psychology evolved out of Freud's later thinking and was the dominant form of psychoanalysis practiced until the 1970s. Freud's daughter, Anna Freud (1895–1982), played a significant role in its development. It focuses on the ego's normal and pathological development and its adaptation to reality. Unlike the focus on libidinal and aggressive impulses of classical psychoanalysis, ego psychology focuses directly on the ego and its defenses. Through clarifying, confronting, and interpreting the client's commonly used defense mechanisms, the goal is to assist the client in gaining control over these mechanisms.

Object relations. Since the 1970s major reformulations of psychoanalysis have emerged. Among these was object relations theory which emphasizes interpersonal relations, especially between mother and child. Melanie Klein (1882–1960) was a key architect of this approach. "Object" refers to a significant other who is the object of another's feelings or intentions. "Relations" refers to interpersonal relations and refers to the residues of past relationships that affect a person in the present. Object relations therapy focuses on the ways the client projects previous object relationships into the relationship with the therapist. The goal is to assist clients in resolving the pathological qualities of past relationships through the corrective emotional experience. Like other psychodynamic approaches, some interpretation and confrontation may be involved. However, the working through of the original pathological components of the patient's emotional world and the objects is the primary therapeutic strategy.

Self-psychology. Another reformulation initiated by the Hungarian psychiatrist Heinz Kohut (1913–1981) is called self-psychology. This approach emphasizes the development of a stable and cohesive or integrated sense of self through empathic contacts with significant others (selfobjects). These selfobjects meet the developing self's needs and serve to strengthen it. Treatment proceeds through reflection of feelings and interpretations in which the client gradually internalizes the selfobjects' functions provided by the therapist.

Interpersonal psychoanalysis. There is also some reformulation of psychoanalysis based on relational themes. Psychologist and psychoanalyst Stephen A. Mitchell (1946–2000) distinguished between psychoanalytic theories emphasizing biological drives (drive/conflict theories) and theories emphasizing human relationships (*relational/conflict theories*). Mitchell argued that drive and relational theories were conceptually incompatible and that the field must choose between them. He is credited with developing interpersonal psychoanalysis. This approach emphasizes the way in which individuals protect themselves from anxiety by establishing collusive (unhealthy) interactions with others. It emphasizes how the individual's personality is shaped by both real and imagined relationships with others, and how these relationship patterns are reenacted in the interactions between therapist and client.

Time-limited dynamic psychotherapy is a brief form of relational psychoanalysis. It was developed for clients with chronic, pervasive, dysfunctional ways of relating to others by psychologist Hans Strupp (1921–2006). Essentially, this approach assumes that individuals have unintentionally developed self-perpetuating, maladaptive patterns of relating to others and that these patterns underlie their present problems. The therapist's role is to use the therapeutic relationship to facilitate in clients new experience of relating, which allows them to break their maladaptive pattern and thereby resolve their presenting problem. This approach is also called brief dynamic therapy and has become one of the more commonly practiced psychodynamic psychotherapies today.

Psychoeducation

"Psychoeducation" is a general term used to describe the assessment and therapeutic process involved in identifying an individual's present state of physical health, behavioral, academic, and psychological functioning, determining an accurate diagnosis, and assisting the person and his or her family in dealing with the new diagnosis.

Definitions

- **Psychoeducational groups** are a type of small group therapy that focus on educating people on how to cope with a medical diagnoses, learning disability, and/or psychiatric disorders.
- **Psychoeducational testing** is a form of assessment that is comprised of both psychological and educational components, which seeks to determine what an individual has learned and what capacity the individual has to learn in the future.
- **Psychoeducational therapy** defines the therapeutic treatment, either individually or in small groups, of those with disabilities and medical illnesses so they can learn to manage and cope with their new diagnosis.

Description

"Psychoeducation" refers to the evaluation, education, and treatment of persons diagnosed with various conditions, including learning disabilities, medical illnesses, and psychological disorders. This intervention offers teaching, counseling, and skill-building support. Attention-deficit hyperactivity disorder, reading and processing difficulties, anxiety-related issues, eating disorders, depression, personality disorders, schizophrenia, and health-related concerns including diabetes, epilepsy, and cancer have all been addressed with psychoeducation. Psychoeducation is meant to impart knowledge and skills so that patients and their loved ones become better able to cope with their conditions. New diagnoses can result in feelings of stress, anxiety, and confusion, which can be dissipated with appropriate intervention. The goal of psychoeducation is to promote self-management strategies and prevent relapse by increasing overall well-being.

Psychoeducation is a broad term that includes both the assessment process, *psychoeducational testing*, and the intervention, *psychoeducational therapy*. Proper diagnosis is the first step in the psychoeducational process, typically conducted by a physician, specialist, psychiatrist, or licensed psychologist. Physical illnesses require testing and analysis by a medical doctor who specializes in the area of concern. Learning, behavior, or psychological disabilities are determined through a full psychoeducational evaluation by a psychiatrist or psychologist, which assesses the client's present psychological functioning as well as his or her retention of knowledge and capacity for future academic learning. Once a proper diagnosis has been determined, the client/patient may then be referred for psychoeducation to assist in educating and helping cope with his or her new status. Psychoeducation for physical illnesses may be offered by physicians, nurses, specialists, physical therapists, or home health-care workers, while psychoeducation for learning, behavior, and psychological concerns may be delivered by mental health professionals, behavioral interventionists, or clinical social workers. This treatment intervention can be offered to patients on an individual basis or in small group settings with peers or family members.

Psychoeducation can be implemented in a variety of settings, including hospitals, treatment centers, and schools. Patients who receive psychoeducation benefit by gaining information and increased awareness on their diagnosis. Information regarding client symptomatology, treatment options, outcomes, resources, and support networks available is imparted to clients and their loved ones during psychoeducational sessions. This results in reducing feelings of hopelessness, anger, anxiety, and fear and in raising the client's level of acceptance of, sense of control over, and healthy coping with his or her condition. The effectiveness of psychoeducational groups in particular has been proven as support from peers who are experiencing, or have experienced, similar issues is important. Peers can relay helpful tips and provide firsthand knowledge and support is key. The format of

a psychoeducational session can vary from discussion based to more structured; however, each session typically has specific goals and content. Information can be imparted through lecture, open question–answer, and the reading/writing of print materials, or use of CDs, DVDs, or computer-based learning. The number of sessions can also differ.

Development (History and Application)

Though psychotherapist John E. Donley was the first to refer to the concept of psychoeducation in his article "Psychotherapy and Re-education" in the *Journal of Abnormal Psychology* in 1911, the term "psychoeducation" was actually coined by Brian E. Tomlinson in the 1941 book *The Psychoeducational Clinic*. Psychoeducation as it is presently used, however, is attributed to the work of American researcher C. M. Anderson, who focused on the effectiveness of this intervention approach with patients suffering with schizophrenia. Her work referred to the benefits of educating patients and their families and increasing their emotional and coping skills in order to improve their prognosis and postpone relapse. Psychoeducation has since been applied to treat other psychological conditions, as well as medical illnesses, physical disorders, and learning disabilities.

Current Status

The psychoeducational approach has been proven effective in helping to mitigate the symptoms of various mental illnesses. Most of the research on this intervention notes the benefits of psychoeducation for those suffering with schizophrenia, clinical depression, and bipolar disorder. Recent application has addressed the positives of this treatment with clients suffering from other conditions, including eating disorders, personality disorders, behavioral challenges, and learning needs. There is limited research on the difference between various psychoeducational formats and delivery methods. Much of the benefit one gains from this type of intervention depends on individual characteristics, including the client's willingness to participate, openness to new information, attitude, and mindset toward his or her diagnosis.

Psychoeducational Groups

Psychoeducational groups provide therapeutic support in small group settings to assist members struggling with similar issues or diagnoses and educate them so that they can manage their symptoms and conditions in everyday life.

Definitions

- **Psychoeducation** is a general term that describes the educational and therapeutic process involved in assisting an individual and his or her family in coping with a medical or psychological illness, or physical, behavioral, or learning disability.
- **Psychoeducational therapy** defines the therapeutic treatment, either individually or in small groups, of those with disabilities and medical illnesses so they can learn to manage and cope with their new diagnosis.

Description

Psychoeducational groups are a form of psychoeducational therapy that helps individuals diagnosed with a wide variety of conditions, ranging from medical illnesses, physical impairments, psychological disorders, and learning disabilities, effectively cope with their symptoms and deal with their new diagnoses in healthy, appropriate ways. These groups can be offered to individuals of all ages across a wide range of settings, including hospitals, treatment centers,

churches, and schools. Those diagnosed with autism, ADHD, anxiety-related issues, certain phobias, eating disorders, depression, personality disorders, schizophrenia, substance abuse, eating disorders, diabetes, and cancer have all benefited from psychoeducational groups. Psychoeducational therapy is typically provided by a mental health professional, such as a counselor, therapist, social worker, or psychologist. Group psychoeducation focuses on providing information, support, and strategies. New diagnoses can result in feelings of stress, anxiety, and confusion, all of which can be dissipated with appropriate intervention. The goal of a psychoeducational intervention is to promote self-management strategies and prevent relapse by increasing the participant's overall well-being. Membership is usually comprised of peers who are dealing with similar diagnoses, symptoms, or behaviors. The structure of a psychoeducational group can vary from lecture-based to informal, open discussion. Group leaders may impart information pertaining to the diagnosis itself, including physical symptoms, treatment options, and prognosis. Topics center around particular conditions or diagnoses. In addition, coping strategies and skills may be taught.

Development (History and Application)

Psychoeducational group therapy is considered a holistic intervention that stresses competency, collaboration, strength, empowerment, and choice. Patients/clients who participate are encouraged to focus on the present rather than the past or future. Psychoeducation has been in existence for decades and has developed as an alternative approach to traditional psychotherapy. This therapeutic intervention responds to patient needs by providing a skills-based approach to treatment. Psychoeducational facilitators focus on collaboration and operate from an egalitarian mind-set, respecting the patient's autonomy and arming him or her with information that will allow him or her to feel more control over his or her diagnosis.

Current Status

The effectiveness of psychoeducational group therapy has been well documented. Numerous studies support this intervention as a viable choice in mitigating symptomatology and recurring episodes for those suffering from schizophrenia, depression, and bipolar disorder. Eating disorders and substance abuse issues are also regularly treated with this form of therapy. Alcoholics Anonymous is a popular example of a psychoeducational group that has had much documented success. More recently, psychoeducational groups have been implemented in school settings to assist adolescents in dealing with common problems like teen pregnancy, alcohol and drug use, learning, and behavioral struggles. Little research exists on the degree of effectiveness between different psychoeducational formats and delivery methods. An individual's willingness to participate, interest in learning the information imparted, and commitment to the group process are key.

Psychological Factors Affecting Other Medical Conditions

Psychological factors affecting other medical conditions is a mental disorder characterized by emotional factors that worsen a medical condition.

Definitions

- **Cognitive behavior therapy** is a type of psychotherapy that focuses on maladaptive (faulty) behaviors, emotions, and thoughts.
- **DSM-5** stands for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, which is a diagnostic system used by

professionals to identify mental disorders with specific diagnostic criteria.

- **Mindfulness practices** are intentional activities that foster living in the present moment and awareness that is nonjudgmental and accepting.
- **Somatic sensitivity** refers to the high level of sensitivity and attentiveness to bodily sensations of emotionally reactive individuals. This often leads to a preoccupation with bodily symptoms.
- **Somatic symptom and related disorders** are a group of DSM-5 mental disorders characterized by prominent somatic symptoms and significant distress and impairment. They include somatic symptom disorder and psychological factors affecting other medical conditions.
- **Stress management** is a set of psychological techniques for increasing the capacity to better cope with psychological stress. It usually includes relaxation methods.

Description and Diagnosis

Psychological factors affecting other medical conditions are one of the somatic symptom and related disorders. They are characterized by one or more emotional or behavioral factors that exacerbate or adversely affect an existing medical condition. Psychological factors can be a contributing or exacerbating factor in several medical disorders. For example, heart disease, diabetes, high blood pressure, and cancer are commonly impacted by psychological factors. Immune and endocrine disorders like hyperthyroidism (overactive thyroid) as well as migraine, irritable bowel syndrome, and pain disorders are also impacted.

There are various ways in which psychological factors can worsen a medical disorder. For example, psychological distress can signal the thyroid gland to increase hormones that in time can result in hyperthyroidism (overactive thyroid gland). Similarly, chronic activation of the stress response can negatively affect the immune system and worsen asthma or allergies. Mood disturbance also plays a role in medical disorders. For example, clinical depression is both a risk factor in heart disease and a factor that negatively influences recovery from a heart attack.

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, individuals can be diagnosed with this disorder if they exhibit a medical condition or symptom and behavioral or psychological factors adversely affecting that condition. These factors can be shown to influence the course of the medical condition or interfere with its treatment. In addition, these factors can precipitate or worsen its symptoms, or serve as health risks for the condition. Finally, these factors cannot be better explained by another mental condition such as a depressive or a panic disorder (American Psychiatric Association, 2013).

The cause of this disorder is not well understood. It may be that those with it are more sensitive to their own bodily sensations (somatic sensitivity) than others. This means that those with this disorder tend to amplify and interpret these physical sensations as indicators of physical illness even when the cause is emotional. This means that when they experience emotional stress they inevitably interpret it as a physical symptom. In addition, they are likely to view life as threatening and overwhelming. They are also likely to view themselves as unable to control and deal with overwhelming circumstances. These views reflect an external locus of control. It not only confirms and perpetuates their suffering but also explains their reliance and overuse of medical treatment.

Treatment

Effective treatment of this disorder usually involves counseling or psychotherapy. Typically, this requires a team approach in which the psychotherapist collaborates with physicians to reduce symptoms, increase treatment compliance (willing to follow treatment recommendations), and ensure that care is coordinated. Effective psychological treatment results in decreased symptoms and increased functioning. Intervention strategies should target physical functioning by teaching relaxation and other stress management skills. Such interventions can greatly help individuals feel better physically and increase their sense of self-efficacy.

Mindfulness practice can also help in both reducing their preoccupation with and acceptance of physical symptoms. In addition, instructing these individuals to get regular exercise and sufficient sleep is crucial. Finally, helping them increase their support network and connection to others provides them with an effective buffer against stress and also reduces their symptoms.

Psychologist

Psychologists are social scientists who study behavior and mental processes, typically in teaching, research, business, or clinical settings.

Definitions

- **Behaviorism** is the psychological theory and scientific approach that emphasized the role of observable, quantifiable facts rather than subjective thoughts and emotions as in structuralism.
- **Clinical psychologist** is a graduate trained and licensed psychologist who can provide clinical assessment, diagnosis, psychotherapy and other interventions, and consultation.
- **Clinical psychology** is a form of psychology that integrates science, theory, and practice to increase the knowledge of the psyche and its function. It is also concerned with predicting, assessing, diagnosing, and alleviating psychological problems and related disability.
- **Clinical social worker** is a graduate trained and licensed professional who provides a broad range of mental health services for individuals, families, and groups.
- **Functionalism** is the psychological school of thought that views mental life and behavior in terms of its functions and active adaptation to external challenges and opportunities.
- **Mental health counselor** is a graduate trained and licensed professional who provides psychotherapy or therapeutic counseling to individuals, families, and groups.
- **Psychiatrist** is a licensed physician who specializes in the diagnosis and treatment of mental disorders usually with medications and/or psychotherapy.
- **Psychoanalysis** is the psychological theory developed by Sigmund Freud in which much of mental activity is considered to be unconscious (not available to the conscious mind).
- **Structuralism** is the psychological school of thought that identifies the components (structure) of the mind to learn about the brain and its functions.

Description

A psychologist is a graduate trained social scientist who studies behavior and mental processes. These professionals work in schools, universities, research settings, and business and corporate settings. Clinical psychologists are likely to practice in clinical settings such as hospitals, clinics, or private practice.

Psychology can be categorized into various subfields or specialties. The two major areas of psychology are basic psychology and applied psychology. Basic psychology encompasses the subfields concerned with the advancement of psychological theory and research. Experimental psychology employs laboratory experiments to study basic behavioral processes shared by different species, including sensation, perception, learning, memory, communication, and motivation. Physiological psychology is concerned with

the ways in which biology shapes behavior and mental processes, and developmental psychology is concerned with behavioral development over the entire life span. Other subfields include social psychology, quantitative psychology, and the psychology of personality.

Applied psychology is the broad area of psychology that applies psychological research and theory to problems posed by everyday life. It includes clinical psychology, which is the largest subfield in psychology. Clinical psychologists account for 40% of all psychologists. Although clinical social workers, psychiatrists, and mental health counselors typically work in mental health settings, their focus, training, and licensure are different. In contrast, counseling psychologists have training that is similar to clinical psychologists. Like clinical psychologists, they apply psychological principles to diagnose and treat individual emotional and behavioral problems. However, counseling psychologists are more likely to focus on career and development issues.

Other subfields of applied psychology include school psychology, educational psychology, industrial and organizational psychology, community psychology, health psychology, and consumer psychology. School psychologists are involved in the evaluation and placement of students in school settings. Educational psychologists investigate the psychological aspects of the learning process. Industrial and organizational psychology study the relationship between individuals and their jobs. Community psychologists study environmental factors that impact mental disorders. Health psychologists investigate the psychological aspects of health behaviors and medical conditions. Consumer psychologists investigate the preferences and buying habits of consumers and reactions to advertisements.

More recent specialization includes environmental psychology, forensic psychology, and sports psychology. Environmental psychologists study the relationship between individuals and their physical surroundings. They address such issues as the effects of noise and overcrowding, and the effects of building design. Forensic psychologists apply psychology to law, particularly to the criminal justice system. They are involved in competency to stand trial evaluations, jury selection, criminal profiling, and custody evaluations. Sports psychologists focus on the psychological and mental factors that influence participation and performance in sport, exercise, and physical activity.

Most psychologists earn the PhD degree. This degree requires four to six years of graduate training in psychology beyond the bachelor's degree. PhD study includes both general and specialized coursework and the completion of a dissertation. For those training for careers in clinical, counseling, and school psychology, an internship is also required. Such PhD training prepares the graduate for teaching and research, and for those in applied psychology programs, clinical practice. Students who intend to practice only applied psychology have the option of obtaining a doctor of psychology (PsyD) degree. The PsyD degree has a limited emphasis on research, and the dissertation or final project does not require an original, empirical research study.

Developments and Current Status

Psychology has grown and changed throughout history. Starting in 400 BC, Greek philosophers have proposed theories to explain human behavior. The emergence of scientific method in the late 19th century shifted psychology's focus from philosophy to science. In 1879, psychologist Wilhelm Wundt (1832–1920) opened the first psychological laboratory ever in Leipzig, Germany. As a result of his research and publications, Wundt helped in establishing psychology as the study of conscious experience. This became known as the school of structuralism. It was surpassed by functionalism. Afterward, psychologist G. Stanley Hall (1844–1924) established the first American experimental psychology lab in the United States at Johns Hopkins University. The American Psychological Association (APA) was founded in 1892. Its purpose was to encourage research, enhance professional competence, and disseminate knowledge about psychology, its research, and its applications to everyday life. Hall was elected the first president of the APA in 1892.

The late 19th and early 20th centuries saw the development of behaviorism and psychoanalysis. Because of psychology researchers like B.F. Skinner (1904–1990), behaviorism became the dominant theory in the United States in the 1950s and 1960s. Since the 1970s, psychology has been influenced by

the cognitive approach. Unlike behaviorism and psychoanalysis, the cognitive approach focuses on how individuals receive, perceive, store, process, and act on information.

Psychology is a flourishing field and for years has been one of the most popular undergraduate majors. Job prospects for those with psychology training are quite bright. Employment of psychologists is expected to increase by 22% from 2010 to 2020. This is above average for all occupations. More jobs will be available to those with doctoral degrees in an applied specialty of psychology. The most jobs are projected for those with a specialist degree or doctoral degree in school psychology.

Psychology of Self Esteem, The (Book)

The Psychology of Self Esteem is a book written by Nathaniel Branden and published in 1969 about how choices and values influence self-esteem.

Definitions

- **Behavior therapy** is a psychotherapy approach that focuses on identifying and changing maladaptive behaviors. It is also referred to as behavioral therapy.
- **Behaviorism** is a theory of human behavior that limits the study of psychology to measurable or observable behavior.
- **Psychoanalysis** is a theory of human behavior and a form of therapy that explains behaviors as the result of unconscious, sexual, and biological instincts.
- **Self-esteem** is the personal evaluation of one's worth. It can range from high to low and is associated with an individual's emotions and behaviors.

Description

The Psychology of Self Esteem popularized the idea of self-esteem as a focus of psychology. Prior to its publication, this topic was seldom discussed. The author, Nathaniel Branden (1930–2014), was a follower of the famous Russian American philosopher Ayn Rand (1905–1982). *The Psychology of Self Esteem* is written in philosophical language. The book explains that individuals are rational beings in full control of their destiny. Those who take control of their lives are likely to view themselves positively and have high self-esteem. Those who do not take control of their lives are likely to view themselves negatively and have low self-esteem. Branden explains that human beings are different from animals because they need to make sense of their lives. Examples of such concepts include "meaning" and "humanity." While animals can have awareness, only humans have the ability to make conscious choices about how they will live life. *The Psychology of Self Esteem* disagrees with the two main schools of psychology of the time, psychoanalysis and behaviorism. Branden believes that psychoanalysis saw individuals as puppets driven by unconscious drives. He criticizes behaviorism and behavior therapy for treating individuals like robots who just responded to stimuli. Instead, he insists that individuals are able to use concepts and self-awareness to make conscious choices and take control of their lives. If individuals fail to use this ability, they will become unhappy. In order to truly love themselves, individuals must actively use their ability to think.

The Psychology of Self Esteem discusses the difference between emotions and rational (logical) thought. Branden argues that individuals should put their values and intellectual knowledge ahead of their feelings. This is psychological maturity and is the opposite of acting on irrational emotions. He calls that

psychological immaturity and it results in self-doubt, unhappiness, and low self-esteem. Branden believed that happiness was not so much a feeling but rather the result of living according to our values. For example, individuals who seek immediate pleasure or the approval of others will not have much self-esteem and will be unhappy. However, those who are guided by facts and behave rationally will be happy. Branden explains that psychological pain was a sign of unhealthy choices. This is similar to how physical pain is a sign of an unhealthy body. This pain alerts individuals to the need to change. *The Psychology of Self Esteem* makes the case that self-esteem is not a luxury but rather a core need for all individuals.

Psychopathic Personality

Psychopathic personality disorder is a mental disorder characterized by amoral behavior, extreme self-centeredness, and the inability to love and understand others' feelings (empathy). It is also referred to as psychopath and psychopathy.

Definitions

- **Antisocial personality disorder** is a mental disorder characterized by a pattern of disregarding and violating social norms (rights of others).
- **DSM** stands for the *Diagnostic and Statistical Manual of Mental Disorders*, which is the handbook mental health professionals use to diagnose mental disorders. The current edition (fifth) is known as DSM-5.
- **PDM** stands for the *Psychodynamic Diagnostic Manual;* it is a diagnostic framework that characterizes individuals in terms of their psychodynamics.
- **Personality disorder** is a long-standing pattern of maladaptive (problematic) behaviors, thoughts, and emotions that deviates from the accepted norms of an individual's culture.
- **Sociopathic personality** is a form of antisocial personality disorder that manifests as amoral and criminal behavior and lacks a sense of moral responsibility or social conscience. It is also known as sociopathy and sociopath.

Description and Diagnosis

Psychopathic personality disorder is a personality disorder that manifests as amoral behavior, inability to love and be empathic, extreme self-centeredness, and failure to learn from experience. While the PDM uses the original term "psychopathic," the DSM uses the more contemporary term "antisocial" for this personality disorder. However, many individuals with psychopathic personality do not meet DSM-5 criteria for the antisocial personality disorder since they disregard social norms. Conversely, many who meet DSM criteria for antisocial personality do not exhibit some or all of the characteristic features of the psychopathic. Some individuals with psychopathic personality disorder can function well in some jobs and work settings where their psychopathic behavior is considered socially acceptable and even rewarded. Although some psychopathic individuals are held legally accountable for their actions, others are able to evade responsibility for the harm they do to others.

Sociopathic personality has been used interchangeably with psychopathic personality. Currently, clinicians and researchers tend to distinguish them in terms of behavior and etiology (cause). For example, there are specific deficits in psychopaths that distinguish

them from sociopaths. These include interpersonal deficits, such as grandiosity, arrogance, and deceitfulness, as well as affective deficits, such as a lack of guilt. In addition, psychopaths are characterized with global deficits of empathy. In contrast, sociopaths can emotionally attach to others and may feel bad when they hurt those individuals to whom they are attached. Yet sociopaths can lack empathy and attachment toward society in general. As a result, they are not likely to feel guilty in harming a stranger or breaking laws. So while both psychopaths and sociopaths are capable of committing hateful crimes, the psychopath can commit crimes against family members or friends and feel little or no remorse. Also, the etiology of psychopathy appears to be largely inherited, whereas sociopathy results more from environmental factors such as poverty, exposure to violence, and overly permissive or neglectful parenting. For diagnostic purposes, the last three editions of the *Diagnostic and Statistical Manual of Mental Disorders*, including DSM-5, use the designation "antisocial personality disorder" in place of psychopathic or sociopathic personality.

Psychopathic individuals can be charming and are quite good at "reading" others' emotions and needs. While they tend to be sensitive to feelings and social cues, their own expression of emotions is often insincere and intended to manipulate. They will emotionally disconnect and lose interest in others they no longer consider useful to them. Another indication of their lack of empathy is their inability to describe their own emotional reactions in depth. Not surprisingly, these individuals experience anxiety less frequently and intensely than non-psychopathic individuals. Furthermore, these individuals tend to seek out emotional stimulation (thrill-seeking) and so engage in high-risk activities.

According to the *Psychodynamic Diagnostic Manual* the psychopathic personality disorder is diagnosable by the following criteria. Individuals exhibit high threshold for emotional stimulation and aggressiveness. They are preoccupied with manipulating others. Their basic emotions tend to be rage and envy. Their basic belief or view of themselves is that they are omnipotent, the belief that they can make anything happen and control everything. Their basic belief or view of others is that everyone is selfish, manipulative, or dishonorable. Furthermore, their basic way of defending themselves is attempt to control everything around them.

Treatment

Treatment of individuals with this disorder tends to be challenging. Attempts to engage these individuals in therapy with kindness, empathy, and compassionate care are likely to fail. The reason is that psychopaths consider caring and kindness to be ineffective and illusory. So they will devalue therapists who manifest these qualities. In contrast, therapists can effectively engage such individuals if they convey a powerful presence, act with scrupulous integrity, and recognize that these individuals want to be acknowledged as powerful. These individuals tend to be more receptive to therapeutic influence when they have experienced a decline in physical power and influence. Having experienced limits to omnipotence increases their receptivity to engaging in the process of therapy.

Psychopharmacology

Psychopharmacology is the study of drugs that affect thinking, feeling, and behavior. It includes

antipsychotic, antianxiety, antidepressant, and antimanic medications.

Definitions

- **Antianxiety medications** are prescription drugs that relieve anxiety symptoms. They are also called anxiolytics or tranquilizers.
- **Antidepressant medications** are prescription drugs that are primarily used to treat depression and depressive disorders. They are known as antidepressants.
- **Antimanic medications** are prescription drugs that are primarily used to treat bipolar disorder (manic depression). They are also called antimanic and mood stabilizers.
- **Antipsychotic medications** are prescription drugs used to treat psychotic disorders. They are sometimes referred to as antipsychotics or neuroleptics.

Description

Psychopharmacology is the scientific study of drugs that affect mental and emotional functions. It focuses on the pharmacology (drug functions) of cognition, emotion, and behavior. Because it emphasizes drugs that affect abnormalities in thought, affect, and behavior, it is central to psychiatry practice. Psychopharmacology is primarily concerned with the major classes of drugs that treat four major categories of psychiatric disorder: anxiety, depression, mania, and schizophrenia. Each of these major drug classes are briefly described here.

Antianxiety medications. Antianxiety medications, or "anxiolytics," have a powerful effect on dampening the central nervous system when it is overexcited. This class of medication is prescribed to reduce feelings of tension and anxiety, as well as to induce sleep. Antianxiety medications are usually taken orally, and although they work differently, they all produce a pleasant drowsy or calming effect. When they are used for a long time, tolerance can develop. This means that larger doses are needed to achieve the initial effects. Continued use can lead to physical dependence and withdrawal symptoms when the dosage is reduced or stopped. Common medications in this class are Valium, Librium, Xanax, Halcion, and Seconal.

Antidepressant medications. Antidepressant medications are used primarily to reduce symptoms of depression. They also have been found useful in the treatment of seasonal affective disorder. Some individuals with anxiety disorders, eating disorders, pain syndromes, migraine headache, smoking cessation, fibromyalgia, and sleep disorders have found these medications helpful. The specific antidepressant prescribed depends on the particular array of symptoms. There are several different types, and each works by altering the level or activity of neurotransmitters (chemical messengers) in the brain. The most common type are selective serotonin reuptake inhibitors (SSRIs). These include Celexa, Lexapro, Prozac, Luvox, Paxil, and Zoloft.

Antimanic medications. Antimanic medications are used to balance neurotransmitters (chemical messengers) in the brain that control emotional states and behavior. They are effective in treating and preventing the return of both manic and depressive episodes in bipolar disorder. They are also helpful in treating mood problems associated with schizophrenia. There are several medications in this class of drugs. These include lithium, Tegretol, Lamictal, Neurontin, and Depakote.

Antipsychotic medications. Antipsychotic medications are used to treat psychotic disorders, ranging from schizophrenia, delusional disorder, and psychotic depression. They are also be used to treat the psychosis associated with other medical conditions, such as dementia. These medications work by blocking dopamine (a chemical messenger) in the brain. There are two classes of these drugs: "typical" and "atypical" antipsychotics. The most commonly used typical antipsychotic today is Haldol. The most commonly used atypical antipsychotic today are Clozaril, Risperdal, Zyprexa, and Geodon.

Psychosexual Development, Stages of

The stages of psychosexual development are based on Sigmund Freud's theory of sexual motivation in the process of development through the life span.

Definitions

- **Oedipus complex** is the desire for sexual involvement with the parent of the opposite sex and a concurrent sense of rivalry with the parent of the same sex. Freud considered the complex a critical stage in normal developmental.
- **Psychoanalysis** is a theory of human behavior and a form of therapy based on psychoanalytic theory. In psychoanalysis clients are encouraged to talk freely about personal experiences, particularly their early childhood and dreams. It was initially developed by Sigmund Freud.
- **Psychoanalytic theory** is a psychological theory that explains behaviors and perceptions as the result of unconscious, sexual, and biological instincts. It was originally developed by Sigmund Freud.

Description

The psychosexual stages of development is a concept from Sigmund Freud (1856–1939). Freud was a medical doctor who developed psychoanalytic theory. Freud's theories were heavily based on sexual motivation. He believed that even as children there is a connection to sexual motivators. Freud felt it was important to look into the symbolic meanings and not just the actual behavior in order to have a more complete understanding of the person.

Freud felt that early parental interactions strongly shaped the development of a child. Working with clients Freud would analyze his patients and ultimately became convinced that their problems were all results of experiences from early in their life. He felt that as children grow their focus of pleasure shifts through different parts of their body, resulting in the five stages of psychosexual development: oral, anal, phallic, latency, and genital. If conflicts in these stages are unresolved or overindulged, problems will occur later in life.

The first stage is oral, which is considered to be from birth to approximately age one and a half. At this point in their life, infants' pleasure stems from their mouth. Too much or too little stimulation and satisfaction can result in oral fixation later in life, which may be seen in traits either actively such as smoking or symbolically such as being overdependent.

The second stage is anal, which is from about one to three years old. At this stage the anal region provides the greatest pleasure to the toddler. Toilet training that is considered too harsh or indulgent can lead to the idea of anal fixation. As an adult, this can look like being greedy or messy.

The phallic stage is from about age three to six. Here pleasure is achieved through genitalia. Freud felt at this stage the child developed sexual desires toward the opposite-sex parent and jealousy toward the same-sex parent. This is often referenced as the Oedipus complex. If the child struggles with balancing these emotions, it may lead to deviant behavior in adulthood.

The fourth stage is latency, which is from age six to puberty. Here sexual desires are repressed and energy is focused into play and work. The final stage is genital, which is from puberty through adulthood. Here sexual needs become the critical motivator behind behavior. This is considered to be a reawaking of sexual pleasure that the person can reach with someone outside of his or her family.

While this idea originally gained great popularity, it currently receives little attention. Modern research does not support the positions that Freud once took and looks to other theories of development, such as that of Erik Erikson and Jean Piaget.

Psychosis

Psychosis is a severe mental condition in which an individual loses touch with reality.

Definitions

- **Antipsychotic medications** are prescribed drugs that are intended to reduce psychotic symptoms. It is also known as neuroleptics.
- **Catatonia** is disorganized, limited, or complete absence of normal physical behavior.
- **Delusions** are fixed false beliefs that persist despite contrary evidence.
- **DSM-5** stands for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, which is a diagnostic system used by professionals to identify mental disorders with specific diagnostic criteria.
- **Hallucinations** are false or distorted sensory perceptions that appear to be real perceptions that are generated by the mind rather than by an external stimuli.
- **Neurosis** is an outdated but still used term for various mental disorders characterized by considerable anxiety, irrational fears, depression, or obsessive thoughts.
- **Psychotic symptoms** are a group of severe symptoms that include hallucinations, delusions, disordered thinking, or disorganized movement.
- **Schizophrenia spectrum and other psychotic disorders** are a group of mental disorders characterized by psychotic features. These disorders include schizophrenia, delusional disorder, and brief psychotic disorder.

Description

Psychosis is a mental condition whereby an individual's subjective (private) experience is severely disconnected with reality. Psychosis is characterized by psychotic symptoms such as hallucination, delusions, and catatonic behavior. Individuals who are experiencing psychosis may have false perceptions involving any of their five senses (hallucinations). For example, they may hear voices or see things that others don't see. They may be extremely paranoid and convey elaborate stories (delusions). They may be completely incoherent or move erratically and without purpose (catatonia). Although the symptoms of psychosis are variable, they all share the principal attribute of a significant disruption in their normal experience of reality. Psychosis is distinguished from neurosis. With neurosis individuals do experience an impairment of functioning. However, it is less severe than with psychosis and they maintain full awareness of reality.

Psychosis is not a standalone disorder, but a broadly defined condition that is often associated with certain mental disorders, medical illnesses, and drugs. Psychosis is usually experienced as one of the DSM-5 schizophrenia spectrum and other psychotic disorders, which are also referred to as psychotic disorders.

Treatment for psychotic disorders usually involves antipsychotic medications. Psychosis is also associated with a number of medical conditions such as Alzheimer's, stroke, and certain infectious diseases. For individuals with such conditions along with psychotic symptoms, treatment is first aimed at the underlying medical condition in the hope of reducing the symptoms of psychosis. If psychotic symptoms persist, then antipsychotic medication is added. Psychosis is also associated with a number of drugs, including LSD, cocaine, methamphetamine, and alcohol. For individuals with drug- or substance-induced psychoses, symptoms typically subside with the body's breakdown and elimination of the substance. Also, some individuals may manifest psychotic symptoms when under extreme stress. Generally, the appearance of

psychotic symptoms whatever the cause often involves hospitalization.

Psychosocial Development, Stages of

The stages of psychosocial development are based on Erik Erikson's concept of personality development throughout the life span.

Description

The stages of psychosocial development is a concept established by Erik Erikson (1902–1994). Erikson was an American development psychologist. He originally studied with Sigmund Freud but then went on to propose his own theory of personality development that differed from the psychosexual stages of development. Erikson's theory put far less emphasis on the sexual motivators. Erikson felt the main motivator for people was that of social desires to connect with others.

Development

The psychosocial stages of development are sometimes referred to as the "Eight Stages of Man." In each of the stages the individual faces a crisis or dilemma to be resolved. The crisis is not necessarily a catastrophe but rather a turning point for the individual. With successful resolution the person will be a more emotionally healthy person.

The first stage of trust versus mistrust occurs in infancy. This stage is largely connected to the caregiver. The second stage is also in infancy and begins at about ages 1 to 3; this is the stage of autonomy versus shame and doubt. The infant is becoming more independent. If infants experience punishment that is too harsh or are restrained too much, they develop an increasing sense of shame or doubt. The third stage is in early childhood from about ages 3 to 6 and is called initiative versus guilt. Children are facing more tasks and getting more responsibility with the hope of achieving purpose. If this is not achieved, children may experience guilt over their actions. The fourth stage of industry versus inferiority occurs at about ages 6 to 12 where the hope is to help instill competence in children. The fifth stage identity versus role confusion is from ages 12 to 20 where they begin making choices about their goals and future with the hope of establishing themselves. The sixth stage is intimacy versus isolation, which occurs in young adulthood. This stage focuses on love and the ability to share oneself with others. The seventh stage of generativity versus stagnation occurs in middle adulthood, which focuses on giving back to the next generation. The final stage of ego integrity versus despair is in late adulthood, with the goal being wisdom where adults come to terms with their success and failures in life.

Erikson felt that even if one of these crises or stages went unresolved, it could be resolved later in life. He was an optimist and his theory is considered to be very appealing to those in the helping professions. However, some theorists have raised concern over Erikson's final stage, especially since he himself had not yet reached that stage in his own life when he wrote it. Later in his life when his health was failing, he and his wife, Joan—a frequent collaborator—began to reconsider the eighth stage. Joan Erikson (1902–1997) created a ninth stage she called transcendence. Here the person confronts all previous eight stages again in hopes of reaching peace.

Psychosomatic Disorder and Psychosomatic Medicine

"Psychosomatic" refers to the belief that the mind (psyche) influences diseases affecting the body (soma). Psychosomatic medicine is the branch of medicine that emphasizes the role of psychological factors in causing and treating medical conditions.

Definitions

- **Behavioral medicine** is an interdisciplinary form of modern medicine that integrates the behavioral, biomedical, and social sciences.
- **Biopsychosocial model** is a way of conceptualizing (thinking about) health and illness in terms of biological, psychological, and social factors rather than purely in biological terms.
- **Psychoanalytic psychology** is the form of psychology largely developed by the work of Sigmund Freud, which emphasizes the conflicts and compromises between the unconscious and conscious mind.
- **Psychosomatic illness or disorder** refers to a condition characterized by physical symptoms that result from psychological factors.
- **Psychosomatic model** is a way of conceptualizing (thinking about) certain medical conditions as caused by or resulting from psychological factors.
- **Somatoform** is a group of psychopathologies marked by physical symptoms that suggest a general medical condition but do not manifest in an actual physiological disease.

Description

"Psychosomatic" describes the belief that the mind (psyche) influences diseases affecting the body (soma). Psychosomatic medicine is the approach to clinical practice based on this belief. The term "psychosomatic" is also used to describe psychological factors that worsen or trigger a medical condition. Psychological factors may initiate, worsen, or maintain psychosomatic illnesses. The underlying assumption of psychosomatic illnesses is that human beings are composed of integrated systems. For example, there is an interrelationship between body and mind. The immune system can be compromised by extreme emotion or psychopathology. Depression and anxiety are common psychological elements that contribute to the manifestation or worsening of physiological illness. It is common for individuals to be minimally afflicted by psychosomatic ailments. A psychosomatic disorder is similar to but very different from somatoform disorders. The primary difference is that psychosomatic diseases are diagnosable by medical testing. In contrast, in somatoform disorders, presenting symptoms are not due to general medical condition.

Psychosomatic presentations may not include detectable toxins, viruses, bacteria, or other medical cause. The psychosomatic illness itself is medically diagnosable, however, even if the cause remains elusive to medical examination. Psychological assessment often offers clues to the root cause of psychosomatic complaints. The emotional state or psychopathology of the ill person may be the only available explanation for his or her presenting physiological complaint. Psychosomatic complaints may include various pain presentations, gastrointestinal problems, sexual dysfunction, skin disturbances, and respiratory and cardiovascular disturbances. Asthma, hypertension, headaches, and skin disturbances such as rashes or hives are common psychosomatic ailments. These psychosomatic symptoms may be dismissed as faking illness to avoid responsibility (malingering). A highly skilled mental health professional will assess for possible contributions of personality and developmental abnormalities.

An individual's constitution and maturational patterns may indicate susceptibility to psychosomatic complaints. Poor ego integrity, poor self-image, and poor emotional awareness or sensitivity may also increase the probability of developing psychosomatic illnesses. Pervasive psychopathological views of self and others (schemas) may also contribute to psychosomatic disease.

Development and Current Status

Since the middle ages, Christianity's view of human nature has influenced both the philosophy of mind-body dualism and the practice of Western medicine based on it. Mind-body dualism views illness as either a medical condition caused by biological dysfunction, such as an infection, or a psychological dysfunction caused by trauma or evil spirits. The philosophical distinction between mind and body has been an ongoing discussion beginning with the Greek philosophers. But it was René Descartes (1596–1650), the French philosopher and physiologist, who provided the first systematic account of the mind-body relationship. He proposed that the immaterial mind and the material body are distinct substances (entities) but interact causally with each other. This means that mental events can cause physical events, just as physical events can cause mental events. Unfortunately, Descartes was unable to convincingly explain exactly how the mind can cause changes in the body, and vice versa.

Starting in the 1940s, an early version of psychosomatic medicine emerged. Franz Alexander (1891–1964) was the Hungarian American physician and psychoanalyst who is credited with advocating for one such psychosomatic viewpoint. His view of psychosomatic medicine was largely a psychological explanation that emphasized the power of the mind over the body. For example, Alexander believed that asthma was the body's response to unresolved dependency. Duodenal (stomach) ulcers were believed to be caused by frustration and emotional stress. Also, the belief was that rheumatoid arthritis was caused by repressed rebellion, while migraine headaches were caused by repressed hostility. This view of psychosomatic model began to wane as research determined that there was, in fact, both biological *and* psychological factors involved. For instance, research identified an infection with the *Helicobacter pylori* bacteria along with psychological stress as causative factors in duodenal ulcers. Around this time, psychiatrist George L. Engel (1913–1999) wrote about the need for a new medical model in a landmark article in *Science* in 1977. Engel proposed the biopsychosocial model that could integrate such an early psychosomatic model with the biomedical model.

Currently, there are several other psychological conceptualizations of the mind-body relationship. Each theory maintains its own ideas of contributive factors of psychosomatic illnesses. The psychoanalytic theory suggests that unconscious conflicts are the reason for psychosomatic conditions. The type of unconscious conflict will predict the type of physiological illness that is psychosomatically manifested. The psychodynamic theory suggests that various personality characteristics and traits react to stressful life events differently. Different life stressors interacting with different personality types lead to different physical diseases. In addition, certain personalities are more likely to develop certain physical illnesses. Psychosocial family systems theories state that dysfunctional families create emotional trauma for children and this is the cause for psychosomatic disease. The biological theories of psychosomatic disease suggest that there are genetic predispositions for psychological influence in illness. A more recent psychosomatic viewpoint views human beings as psychosomatic wholes. It integrates mind and body with a more unified view of life that encompasses polarities (opposing but attracting influences). For instance, in the being versus nonbeing polarity, while individuals are continually threatened by illness and nonbeing, they can constantly reassert their being by engaging in healthy behaviors. Health problems arise when the polarities become unbalanced. Such an understanding appears to avoid mind-body dualism and the overemphasis of the mind over the body in Alexander's viewpoint.

It is noteworthy that psychosomatic medicine became a certified subspecialty of the American Board of Psychiatry and Neurology in 2005. This certification acknowledges the expertise needed to diagnose and treat psychiatric disorders and symptoms in complex medically ill patients. This subspecialty includes

treatment of patients with acute or chronic medical, neurological, obstetrical, or surgical illness in which psychiatric illness is affecting their medical care and/or quality of life such as organ transplantation, heart disease, renal failure, cancer, stroke, traumatic brain injury, and high-risk pregnancy. Patients also may be those who have a psychiatric disorder that is the direct consequence of a primary medical condition, or a somatoform disorder or psychological factors affecting a general medical condition. Psychiatrists specializing in psychosomatic medicine provide services in general medical hospitals, on medical psychiatry inpatient units, and in primary care settings.

Psychotherapist

Psychotherapists offer a form of treatment known as talk therapy with individuals, couples, and families, in order to help clients overcome a wide range of psychological and emotional challenges. They are usually psychologists, mental health counselors, or social workers.

Description

Employing a variety of theoretical approaches, psychotherapists work to build rapport and trust with clients in an effort to help them address maladaptive thought processes, feelings, and behavior. Psychotherapists also help clients to understand and potentially resolve inner conflicts as well as to develop new and healthier ways of coping with life's many challenges. Although many different theoretical approaches are used by therapists today, the roots of psychotherapy are often traced back to the work of Sigmund Freud in the late 1800s in Vienna.

The role of a psychotherapist typically involves working with clients on a weekly or semiweekly basis in sessions lasting between 45 minutes and an hour on a mutually agreed-upon set of goals. Depending on the psychotherapist's training and specialty, clients may include children, adolescents, teens, adults, couples, families, and groups. Psychotherapists use a wide variety of theoretical approaches, such as cognitive behavior therapy, psychoanalysis, psychodynamic therapies, and humanistic therapies. "Psychotherapy" and "counseling" are terms that are often used interchangeably; however, while there is considerable overlap between these two, counseling often refers to shorter-term treatment (weeks or months) of a specific symptom or stressful situation. In contrast, psychotherapy is usually a longer-term treatment (months or even years) that addresses a client's maladaptive thought processes, rather than specific behaviors or problems.

There are a variety of job titles and training for psychotherapists based on their level of education, area of expertise, and their role. Before becoming a licensed therapist, training normally requires a graduate degree—most psychotherapists have a master's or doctoral degree with specialized training in psychological counselling. Psychiatrists, psychologists, licensed professional counselors, licensed clinical social workers, licensed marriage and family therapists, and psychiatric nurses are just some of the examples of mental health professionals who can provide psychotherapy. Notably, psychiatrists are medical doctors who are mental health specialists and who can prescribe medications, as well as offer psychotherapy.

Psychotherapy

Psychotherapy is a psychological method for achieving desired changes in thinking, feeling, and behavior. It is also called therapy and therapeutic counseling.

Description

According to the National Institutes for Mental Health, psychotherapy is a form of talk therapy that helps clients with a mental disorder understand their illness. It offers clients strategies and tools to address their maladaptive thoughts and behaviors. The goal is often to help clients cope with their symptoms and improve their levels of coping with everyday life by learning about their moods, feelings, thoughts, and behaviors. A treatment plan is created with an individual or family in order to establish appropriate treatment goals. The treatment plan is like a map that guides the clinician and helps to measure whether or not progress is being made in therapy. Talk therapy is appropriate for many people with mental health diagnoses; however, depending on the mental health issue facing a client, psychotherapy may be combined with medications prescribed by a psychiatrist or other mental health specialist.

Psychotherapy is often an effective way of helping people overcome a mental illness, whether it is a mild disturbance, such as an adjustment disorder, or something more severe, such as a personality disorder. A person who is suffering mentally or emotionally can work with a psychotherapist to improve his or her ability to cope with and manage specific challenges in his or her life. The client normally meets with the therapist weekly to discuss the challenges he or she is having. For example, the client may be experiencing difficulty with bitterness and resentment following a divorce, or parent may bring in a child who is cutting.

To address the presenting issue, the therapist may use a single therapeutic approach, such as cognitive behavior therapy, or multiple modalities based on what the client's concern may be. Psychotherapy can include a wide variety of theoretical approaches, such as cognitive behavior therapy, psychoanalysis, psychodynamic therapies, and humanistic therapies. "Psychotherapy" and "counseling" are terms that are often used interchangeably; however, while there is considerable overlap between these two, counseling often refers to shorter-term treatment (weeks or months) of a specific symptom or stressful situation.

In contrast, psychotherapy is usually a longer-term treatment (months or even years) that addresses a

client's maladaptive thought processes, rather than specific behaviors or problems. However, there is overlap between the two and counseling can often include psychotherapy and psychotherapy can often include counseling. Psychotherapy is often referred to as talk therapy, counseling, or just therapy.

Psychotherapy Integration

Psychotherapy integration is a process that treats individuals by using a combination of psychotherapy techniques.

Description

It is based on the understanding that while there are different approaches to psychotherapy, there are common factors that can be found in nearly every type of treatment. Therapists using psychotherapy integration believe that in order to understand human behavior, it's important to apply a variety of treatment theories. They have a theoretical understanding of various techniques and are aware that each treatment has limitations. However, when they combine techniques, they can create a synergistic effect that leads to a more effective treatment for the patient.

Development and Current Status

Psychotherapy integration was first named by the Society of Psychotherapy Integration (SEPI) when it formed in 1983. SEPI began publishing the *Journal of Psychotherapy Integration* in 1991. The movement, however, has roots going back many years. Publications have been talking about integrating or combining psychotherapy techniques for decades. Even Freud alluded to it in 1905 when he said that there are many ways and means of practicing psychotherapy and that all that lead to recovery are good.

Psychotherapy integration is often compared to eclectic therapy. Integration is a process that places importance on the theories of treatment. By contrast, eclectic therapy chooses methods because they work. Practitioners of eclectic therapy may choose therapies randomly, rather than based on what is likely to benefit their patient. To successfully practice psychotherapy integration, a therapist must have an understanding of a wide range of skills and knowledge, instead of specializing in one type of therapy.

The benefit of psychotherapy integration is that it is unencumbered by the possible limitations of any particular therapeutic approach. This allows the practitioner to be open and explore other therapy options to help their patients change. However, psychotherapy relies more these days on evidence-based practice. Because of this it's important for therapists and researchers to collaborate. However, in psychotherapy integration, most practitioners use the data they collect from their private practices, rather than from research. In fact, there has been little psychotherapy integration research in the past 20 years.

As a result, one of the goals of the psychotherapy integration community is to increase the effectiveness of psychotherapy by increasing research and integrating the findings into clinical practice. Closer ties between research and clinical practice will lead to a greater impact of psychotherapy and an increased understanding. It's also worthwhile to study the differences between individual therapists. Though the preferred approaches of most therapists are not much different from each other, some therapists perform better than others, and nearly all therapists have good results with their treatment specialties.

Research on this element could lead to guidelines to improve therapy. For many practitioners, psychotherapy integration represents the ability to combine the best parts of differing orientations and thereby develop more efficient treatments. Today, psychotherapy integration is internationally accepted and practiced, and is taught to most therapists in training. The objectives of the movement are to develop more effective intervention procedures by providing a greater understanding of the process of change. It is a popular approach to treating patients, which is likely to continue to be used worldwide.

Psychotherapy Skills and Competency

Psychotherapy skills involve therapeutic techniques, while psychotherapy competency involves the appropriate and effective use of those skills. Both are essential in the practice of evidenced-based psychotherapy.

Definitions

- **Accountability** is the expectation or requirement to conduct evaluations, particularly of outcomes, and to report performance information.
- **Capability** is the attitude to strive to achieve more than the minimal or required level of competency and the capacity to adapt competencies to changing circumstances.
- **Case conceptualization** is a method summarizing case information and an explanation or formulation and a strategy for planning and focusing treatment interventions to increase the likelihood of achieving treatment goals.

- **Competency** is the capacity to integrate technical skills along with knowledge and positive professional attitudes, which is reflected in the quality of clinical practice. It is developed through professional training and reflection and can be evaluated by external standards.
- **Core competencies** are the basic competencies common to the effective practice of all psychotherapeutic approaches. They include the therapeutic relationship, intervention planning, intervention implementation, and intervention evaluation and termination.
- **Evidence-based practice** is a form of practice that is based on integration of the best research evidence with clinical experience and client values.
- **Managed care** is a system of health care that controls costs by placing limits on physicians' fees and by restricting access to certain medical procedures and providers.
- **Master therapists** are psychotherapists who are considered by fellow therapists to be "the best of the best" in terms of expertise in psychotherapy.
- **Practice** is a method or process used to accomplish a goal or objective.
- **Psychotherapy** is a psychological method for achieving desired changes in thinking, feeling, and behavior. It is also called therapeutic counseling.
- **Skill** is a capacity that has been acquired through training.

Description

Psychotherapy skills and competency are required for the practice of highly effective psychotherapy. Both represent the therapist's contribution to positive therapeutic outcomes. Highly effective psychotherapy is competency based and is practiced by those who exhibit capability and can think, act, and reflect much like master therapists.

Core competencies are similar to but different from psychotherapy skills. Competencies are larger in scope than psychotherapy skills. Skills are but one component of a competency. That means it is possible to master a skill and not necessarily develop its related competency. For example, one can master a skill but not know how or when to appropriately and effectively utilize that skill. Competencies require thinking and acting like an effective and ethically and culturally sensitive therapist in addition to the application of a specific clinical skill. Competencies inform the clinician how and when to use each therapeutic skill. A competent psychotherapist is able to put skills into practice with wisdom (knowledge) and compassion (attitude). Four core clinical competencies are briefly described next along with their related skills.

The most basic and important of the core competencies is the establishment of an effective therapeutic alliance (relationship). The therapist–client relationship is the most significant predictor of therapeutic outcomes. Authentic human connection can be therapeutic in and of itself. Intervention planning is a second important core competency. This competency requires assessment skills and a sufficient understanding of client characteristics, such as culture and treatment preference which form the basis of a case conceptualization. Intervention planning is informed by the diagnosis of a client's presentation. Determining a diagnosis requires a specialized set of assessment skill. Another set of treatment planning skills is needed for predicting obstacles to treatment. Understanding the unique obstacles to the treatment of each client facilitates the implementation of interventions. Because therapeutic interventions have better outcomes when they are tailored to the unique culture and preference of the client, specialized skills in planning culturally sensitive treatments are also needed.

Intervention implementation is another core competency. There are several essential skills associated with this competency. Implementing the various interventions requires specific skills for modifying a client's maladaptive thoughts, behaviors, feelings, and interpersonal relationships. In addition, other skills are needed to establish and maintain the treatment focus. To promote successful therapeutic outcomes, the core

competency of monitoring treatment progress and evaluating interventions is essential. The evaluation of the success of therapeutic interventions is a fundamental aspect of the practice of highly effective therapy. This competency allows a psychotherapist to monitor therapeutic progress and alter it as necessary. Evaluation of therapy helps the therapist and client work effectively together to achieve therapeutic goals and prepare for terminating the therapeutic relationship. Even highly effective therapists are able to appraise and enhance their counseling competencies through the use of active and ongoing reflection and guidance offered by a clinical supervisor.

Development and Current Status

The professional understanding of psychotherapy skills and competencies has undergone much development. Several have contributed to this development, including Len Sperry (1943–), an American psychologist and physician. He developed a systematic model of the core competencies that are common to psychiatry, psychology, marital and family therapy, counseling, and social work. This model is a synthesis of the various and sometimes competing clinical competencies. It provides a unified language and a way of categorizing the various competencies into a model that is easily teachable and researchable. The model is particularly relevant in training mental health professionals. There has been a significant paradigm shift in the training and practice of psychotherapy.

Changes to the health-care system effect mental health and psychological services in the United States. Many of these changes are the result of the increasing expectation for accountability. Accountability is maintained in part through the use of evidence-based practices. Evidence-based treatments are largely about the effort to get the best results for less money and in the shortest amount of time. Resources for health-care interventions are limited. This fact has created an effort to conduct medical and psychological practice in the most efficient manner possible. However, all things being equal, the most ethical mental health treatment is one that achieves therapeutic goals in the least amount of time. Managed care was established to increase the efficiency and cost effectiveness of health care. Evidence-based practice has a critical role in managed care. Managed care encourages and often requires health-care professionals to incorporate evidence-based treatments into the health-care process. As a result of this accountability movement, the training and practice of psychotherapy has become more competency based.

Standards of psychotherapy practice have evolved in the recent past. Because of both accountability and psychotherapy research, new psychotherapy skills, competencies, and standards of practice have emerged. There has been a distinct shift away from the previous focus on requirement-based standards and training. Requirement-based standards and training focused primarily on meeting degree requirements, logging supervised hours, and passing written licensure examinations. But meeting requirements does not demonstrate competency in the practice of psychotherapy. This contrasts with competency-based standards and training, which focus on demonstrating mastery of the core competencies of psychotherapy. Competencies require the critical thinking, analysis, professional judgment, and attitudinal stance to effectively implement evidence-based standards of practice. It is predicted that competency-based training will increasingly become the standard of education of therapists. The reason this will happen is the increasing demand for accountability in the guise of evidence-based practice. When treatment is informed by research-based practices and skills, the therapist' expertise, and the client's needs, expectations, and values, effective psychotherapy is likely to result, and everybody wins.

Psychotherapy Stages and Process

Psychotherapy stages describe the natural progression that occurs within the psychotherapy process. It begins with developing a therapeutic relationship and ends with termination.

Definitions

- **Assimilative integration** occurs when one theoretical orientation primarily informs the psychotherapeutic process and techniques of other theories are deliberately adjunctive.
- **Common factors** are the similarities among theories of psychotherapy and the belief that these common factors are the real therapeutic factors. They are also known as convergence factors.
- **Evidence-based practice** is a form of practice that is based on integration of the best research evidence with clinical experience and client values.
- **Managed care** is a system of health care that controls costs by placing limits on physicians' fees and by restricting access to certain medical procedures and providers.
- **Psychotherapy** is a psychological method for achieving desired changes in thinking, feeling, and behavior. It is also called therapeutic counseling.
- **Technical eclecticism** is the psychotherapeutic use of intervention techniques from various theories without endorsing the theories themselves.
- **Theoretical integration** is the assimilation of two or more theories of psychotherapy.
- **Therapeutic alliance** is the therapeutic relationship between therapist and client that occurs within the context of psychotherapy and is characterized by an affective bond leading to the negotiation of working goals and tasks, as well as explanations of problems and expectations for his or her treatment.
- **Transtheoretical model** is an integrative approach to psychotherapy that identifies the processes of change, the stages of change, and levels of change to tailor treatment to the client.

Description

Psychotherapy stages are a way of conceptualizing (thinking about) the psychotherapy or counseling process. These stages reflect the changing emphasis of psychotherapy over time, which progresses from one stage to the next. Basically, psychotherapy has a beginning, a middle, and an end. Typically, these stages are progressively focused on over time. The first few sessions typically focus on the earlier counseling stages. The therapeutic counseling process works through the remaining stages. The last few psychotherapy sessions usually focus on the last stages or stages of the process. Alternatively, each 50-minute session may run through all six of the stages. The number of sessions required for effective treatment varies based on therapeutic goals, diagnosis, the type of psychotherapeutic interventions utilized, and available resources. Based on these factors, managed care will dictate the number of sessions by limiting their financial contribution. Due to the influence of managed care, the psychotherapy process typically lasts 6 to 12 sessions. Despite these imposed limitations there is a measure of consistency to all psychotherapy processes. The uniformity of the counseling process is maintained despite the varied theoretical orientations utilized by psychotherapists. There are considerable commonalities among the various psychotherapy approaches. These convergence factors characterize the stages of psychotherapy. These stages provide a structure to the therapeutic process. While there is yet to be consensus about the number of

stages of successful psychotherapy, a six-stage process is described here.

Stage one emphasizes developing a therapeutic alliance (relationship) with the client. The establishment of an effective therapeutic alliance is essential for psychotherapy to be successful. That is because the therapeutic relationship is the best predictor of therapeutic outcomes. One of the most valuable therapist-offered conditions is a nonjudgmental and empathetic presence. It is important that the psychotherapist communicate a sense of unconditional positive regard. These therapist-offered conditions help to establish rapport, promote client's sense of acceptance, and increase the chance of developing an effective therapeutic alliance. Stage two is concerned with assessment and diagnosis. Assessment and diagnosis informs all stages of the therapeutic process, including the development and maintenance of a therapeutic alliance. The third stage refers to the formulation of counseling goals. Goals of psychotherapy should be agreed upon by both client and therapist. The goals of psychotherapy provide purpose and direction to the therapeutic relationship. Therapeutic goals foster client motivation for change, provide a contextual framework for psychoeducation, and allow evaluation of therapeutic outcomes.

After the goals of therapeutic counseling have been agreed upon, treatment interventions can be planned. Stage four develops a treatment formulation specifying specific treatment targets that reflect therapeutic goals. Interventions are personalized for the client's needs and therapeutic obstacles are predicted. This stage also is devoted to the problem solving necessary to navigate these therapeutic obstacles. Surmounting obstacles to treatment is a major component of client change and achievement of successful therapeutic outcomes. The last counseling stage dedicated directly to the client–counselor relationship is stage five. Stage five prepares a client for termination and schedules follow-up work as necessary. One of the most preferable outcomes to highly effective therapy is for the client to develop the capacity to function as his or her own therapist. More frequently, a client and therapist will both agree that the client has made sufficient progress toward therapeutic goals. Termination also can refer to a stage of client change that is stable enough to reduce the likelihood of relapse. At this point, psychotherapy can be terminated. There are four components to successful termination of the therapeutic relationship. They are the discussion of the end of psychotherapy, a review of the course of psychotherapy, providing closure to therapist–client relationship, and planning for the future. Highly effective therapy can be very influential in the life of a client. It is critical that therapists allow for processing of the experience and discussions about the client's future goals. Finally, stage six involves evaluation of the process and outcomes of the therapy.

Development and Current Status

"Psychotherapy stages" refer to the art and science of the psychotherapy process. Psychotherapists must undergo a subjective process of implementing the evidence-based knowledge and techniques while remaining interpersonally connected to clients in a meaningful way. Clearly there is an art and a science to the psychotherapy stages. There is also consensus that an effective psychotherapy process is related to positive therapeutic outcomes. While there is some research on topics related to specific aspects of the therapeutic process, there is much less on the overall stages and process of psychotherapy. Instead, research commonly studies one or more static elements of the stages. While useful in some respect, this research has limited clinical value. However, research on "common factors" among the various psychotherapy approaches has been clinically useful. Common factors were first described by psychologist Saul Rosenzweig (1907–2004) in a paper published in 1936. Since then three distinct approaches to common or integrative practice have been identified. They are technical eclecticism, theoretical integration, and assimilative integration. To date, the most clinically useful way of specifying commonalities in the psychotherapy process among all psychotherapy approaches is called the transtheoretical model. It was introduced in 1983. Other models have since been published with varying number of psychotherapy stages. Typically, the content of the stages is similar among different theories. Differences are largely related to the organization and grouping of the stage processes. This research not only informs the clinical practice of

psychotherapy but is also essential in the training of psychotherapists.

Publication Manual of the American Psychological Association

The *Publication Manual of the American Psychological Association* is a reference book that provides standards for academic writing. It is also known as the APA Style Guide.

Definition

- **American Psychological Association** is the largest professional organization of psychologists in the United Stated and Canada. It publishes the *Publication Manual of the American Psychological Association*.

Description

The *Publication Manual of the American Psychological Association* is a reference book that provides specific guidelines for scientific writing. It is intended to be used for those writing about behavioral and social sciences; however, it has become the standard for writing in many other disciplines such as education, business, and nursing. The *Publication Manual* is used by students as well as professionals. Its purpose is to make communication clear so readers understand the information presented. The *Publication Manual* covers topics such as grammar, writing style, spelling, punctuation, word choice, quotations, capitalization, and abbreviations. It also describes how to create bibliography and reference pages. This specific way of writing is commonly referred to as "APA style." The *Publication Manual* includes instructions for preparing manuscripts to submit to academic journals. These instructions cover standards regarding title pages, appendices, page indentation, margins, and numbering. Guidelines are also offered to reduce bias and discrimination with regard to race, gender, sexual orientation, and ethnicity. Also included is information about copyrights, permissions, and reprints for published articles. Many professional organizations, such as the American Counseling Association, use the *Publication Manual* as the standard for publishing in their journals.

The idea for the *Publication Manual* began in a meeting in 1928. Publishing editors from the fields of anthropology and psychology came together to create instructions for writing journal manuscripts. These instructions were initially meant to give authors guidelines to reference. They were not intended to be the strict rules they are often seen as today. The first manual was only seven pages long. It was published in 1929 in the *Psychological Bulletin*, which came before the *Publication Manual*. The first official edition of the *Publication Manual* came out in 1952. It was 60 pages in length. Since that time, the *Publication Manual* has been revised six times. Later revisions occurred in 1957, 1967, 1974, 1983, 1994, and 2001. The most recent sixth edition was published in 2010 and is 272 pages. As new technology and media became available for research, new guidelines were included in the *Publication Manual*. For example, the sixth edition addresses how to cite Internet message boards, podcasts, and wikis. The sixth edition also maintains a companion website.

Pyromania

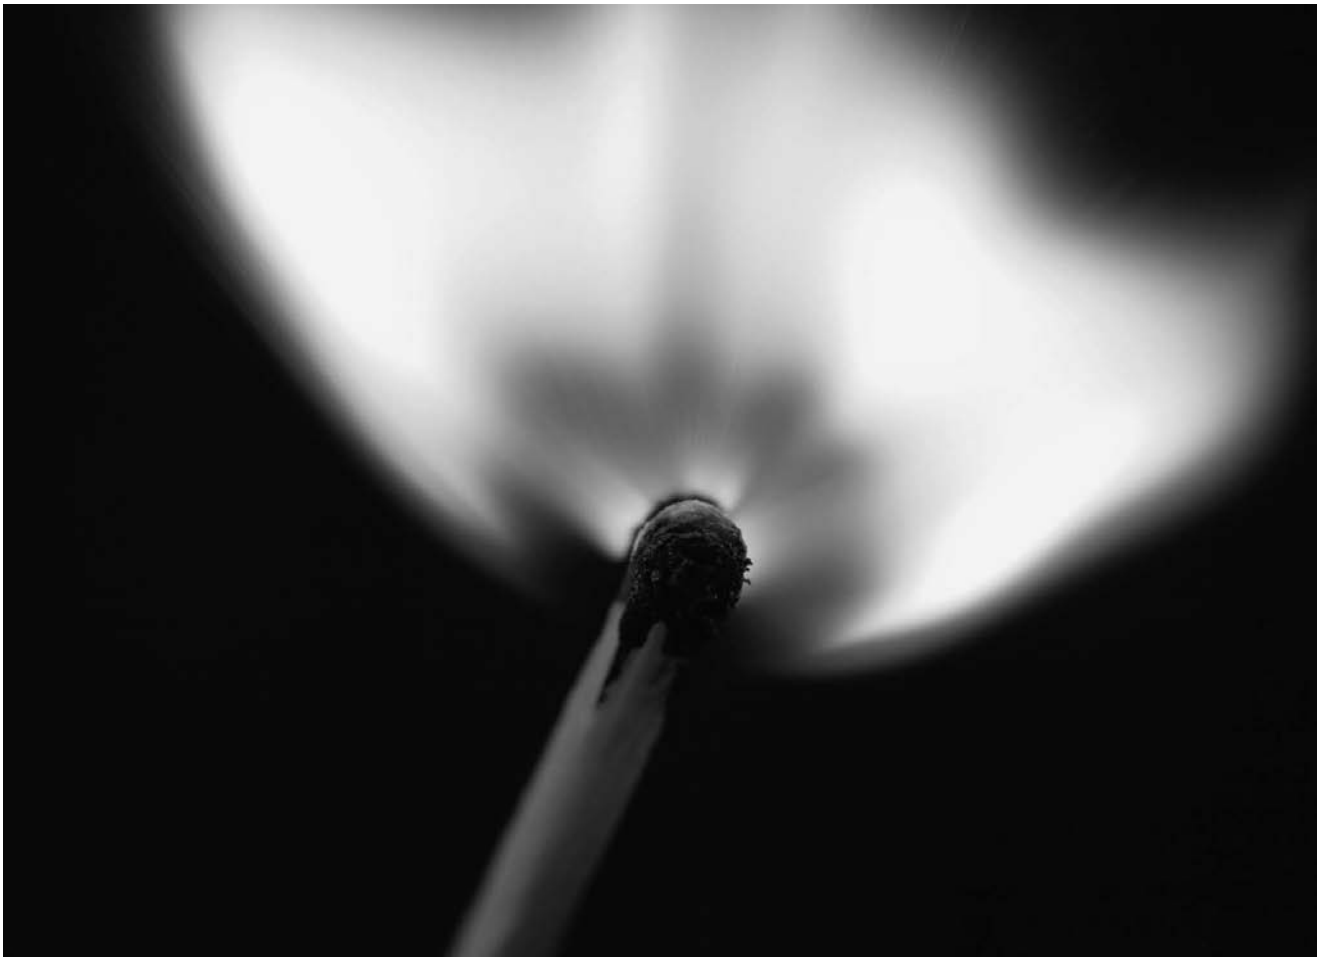
Pyromania is a mental disorder characterized by intentional fire setting for pleasure or satisfaction.

Definitions

- **Cognitive behavior therapy** is a form of psychotherapy that focuses on changing maladaptive (faulty) behaviors, emotions, and thoughts. It is also known as CBT.
- **Cognitive restructuring** is a psychotherapy technique for identifying maladaptive (unhealthy) thoughts and changing them to a more accurate view of a situation.
- **Conduct disorder** is a disorder diagnosed in childhood or adolescence characterized by repeated and persistent pattern of behavior in which the basic rights of others are violated.
- **Delusions** are fixed false beliefs that persist despite contrary evidence.
- **Depression** is an emotional state characterized by feelings of sadness, low self-esteem, guilt, or the reduced ability to enjoy life. It is not considered a disorder unless it significantly disrupts one's daily functioning.
- **DSM-5** stands for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, which is a diagnostic system used by professionals to identify mental disorders with specific diagnostic criteria.
- **Hallucinations** are false or distorted sensory perceptions that appear to be real perceptions that are generated by the mind rather than external stimuli.
- **Impulse control** is the degree to which an individual can control the impulse to act or the desire for immediate gratification.
- **Mood disorders** is a group of diagnoses in the DSM-5 classification system where a disturbance in the individual's mood is presumed to be the main underlying feature.
- **Obsessive-compulsive disorder** is a mental health disorder characterized by repeated and unwanted thoughts and feelings (obsessions) or behaviors that one feels driven to perform (compulsions). It is commonly referred to OCD.
- **Paranoia** is an unfounded or exaggerated distrust or suspiciousness of others.
- **Psychotic features** are characteristics of psychotic disorders: delusions, hallucinations, disorganized thinking and speech, grossly disorganized or abnormal motor behavior, and negative symptom (e.g., lack of initiative and diminished emotional expression).
- **Sexual abuse** involves nonconsensual contact of any kind, coercing an elder to witness behaviors.
- **Substance abuse disorders** are characterized by a pattern of continued pathological use of medication, which results in distress and significant impairment in several areas of an individual's life.

Description and Diagnosis

Pyromania is one of the DSM-5 disruptive, impulse-control, and conduct disorders. It is characterized by the inability to resist fire setting. Individuals engage in this behavior to achieve relief of tension and immediate gratification despite potentially negative or harmful consequences. The presence of several episodes



Pyromania is a mental disorder characterized by intentional fire-setting for pleasure or satisfaction. (Dr_harry/Dreamstime .com)

of intentional and purposeful fire setting characterizes this disorder. Individuals with this disorder usually experience emotional arousal and tension prior to the act of setting a fire. They have a fascination with, interest in, or attraction to fire, and may set off fire alarms in stores and schools. They often take pleasure in anything associated with fires (e.g., fire departments and fire equipment). Individuals with this disorder repeatedly fail to resist impulses in intentionally starting fires. Another characteristic of this disorder is to induce euphoria. Often, pyromaniacs observe fires in their neighborhoods. Some may become affiliated with local fire departments and even become fire fighters themselves. Not only do they receive pleasure and relief from setting fires, but they also witness the destruction and participate in the aftermath (American Psychiatric Association, 2013).

Pyromania occurs more often in adolescent males, particularly those with learning disabilities and poor learning skills (American Psychological Association, 2013). Often children between the age of 5 and 10 years of age do not understand the dangers and consequences of playing with fire. Those who are pathological fire setters exhibit the following features. They may set fires as a cry for help. They may be neglected or ignored by their caretakers, suffer from depression, or have been sexually abused. Others may be severely disturbed. They may be diagnosed as either psychotic features or paranoia, and may even engage in fire setting as part of a suicide attempt. Pyromania in adults has a high rate of dual diagnoses with other disorders such as obsessive-compulsive disorders, substance abuse disorders, and mood disorders.

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, individuals can

be diagnosed with this disorder if they intentionally and purposefully engage in fire setting on more than one occasion. Affective arousal and tension must be present prior to the act of fire setting. They must have an interest, fascination, curiosity, or attraction to fire or when in the presence of witnessing the act or participating in the aftermath of the fire. The act of fire setting must not be due to financial gain, to conceal criminal activity, due to expression of anger, an expression of a sociopolitical ideology, to improve one's living situation, in response to hallucinations or delusions, or a result of blind judgment. In order to make the diagnosis of pyromania, fire setting cannot be better explained by a manic episode, antisocial personality disorder, or conduct disorder (American Psychiatric Association, 2013).

The exact causes of this disorder are unknown. There are several theories that exist for why children and adolescents engage in fire setting. Some individual factors that may be associated with fire setting include antisocial behaviors and attitudes. For example, some adolescents may have committed vandalism of another's property, nonsexual offenses, and forcible rape. Another theory is that individuals set fires due to an attention seeking behavior. They may be bored and not engage in positive recreation. Environmental factors may also be involved. These include a lack of supervision of their parents or other adults. This may include parental neglect or lack of emotional involvement. Stressful life events (e.g., divorce and lack of coping skills with a personal crisis) may be associated with pyromania. Pyromania in adults has been associated with depression, difficulty in interpersonal relationships, and suicidal thoughts.

Treatment

The age in which an individual engages in pyromania will depend on specific treatment options. For children and adolescents cognitive behavior therapy may be an effective form of treatment. An individual's behavior may become apparent during therapy sessions, and as to what may have caused this impulsive behavior (pyromania). Ongoing therapy can help the child or adolescent in his or her recovery. Some other treatments for children and adolescents include parental training, communication skills, problem-solving skills training, relaxation training, individual and family therapy, cognitive restructuring, and medication. Recovery from pyromania is more positive in children and adolescents than in adults (American Psychological Association, 2013). However, it also depends on the environmental and individual factors at play. Pyromania in adults is generally more difficult to treat due to the lack of cooperation by the individual. Treatment usually consists of medication to prevent emotional outbursts and prevent stress. Long-term therapy is recommended for adults with this disorder (American Psychological Association, 2013).

Manufactured in the United States of America

This book discusses treatments (including types of medication and mental health therapies), diagnostic tests for various symptoms and mental health disorders, and organizations. The authors have made every effort to present accurate and up-to-date information. However, the information in this book is not intended to recommend or endorse particular treatments or organizations, or substitute for the care or medical advice of a qualified health professional, or used to alter any medical therapy without a medical doctor's advice. Specific situations may require specific therapeutic approaches not included in this book. For those reasons, we recommend that readers follow the advice of qualified health care professionals directly involved in their care. Readers who suspect they may have specific medical problems should consult a physician about any suggestions made in this book.

Preface

The quest to understand mental health and its disorders is first noted in the writings of the ancient Greeks. With today's new technologies and constant research, scientists have uncovered many causes of mental disorders and conditions as well as new treatments to reduce symptoms as well as prevent these conditions. "Mental health" is a broad term that encompasses both dysfunction and well-being from conception through the life span.

The purpose of this encyclopedia is to provide a wide-ranging reference source on mental health and its disorders, written at a level accessible for upper high school and college students as well as for the layperson. The encyclopedia provides insights into the discipline of mental health and covers both healthy functioning and mental disorders or conditions, treatment methods, and factors that promote mental health and well-being.

Mental Health and Mental Disorders: An Encyclopedia of Conditions, Treatments, and Well-Being aims to open the door to mental health research for readers, as well as direct them to accurate and current resources for further investigation.

Scope

This encyclopedia helps the reader understand mental disorders and their treatment as well as normal development and prevention of mental illness. This reference work covers virtually every topic and consideration involving mental health. The reader will find that the 875 entries in this three-volume work comprise six areas of emphases:

- Mental disorders and conditions. These include both common and relatively rare disorders. Also included are diagnostic characterizations that follow the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, commonly known as DSM-5.
- Treatment of these disorders. These include prescribed medications, psychological therapies, and herbs and other natural remedies.
- Tests and assessment methods used in evaluating or diagnosing mental conditions. These include standardized paper and pencil tests as well as biological and brain-imaging methods.
- Common psychological terms and concepts associated with mental and emotional well-being.

- Highly regarded individuals and organizations influential in researching disorders, developing treatments, or fostering professional development.
- Popular and classic books and films as well as high-profile individuals and culture-changing events. These have significantly influenced our understanding of mental health and illness and are also profiled.

To increase readability, technical terms are defined near the beginning of most entries. Terms are also included in the glossary at the end of volume three.

Contributors

The 13 contributors to this encyclopedia are all uniquely qualified to speak with authority regarding at least one aspect of mental health and its disorders. They have formal training and experience in psychiatry, clinical psychology, clinical mental health counseling, or child and adolescent development. Most have specialized in working with children, adolescents, and young adults and recognize the critical role of culture in mental health and illness. The collective expertise of these contributors allows a much broader understanding of mental health issues than a single author could ever provide.

User-Friendly Features

Mental Health and Mental Disorders: An Encyclopedia of Conditions, Treatments, and Well-Being is organized in the customary A–Z encyclopedia format. At the front of each volume is an alphabetical listing of all entry headings ("Alphabetical List of Entries"), allowing the reader to scan the list of all entries. A "Guide to Related Topics" is an additional aid, listing all the entries in the book under broad topics. Readers can look under topics such as "Disorders," "People," and "Social Issues" to quickly see all the entries included for that topic.

All entries have a "See also" section that connects the reader to other relevant topics. For example, in the entry "Anxiety Disorders in Adults" the connecting and cross-references will direct the reader to other entries that discuss similar disorder symptoms (Agoraphobia, Generalized Anxiety Disorder, Panic Attack, Panic Disorder, Social Phobia, Specific Phobia), and various treatment methods and approaches (Antianxiety Medication, Antidepressant Medication, Cognitive Therapy, Exposure Therapy).

Further Reading and Selected Resources

Each entry also includes current, reliable sources for additional statistics, research, or consumer-friendly education. Books, articles, and websites are included, allowing the reader to choose the level of detail and depth for further data and material. "Recommended Resources," a specially chosen short list of good books and online resources that are helpful to the layperson or student, is featured at the end of volume three. That volume also includes the "Glossary" of terms, with succinct definitions or descriptions of concepts, disorders, treatments, tests, and important people. The "List of

Organizations" features more than 120 groups and resource centers, ranging from the Albert Ellis Institute to the Association for Applied Sport Psychology to the Workplace Bullying Institute. The encyclopedia concludes with a comprehensive index.

Where to Start?

Obviously a reader's starting point is individually driven; however, if you are interested in a specific mental disorder, please read that entry first and follow it up with reading the "See also" selections. If you are using this reference for a research paper on a specific topic, simply start at the index or list of entries to guide you through the encyclopedia. Moreover, the further reading sections at the end of every work will provide you with additional references for your investigation. Finally, if you have an inquisitive mind and are a lifelong learner, allow yourself to be immersed in this ever-growing field of mental health as detailed in entries in these three volumes. You will find interesting and valuable information about this ever-developing field that may just pique your interest as it has mine.

Concluding Note

While this encyclopedia broadly overviews the expanding field of mental health in its extensive number of entries, it does not provide complete information on any one topic. The "Recommended Resources" section at the end of volume three provides readers with additional information to explore selected topics more fully. Furthermore, the material in this encyclopedia is not intended to be used for diagnostic purposes or for psychological treatment. While self-knowledge can be very helpful, it is not a substitute for professional help. Finally, because indications for psychological treatments continually change, readers are advised to seek updates from health professionals, professional literature, or authoritative websites.

Acknowledgments

This project was a joy to work on as it allowed me to share my passion about mental health and well-being with everyone. However, this project was enormous and could not have been completed without the help and devotion of my coeditors, Alexandra Cunningham, PhD, Melissa Mariani, PhD, Mindy Parsons, PhD, and Steven Vensel, PhD, and the other contributing authors.

Len Sperry, MD, PhD

Introduction: Mental Health

Mental health is a continuum, ranging from states of well-being to stressful life experiences to severe mental disorders. We hope that readers of *Mental Health and Mental Disorders: An Encyclopedia of Conditions, Treatments, and Well-Being* will find it a useful reference source for specific purposes like academic assignments, term papers, job reports, or, more generally, for better understanding themselves and others.

This three-volume encyclopedia is subtitled *An Encyclopedia of Conditions, Treatments, and Well-Being*. The following paragraphs will focus on these three concepts: conditions or mental disorders, treatments, and well-being. Before that let's first look at mental health.

Mental Health

So what is mental health? Mental health can be thought of as successful mental functioning that results in productive activities, fulfilling relationships, and the ability to cope with change and adversity. Another way of saying this is that mental health is indispensable to effective personal functioning, interpersonal and family relationships, and community life.

Change exerts a constant influence on mental health and can be a major source of anxiety for many in their personal and professional lives. Change, by itself, whether for good or not, can be a source of stress and can negatively influence mental health. For example, technological changes continue at an accelerating pace, and while they can be useful to many individuals, they pose a stressful challenge to others.

Advances in health care can positively or negatively affect mental health. For example, older adults today have increased their life and health expectancies compared with Americans 10 years ago. That means that those over the age of 65 have fewer physical health concerns. But a decline in mental faculties among an increasing number of aging adults can create significant mental health concerns. For instance, dementia and Alzheimer's disease were not major health and mental health concerns in the past because relatively few lived past the age of 60. In 1900 there were 120,000 Americans over age 85, while today there are more than 4 million older adults of that age, making them the fastest-growing age group. The U.S. Census Bureau estimates that by 2030 there will be 72 million adults over the age of 65, which represents 20% of the American population. Among those 85 and older it is estimated that 50% will be diagnosed with Alzheimer's disease (Vincent and Velkof, 2010). The point of these examples is that mental health and mental disorders are influenced by various factors.

Mental Disorders

Mental disorders are primarily disorders of the brain. These conditions usually have multiple causes and result from complex interactions between individuals' genes and their environment. Lifestyle factors and health behaviors, like smoking and exercise, and life experiences, such as severe and prolonged stress or a history of abuse, are such factors. Typically, such factors interact with an individual's genetic or biological predisposition to a mental disorder. For example, a traumatic brain injury or a mother's exposure to viruses or toxic chemicals while pregnant may play a part. Other factors that can increase the risk for mental illness are the use of illegal drugs or having a serious medical condition like cancer. Research on the causality of mental illness has convincingly replaced the now-disproved belief that mental illness is a moral failure.

Mental illnesses occur at similar rates around the world, in every culture and in all socioeconomic groups. Statistics reveal that one in five individuals suffer from a mental disorder. This represents at least 20% of Americans. However, only one-fourth of those individuals with disorders are receiving treatment (SAMHSA, 2014). And, currently, only about 4% of America's health-care budget is spent on mental health treatment and prevention.

The *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (called DSM-5), published by the American Psychiatric Association, provides a common language and standard criteria for the classification of mental disorders. It is the most commonly used clarification system in North America. It classifies mental disorders into categories. There are more than 20 categories of which the following are the most common.

- Anxiety disorders are disturbances in brain mechanisms designed to protect you from harm.
- Mood disorders are disturbances in usual mood states.
- Psychotic disorders are disturbances of thinking perception and behavior.
- Personality disorders are maladaptive personal characteristics.
- Eating disorders are disturbances of weight and feeding behavior.
- Substance-related and addiction disorders are disturbances of cravings.
- Neurodevelopmental disorders are early disturbances in usual brain development.
- Trauma- and stressor-related disorders are disturbances related to significant stressful events.

For example, post-traumatic stress disorder (PTSD) is one of the trauma- and stressor-related disorders. It is a common occurrence in those who witnessed or survived traumatic situations. Many veterans of the war in Iraq and Afghanistan suffer from PTSD and experience symptoms of flashbacks, nightmares, feelings of constant vigilance, and depression. But not all who were deployed to Iraq experience PTSD. Rather, it is most likely to occur in those with a biological predisposition.

Depression is a mental disorder experienced by more than 120 million American adults each year. Depression is a leading cause of drug and alcohol use. Sleep difficulties result in nearly 50 million prescriptions being written for sleep medications per year. Many individuals manage their anxieties by overeating or smoking. Over

time, unhealthy ways of coping take their toll on physical as well as mental health, particularly in those who are predisposed to such conditions.

Treatment

Significant advances have been made in the treatment of mental disorders. This increased understanding of the causes of mental health disorders (at least some of them) and increasingly effective treatments allow clinicians to better tailor treatment to those disorders. As a result, many mental health disorders can now be treated almost as effectively as medical conditions.

Generally, treatment for mental health disorders is characterized as either somatic (biological) or psychological. Somatic treatments include drugs, electroconvulsive therapy, and other therapies that stimulate the brain. Psychological treatments include psychotherapy (individual, group, or family and marital), behavior therapy techniques (e.g., relaxation training or exposure therapy), and hypnotherapy. Research suggests that for major mental health disorders like major depressive disorder, a treatment approach involving both drugs and psychotherapy is more effective than either treatment method used alone.

Clinicians who treat mental disorders include psychiatrists, clinical psychologists, mental health counselors, social workers, and psychiatric nurse practitioners. However, in most states, psychiatrists and psychiatric nurse practitioners are the only mental health clinicians licensed to prescribe drugs. Other clinicians practice psychotherapy primarily. Many primary care doctors and other medical specialists also prescribe drugs to treat mental health disorders.

Well-Being

In the past, mental health treatments focused largely on reducing symptoms or returning the individuals to their previous level of functioning. Today, however, treatment may also focus on increasing individuals' functioning, resilience, and prevention. This focus is known as well-being. Well-being is defined as how individuals think about and experience their lives. It is an indicator of how well individuals perceive their lives to be going. It reflects several health, job, family, and social outcomes. Accordingly, higher levels of well-being are associated with decreased risk of disease, illness, and injury. It is associated with faster recovery for illness, better immunity, increased longevity, and better mental health. Those with high levels of well-being are more productive at work, tend to get along better with others, and are more likely to contribute to their communities.

While there is not yet consensus among researchers or clinicians on the definition of well-being, most agree that well-being involves the presence of positive emotions and the absence of negative emotions. Most would agree that it includes satisfaction with life, a sense of personal fulfillment, and positive functioning. In short, it is about judging life positively and feeling good. Furthermore, most agree that well-being is broader and more inclusive than mental health. In fact, several kinds of well-being can be described and are currently being researched. These are physical well-being, economic well-being, social well-being, emotional well-being, and psychological

well-being. Depression, anxieties, addictive behaviors, and severe physical pain make it difficult to attain and maintain well-being. The reason is that these conditions interfere with the ability to see beyond one's immediate negative experience.

Q

Qualitative Research

Qualitative research describes investigative methodologies that provide more detailed descriptions, explanations, and observations of an individual subject, or smaller, focused samples of subjects, and the related variables that occur in naturalistic settings.

Definitions

- **Ethnography** is a form of qualitative research aimed at the investigation and interpretation of different cultural groups.
- **Positivism** theory posits that everything in the objective world can be confirmed or denied by gathering data and then verifying the validity and reliability of this data through empirical analysis.
- **Quantitative research** is a research methodology that relies on quantities, or numbers, to answer investigative questions.
- **Subjectivism** is a theory that holds that there are a variety of possible explanations or reasons for human behavior, rather than one, universal truth.

Description

Qualitative research is a type of methodology commonly employed in the social sciences that is interested in revealing more in-depth information or a greater understanding of the topic, person, or setting under investigation. It is interested in the quality, essence, or nature of something rather than the quantity. This type of inquiry is based on subjectivism, or the belief that there are many different versions of the truth and/or a variety of possible meanings for occurrences. The opposite of this is positivism, or realism, which is a worldview that holds that a true reality exists and that it can be discovered by maximizing objectivity and the use of rigorous scientific methodology. "Qualitative research" is an umbrella term that encompasses various forms of inquiry that helps investigators explain social phenomenon with as little disruption to the natural setting as possible. Qualitative researchers look for patterns, themes, or trends in the data rather than relying solely on what the numbers indicate, relying on subjective rather than objective data. Findings are specific to the subject under study and should not be generalized to larger populations. However, qualitative findings may also generate new hypotheses for subsequent, larger-scale quantitative studies. These types of studies differ from quantitative studies in that they require smaller sample sizes, focus more on answering the how and why behind the problem, and, thus, take a longer amount of time to conduct. Naturalistic inquiry, participant observations, interpretive research, inductive research, ethnography, focus groups, case studies, and pilot tests are forms of qualitative research. Ethnography is a type of qualitative research that investigates the differences between various cultural groups. Focus groups involve a moderator that leads a group of selected individuals through a discussion on a particular topic to gauge their opinions, thoughts, and feelings. Market research frequently uses this form of qualitative inquiry. Another readily used form for gathering qualitative data is the case study, which is a detailed investigation of an individual, group, or institution.

Case studies often reveal the deep complexities of the subject under study. Methods for collecting qualitative data include observations, interviews, discussions, notes, and pictures. Subjective though they may be, these methods provide the researcher with a vast amount of rich, descriptive information.

When conducting qualitative research, one seeks to gain a complete picture of the problem under investigation. This is referred to as a holistic perspective. There are several advantages to engaging in this type of inquiry such as the richness, depth, and comprehensiveness of the information gathered. The ease of collection methods is another advantage since these are not as rigid in a natural setting as they are in a controlled environment. In addition, the knowledge gained from qualitative means often provides the researcher with a better understanding of the real environment. Qualitative research, however, is not without its limitations. For example, given the subjectivity of the data gathering, reliability and validity of the findings are often questioned. Researcher bias is another limitation. Finally, this type of research often takes a longer amount of time to gather and the information itself can be lengthy and tedious to code and review.

Development

Both psychology and the social sciences have a long history of employing qualitative research methods dating back to the early 1900s. Seven phases or moments have been outlined documenting this progression in the United States. The first of these, referred to as the traditional period, ranged from the first part of the 20th century to World War II and was characterized by Malinowski's research in ethnography and the influence of the Chicago School in sociology. The focus of qualitative inquiry at this time was on understanding those different from mainstream culture or society. Wilhelm Wundt, the founder of scientific psychology, was one of the first psychologists to use qualitative methods in the experiments he conducted from 1900 to 1920. Next came the modernist phase that lasted till the 1970s and was concerned with formalizing qualitative research practices. Many textbooks on qualitative methodology were written during this time. The following phase that lasted up to the mid-1980s, termed "blurred genres," was characterized by the development of alternative paradigms. A crisis of representation then occurred in the mid-1980s with the birth of artificial intelligence. Researchers began to question how the continuous construction of new realities could potentially impact study findings and interpretations. Narratives replaced theories in the next phase, coined the fifth moment, which took place during the 1990s. The sixth moment (up to 2000) focused on post-experimental writing and the seventh moment (2000–2004) on further establishing qualitative research through successful journals. The final phase, or the eighth moment, is characterized by current emphasis on evidence-based practice.

Current Status and Results

The debate over which is more valuable, qualitative (soft) data versus quantitative (hard) data is ongoing. Some researchers argue that qualitative research is not scientific, lacking the structure, rigor, and objectivity of quantitative methods. However, the fields of anthropology, sociology, philosophy, and psychology readily engage in this type of research given the depth and breadth of the information it provides.

Quantitative Research

Quantitative research is a type of investigative research involving the collection of numerical data and subsequent analysis of that data using mathematical, or statistical, methods.

Definitions

- **Mixed-methods research** defines a flexible type of research methodology that makes use of both qualitative and quantitative components.
- **Positivism** theory posits that everything in the objective world can be confirmed or denied by gathering data and then verifying the validity and reliability of this data through empirical analysis.
- **Qualitative research** is a type of research methodology that gathers "soft" data, subjective and non-numerical, for the purpose of gaining insight and in-depth information about a person, thing, setting, or problem in its natural environment.
- **Realism** is a paradigm that proposes that research, the gathering and verifying of data through empirical analysis, can be used to uncover existing realities in the world.
- **Subjectivism** is a theory that holds that there are a variety of possible explanations or reasons for human behavior, rather than one, universal truth.

Description

Quantitative research uses scientific inquiry and descriptive or inferential statistics to investigate and then determine conclusions about real-world problems. Drawing from the paradigms of realism and positivism, quantitative research is grounded in the belief that true realities exist in the world that can be measured objectively and then quantified through the use of empirical analysis. Researchers use quantitative methods to test hypotheses, determine possible cause and effect relationships, and make predictions about something. This type of research is readily used in the social sciences, including psychology, sociology, and political science; however, it is also applied in mathematical sciences such as physics and statistics.

There are apparent differences between qualitative and quantitative methodologies. Foundationally, qualitative processes are grounded in subjectivism, while quantitative studies are rooted in positivism. In addition, qualitative studies identify patterns, features, or themes (subjective), while quantitative studies identify numerical or statistical relationships between variables (objective). Qualitative data types vary from words, pictures, and objects, while quantitative data is of a numerical or statistical nature. Collection of data for qualitative studies can be obtained through the use of open-ended questions, interviews, observations, case notes, and personal reflections. For quantitative studies, data is based on precise measurements derived from standardized, structured, and validated instruments. Final reports of findings for qualitative research typically come in a narrative form, while those for quantitative studies are of a statistical nature. Narratives may include lengthy descriptions of the person, group, or organization under investigation as well as direct quotes or comments from study participants, while statistical reports contain mathematical calculations such as correlations, comparisons of means, indications of statistical significance, and measures of effect size. Though both research methodologies employ steps in the scientific method, qualitative studies are described as exploratory, while quantitative studies are confirmatory. Another difference lies in the role of the researcher. In qualitative designs, the researcher often plays a primary role in collecting data and may interact with the subjects under study; in quantitative research, the researcher's role is limited in order to reduce bias. Next, qualitative researchers study behavior that occurs in a natural environment, while quantitative researchers investigate behavior under controlled conditions. This allows the researcher to generalize his or her findings to other populations. Quantitative studies also focus on larger-scale problems with randomized samples. This allows the researcher to generalize his or her findings to other populations.

As with qualitative designs, quantitative research is not without limitations. First, quantitative research is limited in the information it provides. Though numbers can indicate increases, decreases, trends, and relationships between variables, they are limited in depth and breadth they offer. Next, given their controlled conditions, quantitative studies indicate little about how the subject under study behaves in their natural environment. Finally, quantitative research views human

behavior as regular and predictable; however, this is typically not the case as each individual, organization, and setting is unique and each situation, controlled or not, may be different.

Development

Quantitative inquiry has existed since people began recording events and counting objects; however, quantitative research, in the formal sense, can be attributed to the work of French philosopher Auguste Comte. Comte is credited as the founder of sociology and the theory of modern positivism. In his book *A General View of Positivism*, he detailed the empirical goals of the scientific method in sociology. His work emphasized quantitative, mathematically based decision making, which remains the basis for current practices in statistics and business.

Current Status and Results

Quantitative methods have dominated research practices for the better part of the 20th century on into the 21st century. Though there is apparent value in qualitative designs, quantitative research with its focus on "hard" data is viewed as more salient and the results more powerful. One of the dominant themes in current social science research is an emphasis on evidence-based practices and research-based interventions, with quantitative data playing a central role.

R

Racial Identity Development

Racial identity development describes how individuals achieve an awareness of their self within the social, cultural, and historical context of their race.

Definitions

- **Culture** refers to the knowledge and values; patterns of though, speech and actions; and customary beliefs, social forms, and speech shared by a society.
- **Discrimination** is the unjust treatment of others based on racist beliefs.
- **Ethnicity** refers to a group of people sharing a common and distinctive racial, national, religious, linguistic, and cultural heritage.
- **Heritage** refers to the practices, traditions, or characteristics that are passed down from one generation to the next.
- **Prejudice** is a preconceived opinion about a group or class of people based on limited, inaccurate, or assumed information.
- **Race** refers to a socially constructed system of classifying individuals according to observable characteristics such as physical attributes (skin tone, height, eye shape, etc.) or language.
- **Racism** is a socially shared belief that all members of a particular race possess characteristics that are inferior to another race, resulting in oppression.
- **Stereotype** means to categorize, characterize, or group people into oversimplified and inaccurate classifications.

Description

Racial and ethnic identity is an essential component of an individual's overall self-identity. Racial identity is based on an individual's perception of shared genetic and physical characteristics of a particular racial group. Ethnic identity is based on an individual's identification with the customs, traditions, culture, and values of a shared and embraced heritage.

Racial identity development has received considerable attention in the United States, with much of the research being focused on the unique experience of African Americans. The concept of racial identity has been considered from both biological and social perspectives. Early concepts of racial identity were derived from a biological perspective in which race was seen simply as an individual's physical features and genetic characteristics. Seen from this narrow perspective people were grouped according to physical ability and difference in appearance, most often skin color, leading to social stereotype, racism, and oppression. Today racial identity is viewed from a social perspective, with research focusing on how groups of people develop a sense of collective identity over their lifetime.

There are multiple models of racial identity development, and many of the theories have their roots in the developmental stage models of Erik Erikson. Most theories focus on the psychological and emotional development of individuals within the context of their social environment. One of the most

prevalent and researched models of racial identity is that proposed by William E. Cross, a psychologist and leading researcher in the field of racial identity development. Cross proposed five stages in the development of what he referred to as "the process of becoming black." Cross called his theory "Nigrescence" in which a healthy Afro-American progresses from a non-Afrocentric to an Afrocentric to a multicultural identity. Cross originally identified five stages: Pre-Encounter, Encounter, Immersion-Emersion, Internalization, and Internalization-Commitment. An individual begins in the Pre-Encounter identity stage in which he or she seeks to assimilate and be accepted by whites. The individual has a nonracial perspective and is unaware of race and race issues. At some point there is a racial "Encounter" in which the individual, for the first time, is treated differently because of the color of his or her skin. This encounter with racism results in the individual focusing on his or her identity as a member of the group targeted by racism. The third stage, Immersion-Emersion, is highly emotional and individuals immerse themselves in black culture. They are obsessed with and take pride in their blackness; surround themselves with symbols of their racial identity; disparage white culture and avoid symbols of whiteness; and become more involved with their own racial group and exclude those from different groups. As they emerge from this stage and enter into the Internalization stage, they become less psychologically defensive and more emotionally and cognitively open to analyze and consider their racial worldview. There is an inner security, comfort, and satisfaction with being black as well as an ability to see both positive and negative elements of being black or from another racial group. An individual with an internalized racial identity is willing to establish meaningful relationships with individuals from other racial groups. The final stage of racial identity is Internalized-Commitment in which individuals have internalized a positive racial identity and are able to use their experiences to take action for other oppressed groups. They are committed to social change, political justice, and social equality for all oppressed minorities.

There are multiple theories of racial identity development, and no single model could capture all of the challenges unique to the African American community. As the social environment changes, racial and ethnic identities evolve and change over time. A positive and healthy perception of racial identity is a core component of an individual's sense of self-concept and well-being. Understanding how healthy identities form will continue to be an important area of research.

Rage

"Rage" refers to uncontrolled, intense, and often violent fits of anger.

Description

Rage is an intense emotional state of anger that is often experienced as being "out of control." Rage is an intense form of anger. When people are "in a rage," they are unable to control their impulsive aggressive behaviors and become verbally hostile, destructive, and violent toward others.

Causes and Symptoms

Anger includes a wide range of emotional states from minor annoyance and frustration on one end of the spectrum to rage on the other end. Rage occurs in response to helplessness, threat of harm, threat of loss of relationship, perceived or real injustices or disrespect, and real or imagined provocations. Rage is triggered

by how individuals interpret and appraise events. The emotional response is usually so automatic, immediate, and intense that individuals in a rage are unable to access more rational forms of thought in order to control their aggressive impulses. A common explanation given by people who rage is that "something snaps" and they lose control. However, research indicates that rage may, at least at times, include an element of calculation and intentionality as when a person wraps his or her hand in a cloth to avoid injury prior to hitting a window. Nonetheless, individuals who are in a "fit of rage" consistently report an inability to think about anything other than what is angering them. They also report being able to easily find additional evidence of wrong to further feed their rage. Verbal symptoms of rage include yelling, ranting, cussing, and making verbal threats. Physical behaviors include combative and provocative gesturing, destroying objects, vandalizing property, engaging in physical fights, and assaulting others.

Diagnosis and Prognosis

Rage is very damaging and often results in loss of personal relationships, job loss, legal difficulties, arrest, and incarceration. Rage is included as a behavior indicator associated with some mental health disorders, including intermittent explosive disorder. Anger expressions that are out of proportion to events are a frequent focus of counseling. Psychotherapies such as cognitive behavior therapy, rational emotive therapy, and cognitive behavioral analysis system of psychotherapy have been found to be effective by assisting individuals in understanding and changing their anger-related thinking and behaviors. Self-help and professional anger management groups are widely available and provide effective psychoeducational and anger control skills development, including conflict resolution skills, communication skills, mindfulness, reflection, and emotional regulation. Although rage is an emotionally intense and destructive form of anger, it is easily treatable.

Rational Emotive Behavior Therapy (REBT)

Rational emotive behavior therapy (REBT) is a form of psychotherapy developed by Albert Ellis (1913–2007).

Description

Ellis first began writing about his theories in 1955 and published his book *Reason and Emotion in Psychotherapy* in 1962. Albert Ellis's book, which was revised in 1994, is still the most important source for practitioners of REBT. Originally called rational psychotherapy, Ellis renamed his theory rational emotive therapy, and then changed the name to REBT. REBT uses an A-B-C model to explain the cause of distress in a patient. In this model, the patient experiences an activating event (A). This event triggers beliefs (B) about the event and emotional consequences (C) happen because of their beliefs.

According to Ellis, people create their own reactions to event. Reactions are natural when they are based on functional, rational beliefs and lead to appropriate, healthy consequences, such as regret, annoyance, or sadness. The problem arises when people instead have dysfunctional or irrational beliefs. These lead to negative or unhealthy consequences, such as guilt, anger, or depression. Where REBT differs from other cognitive behavior therapy approaches is that it points out the distinction between healthy and unhealthy emotions.

Ellis's theories on REBT came about after a 1953 session with a patient. The patient was afraid of men and stated her fear was because her father beat her as a child. Ellis reminded her that her father was dead. The

patient wondered if it wasn't her father causing her fear, then perhaps it was because of what she was saying about what he did in the past. Ellis agreed that her fear came from her own action of telling herself that her father is responsible for the way she thinks now. This patient's interaction led Ellis to the basic principle of REBT, which is the way people think makes them behave in a certain way.

REBT states that it's natural for people to experience emotions in response to events. A therapist can work with a patient to replace unhealthy emotions with helpful, more appropriate ones. The REBT therapist's major job is to point out negative emotions and discuss them with his or her patient. Cognitive intervention is then used to replace the negative emotions with positive, healthy emotions. Therapists see this as one of the major advantages of REBT.

Healthy, positive emotions come from rational beliefs about situations. Positive illusions, like thinking that things are okay when they really are not, are associated with unhealthy, irrational beliefs. Unconditional self-acceptance is a cornerstone of REBT, and patients are urged to love the self unconditionally. Ellis advised patients not to rate or evaluate themselves, but only their roles. For instance, you may judge something you did, but you shouldn't judge yourself.

People struggle between extreme and non-extreme, or dogmatic and non-dogmatic beliefs. For instance, it's unhealthy for a person to believe that an outcome must happen, or "all will be lost." Therapists encourage patients to be passionate about their desires, but not believe that it will be the end of the world if they are unable to obtain them. It's the job of a therapist to help a patient let go of his or her irrational beliefs and instead have a rational belief with an appropriate negative emotion.

Ellis believed problems arise when people have trouble separating feeling from thinking, or vice versa. Inappropriate emotions come not from what has happened to us but from how we interpret these events. Ellis's approach differed from other forms of psychotherapy, especially the nondirective approach, which was popular in the 1950s. It's important to note that REBT is direct, active, provocative, and confrontational. Ellis interrupted patients during therapy sessions, made fun of their irrational beliefs, and pointed out the thoughts that were bothering them. This made for many uncomfortable therapy sessions.

In REBT, the therapist must challenge the patient to think differently. This can save time by not letting a patient ramble on during a therapy session, but by getting to the point and achieving a resolution. However, REBT therapists can find it difficult to be direct. They are not immune from the desire to be liked and may be afraid if they are direct and confrontational, their clients won't like them. Many of Ellis's colleagues dismissed his therapy tactics. However, his patients reported that they were effective and that it was worth any discomfort they experienced at the time.

Development and Current Status

During his career, Ellis documented REBT with 934 articles, books, pamphlets, audiocassettes, and video tapes. He worked hard to keep REBT from being influenced by other approaches and insights. As a result, REBT hasn't absorbed much or merged with other therapies, as is often the case in psychotherapy. To this day, REBT continues to stay true to its non-psychoanalytic beginnings.

That is not to say that REBT has remained stagnant, however. Ellis worked on refining it for 50 years, from 1955 to 2005. He continually tested his ideas in clinical sessions during this time, holding up to 90-patient sessions a week. Changes to REBT were a result of his clinical findings. However, not everyone feels REBT is well documented enough. REBT is viewed by some as too loosely formulated and based too much on anecdotal evidence. Another downside to REBT is that there are few rigid, set rules for practitioners to follow. There is no clear standard for what constitutes REBT and what doesn't, and few educational standards for therapist training. This can be an advantage for therapists, since it allows them the flexibility to develop their own ideas. However, it also means that without standardization, some therapists practice REBT quite differently than others.

Since Ellis continually refined and changed his approach to REBT over the years, but didn't issue strict guidelines, not every practitioner was aware of the changes. Therefore, not everyone followed the same practices. However, what remains is that REBT is an effective cognitive behavior therapy and a way for

therapists to guide their patients into resolving their issues. It has been a major influence on psychotherapy during the last century.

Reactive Attachment Disorder

Reactive attachment disorder is a mental disorder in children characterized by disturbed and developmentally inappropriate social relatedness.

Definitions

- **Attachment** is the emotional bond between children and caregivers that provides a secure (healthy) base from which children are able to safely explore their environment and relate to others.
- **Cognitive behavior therapy** is a type of psychotherapy that focuses on maladaptive (faulty) behaviors, emotions, and thoughts.
- **Disinhibited social engagement disorder** is a mental disorder in children characterized by an overly familiar and culturally inappropriate behavior with strangers.
- **Trauma- and stressor-related disorders** are a group of mental disorders characterized by exposure to a traumatic or stressful event. These include post-traumatic stress disorder, reactive attachment disorder, and disinhibited social engagement disorder.

Description and Diagnosis

Reactive attachment disorder is one of the trauma- and stressor-related disorders. It is characterized by disturbed and developmentally inappropriate social relatedness in children. The most obvious and prominent behavioral presentation of children with this disorder is the avoidance of and withdrawal from caregivers, other adults, and peers. When distressed, these children tend to reject attempts at comforting and soothing. Instead they engage in self-calming and soothing behavior, and tend to be calmer when left alone. As young children they seldom smile and do not respond when being hugged or picked up. Typically, they show little interest in playing childhood games like hide-and-seek. Older children avoid social activities and become isolative, and when frustrated, they may engage in aggressive behavior toward adults and peers.

Children with this disorder seldom have any friends. This probably results from their disinterested attitude toward making friends with peers and relating to caregivers. With peers, these children send the message, "I don't want you as a friend." Unfortunately, this becomes a self-fulfilling prophecy as peers stop their efforts to relate to such children. Similarly, these children and their caregivers tend to get caught in a negative cycle. In this cycle both interpret disinterest and avoidance in each other's behavior, which leads to further disinterest and avoidance. It is unknown how common reactive attachment disorder is among children. While found in children placed in intuitions or raised in foster care, it appears in less than 10% of such children (American Psychiatric Association, 2013). In some ways, this disorder is the mirror opposite of disinhibited social engagement disorder. Whereas children with disinhibited social engagement disorder relate indiscriminately to individuals they do not know, those with reactive attachment disorder cannot easily relate to individuals they do know.

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, children can be diagnosed with this disorder if they exhibit an ongoing pattern of emotional distance and general inhibition in relating with adult caregivers. Specifically, the child will rarely seek comfort and support from caregivers when distressed, and will rarely respond when comfort and support is provided. This inhibition and lack of emotional responsiveness extends to others within the child's environment. This includes teachers, relatives, and peers. These children have a history of neglect and deprivation or have had several primary caregivers. It is believed that while they have the capacity to form appropriate social attachments, due to significant social neglect and lack of opportunities for receiving developmentally appropriate comfort, affection, and stimulation from caregivers, this capacity is not fully realized. This diagnosis is not made unless the child is at least nine months of age and the symptoms have been present prior to five years of age (American Psychiatric Association, 2013).

The cause of this disorder is not well understood. However, withdrawal and avoidance seem to be logical responses to an early childhood experience of neglect or trauma. The core feature of this disorder is the failure to form a secure (healthy) attachment to the primary caregiver. Reasons for this include abuse, extreme neglect, abrupt separation from caregivers, or a repeated lack of responsiveness of the caregiver when the child attempted to interact. Or, several of these reasons may have been involved. Accordingly, these children came to believe and feel that they did not belong, were not good enough, or were not accepted. The result was their pattern of avoidance of and withdrawal from others and a failure of a secure attachment. There may also be some genetic factors that contribute to this pattern of behavior, but so far nothing has been determined except that between the infant and the earliest caretakers was not established and further training of the child's social interest was not continued.

Treatment

Treatment of this disorder consists primarily of psychological interventions. First and foremost, it is important that the child be in a secure, safe, and supportive environment. If the child is in a neglectful environment, referral to appropriate state, tribal, or federal agencies should be made. Another essential goal of treatment is to foster the development of a secure (healthy) attachment between the child and caregiver. This can be accomplished directly with the caregiver through parenting classes or in individual psychotherapy. Cognitive behavior therapy can help in reducing stress and negative emotions associated with caring for a child with this disorder.

Reading Disorder

Reading disorder, commonly called dyslexia, is a type of learning disability that negatively affects a person's reading ability.

Definition

- **Dyslexia** is a learning disorder that impairs a person's ability to read.

Description

Individuals who exhibit dyslexia typically read at levels significantly lower than expected for their age even though they have average or above-average intelligence. Characteristics vary for each person with dyslexia. This problem occurs when someone is unable to distinguish the significance and specific differences between letters. Some common characteristics are difficulty with basic reading, such as letter and word identification and sounding out letters.

There is dispute about the accuracy of how reading disorder is measured. Reading disorder is generally thought to be two or three times more common in boys than in girls. And while approximately 10% of school-age children struggle to read successfully, only about 4% of these children have dyslexia. For many children dyslexia is also associated with other learning disorders such as mathematics disorder. When it occurs in adults, dyslexia is usually the result of a brain injury or occurs in the context of dementia.

Causes

Reading disorders seem to have a biological basis and run in some families. Studies of brain structure, brain function, and genetics would seem to point to a biological basis in many cases. Recent research suggests that there are environmental factors that can cause reading disorders as well. At the same time, some children who exhibit reading difficulties do so based on poor instruction and negative experiences while reading.

A child's ability to acquire the complex skills necessary for reading is dependent on the development and functioning of various systems. These include coding and memory systems and related processes. Reading difficulties could result either from a deficit in brain development or from a combination of a child's genetic inheritance along with environmental and instructional experiences. In addition, emotional and psychological stressors should also not be ignored when students are being assessed.

Symptoms

Students with reading disorder or dyslexia will struggle with or be unable to master the process of understanding the meaning of written text. Therefore, key symptoms of reading disorder are inability to identify words and to comprehend sentences, paragraphs, or longer forms of written expression. Although reading is primarily a linguistic rather than a visual skill, it is important to ensure that students being assessed for reading disorder are not suffering from vision problems.

Treatment

As in most learning disorders, the creation of a supportive team of parents, family members, and educators is important. This will provide the child with the greatest chance of enhancing his or her reading skills. Great improvement can be made to help children read better through instructional activities that are tailored to the child's specific challenges as well as the child's strengths. The focus should be on the reading process and reading development. The teacher should individualize instruction around what the child is already able to do. Recently, it has been proposed that a combination of evidence-based teaching practices and cognitive neuroscience measures based on plasticity in the brain is the best way to prevent and treat dyslexia in many children.

Reality Television (TV)

Reality television (TV) is a program genre that claims to represent real people, not actors or actresses, in unscripted, "real-life" situations.

Definition

- **Reality shows** are sitcoms, documentaries, talk shows, game shows, and sports shows that feature real people, rather than professional actors, in supposedly unscripted events.

Description

Reality TV is a type of television program that presents everyday people in unscripted, actual events in

their life. Instead of employing professional actors, as in other programming genres, reality shows contain regular people. Different types of reality shows include competition-based reality shows, game shows, documentaries, sports shows, family reality, and talk shows. There has been debate about the reality of reality programming, as it has been revealed that some of these shows are not naturally occurring events and would not naturally occur on their own without some provoking, urging, or script writing from show producers.

Reality programming arguably began in the 1940s and 1950s with game shows such as *Cash and Carry, Beat the Clock*, and *Truth or Consequences*. The hidden camera show *Candid Camera* was another reality hit during this time. Another milestone for this genre was the first *Miss America* pageant where beauty queens competed for the renowned title and crown. A well-known reality series on British television that started in the 1960s was the U.K. documentary *Seven Up!*, which chronicled the lives of 14 seven-year-olds. The series has followed up with almost all of the same children first seven, and then 14 years later, with the shows *7 Plus Seven* "*21 Up*," and so forth, every seven years to the most recent show, *56 Up* (in 2013). In 1966, Andy Warhol's *Chelsea Girls* was released and is supposedly to blame for reality television's craze. The 1970s series *An American Family* was most closely related to reality programming as it is thought of currently. This show followed an upper middle-class American family through their trials and tribulations. The 1970s launched a string of reality game shows, including *The Dating Game, The Newlywed Game*, and *The Gong Show*, all featuring real-life people willing to expose their private lives for sport. The 1980s and 1990s introduced another take on reality TV with shows where people put themselves in dangerous situations. These shows included *That's Incredible*, *Thrill of a Lifetime, Expedition Robinson*, and the crime-fighting reality show *Cops*. It was programming like this that led to the later success of reality shows like *Survivor* and *The Amazing Race*. Another reality program subset featured putting a bunch of strangers together for an extended period of time to record their interactions and reactions. Programs like these included the original, *Nummer 28*, the MTV smash series, *The Real World*, *The Apprentice*, and *Big Brother*. This time period also saw a major development in reality television with the invention of computer-based, nonlinear editing for video, making it possible to record and edit hours of footage with ease.

Impact (Psychological Influence)

Due to the popularity of reality television, some cable channels now comprise mainly this type of programming. Fox Reality, Bravo, E!, TLC, and MTV are some of the most popular. The early 2000s saw another explosion in the popularity of reality TV. Several of these competition series have had continued success with adaptations worldwide. Shows like the *American Idol*, the *X-Factor, Dancing with the Stars, Deal or No Deal*, the *Weakest Link, Who Wants to Be a Millionaire*, and *The Voice* are examples. Family reality shows such as *Jon & Kate Plus 8, The Osbournes, Keeping Up with the Kardashians, Duck Dynasty, Teen Mom*, the *Real Housewives* series, and the *Jersey Shore* have been megahits resulting in fan-craze. Reality television nowadays seems to encompass every area, romantic relationships (*The Bachelor/Bachelorette*), self-improvement (*The Biggest Loser, Intervention, Celebrity Rehab*), culinary arts (*Hell's Kitchen*, *Top Chef*, *Rachael Ray*), and even antiques (*Pawn Stars, Storage Wars*). One of the major criticisms of reality programming is that it is not actually depicting reality, as many shows are fabricated settings and somewhat scripted to provide more drama or entertainment. Furthermore, editing can be used to misrepresent characters or mislead viewers as to the events that really transpired on set. Whether they are viewed as positive or negative, the fact remains that reality show participants are often catapulted into instant celebrity status, which many are unprepared for. Nearly 60% of all TV shows currently running are considered in the reality genre. Viewers tune in to watch in record numbers, and many report it as their guilty pleasure.

Reality Therapy

Reality therapy is a type of counseling developed by William Glasser, which is firmly based on the principles of choice theory and focuses on developing successful connections between people in order to alleviate emotional, behavioral, and psychological problems.

Definition

- **Choice theory,** first termed "control theory," was developed by William Glasser to explain human behavior, which states that all humans choose to behave in ways that satisfy five basic needs, the most important being love and belonging.

Description

Reality therapy (RT) is an approach to counseling that was founded by Dr. William Glasser in the 1960s. It is grounded in choice theory, which emphasizes the power of personal choice in determining life's outcomes. RT is different from other forms of psychotherapy as it focuses on what Glasser termed the three Rs: realism, responsibility, and right-and-wrong. This is in stark contrast to other therapeutic approaches based on a medical model that attribute problems to chemical imbalances or disorders and encourage the use of psychotropic medications to help alleviate symptoms. The goal of RT is to assist the client in building supportive, fulfilling connections with others. The belief is that all human angst is derived from a lack of positive relationships, and if one is assisted in building these connections, one will have better coping skills and have the wherewithal to withstand difficulties that may arise. Five basic needs that all humans strive for are at the heart of RT: (1) power—a sense of self-worth attained from winning or achieving something; (2) love and belonging—connection to one's family, community, or other loved ones; (3) freedom—sense of personal autonomy or independence; (4) fun—sense of enjoyment, pleasure, and satisfaction; and (5) survival—basic physiological needs such as food, drink, shelter, safety, and sexual fulfillment. If one or more of these basic needs are unmet, then discord, unhappiness, and loneliness can result.

Reality therapy begins with a therapeutic alliance. Emphasis is placed on forming a trusting, empathetic, and supportive bond between the counselor and counselee. This relationship is then used as a vehicle to address outward problems. A reality therapist will focus on the present instead of the past; empower the client to make own choices and accept responsibility for those; avoid criticism, blame, and complaints; assist the client in making specific plans and steps toward growth; and use encouragement and support throughout this process. Once a trusting relationship is established between counselor and client, the focus then moves to an action plan taking into account personal choices and reinforcing responsible behavior. The therapist focuses on "getting real" or looking at the objective reality of the client's current situation. Accountability is key as the client moves from blaming and criticizing to accepting change and establishing supportive connections with loved ones. It is from these relationships that people feel safe, cared for, and empowered, and are thus able to create new realities.

Development (History and Application)

Dr. William Glasser and his mentor, Dr. G.L. Harrington, developed RT at the Veterans Administration Hospital in Los Angeles, California, in the early 1960s. His first book on the topic *Reality Therapy: A New Approach to Psychiatry* was published in the United States in 1965. This was a client-centered process that empowered people to recognize how much control they have over the choices they make in life. By the 1970s, he came to refer to his theory as control theory, later changing the name to choice theory in the 1990s. Glasser founded The Institute for Reality Therapy in Tempe, Arizona, in 1967, which he changed to The Institute for Control Theory, Reality Therapy, and Quality Management and finally to The William Glasser Institute in 1996. Branches are now located throughout the United States as well as in several other countries.

Current Status

On August 23, 2013, William Glasser died of respiratory complications at his home in Los Angeles, California. However, the practice of RT remains a foundational approach in the ongoing work of choice theory followers. It has proven to be a successful intervention for addressing a wide range of complicated issues, including anxiety disorders, substance abuse problems, health concerns, and other life-changing events. Furthermore, RT has been effective in assisting clients from different backgrounds and cultures due to its emphasis on personal choice and decision making. RT principles have been applied in educational settings, most recently to school counseling programs, to foster productive relationships between counselors and students.

Recovery

Recovery from alcohol and drug addiction involves achieving abstinence and improved health, wellness, and quality of life.

Definitions

- **Abstinence** is the restraint of indulging oneself in bodily activities that typically gives an individual pleasure (e.g., alcohol and drugs).
- **Addiction** is the compulsive, continued, out-of-control use of substances, or engagement in behaviors (e.g., gambling), despite physical harm or negative consequences. Addiction is also the physical state of being dependent on a substance.
- **Alcoholics Anonymous** is a self-help fellowship that was founded by Bill Wilson and Dr. Bob Smith in 1935 to help people struggling with alcoholism. It is also called Twelve-Step Program.
- **Dependency** refers to the body's physical need for continued or increasing use of a substance in order to maintain the effect or to ward off withdrawal symptoms.
- **Mental disorder** is a bodily or mental condition evident by adequate disorganization of mind, personality, and emotions that seriously impairs an individual's normal functioning. Schizophrenia is a serious and debilitating mental disorder.
- **Sobriety** refers to the state of being sober and of not having any mood-altering substances such as drugs or alcohol in one's system.
- **Substance use disorders** are a category of conditions associated with the continued use of substances, such as alcohol or drugs, despite causing significant cognitive, social, behavioral, health, and psychological consequences.
- **Withdrawal** is the body's physical reaction (e.g., cravings, depression, pain, trembling, hallucinations) to a decreased or discontinued use of a substance.

Description

"Recovery" is a broad term meaning recuperation or a return to a previous or higher level of functioning. The recuperation can involve a physical condition, like a broken bone or a mental condition like schizophrenia. Here, it refers specifically to alcohol and drug addiction. In substance abuse treatment the phrase "recovery" or "in recovery" is used to mean someone who is in the process of recovering from a substance use disorder. More explicitly recovery refers to successful

abstinence from alcohol, drugs, and other substances. Recovery and the recovery movement have their roots in Alcoholic Anonymous (AA), which remains the most well-known recovery program. Although there were other approaches to recovery in the 1930s, the founders of AA developed an approach to help alcoholics recover from their addiction.

Recovery approaches share many elements in the recovery process. Typically recovery is a group-oriented, supportive, social approach to sobriety. Most recovery groups such as AA are not led by professionals but rather by people in recovery themselves. Social support is critical to recovery, and mentors, referred to as "sponsors," who have experienced long-term sobriety, play a crucial role in the care, encouragement, accountability, and support to those new to recovery. Common themes include the recognition of powerlessness over their addiction, the need for a higher power to rely upon for help in recovery, and surrendering one's helplessness to that higher power; making amends to people who have been harmed; and attending meetings as often as needed in order to stay sober.

Recovery Process

Recovery is a series of steps individuals take beyond an addiction to improve their wellness and health, while living a self-directed (responsible) life and striving to reach their highest potential.

Definitions

- **Abstinence** is the restraint of indulging oneself in bodily activities that typically gives an individual pleasure (e.g., alcohol and drugs).
- **Addiction** is a chronic disease of the brain, which involves compulsive and uncontrolled pursuit of reward or relief with substance use or other compulsive behaviors.
- **Detoxification** is a process of purging the body of the toxic effects of a drug or substance. During this process the symptoms of withdrawal are also treated. It is also called detox.
- **Sobriety** is the condition of complete abstinence from all mind-altering substances as well as increased mental, physical, and spiritual health.
- **Substance Abuse and Mental Health Services Administration** is a federal agency that promotes health and well-being by reducing the impact of substance abuse and mental illness in communities.
- **Substance use disorder** is a disorder in which one or more mind-altering substances lead to clinically significant distress or impairment in an individual.
- **Twelve-Step Programs** are self-help groups whose members attempt recovery from various addictions based on a plan called the Twelve Steps.
- **Withdrawal** is the body's physical reaction (e.g., cravings, depression, pain, trembling, hallucinations) to a decreased or discontinued use of a substance.

Description

Recovery is a series of steps an individual takes in moving beyond an addiction to health. Abstinence is

the first step and working to achieve sobriety is another step in the recovery process. Recovery and the recovery movement have their roots in Alcoholic Anonymous (AA), which remains the most well-known recovery program. Although there were other approaches to recovery in the 1930s, the founders of AA, Bill Wilson and Bob Smith, developed the approach to help alcoholics recover from their addiction. While the recovery movement has its roots in AA, it is much broader than Twelve-Step Programs.

The Substance Abuse and Mental Health Services Administration (SAMHSA) describes recovery from mental disorders and substance use disorders as a process of change in which an individual improves his or her wellness and health, and lives a self-directed life, while striving to reach his or her highest potential. SAMHSA describes four major elements that support a life in recovery. The first element includes health, which attends to managing or overcoming an individual's disease(s), in addition to living in an emotionally and physically healthy manner. The second element involves living in a stable and safe place. The third element includes finding purpose in meaningful daily activities (e.g., school, job, and family caretaking). The fourth element involves engaging in relationships and social networks that provide support, love, hope, and friendship (e.g., becoming involved in the community).

In 2011 the Substance Abuse and Mental Health Services Administration developed a working definition of "recovery" in order to assist policy makers, providers, and others to better design, deliver, and measure services to those in need. SAMHSA defined recovery as "a process of change through which individuals improve their health and wellness, live a self-directed life, and strive to reach their full potential" (SAMSHA, 2012). SAMHSA also listed the following guiding principles: recovery emerges from hope; is person driven; occurs via many pathways; is holistic; is supported by peers and allies; is supported through relationship and social networks; is culturally based and influenced; is supported by addressing trauma; involves individual, family, and community strengths and responsibility; and is based on respect. SAMHSA also led the "Recovery Support Strategic Initiative" in order to partner with people in recovery from mental and substance use disorder to guide behavioral health systems and promote approaches that foster health and resilience and provide housing, employment, and educational support.

Mental health professionals and individuals in recovery are aware there is hope that is found in recovery. In many cases, individuals with the disease of addiction feel hopeless. However, recovery is available even when an individual perceives there is not any hope for changing his or her behaviors and living a healthy life. Taking care of oneself and having a good support group (e.g., Twelve-Step Programs) are a very important part of recovery. Having peer support and participating in self-help activities can benefit an individual in recovery. Furthermore, it can optimize the health status of the individual and influence positive outcomes in recovery.

Treatment

Addiction that is untreated or treated inadequately can cause disability or premature death. Addiction must be managed and monitored over time in order to decrease the occurrence and intensity of relapses, sustain periods of remission, and optimize an individual's level of functioning during periods of remission. In many cases medication management can improve treatment outcomes. Integrating rehabilitation with medication management has been shown to provide effective outcomes. Furthermore, recovery from addiction can be achieved through a combination of mutual support and professional care provided by trained and certified professionals.

The recovery process has also been adapted to the treatment and management of mental health disorders, including mood, psychotic, and personality disorders. Recovery approaches to treatment have been included in many, if not all, substance use rehabilitation treatment centers. Many other addictive-type problems have also benefited from a recovery approach such as gambling, sex, and food addictions.

Reggae Music

Reggae is a musical style built on an irregular, offbeat rhythm accompanied by spoken-song lyrics.

Description

Reggae music is widely considered the sound of countercultural and underprivileged peoples around the world. Emerging in the 1960s in Jamaica, its irregular rhythms and native-slang lyrics contained stinging social commentaries designed to agitate for change. It is almost exclusively performed by mixed race or black singers, who often espouse a Rastafarian worldview.

Reggae is a musical style built on an irregular, offbeat rhythm accompanied by spoken-song lyrics. It has been a conduit of self-expression for many poor, underprivileged, and marginalized individuals around the world. (Bunyos/Dreamstime.com)

As a result, it has been viewed with wariness, disdain, and, in some cases, open hostility by traditional Eurocentric ruling classes.

Official hostility has not diminished the power or popularity of reggae. On the contrary, for many performers, upsetting and annoying the status quo is the whole point. For others, the revolutionary elements of the music serve as a force of unification and a way for marginalized groups to share a feeling of solidarity between countries, languages, and continents.

Reggae was born in the 1960s, growing out of ska, jazz, and R&B traditions. At the time, it was treated as a dangerous, ethnic, countercultural sound that highlighted the lower-class experience. Jamaican performers such as Bob Marley—perhaps reggae's best-known voice—lifted the style to the world stage. In this way, Marley and others like him brought the discussion of modern racial identity to the forefront and provided a platform for voices outside the Eurocentric power structure.

Early reggae stars came primarily from Jamaica, but reggae is now performed worldwide. Songs often focus on social issues with a view toward illuminating injustices and inspiring marginalized peoples (particularly of African heritage) to take action and make changes. While reggae is not inherently religious, it is often associated with and performed by those with a Rastafarian worldview.

The unique rhythmic sound of Reggae seems more suited for a relaxed party than a revolution. However, traditional reggae music was intended as a vehicle for expressing what could not be openly said, particularly with regard to black/white power imbalances, economic injustices, and rejections of colonial/imperial power structures. As it spread, it was a way for performers to advocate unification of peoples—particularly traditionally oppressed black and mixed-race peoples—and deliver sharp political takedowns disguised as catchy dancehall music.

Development and Current Status

As the sound spread, key style points emerged. For example, reggae was to use as much of the local slang as possible, pushing back against power structures who tried to stamp out native dialects in the islands, Africa, and Central America. This also gave reggae a touch of "in-group" cachet, as outsiders (cultural or economic) would miss the real meaning of many verses.

Songs were to contain a social message. This might be a celebration of a cultural experience unique to pan-African or mixed-race peoples or a cautionary tale about the workings of "the man" in the country. Often, songs were an exhortation to listeners to band together as brothers in a common experience of oppression/repression and work for peace, unity, and love among mankind.

Finally, and perhaps most controversially, reggae songs were to feature Rastafarian ideologies. This belief system had become associated with "pure" reggae, since many early genre pioneers were Rastafarians. However, marijuana use, dreadlocks, and orthodoxy of Rasta sometimes served as a barrier to the spread of the music, particularly in strong Catholic countries, and this style point is inconsistently applied in modern, commercialized reggae.

Yet even with varied stylistic elements, modern reggae builds on the original drive to inspire underprivileged peoples from all backgrounds. Even as it influences and blends into rap, *reggaeton*, and punk movements, reggae retains its traditional association with the marginalized, independent, and countercultural forces in society. This association does fade in some of the most commercialized forms of reggae. These newer songs are more highly sexualized with only light touches of social commentary or Rastafarian beliefs. As a result, there is some tension between "original" reggae artists focused on raising awareness of the "inferior" classes who continue to be exploited and artists who focus on *reggaeton* club hits that often receive lucrative mainstream radio play.

Impact (Psychological Influence)

Despite the tension between ideology and financial success among artists, as reggae matures it continues to build on its popularity. Its evolution does not diminish its role as a voice for revolution, racial awareness, and respect for all peoples.

Rehabilitation Counseling

Rehabilitation counseling is a type of counseling that focuses on helping individuals who have disabilities to achieve their career, personal, and independent living goals.

Definitions

- **Rehabilitation** is the process of restoring to good health or improved quality of life through therapy or education.
- **Rehabilitation counselors** are certified counseling professionals who help people with emotional and physical disabilities live independently.

Description

The practice of rehabilitation counseling aims to improve the lives of people with physical, mental, and emotional disabilities. The counseling process is interested in helping clients achieve independence in their work and personal life. Rehabilitation counselors apply communication, behavioral goals, social integration, and vocational therapy to help meet their client's goals.

Rehabilitation counseling also focuses on the use of assessment, diagnosis, and treatment planning like counselors in other fields. What makes them different is that they are often focused on case management and advocating for their clients. Advocacy is used to make changes in the environment to remove barriers and use policy to create more access to help for their clients. Counselors may focus on rehabilitation work in private practice, hospitals, colleges, universities, government agencies, and more.

Development

At its start, rehabilitation counseling was focused on adults with disabilities. In the 1940s programs in education began to focus on helping people with disabilities. But it wasn't until 1954 that the federal government provided funds to establish rehabilitation programs. At this time federal and state vocational rehabilitation programs were funded and regulated by different governing bodies. These programs help place people with disabilities in jobs and careers. The creation of professional associations for rehabilitation counselors, such as the Commission on Rehabilitation Counselor Certification and the Council on Rehabilitation Education, has solidified the field of rehabilitation counseling.

Current Status

The Bureau of Labor Statistics predicts that jobs in rehabilitation counseling are expected to grow at a rate that is greater than the average career. In the United States, many rehabilitation counselors currently work in different arenas. Rehabilitation counselors work most commonly in state rehabilitation programs, in social service agencies, and in colleges as disability or career counselors.

The biggest need for rehabilitation counselors is within federal- and state-funded vocational rehabilitation programs. Rehabilitation counselors can work in the not-for-profit corporate sector through career counseling or at the administration level in supervising staff or directing programs for people with disabilities. Some may supervise staff in case management programs that serve people with disabilities.

In addition to this, rehabilitation counselors may work with independent living centers doing community engagement, advocacy, and referrals for people

with disabilities. Rehabilitation counselors who have a business or corporate focus also work as consultants, establishing their own private service agencies. Counselors working with corporations focus on community relations or corporate service, serving as liaisons between companies and charities or service programs.

Legally, colleges and universities are required to make accommodations for students with disabilities. This occurred as a result of the Americans with Disabilities Act. Most academic settings have an office and staff dedicated to helping students with disabilities. Services offered in college disability services usually include counseling, technology assistance, referral services, note taking, and tutoring. The help they provide is usually to ensure that students achieve academic, social, and emotional success in college.

Reinforcement

In psychology, the term "reinforcement" is used to describe any stimulus that increases or strengthens the likelihood of a certain response or behavior.

Definitions

- **Behaviorism** is a theory developed by psychologists John B. Watson and B.F. Skinner that is concerned with measureable, observable behavior rather than inner processes such as thoughts and feelings.
- **Extinction** refers to the diminishing of a conditioned response, which occurs when a stimulus no longer has an effect on behavior.
- **Operant conditioning,** a theory of learning proposed by B.F. Skinner, teaches that behavior can be modified through the use of positive and negative reinforcements.
- **Punishment** is a consequence imposed following an operant response that decreases, or is meant to decrease, the likelihood of the same response occurring again.

Description

Reinforcement, or any stimulus that prompts behavior to increase or strengthen, is a principal component of behaviorism. When actions are reinforced, they are more likely to occur again. Reinforcement can be categorized as either primary or secondary. Primary, also known as unconditional reinforcement, is naturally occurring and does not require any learning to take place. Air, water, food, sleep, and sex would be examples of primary reinforcers. Secondary reinforcers, those dependent on conditioned reinforcement, can be both positive and negative.

Based on the theory of operant conditioning, coined by behaviorist B.F. Skinner, the introduction or removal of positive and negative reinforcers is responsible for behavior change. "Positive reinforcement" refers to the adding of stimulus (i.e., praise, tangible rewards such as toys, prizes, tokens, money) in hopes of increasing the desired behavior; "negative reinforcement" refers to the removal of a stimulus (i.e., time out, ignoring, removing privileges) in order to increase the desired action. Negative reinforcement differs from punishment, or a consequence that when introduced is likely to result in a decrease or disappearance in the behavior. When a conditioned response is extinguished, due to an ineffective stimulus, this is referred to as extinction. Reinforcement can be dispensed continuously or at variable schedules, and at fixed times or at set intervals. The schedule at which the reinforcement is delivered typically correlates with differing rates (in terms of duration, frequency, and magnitude) of the desired behavior. Once a behavior is acquired, it is advised to change this schedule in order to prevent the behavior from extinction.

Current Status and Impact (Psychological Influence)

In contrast to psychoanalytic and cognitive-based theories, the founding fathers of behavioral research, Ivan Pavlov, Edward Thorndike, John B. Watson, and B. F. Skinner, proposed that behavior change occurs in response to external stimuli rather than internal processes (thoughts and feelings). Countless experiments have been conducted since in support of this theory. The salience of positive reinforcement in particular has been well studied, and its concepts have been applied to the fields of psychology, sociology, politics, and education. Behavior modification programs, token economies, and learning communities have all derived from positive reinforcement concepts. Parents and teachers who employ these types of strategies report positive effects related to behavior, affect, motivation levels, self-concept, relationships, and achievement. Negative reinforcement, though also proven effective, is more susceptible to extinction if not delivered consistently.

Relapse and Relapse Prevention

Relapse is the recurrence of symptoms after a period of improvement or recovery. Relapse prevention is the effort to maintain health and prevent the recurrence of relapse.

Definitions

- **Addiction** is a chronic disease of the brain that involves compulsive and uncontrolled pursuit of reward or relief with substance use or other compulsive behaviors.
- **Addiction recovery** is the state of abstinence from addictive behaviors, usually achieved through self-reflection and spiritual exploration.

Description

Although the original use of the terms "relapse" and "relapse prevention" was strictly medical, both words have come to be used in the field of mental health in an extended way. Relapse was first extended to those combating addiction, especially to alcoholics and drug users. It is today often applied to the behavior of those suffering from severe personality disorders when treatments they have been using, whether drugs or cognitive behavioral interventions, fail. For example, this can happen for people experiencing psychosis who might not be properly medicated.

While there are different measures of relapse rate, two widely accepted criteria are a significant worsening of symptoms after a more stable period and the need for rehospitalization within a few years of first hospitalization. Not adhering to medication is a principal cause of relapse, especially in schizophrenic or bipolar patients.

Relapse is a constant and difficult challenge in the treatment of mental disorders. Success in changing or controlling problematic behaviors depends on many individual, social, and medical conditions. When a person with behavioral issues is confronted with the elements that encourage or provoke his or her dysfunctional behavior, there is always a risk that the person's ability to respond with appropriate coping mechanisms may fail. The factors that cause relapse can vary but might include the availability of a drug, the presence of a person who is threatening, or simply the terror of being out of control in a social situation.

Relapse prevention is an activity of vital interest to the person suffering from behavioral issues. It is also important to the person's family and friends, as well as professionals for both humane and economic reasons since hospitalization and treatment can be expensive. Comprehensive treatment plans need to include the

identification of high-risk situations. Identifying key relapse triggers and emergency interventions that may go from the most critical, such as hospitalization, to a simple low-impact therapy highlights the dangers and reinforces the patient's effective coping strategies. Educating the patient about the dangers and possibilities of behavioral relapse also lays the groundwork for the possibility of a more cooperative intervention if one should be needed.

A holistic approach to relapse prevention should include regular interactions with counselors and medical professionals. This includes supervising and updating drug protocols and a range of healthy living activities. Meditation and mindfulness exercises have been shown to have positive results in the treatment of such behavioral disorders as depression and anxiety. Learning to control the stressors in daily life, regular exercise, and a healthful diet are activities that reinforce calm and balance in those being treated both with drugs and with cognitive behavioral activities.

Current Status and Impact (Psychological Influence)

Since the 1990s many studies have been done on the effectiveness of a variety of relapse prevention programs. This is partly because it has become clear that antipsychotic drugs do not completely resolve hallucinations and delusions in some patients. In addition cognitive behavior therapy has been shown to be effective in controlling symptoms in such diverse behavioral dysfunctions as depression, obsessive-compulsive disorder, bipolar disorder, and schizophrenia.

Recent studies indicate that family intervention and family involvement with the patient significantly decrease the relapse rate. In clients diagnosed with schizophrenia, the involvement of relatives in the treatment protocols was seen to reduce the relapse rate by as much as 20%. This seems to support a movement away from sole dependence on medications to control symptoms and reinforces the importance of psychosocial interventions for more effective relapse prevention.

Relaxation Therapy

Relaxation therapy is a practice by which anxiety or tension in the mind is released in order to improve physical and mental health.

Definitions

- **Mindfulness** is the moment-by-moment awareness of one's thoughts, feelings, sensations, and environment without evaluating or judging them.
- **Relaxation** is the state of being free from tension and anxiety or the restoration of equilibrium following emotional disturbance.
- **Stress management** is a set of psychological techniques for increasing the capacity to better cope with psychological stress. It usually includes relaxation methods.

Description

During the 20th century, a group of famous yogis brought eastern meditative approaches to the West. These approaches were an alternative and a challenge to some of the practices of Western medicine. Therefore, groups began to develop a plan to legitimize relaxation and meditative practices through scientific study.

When research on meditation was conducted by medical practitioners at many universities, it turned out that quieting the mind and body helped subjects in achieving a state of physical and mental relaxation. These states of relaxation led to faster and better healing, both physically and psychologically. With scientific research to support its effectiveness, relaxation, meditation, and mindfulness therapies are now proven

therapeutic approaches and recommendations for those with mental and physical disorders. It is now practiced in many clinical settings under a variety of different names and with slightly different approaches.

Development

Dr. Edmund Jacobson was the first American physician to become widely known for using relaxation therapy as a therapeutic technique. He began using it especially to release tension from muscle groups. His seminal work *Progressive Relaxation* was published in 1938. In the 1950s, Dr. Joseph Wolpe, a behavior therapist, used similar ideas and therapeutic techniques to help treat anxiety and other behavioral disorders. Progressive relaxation became an effective method of stress management.

One of the most famous American physicians and advocates of relaxation therapy is Dr. Herbert Benson. He first published his popular book *The Relaxation Response* in 1976. It was based on the teachings of Maharishi Mahesh Yogi and his transcendental meditation that became very popular as a cultural phenomenon in the early 1970s. Cultural icons such as the Beatles went to India and learned from the Maharishi. In part, this helped popularize meditation and relaxation approaches among young people.

Dr. Benson's success was partly based on his ability to clearly explain the benefits of meditative relaxation. He could scientifically describe and show how the regular practice of relaxation therapy, with or without spiritual roots, could help treat a wide range of stress-related disorders. Dr. Benson went on to found Harvard University's Mind Body Medical Institute to study the methods and effects of meditation, mindfulness, and similar therapies on healing.

Current Status

Today many hospitals and clinical settings regularly use or recommend the use of meditation or relaxation techniques. These recommendations are made to decrease tension as a key factor in the promotion of recovery and better health. In clinical trials, patients suffering a diverse range of problems, from cardiac and cancer patients to those suffering from depression and anxiety disorders, all showed significant improvement through the use of relaxation therapy. With these results, it is no wonder that at least 20 million Americans practice meditation, yoga, and other methods of relaxation as a systematic treatment to prevent problems experienced by the mind and body.

Religion and Religiosity

"Religion" refers to the beliefs, doctrines, theology, and practices associated with specific religious institutions.

Definitions

- **Adherents** are people who are followers or members of a religion, cause, movement, or belief.
- **Fundamentalism** refers to strict, narrow, and demanding religious beliefs and practices.
- **Intrinsic** means to genuinely and deeply value something as if it's a natural part of who you are.
- **Sacred** is defined as those things that are holy, "set apart," and include objects, rites, and rituals.
- **Theology** refers to the study and concepts of the nature of God.
- **The Transcendent** refers to a spiritual force or entity that exists beyond the physical realm of ordinary consciousness.

Description

Americans' self-reported belief in God, or a universal spirit, has remained relatively constant since the 1940s. According to a 2011 Gallup poll, 91% of Americans sampled stated they believe in God or a universal spirit. Religion deals with important questions about life, relationships, morality, meaning, purpose, life after death, and how people should live their lives. Religious beliefs and practices evoke considerable passion for adherents, and few people, even atheists, remain neutral when it comes to their beliefs. Given the significance of religion in people's lives, mental health researchers have long been interested in the role religion plays in a person's mental, emotional, and psychological health. Researchers investigating the value of religion, religiosity, and religious practices have reached opposing conclusions. Religion has been described as a source of wholeness, balance, harmony, and peace—a pathway to healing, wisdom, maturity, and the highest of human potentials. It has also been criticized as being punitive, exploitive, irrational, pathological, dangerous, and opposed to the goals of mental health.

In the past the terms "religion" and "spirituality" were used interchangeably but are now used to characterize different aspects of the spiritual experience. Religion is distinguished as having an institutional dimension connected to specific faith traditions. The term "spirituality" has yet to be clearly defined and is most often used to describe a wide array of personal spiritual experiences that may, or may not, be associated with any specific religion. Researchers define religion in different ways but most agree on its basic elements, which include an organized communal belief system with shared doctrine, rituals, and practices.

Psychologist Kenneth Pargament (1950–), one of the leading scholars of religion and religiosity, broadly defines religion as a search for significance in ways related to the sacred. This definition is broad enough to be inclusive of many forms of organized religious traditions, some of which are very positive and some very negative. Religion is experienced through various ways of thinking, behaving, feeling, and relating. Thinking includes a person's beliefs, theology, and ideologies. Behaving includes rituals and practices such as singing, prayer, and participating in sacred rites. Feeling involves emotional states such as awe, peace, fear, and guilt. Relating includes social bonding through shared practices and interactions in congregations or fellowships.

People turn to religion for a variety of reasons. Some embrace religion for personal reasons such as finding meaning or peace or developing self-control. Others enjoy religion through social dynamics, such as developing connection with others. Many embrace religion as a way to know God, to connect with the transcendent, and to live according to a sacred set of values. The definition stated earlier also includes some very destructive aspects of religion, such as terrorism, hate speech against marginalized groups, and self-glorification.

Current Status and Impact (Psychological Influence)

Pargament analyzed the empirical research literature and drew several conclusions about religion and its impact on individuals. Some forms of religion are more helpful than others. Religion that is intrinsic and built on a secure relationship with God accompanied with a sense of connectedness to others is positively associated with a sense of well-being, higher self-esteem, greater tolerance, and positive religious coping. Religion that is imposed, built on fear and guilt, or unexamined does not have these benefits. How people cope with stressful experiences is related to their conceptions of divine power and can have a positive or negative impact on their mental health. Positive religious coping is associated with a sense of a loving and supportive relationship with God, spiritual connectedness to others, support of clergy and congregation members, and a belief that there is meaning and purpose connected to the experience. Positive religious coping is beneficial and has been linked to less depression and anxiety, greater stress-related personal growth, and better quality of life. Negative religious coping is associated with an unstable relationship with God, questioning the power of God, anger toward God, discontent with clergy and congregation members, attributing troubles to demonic forces, and an ominous view of the world. Negative religious coping has been linked to anxious and depressed mood,

greater psychological distress in disaster, poorer physical health, and more trauma symptoms.

There are advantages and disadvantages to all religions, even controversial ones. For instance, religious fundamentalism found in many of the world's religions has been associated with greater prejudice and bigotry toward blacks, women, Jews, and homosexuals, as well as narrow mindedness and willingness to support torture. In spite of these criticisms, strict belief systems offer some benefits to its adherents, including an unambiguous sense of right and wrong with clear rules for living; a distinct identity; social closeness, community, and belonging with like-minded believers; and a strong sense that they are supported and sanctioned by God.

Religiousness is more helpful to marginalized groups such as the elderly, the poor, the less educated, women, and minority groups. This may be due to positive social dynamics linked with religious communities, such as access to emotional support and resources. Religious beliefs and practices are more helpful during stressful situations that push people to the limits of their personal and social resources, such as the death of a loved one or job loss. Levels of religiosity vary a great deal, and those who more fully integrate religion into their daily lives benefit most. Individuals whose faith includes a larger supportive social group and blend their beliefs, practices, and motivations in a shared social context benefit most.

America is becoming increasingly diverse in its religious and spiritual affiliations, and traditional forms of worship, membership, and religious practices are significantly changing. Interest in how these changes are impacting American society will continue to be of great interest to mental health and social researchers.

Religious Coping

Religious coping describes how individuals utilize their faith to evaluate problems and cope with stressful events.

Description

Religion plays an important role for religiously oriented people in coping with stressful life events by offering guidance, support, and hope. Religious beliefs can be a source of meaningful explanations for difficult events and provide a basis for defining and resolving problems. Kenneth Pargament, a leading researcher in religious coping, has conducted extensive research into how religious beliefs and practices may guide individuals in the coping process.

Pargament proposed that individuals whose religious beliefs and practices are a large part of their general orientation to the world utilize religious coping methods in response to stressful events. Building on Richard Lazarus's comprehensive theories of stress, appraisal, and coping, Pargament identified three religious coping styles: deferring, collaborative, and self-directing religious coping styles. These three styles represent consistent patterns of coping response and vary on two key dimensions underlying the individual's relationship with God. The first dimension focuses on who is primarily responsible to solve the problem: God or the individual. The second

dimension focuses on the level of individual activity in the problem-solving process: the individual is highly active and God is passive or the individual is passive and God is active.

The individual who takes an active stance in the problem-solving process and is solely responsible to resolve the problem characterizes a self-directing style. God is passive and not directly involved. This style stresses the power of the person rather than the power of God. This is not an antireligious stance but rather God is viewed as giving people the freedom and resources to direct their own lives. Although it is active, a self-directing style relies on personal rather than religious resources to resolve problems.

A deferring coping style is characterized by the individual who waits for solutions to emerge through the active efforts of God, thus deferring the responsibility of problem solving to God. From this perspective God is the source of solutions, rather than the person. This style stresses the omnipotence of the deity and relative insignificance of the individual who is submissive to God's power.

In a collaborative coping style, the responsibility for problem solving is held jointly by the individual and God. Neither is seen as a passive participant as God is active in the problem-solving process by prompting the person to do what is right through the inner voice of the Holy Spirit. A collaborative style relies on practices, which facilitate and maintain a personal relationship with god.

Building on Pargament's work Anna Wong-McDonald and Richard Gorsuch proposed surrender to God as a fourth coping style. Surrender represents the concept of self-relinquishment and differs from a deferring style in that it is not passively waiting for God to solve problems but rather an active choice to surrender one's will over to God's rule. The authors note that surrender may be more related to collaborative coping in that both the individual and God are active. However, surrender style differs from collaborative style in that when an individual's solution differs from God's solution the individual chooses to follow God's way. Surrendering to God requires self-sacrifice and obedience while the believer lets go of personal desires to follow God's way.

Resilience

Resilience describes an individual's ability to overcome challenges, adapt to new situations, and cope well when faced with adversity or stressful life events.

Definitions

- **Learned helplessness** is a psychological phenomenon that occurs when an organism, repeatedly subjected to aversive or painful stimuli in the past, continues to endure that stimuli in the present circumstance even though it has the means to escape it.
- **Learned optimism,** contrasted with learned helplessness, is a concept from positive psychology that teaches individuals the transformative power of replacing negative self-talk with optimistic thinking.

Description

Those who respond well to life-changing events including stress, trauma, loss, and adversity are characterized as resilient. Resilience is defined as one's ability to preserve adaptive capacity or "bounce back" when faced with challenges. Those who are resilient maintain healthy thoughts, feelings, and behaviors, which serve as "protective factors" to stress. Resilience is viewed as a process, or something that one does, rather than as a stable personality trait that one

either has or does not have. Findings suggest that a host of factors contribute to promoting resilience, the most salient being the existence of positive social support. Additional factors include possessing a healthy self-concept and adequate communication skills, as well as being able to self-regulate, problem solve, and set realistic goals.

Though it may seem to come more naturally to some, resilience can be taught and developed in anyone. Optimists, those who tend to have a positive outlook on the world, are likely to be more resilient than pessimists, or those who view the world through a negative lens. Positive psychologist Martin Seligman's research into learned helplessness resulted in a new concept he termed "learned optimism," which holds that replacing negative thinking with optimistic thought patterns results in psychological, emotional, relational, and physiological benefits.

Current Status and Impact (Psychological Influence)

Drawing on principles from positive psychology, choice theory, social learning theory, and cognitive behaviorism, resiliency research began in the early 1970s with the seminal work of clinical psychologist Norm Garmezy, deemed the "grandfather of resilience theory." Other researchers followed applying this concept to the areas of health, wellness, medicine, education, criminology, anthropology, and sociology. Ann S. Masten's work has been particularly influential in demonstrating how resiliency can impact student behavior and achievement.

There is evidence to support that resilience is commonly displayed by people all over the world of various ages, abilities, intellectual capacities, health, and economic circumstances. However, differences can exist based on one's culture as certain factors associated with resiliency, such as communication skills, degree of openness, and the value placed on relationships, can vary. Research indicates that resilient behavior can protect against further psychological harm, emotional distress, or health-related problems.

Resistance

In psychological terminology, resistance is a client's opposition, direct or indirect, to making change in psychotherapy.

Definitions

- **Ambivalence** is a form of a conflict between two courses of action (e.g., indulgence versus restraint) in which each course of action has perceived benefits and costs associated with it.
- **Motivational interviewing** is a counseling strategy for helping individuals to discover and resolve their ambivalence to change.
- **Psychoanalysis** is a theory of human behavior and a form of therapy based on psychoanalytic psychology. In psychoanalysis clients are encouraged to talk freely about personal experiences, particularly their early childhood and dreams.
- **Readiness for change** is the degree of preparedness of the conditions, attitudes, and resources needed for change to happen successfully. It is also referred to as stages of change.

Description

Many seek out counseling or psychotherapy and invest time and money for it. Yet not all will experience changes in their lives as a result of therapy. Some will

experience partial change, while others will experience none at all. Some even appear to sabotage efforts to change. Therapists expect clients to change and when they do not, it is not unusual for therapists to attribute this lack of change to a client's lack of cooperation. Signs of such noncooperation include missing or being late to appointments, not expressing feelings, talking too much, arguing, interrupting, and failing to complete homework.

Resistance to change is a problem that can complicate an individual's personal life and relationships. Understanding why individuals don't change is a complex issue since it can have several determinants, many of which are outside of conscious awareness. Because it is associated with a sense of unpredictability and uncontrollability, change is often resisted, whereas non-change is perceived as relatively safe. It should be noted that outright refusal by a client is not common. Rather, most instances of what is called either resistance or noncompliance may be better understood as ambivalence.

Developments and Current Status

Sigmund Freud (1856–1939) is credited with discovering resistance. It would become a central tenet of psychoanalysis. In fact, Freud considered that psychoanalysis should be a re-education in overcoming clients' resistances. Over the years, a number of other theories and models of resistance have been proposed. Most of these view resistance as failure of the client to cooperate with the therapist and the therapeutic process. However, in solution-focused therapy these behaviors would be considered an individual's unique way of cooperating. What is viewed as resistance may actually be an individual's natural protective mechanism and realistic caution about changing to quickly (Quick, 2008). From the solution-focused therapy perspective, it is the therapist's responsibility to discover and follow the client's unique way of cooperating.

Recently, psychologists Hal Arkowitz (1941–) and David E. Engle have proposed an integrative approach to understanding and working with resistance. In their book *Ambivalence in Psychotherapy* (Engle and Arkowitz, 2006), they emphasize that most resistance is a form of ambivalence, which they call "resistant ambivalence." Resistant ambivalence reflects discrepancies among beliefs relevant to change (beliefs associated with movement toward change and those associated with movement away from change). Most often clients are not fully aware of their beliefs and the discrepancies among them that cause resistant ambivalence. Because it is also an interpersonal phenomenon, it is best understood in the interpersonal context in which it occurs. When it occurs in a therapeutic setting, it is essential that the therapist recognize it as a temporary state rather than a personality trait.

Motivational interviewing (MI) has been found to be effective in resolving ambivalence. MI is focused on increasing the client's readiness for change. It utilizes a number of interventions to resolve ambivalent resistance by fostering change talk. There are four types of change talk that clients make and which therapists should recognize and effectively respond to. They are disadvantages of the status quo, advantages of change, optimism for change, and intentions to change. While MI is not the only strategy for dealing with resistance and resistant ambivalence, it is a powerful intervention that is commonly taught in psychotherapy training programs.

Restless Leg Syndrome

Restless leg syndrome is a sleep disorder characterized by an irresistible urge to move one's legs while attempting to rest.

Definitions

- **Non-REM sleep** is one of the two basic states of sleep consisting of stages 1, 2 (light sleep) and 3, 4 (deep sleep). It is also known as non-rapid eye movement and NREM sleep.
- **Parasomnias** are a group of sleep disorders characterized by abnormal events that occur during sleep, such as sleepwalking, talking, or limb movement.
- **Periodic limb movement in sleep** is a medical condition characterized by involuntary, jerking movements of the legs or arms.
- **REM sleep** is a stage in the normal sleep cycle characterized by rapid eye movement, dreaming, loss of reflexes, and increased brain activity. It is also known as rapid eye movement and REM sleep.

Description and Diagnosis

Restless leg syndrome is a sleep disorder characterized by an irresistible urge to move because of uncomfortable or painful sensations in the legs when attempting to rest and causing a compelling urge to move the legs. The movement makes it difficult or impossible to sleep restfully. Symptoms usually begin within 15 minutes and usually result in significant sleep loss, fatigue, and problems with daily functioning. If asleep these involuntary leg movements, called periodic limb movements in sleep, begin and interrupt sleep.

Restless leg syndrome belongs to a group of sleep disorders called parasomnias. Common to all parasomnias are problems during arousals from REM sleep or partial arousals from non-REM sleep. The parasomnias include nightmare disorder, sleep terror disorder, sleepwalking disorder, and restless leg syndrome.

The likelihood of developing this disorder in one's lifetime is about 4%, a rate that increases until the age of 60. Females are 1.5 to 2 times more likely to develop this disorder than men. Approximately 90% of those with this disorder have periodic movements of sleep involving their legs (American Psychiatric Association, 2013).

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, individuals can be diagnosed with this disorder if they exhibit the urge to move their legs in response to uncomfortable and unpleasant sensations. This urge to move the legs begins or worsens during times of inactivity or rest. In addition, the urge is relieved by movement, is worse at night than during the day, and occurs only at night. These symptoms have occurred three times per week or more and have lasted for three months or more. The episodes must also cause significant distress for the individual or result in significant level of impaired functioning. In addition, the disorder is not the result of a substance, medication, other medical condition, or another mental disorder (American Psychiatric Association, 2013).

The cause of this disorder is not fully understood. However, it appears that iron deficiency and low levels of dopamine may bring on this disorder. Genetic factors also appear to be causative since this disorder commonly runs in family particularly when it is severe and begins early in life. Environmental factors and other medical problems are also associated with this disorder. Restless leg syndrome may begin or be exacerbated during pregnancy. It can also be caused or exacerbated by kidney failure and back problems, and in those with peripheral neuropathy (damaged nerves endings) common in those with advanced diabetes.

Treatment

Treatment of this disorder is based on the cause and severity of symptoms. Regular exercise, stretching, and sufficient sleep may relieve mild symptoms. Also, taking a hot or cold bath, using massage, losing weight, if one is overweight, and eliminating smoking and caffeine could reduce or control symptoms. If symptoms are being caused by iron deficiency or another medical condition, that condition is treated first. It the disorder starts during pregnancy, regular exercise and stretching may be prescribed to relieve symptoms. If symptoms do not improve, medications may be considered when symptoms are severe and interfere with sleep and daily functioning. Medication can be quite useful to both control the urge to move and improve sleep. Commonly used medications include anticonvulsants like Neurontin or sleep medications like Valium, Ambien, or Lunesta.

Retirement

Retirement is a phase of life and developmental period in which individuals are no longer working.

Description

America has often been considered a youth-oriented nation; however, with increasing life expectancies and lower birth rates, there is an increase in the aging population. This trend will have an impact on the culture to accommodate the needs of an aging population. Retirement is something that most Americans will face as a reality at some point in their life. Currently, the retirement age to receive benefits from Social Security is age 65; however, many people are extending their work years far beyond that age, whereas others are looking forward to early retirement.

With the aging baby boomer population, there has been an increasing awareness that retirement will be something different than it was for previous generations. Baby boomers are anticipating working either for enjoyment or out of financial necessity. It is imperative that in working with those preparing for retirement or just joining the workforce that the idea of financial awareness be explored.

For most people retirement is simply having the assets accumulated to provide income as opposed to going to work to earn income. However, with retirement comes financial concerns such as medical expenses, final expenses, and long-term care. Some of these people are able to plan for to some extent so that they can enjoy leisure time to the fullest during their retirement years.

The decision to retire can come as a personal decision or be recommended from one's employment or be due to health concerns. As the decision to leave one's occupation can carry a large impact, it is imperative that counselors are prepared to acknowledge this major life transition for that individual. The transition to retirement is a developmental phase that provides a shift in one's activity at home, work, and the community. It is also a time when the individual must consider his or her financial status looking at investments and future health-care access. It is a time for mindful planning to ensure security, especially with increasing averages of life expectancy. Retirement has moved from simply a description of moving away from the workforce to include new life opportunities. In preparation for retirement it is important to explore and be cognizant of the individual needs and expectations for life as a retiree.

While retirement has been commonly accepted as an absence of paid employment, it may also indicate a move from one form of employment to another or a new chapter of exploration for that individual. The social aspect of retirement must also be an area of exploration. What is this individual hoping to do or accomplish with his or her time? Who will be the active supports in his or her life? It is imperative that individuals be aware of these potential impacts.

Other considerations to be aware of are marital issues, mood changes, grief, caregiving demands, and life decisions. As previously mentioned, this is a developmental phase and the experiences of that are unique to each individual. Retirement counselors must be prepared to potentially address these issues. Returning home after working allows for changes in relationships. There is a period of "getting to know each other" that occurs again. The person may experience anxiety or depression connected to changes experienced from retirement. Generally, retiring is connected to aging and with aging comes health concerns. These health

concerns can be demanding and life altering based on how the individual would like to carry on with his or her remaining days.

Retirement, Psychological Factors

The psychological factors surrounding retirement are defined as mental and emotional factors that impact an individual who is considering retiring or has retired from his or her occupation.

Description

When one chooses to start considering retirement, numerous factors are considered and must be noted as potential impacts. These factors include those of psychological factors such as well-being, self-worth, social supports and networking, goals, and financial stability. A person's individual perception of retirement can largely impact his or her ability to participate or enjoy in separating from the work environment.

The notion of retirement is based on social and organizational policies. Some look at retirement as though it should be a process of transition from one phase of life to the next. In the United States, Americans generally start considering this transition as they approach mid-life, with retirement being considered generally around age 65. Knowing this it is imperative to reflect on some of the psychological factors present.

One argument has been made that when people retire there is a decrease in their cognitive functioning and that there is a connection between drop in employment rate and decrease of cognitive functioning. This argument has been supported by a hypothesis that those who are working are actively engaged in cognitive exercises. The recommendation is then that retirees engage in activities that stimulate the brain (e.g., puzzles) and an active lifestyle to allow for cognitive functioning to remain intact. However, there is also an argument that jobs that have high cognitive demands could lead to an earlier retirement because of the stressors connected to the position.

While we know that factors such as income, security, age, and health weigh in on decisions regarding retirement, there are other factors that carry an impact, such as psychological factors and psychosocial variables. The attitudes and expectations of working as well as life as a retiree have an impact on people. It has been hypothesized that those who expect retirement to be a positive experience are more likely to be interested in retiring early, whereas those who expect it to be negative are more likely to consider a later retirement. For instance, some measure their self-worth based on their job or career. Retiring for that person could be psychologically damaging. For some, retirement is considered a new beginning where they can engage in leisure activities, whereas for others it can bring anxiety due to potential decrease in social contacts, loss of structure, and confusion as to how to spend one's day as well as a fear of financial security.

The psychological resources found in sense of control and adaptation play significant roles. It has been suggested that three factors are connected to expectations of retirement. The first is the perceived self-efficacy of adjustment to retirement. Self-efficacy explores one's ability to effectively cope with changes to one's life that would be experienced in retirement. The second is anticipated social interaction after retirement, and the final factor is attitudes toward leisure.

Differences toward work itself can have an impact on retirement. This would include exploring the impact that working has had on a person and how his or her occupation has defined him or her and been connected to his or her self-identity. Along with this, it's important to consider the potential impacts on health.

With the continued aging of baby boomers, increase in life expectancy, and the rising depletion of social security, there is concern over the ability to maintain these functions that provide health-care support to retirees. The connection between work and health cannot be ignored. The ability to maintain health insurance is often a determinate for potential retirees. Changes to the current Social Security and Medicare system would no doubt influence and impact retirement behavior.

Another important consideration is simply that of happiness and exploring what the individual needs to maintain or increase happiness. Not everyone transitions successfully to retirement and so it's important to explore how an individual is impacted by retirement. The resources that help increase well-being and happiness are connected to social networks and supports such as closeness to a spouse and interactions with friends and family; and financial stability, resources, and goal-directed behavior. A key factor is continuing to find new opportunities and engaging in a fulfilling life per that individual.

Rett Syndrome

Rett syndrome is a neurodevelopmental disorder in children characterized by extreme difficulty with learning, communication, and movements. It is also known as Rett disorder.

Definitions

- **Autism spectrum disorder** is a neurodevelopmental disorder characterized by difficulty learning, communicating, and repetitive bodily movements.
- **Developmental disorders** are a group of mental disorders characterized by abnormal deficits or impairment in the development of learning, language, and coordination.
- **DSM** stands for the *Diagnostic and Statistical Manual of Mental Disorders*, which is a diagnostic system used by professionals to identify mental disorders with specific diagnostic criteria.
- **Neurodevelopmental disorders** are a group of physiological disorders characterized by abnormal growth or functioning of the developing brain or nervous system.

Description

Rett syndrome is a neurodevelopment disorder that manifests at a very young age. Individuals with this disorder develop normally in the early childhood but experience a loss of previously learned ability between the ages of five months and four years. The occurrence of this disorder is rare and almost exclusively females. Rett syndrome is considered to be a lifelong, incurable disorder. It was named for the doctor who first described the disorder, Dr. Andreas Rett (1924–1997). This disorder is often confused with autism and autism spectrum disorders, but is distinctly different.

This disorder was previously included as a formal diagnosis in the previous edition of the DSM. It has been excluded in the new DSM-5 because it is considered a different etiology (cause) than the developmental disorders it was previously grouped with, such as autism. This disorder is caused by a specific mutation of the MECP2 gene. Also, this disorder differs from autism in that Rett syndrome affects primarily females, has a specific time frame of onset preceded by normal development, and has some other specific patterns. The first physical symptom to appear is typically a slowing in the growth of the head. This is followed

by a loss of ability in controlling one's hand and then abnormal walking movements. One of the distinct differences between this disorder and others is that much of the development in these areas is reversed. An individual who was once able to walk, talk, and use his or her hand just like others of the same age loses these abilities. Those with this disorder seldom are able to regain their functioning nor can they learn any significant new skills. They may also experience seizures. Commonly, individuals with this disorder often die in middle age.

There is no effective treatment for the reductions or elimination of this disorder. Treatment is focused on helping the individual and family cope with disorder and navigate the tasks of daily life such as toileting and dressing.

Risk Management

Risk management is the identification, assessment, and management of potential and actual adverse events. Its purpose is to ensure the safety and/or well-being of all involved.

Definitions

- **Involuntary hospitalization** is the legal process whereby individuals are placed in inpatient mental health treatment against their will because they are a danger to themselves or to others. It is also called involuntary commitment.
- **Self-harm** refers to intentional acts of injury to one's own body, such as cutting or burning. It also includes causing self-harm through neglect. It is a maladaptive means for coping with emotional pain, rage, or irritation.

Description

Risk management is the identification, evaluation, and management of situations that may have possible or actual negative events. The events have potential for causing harm to one's self or others. Mental illness increases the possibility of risky and harmful behavior. In mental health clinical practice, the most common risk involves self-harm, violence toward others, or suicide. In such cases involuntary hospitalization may be necessary. Mental illness such as depression may lead to suicidal ideation and completed suicide. Individuals may become violent when they are involuntarily committed or mandated to treatment against their will. These individuals may be also at risk for running away from treatment or leaving against medical advice. Sometimes there is the potential for external violence from family members toward a mentally ill individual. Risk management also includes controlling for treatment errors such as misdiagnoses, inappropriate clinician behavior (e.g., sexual misconduct), and medication misuse or abuse by clients. The delivery of clinical services may help to reduce or eliminate potential risks and maximize client strengths.

Risk management protocol is beneficial not only to individuals (i.e., keeping them safe) but also to the agency or clinical practice. It assists in maximizing the organization's performance and ensuring the safety of staff members. The goal is to achieve a balance between managing risk posed by clients and maintaining a positive therapeutic alliance. A strong therapeutic relationship can help clients assume responsibility for their illness and treatment and manage risky behavior. Clinicians must know how to assess and manage risk and combine this knowledge with clinical judgment. They must assess the risk individuals pose to themselves or others while taking into account potential

threats to the individual caused by the clinician. Clinicians must be aware of risks to clients' autonomy, consumer rights, and self-esteem. Clinicians may need formal training to learn how to assess risk and use risk management tools.

The term "risk management" was originally used by Robert Irwin Mehr (1917–) and Robert Atkinson Hedges (1919–) in their book *Risk Management in the Business Enterprise* written in 1963. This was the first book to be written on the subject of risk management.

Risky Business (Movie)

Risky Business is an iconic movie released in 1983, starring Tom Cruise and Rebecca De Mornay.

Description

Risky Business, written and directed by Paul Brickman, was launched amid a flurry of teen-coming-of-age sex comedies that were wildly popular in the 1980s. This film offers a satirical look at the basic human obsessions of guilt, lust, secrecy, and especially greed. The movie tells the story of Joel Goodson, an affluent high school senior left alone by his vacationing parents. Bowing to peer pressure to not enter college as a virgin, Joel uses his allowance for the services of a hooker.

After a frightening encounter with a transvestite, Joel is given the number of Lana (played by Rebecca De Mornay), who comes to his home and, following a night of teenage boys' dreams, refuses to leave as she's being pursued by Guido the Killer Pimp (played by Joe Pantoliano). Lana soon surveys her surroundings and realizes that with Joel providing a supply of affluent boys for her hooker colleagues, the two have the potential to make serious money with the spacious home currently unoccupied by his vacationing parents.

Perhaps one of the enduring qualities of the film is that *Risky Business* goes beyond raunchy sex humor to address the interplay of sex and intimacy. This movie is both intimate and sexy without sacrificing humor. It also offered one of the most iconic scenes in which Tom Cruise's character comes sliding across the floor in his pressed white dress shirt, underwear, socks, and black wayfarer sunglasses singing Bob Seger's "Old Time Rock and Roll." A search on YouTube shows hundreds of homages to and parodies of this classic scene.

Risky Business offered moviegoers insight into the many advantages of making money through any means necessary, whether it be legally or illegally and regardless of the consequences to you, your family, or friends. In this movie, the message is that money talks and it buys you happiness, including a Porsche, a mansion, and a blonde bombshell. In fact, one line in the movie blithely states that money may not be able to buy you happiness, but it can buy you things that make you happy.

At one point in the movie, Cruise's character asks his friends what their goals are for their lives. One friend succinctly replies, "Make money." His next friend adds, "Make a lot of money." This telling interaction among high school boys in this film helped to glorify the culture of greed and instant gratification so prevalent in American culture starting to unfold in the 1980s and 1990s.

Risperdal (Risperidone)

Risperdal is a prescription medication used to treat the symptoms of schizophrenia and bipolar disorder. Its generic name is risperidone.

Definitions

- **Antipsychotic medications** are prescription drugs used to treat psychotic disorders. They are sometimes referred to as antipsychotics or neuroleptics.
- **Atypical antipsychotics** are a class of newer (second) generation antipsychotic medications that are useful in treating schizophrenia and other psychotic disorders.
- **Neuroleptic malignant syndrome** is a potentially fatal condition resulting from antipsychotic use characterized by severe muscle rigidity (stiffening), fever, sweating, high blood pressure, delirium, and sometimes coma.
- **Schizophrenia** is a mental disorder in which there is difficulty distinguishing real from unreal experiences. Symptoms include hallucinations, delusions, thought and communication disturbances, and withdrawal from others.

Description

Risperdal is in the class of antipsychotic medications known as "atypical antipsychotics" or second-generation antipsychotics. It is used is to treat the symptoms of schizophrenia, bipolar disorder, and irritability associated with autism. Although it is sometimes used in Alzheimer's diseases, Risperdal has not been approved for the treatment of behavior problems in older adults with dementia. Older antipsychotic medications work by blocking dopamine. In contrast, Risperdal is thought to work by maintaining a balance between dopamine and serotonin neurotransmitters (chemical messengers) in the brain. This difference may account for its lower side effect profile and having fewer medication interactions than older antipsychotics.

Precautions and Side Effects

Risperdal should not be used in older adults with dementia because of the increased risk of stroke and heart failure. Those with a history of cardiovascular disease, abnormal heart rhythm, seizures, or low blood pressure should take Risperdal only after discussing the risks and benefits with their doctor. Women who are pregnant should not take Risperdal and should alert their physicians if they become pregnant while on Risperdal. Infants born to mothers who took Risperdal during pregnancy may develop extrapyramidal symptoms and withdrawal symptoms, including agitation, trouble breathing, and difficulty feeding. Breast-feeding is not recommended while taking this medication. Risperdal has been associated with the risk of developing hyperprolactinemia, a blood disorder caused by heightened levels of the hormone prolactin. Symptoms include amenorrhea and lactation in women, and breast development and erectile dysfunction in men.

The most common side effects of Risperdal use include are drowsiness, dizziness, lightheadedness, drooling, nausea, weight gain, and tiredness. More serious side effects include severe dizziness, fast and irregular heartbeat, fainting, and seizures. Rarely, Risperdal can cause a serious condition called neuroleptic malignant syndrome. Risperdal does interact with some other medications. Using Risperdal with blood pressure medications can lead to lowered blood pressure while standing. Risperdal does interact with medications for heart burn and acid reflux such as Reglan. It also increases the sedative effect of alcohol, antihistamines such as Benadryl, medications for sleep or anxiety such as Xanax, Valium, and Ambien, muscle relaxants, and narcotic pain relievers like codeine.

Ritalin (Methylphenidate)

Ritalin is a stimulant medication prescribed for the treatment of attention-deficit hyperactivity disorder. Its generic name is methylphenidate.

Definitions

- **Attention-deficit hyperactivity disorder** is a mental condition characterized by a lack of concentration, impulsive or inappropriate behavior, and hyperactivity.
- **Stimulants** are psychoactive substances that increase wakefulness or alertness. They may be prescribed to treat ADHD and autism; they are also illegally abused.

Description

Ritalin is used primarily in the treatment of attention-deficit hyperactivity disorder (ADHD) in children and adults. It is best used as part of an ADHD treatment program that includes psychological, educational,

and social interventions. Ritalin can help those with ADHD increase attention, focus on activities, organize tasks, and improve listening skills. It is also used to treat a sleep disorder (narcolepsy) and sometimes used to decrease sedation and lethargy from opioid pain medications.

Ritalin is a mild stimulant that is believed to work by activating the brain's arousal system and produce a stimulant effect. This increases levels of electrical activity in the brain resulting in the seemingly paradox response of increasing alertness and attention span while decreasing motor restlessness in ADHD children. It is also believed to work by increasing dopamine levels in the brain.

Precautions and Side Effects

Ritalin use can produce physical and mental dependence. Withdrawal symptoms are common when Ritalin is stopped abruptly. These include anxiety, agitation, paranoid feelings, suicidal thoughts, depression, and sleep disturbances. Ritalin should not be given to those with high levels of anxiety, agitation, severe depression, emotional instability, or a history of alcohol or drug abuse. Nor should it be used by those with Tourette's syndrome, tic disorders, glaucoma, or alcohol or other drug dependence. Ritalin should be used cautiously by those with high blood pressure, those with a history of seizures, and women who are pregnant or are breast-feeding.

The most common side effects of Ritalin are nervousness, difficulties with sleep, tachycardia, and increased blood pressure. It may also cause dizziness, irritability, vision changes, drowsiness, and a poor appetite. Less common side effects include chest pain, palpitations, joint pain, skin rash, and uncontrolled movements or speech. Other side effects may also include a rapid or irregular heartbeat, stomach upset, nausea, headache, blood in the urine or stool, and muscle cramps. Reducing the dose or changing the time the medication is taken can reduce some side effects. Individuals taking Ritalin should have regular blood pressure and pulse checks.

Several drugs may interact adversely with Ritalin, including anticoagulants and drugs to prevent seizures, reduce depression, and treat high blood pressure. Physicians may reduce the dosages of these medications when taken simultaneously with Ritalin.

Road Rage

Road rage is an extreme form of angry or aggressive behavior by a driver of a car or other road vehicle.

Definitions

- **DSM-5** is the abbreviation for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, which is the handbook mental health professionals use to diagnose mental disorders.
- **Impulse control** is the degree to which an individual can control the impulse to act or the desire for immediate gratification.
- **Intermittent explosive disorder** is a mental disorder in DSM-5 characterized by impulsive, aggressive, violent behavior, or angry outbursts.
- **Psychological factors** are mental and emotional factors that affect behavior.

Description

Road rage is a violent criminal act involving the intention of a driver to cause physical harm to another human being. Road rage is aggressive driving that

involves a wide variety of negative behaviors. Some behaviors include tailgating, speeding, cutting off another vehicle, making rude gestures and verbal insults, hitting other vehicles, chasing other motorists, and intentionally driving in an unsafe and threatening manner. Road rage can even lead to more harmful and threatening behaviors and actions, such as altercations, assaults, shootings, and vehicular accidents. The result may be death.

Individuals who engage in road rage have been classified as selfish, vindictive, power hungry, and angry. Road rage may be caused by mental and behavioral impairments. It could involve driver frustration and anger, environmental factors (e.g., heavy traffic), and psychological factors (e.g., displaced aggression, the desire to blame others). Alcohol and substance abuse may also be contributing factors. Those who engage in road rage may also be violent in other areas of their life, particularly family or friends. It may also be a symptom of intermittent explosive disorder. In this disorder individuals may lack impulse control and act on their impulses in a destructive way.

Road rage is a real threat and a major concern to the safety of all road users. A study performed by the Road Safety Unit of the American Automobile Association (AAA, 1995) found in the United States alone more than 1,200 cases of reported road rage. In addition, more than 300 cases of road rage are reported annually that have ended in serious injuries or fatalities. Males with an average age of 33 years are more likely individuals to engage in road rage than females. The National Institutes of Health (DMV, 2015) reported that 5%–7% of nearly 10,000 drivers studied engaged in road rage. The study identified Intermittent Explosive Disorder as a possible cause of road rage. They also reported that the average offender engaged in road rage at least 27 times.

Rogers, Carl R. (1902–1987)

Carl R. Rogers was an American psychologist best known as the originator of the client-centered approach to counseling and psychotherapy.

Description

Rogers's client-centered approach emphasized a person-to-person relationship between the therapist and the client. Rogers insisted that it was the client's role—not the therapist's—to determine the course and duration of therapy. Not surprisingly, this approach has come to be known as person-centered or client-centered therapy. Throughout his career, Rogers also made significant contributions to humanistic psychology, focusing on the worth and dignity of the individual and the human potential for personal growth, awareness, creativity, choice, and self-direction, as well as to humanistic approaches to counseling, which are those that focus on the worth and dignity of the individual and of the human potential for personal growth, awareness, creativity, choice, and self-direction.

Humanistic psychology is an orientation to psychology that assumes that persons are inherently good and that focuses on the exploration of human potential, while emphasizing wholeness and creativity.

Development

Rogers was born, raised, and schooled in a strict, religious environment beginning in Oak Park, Illinois. He then attended the University of Wisconsin where he studied agriculture. However, his interest in psychology was piqued while studying for the ministry at Union Theological Seminary in New York City. After two years he left the seminary and transferred to

Carl Ransom Rogers was an American psychologist who advocated for client-centered therapy. (Everett Collection Historical/Alamy)

Columbia University where he completed his PhD in clinical psychology in 1931.

While finishing his doctoral work, Rogers became involved in research and clinical work with youth at the Society for the Prevention of Cruelty to Children in Rochester, New York. He also lectured at the University of Rochester. Based on his work with troubled youth, he published his first book *The Clinical Treatment of the Problem Child*, in 1939. He then took the position of professor of clinical psychology at Ohio State University in 1940. There he published *Counseling and Psychotherapy* in 1942. In 1945 he became professor of psychology at the University of Chicago. Here he started researching his client-centered approach at the university counseling center that he helped establish. The initial findings appeared in two influential books: *Client-Centered Therapy* and *Psychotherapy and Personality Change*. He moved on to University of Wisconsin–Madison in 1957 where he published his best-known book *On Becoming a Person*. From there he moved to La Jolla, California, where he helped establish the Center for Studies of the Person. During that time he published *Carl Rogers on Personal Power* in 1977 and *Freedom to Learn* in 1983.

Impact (Psychological Influence)

Rogers's client-centered/person-centered approach to therapy has widespread acceptance and has been applied to education, nursing, social work, management, interpersonal relations, and international relations. Rogers's approach has significantly influenced other psychotherapy approaches. He was one of the first psychotherapy researchers to study therapy outcomes and treatment effectiveness, and pioneered the use of recording and transcribing therapy sessions.

Rogers was also a leader in the humanistic psychology movement which was a distinct counterpoint to psychoanalysis and behaviorism, the two reigning orientations in psychology at that time. He is widely regarded as one of the most influential forces in psychology. In a survey of professional psychologists, Rogers was ranked as the sixth most eminent psychologist of the 20th century (Haggbloom et al., 2002).

Role-Playing

Role-playing is a therapeutic technique that is designed to reduce the fear or discomfort that people experience in various social situations.

Definition

- **Social skills training** is a form of therapy used by teachers, therapists, and mental health professionals to help people with social challenges.

Description

Role-playing is accomplished by having clients act out scenarios where they represent the behaviors of themselves or of others. For example, a problematic relationship between a client and one of his or her parents could be dramatized by having the client assume the role of his or her parent. Clients are encouraged to do this with as much detail possible and play it out to gain insight or understanding. Reenactment of past traumatic events through role-play can provide therapeutic value.

Likewise, the experience of acting out feared or avoided social situations may give clients a greater degree of comfort in dealing with these situations in real life. The opportunity to practice and rehearse situations through role-playing is helpful. One of the ways it helps clients is to practice social skills and rehearse them in a simulated situation. Examples of feared or problematic situations might be giving a speech, engaging in small talk, or asking someone out on a date.

The focus during a role-play session is on the acting out of different scenarios, rather than simply talking through them. Different elements of theater are involved in role-play and more specifically in psychodrama. This can include the use of props or scene setting, which enhances and heightens the feeling of reality in the experience. Elements of psychodrama, including role-playing, indicate that the process is more important than the content. This means that the situations and the interactions are often more important than the words or ideas.

Development (History and Application)

Role-playing can be traced back to the work of the influential psychiatrist Jacob Moreno. He first introduced the idea of group psychotherapy to the United States in the 1920s. He developed and refined the theories and tools for role-playing and psychodrama.

Research has examined the advantages and disadvantages of role-playing. One argument is that under most circumstances role-playing is not a legitimate substitute for other psychological methods. Nevertheless, it is this kind of work that laid the foundations for interactive group therapy, which in turn is a key tool for work with different conditions and populations. Role-playing is often used in therapy with children, clients diagnosed with substance use disorders, and those who are socially challenged.

Current Status

Role-play has become a standard and accepted feature of psychological treatment and popular culture. It has been effective enough that it will continue to be used both for general social improvements and in therapeutic applications. When used effectively, role-play can greatly enhance a person's ability to handle situations that were previously difficult for him or her. But like many practices or tools that become commonplace in our culture, it can also be ineffective or even counterproductive. This happens when it is used in too casual or haphazard a manner. Carelessness and lack of fidelity to effective practices will diminish the potential effectiveness of role-playing. Whatever the original social skill capabilities of the participants may be, those skills can usually be improved with the opportunity to practice, which role-playing can help provide. Even small gains in understanding or comfort in dealing with unpleasant or problematic situations can improve the quality of one's social relationships and life overall.

Rorschach Inkblot Test

The Rorschach inkblot test is a psychological test of underlying personality structure revealed through an individual's responses to 10 inkblot designs. It is also known as the Rorschach psychodiagnostic test, the Rorschach test, and the Inkblot test.

Definitions

- **Projective personality test** is a psychological test where the test-taker responds to ambiguous stimuli that reveal his or her unconscious (hidden) emotions and personality characteristics.
- **Psychodiagnostic** refers to methods used to examine and analyze the factors that form human behavior, particularly abnormal behavior.

Description

The Rorschach inkblot test is a projective personality assessment based on the test-taker's reactions to a series of 10 standardized unstructured images or "inkblots." As a projective test, the Rorschach test assumes that individuals will interject their own personalities into neutral-appearing images. By so doing, they reveal their personality characteristics, hidden emotions, unconscious (hidden) conflicts, illogical thinking, reactions to others and the environment, and underlying motivations. It has been used in clinical settings to assess personality structure, to identify emotional problems, and to detect underlying thought disorders, especially in individuals who are reluctant to describe their thinking processes openly.

The Rorschach test is one of the most widely used projective test even though its influence has declined somewhat over the past several decades. It is commonly included in a battery (series) of tests used to assess personality and diagnose psychiatric problems and disorders, including depression, schizophrenia, and anxiety disorders in clinical settings. It is also used in forensic settings such as evaluations of an individual's competency to stand trial and in child custody evaluations. This untimed test is generally administered on an individual basis to adolescents and adults, but has been used with children as young as three years of age.

The test consists of the test-taker being shown inkblots on separate white cards and then being asked a set of standard questions about what he or she sees. Responses are tabulated, placed in summary form, and scored according to a set of criteria. Of the 10 original inkblots, 5 consist entirely of black ink on a white background, while 2 use black and red ink and 3 consist of several colors of ink.

The scoring of the Rorschach test is based on several factors, such as the content of the subject's response. The content observed by the subject is usually classified by the evaluator in one of such groupings as humans, animals, nature, clothing, or abstract. Based on the test-taker's responses and actions, the evaluator should be able to reveal certain underlying characteristics of the individual, such as any conflicts residing within the individual and any perceptions of the world or others. Because the evaluator must interpret the responses and actions of the subject, the interpretations of the subject by different evaluators may vary.

Developments and Current Status

Hermann Rorschach, MD (1884–1922), developed the Rorschach test. While he intended to publish the test with the 15 inkblot cards he regularly used, the only publisher who agreed to publish the test would only include 10 of his inkblots. Rorschach reworked his manuscript to include only 10 inkblots. The test was finally published in 1921. Rorschach did not provide a comprehensive scoring system.

Before the 1970s, five primary scoring systems were used and the evaluator was free to use any of them. In 1969, John E. Exner published the first comparison of these five systems entitled *The Rorschach Systems*. In it he introduced a comprehensive scoring system that has become the standard for scoring the test. The Exner system, as it has come to be called, uses clusters of Rorschach variables as the basis for evaluating responses. It utilizes a standardized procedure to assure unbiased scoring. It is considered to be an objective and reliable method with high reliability among different evaluators. The Exner system uses a computer-based scoring system, which provides

score summaries and personality descriptions of the test-taker.

Rumination Disorder

Rumination disorder is a mental disorder characterized by repeated regurgitation (bringing up swallowed food), which is then re-chewed, swallowed, or spit out. It is also referred to as merycism.

Definitions

- **Aversive conditioning** is a treatment method of pairing specific behaviors with a negative or undesirable stimuli (behavior or sensation). It is also called aversive techniques.
- **Behavioral therapy** is a form of psychotherapy that focuses on identifying and changing maladaptive behaviors.
- **Bulimia nervosa** is a mental disorder characterized by recurrent binge eating with loss of control over one's eating and compensation for eating.
- **DSM-5** stands for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, which is a diagnostic system used by professionals to identify mental disorders with specific diagnostic criteria.
- **Feeding and eating disorders** are a category of DSM-5 mental disorder characterized by recurring disturbances in an individual's eating patterns and behaviors.

Description and Diagnosis

Rumination disorder is a mental disorder characterized by repeated episodes of regurgitating partially digested food. Following the initial regurgitation, individuals with this disorder then re-chew the food and either spit it out or swallow it again. Typically, those with this disorder do not experience nausea or other bodily symptoms that precede vomiting. Rumination disorder usually follows a pattern of regular feeding behaviors and is most common in infants and young children. It is one of the feeding and eating disorders in DSM-5. The prevalence of this disorder is unknown (American Psychiatric Association, 2013).

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, individuals can be diagnosed with this disorder if they regurgitate their food frequently for a period of at least one month. This regurgitation must not be caused by a medical condition known to cause vomiting, such as acid reflux. Also, the behavior cannot be the direct consequence of an alternative feeding and eating disorder such as bulimia. It is important to note that bulimia differs from rumination disorder in that individuals with bulimia exhibit a pattern of uncontrolled binge eating followed by purposeful vomiting in an effort to prevent weight gain (American Psychiatric Association, 2013).

The cause of this disorder is not well understood but is believed to vary between individuals. For some, this disorder manifests following a period of stress or trauma. For others, this disorder may occur with other feeding and eating disorders or medical conditions, including changes in medication regimens. The disorder can cause a number of adverse bodily conditions, including malnutrition, tooth decay, and other digestive conditions.

Treatment

Children with this disorder often outgrow regurgitation. However, treatment is preferred over waiting for behavior to change and is necessary in adults. Treatment for this disorder usually involves behavioral therapy. The aim of this therapy is two-fold. First, the

individual is taught behavioral techniques such as relaxation and diaphragmatic breathing (deep breathing from the lower abdomen). Second, mild aversive conditioning techniques are used. Specifically, regurgitation may be paired with a sour-tasting spray. The more the unwanted behavior (regurgitation) is associated with the aversive stimuli (the sour taste), the less likely the individual is to continue the behavior.

S

Sadistic Personality Disorder

Sadistic personality disorder (SPD) is a mental disorder characterized by a lifelong pattern of getting pleasure and power from inflicting pain and humiliation on others.

Definitions

- **PDM** stands for the *Psychodynamic Diagnostic Manual* and is a diagnostic framework that characterizes individuals in terms of their psychodynamics.
- **Personality disorder** is a long-standing pattern of maladaptive (problematic) behavior, thoughts, and emotions that deviates from the accepted norms of an individual's culture.
- **Psychotherapy** is a psychological method for achieving desired changes in thinking, feeling, and behavior.
- **Sadism** is the act of gaining pleasure from inflicting physical or psychological pain on another.
- **Therapeutic alliance** refers to the relationship between a therapist and client that is a necessary component of effective psychotherapy.

Description and Diagnosis

Sadistic personality disorder (SPD) is a personality disorder characterized by sadism. Those with this disorder are focused on dominating and harming others. Common behaviors of individuals with SPD include emotional cruelty, intentionally manipulating others through the use of fear, and being preoccupied with aggressive and violent behavior. Besides deriving pleasure from imposing pain and suffering, these individuals mistreat and humiliate others to achieve a sense of power over them. Only small numbers of individuals with SPD engage in physical violence. Sadistic individuals tend to inflict mistreatment of others with unemotional calm. This distinctive feature is a form of detaching emotionally or expressing enthusiasm without guilt. This influences an individual with SPD to engage in domination and control (PDM Task Force, 2006).

According to the *Psychodynamic Diagnostic Manual*, SPD is diagnosable by the following criteria. Individuals with SPD are often preoccupied with the suffering and humiliation of others. The contributing developmental patterns for this diagnosis are currently unknown. Individuals with SPD take pleasure in their contempt and hatred for others. Their basic belief is they are entitled to hurt or humiliate others. Their view of others is that they exist as objects to be dominated. Furthermore, the primary way individuals with this disorder defend themselves is by detaching from others and believing they have supreme powers (PDM Task Force, 2006).

Treatment

Psychotherapy has not been shown to be an effective form of treatment for SPD. In part, this is because a therapeutic alliance is rarely developed. Individuals with SPD see human beings as objects that can be tinkered with, rather than developing a respectful relationship (PDM Task Force, 2006). But the main reason

why psychotherapy is not effective is such individuals do not want to change.

SAMe (S-Adenosyl-Methionine)

SAMe is a naturally occurring compound important in normal bodily functioning. It is also a nutritional supplement used to treat depression, osteoporosis, and other conditions.

Definitions

- **Amino acids** are organic compounds that combine to form proteins. Amino acids and proteins are the building blocks of life.
- **Antioxidant** is a substance that protects the body from damaging reactive oxygen molecules.
- **Glutathione** is a peptide made from amino acids (cysteine, glycine, glutamate) and sulfur. It functions as a powerful antioxidant and detoxifies the body of toxins like mercury and lead.
- **Homocysteine** is a sulfur-containing amino acid that can be recycled into methionine or converted into cysteine. High levels of homocysteine increase the risk of heart disease, stroke, Alzheimer's disease, and osteoporosis.
- **Methionine** is an amino acid that supplies sulfur and methyl groups needed for normal metabolism and growth. In the liver, methionine is converted into SAMe.
- **Methylation** is a chemical reaction where methyl groups are added to proteins, DNA, and other molecules to keep them functioning. For example, unless serotonin is methylated it becomes inactive and may result in depressive symptoms.
- **Serotonin syndrome** is a serious medication reaction resulting from an excess of serotonin in the brain. It occurs when medications that increase serotonin are taken together. Symptoms include high blood pressure, high fever, headache, delirium, shock, and coma.

Description

SAMe (S-adenosyl-methionine) is a natural substance synthesized (made) from methionine (an amino acid). When methionine is not fully converted to SAMe, homocysteine accumulates and can cause serious health problems. SAMe is involved in over 40 biochemical reactions in the body and plays a key role in the methylation process. As a methyl donor, SAMe is involved in regulating gene expression and the production of neurotransmitters important in regulating mood. It is also an antioxidant and helps to maintain cell membranes and levels of acetylcholine and glutathione, all of which enhance cognitive functioning and reduce neurodegeneration. As SAMe becomes depleted with illness and aging, it must be replaced by diet and supplementation. SAMe is thought to work by inhibiting the actions of serotonin, dopamine, and norepinephrine.

SAMe is used for treating attention-deficit hyperactivity disorder, anxiety, and depression, and for improving intellectual performance. Several studies have indicated that SAMe is effective in treating depression. It can improve symptoms of depression within two weeks, which is much shorter than for antidepressant medications. Other research suggests that SAMe can lessen attention-deficit disorder symptoms in adults. SAMe is also used for Alzheimer's disease, bursitis, chronic fatigue syndrome, chronic pain, dementia,

fibromyalgia, headache, heart disease, lead poisoning, liver disease, multiple sclerosis, spinal cord injury, seizures, migraine, osteoarthritis, Parkinson's disease, slowing the aging process, and tendonitis. Research shows it is particularly effective in relieving symptoms of osteoarthritis.

Precautions and Side Effects

Increased anxiety has occurred in those with depression when taking SAMe. SAMe should be used carefully by those with a history of bipolar disorder since it may aggravate symptoms of mania. When used with prescription antidepressant medications, life-threatening symptoms may occur. It should be used with prescription antidepressant drugs only under close medical supervision. Individuals should not begin taking SAMe until one week or more after stopping an antidepressant medicine, and two weeks or more after taking monoamine oxidase inhibitors such as Nardil or Parnate. Women who are pregnant or breast-feeding should use extreme caution when using it. To reduce the risk of withdrawal symptoms, SAMe should not be suddenly stopped, but rather discontinued. In addition, alcohol should not be consumed with SAMe. Those with Parkinson's disease have frequently reported a worsening of symptoms while taking it.

Side effects associated with SAMe include stomach upset, gas, vomiting, diarrhea or soft stool, constipation, and nausea. SAMe can also cause dry mouth, headache, mild insomnia, anorexia, sweating, increased thirst, blurred vision, restlessness, dizziness, and nervousness.

The use of SAMe with antidepressant drugs such as Elavil, Prozac, Celexa, and Parnate may cause serotonin syndrome. The combination can also cause insomnia. Individuals should not take it if they are also taking Robitussin DM and other cold medications, levodopa, Demerol, Talwin, or Ultram. SAMe should not be taken with other herbs and supplements that also increase serotonin levels, such as 5-HTP, L-tryptophan, and St. John's wort. On the other hand, SAMe may actually protect the liver from damage caused by some medications, including Tylenol, alcohol, estrogens, steroids, and several other prescription medications.

Sand Tray Therapy

Sand tray therapy is an expressive and projective therapeutic form of treatment that helps clients with mental health challenges by using sand tray materials (e.g., sand, a sand tray, and a collection of miniature figures).

Description

Sand tray therapy is a nonverbal form of communicating thoughts, feelings, emotions, and worldviews through the use of specific materials, such as sand, a sand tray, and a collection of miniatures, symbols, and figurines all guided by a trained therapist. It is a projective technique that helps a client better understand, process, and hopefully resolve intra- and interpersonal issues that have led to mental and emotional challenges. Sand tray, which is considered a form of play therapy, offers an effective therapeutic modality for a wide variety of diverse populations and for clients of all ages. Depending on the clinician's theoretical orientation, the tray can be processed and interpreted with the client or simply completed without interpretation and processing. Both have been shown to be effective for intrapsychic healing.

Sand tray is considered a cross-theoretical form of therapy, meaning that it is not simply used by clinicians trained in a specific theory. Processing sand trays can vary based on a therapist's theoretical orientation. Some use the term "sandplay," which refers to a specific form of sand tray therapy that was originated and developed in Jungian circles and processed based on Jungian theory. The common approach for sand tray is to explain the concept to the client and ask him or her to symbolically create his or her world in the sand using a selection of miniature objects and symbols. The client

creates the tray, while the therapist witnesses the process. When the client is finished, he or she is asked to explain the meanings of the symbols used in the tray. It is then photographed and the tray is dismantled.

The equipment needed for sand tray includes a shallow rectangular sand tray filled halfway with sand and painted blue on the inside so that when moving the sand away from an area, the client gets the impression of water below. The client is allowed to choose from hundreds of miniatures, figurines, and small objects that are displayed on open shelves to create a picture or story in the sand. These figures that are made available should include people representing a variety of historical periods, careers, and functions, as well as animals, houses, buildings, trees, religious symbols, bridges, cars, and mythical creatures.

The use of this therapeutic medium has been shown to serve as a transitional object that creates independence and also a sense of safety and security. It is a modality that offers a calming and soothing experience because it offers a voice to the part of the inner self that doesn't normally have a voice—essentially giving a voice to the inner workings of the unconscious. Most studies on sand tray have found that this method of play therapy is considered to be highly productive. It is a unique therapeutic approach that allows a client to express lost memories and unconsciousness fantasies, as well as promote health and healing.

The use of sand tray therapy is a unique therapeutic tool and arguably the most powerful for creating a metaphoric dialogue as well as for stimulating the visual and kinesthetic areas of the psyche by allowing the psyche to visually express itself. The kinesthetic experience associated with sand tray creates a mind-body dialogue unlike any other form of therapy. Through this form of therapy, it is possible, to be cross the mind and body threshold. The beauty of sand tray includes the ability to access and express this autobiographical memory, which offers a failure-free modality with a high likelihood of success and satisfaction.

Part of the powerful healing qualities of sand tray therapy is the use of miniatures. When these living symbols are used in the sand tray, there is a spontaneous healing in the collective unconscious within the client, which creates a stronger connection between the conscious and the unconscious. Although it may appear to be a chance selection, a client's choice of symbols carries both the personal meaning to the individual and the universally accepted meaning.

The use of sand tray therapy is an active psychological intervention that combines elements of play therapy and analytical work. There are times that clients, no matter what their age, simply don't have words to describe their feelings. Using the symbolic expression of sand tray helps the client find new solutions to his or her challenges. Even a small number of sandplay sessions can be therapeutic. A minimum of 5 to 10 sessions are ideal, but even one session has been found to offer therapeutic benefits. Notably, sand tray offers a failure-free intervention that requires no skill or creative talents, unlike drawing, painting, or writing.

Development and Current Status

Many credit the evolution of sand tray to writings by H. G. Wells, the author of the 1911 classic *Floor Games*, as he observed his sons playing with small toys on the floor. As he watched his boys, he discovered they actually were processing challenges with each other and other members of the family. Two decades later, Margaret Lowenfeld, a pediatrician based in London, remembered reading Wells's account of his sons' play and was able to adapt it to her own practice. She later founded the Institute for Child Psychology in London, where her sand therapy techniques were further refined and researched.

Lowenfeld believed that verbal language offered a limited means of communication, which led to her introducing miniatures in her playroom to be used symbolically as a means of expression of a child's inner world—without the need for verbalization. Within the sand tray, Lowenfeld found a projective tool that allowed for thoughts and feelings to be expressed on a symbolic level without the need for verbal communication and rational/conscious thought. Lowenfeld believed that this unique therapy was compatible with any theoretical orientation. Thus, today sand tray as a therapeutic intervention is used by many professionals with diverse theoretical backgrounds.

Satir, Virginia (1916–1988)

Virginia Satir was a pioneer in the family therapy movement. She was one of the first therapists to work with the entire family, instead of just individuals, and many of her methods are still in use today.

Description

Virginia Satir is best known for her contributions to family therapy. Virginia Satir is also remembered for her theories on family systems and how they affect individuals. According to Satir, family behavior was a result of the search for homeostasis, or a sense of balance. All actions were designed to achieve balance in the family. Families had predictable, repetitive patterns, and family members were affected by these patterns.

Satir graduated from the University of Wisconsin in 1936 and taught at a small rural school. She moved to a career in therapy in 1948 after attending the University of Chicago and earning a master's degree in social work.

At the time, it was common practice in psychotherapy to see only one member of a family at a time. However, Satir had discovered while teaching that her students were affected by her relationship with their families. She drew upon this experience and in 1951 she began seeing families together as a group, instead of just individual patients.

In 1959, she partnered with Don Jackson and Jules Riskin, and cofounded the Mental Research Institute (MRI) in Menlo Park, California. Satir began teaching family therapy courses at MRI in 1959 and focused her work on clinical practice and training. She became MRI's director of training. Under her, MRI received a grant from the National Institute of Mental Health in 1962 that enabled the Institute to offer a formal training program in family therapy.

She began teaching month-long training programs in family therapy at MRI in 1969 and continued to do so until her death in 1988. She also gave family therapy training and workshops around the world throughout her career. Satir was always deeply committed to working with patients, teaching, and sharing her belief in the potential of humans. Because of this focus on her practice, she never formally published her theories on family therapy.

Instead, Satir published a number of books about her experiences. The first was *Conjoint Family Therapy*, published in 1964. A collection of notes and essays about her work, this book also discussed her views on the importance of working with families, and how the family dynamic affects the individuals within. Satir published other books during her career, including *Peoplemaking* in 1972, *Satir Step by Step* (with M. Baldwin) in 1983, *The New PeopleMaking* in 1988, and *The Satir Model: The Family and Beyond* (with J. Banmen, J. Gerber, and M. Gomori), published in 1991, three years after her death.

Those who have studied her family therapy model found it to be based on four major components: a set

Virginia Satir was a pioneer in the family therapy movement. One of the first therapists to work with the entire family instead of individuals alone, she wrote in a commonsense style, and her psychotherapy methods are still used today. (Ed Maker/The Denver Post via Getty Images)

of presuppositions, basic constructs, the therapeutic process, and her methods. One of Satir's main presuppositions was that every family was trying to reach homeostasis, or balance. This makes family members behave in a way that maintains balance within the family relationship. Satir believed family members act and communicate predictably. Any disruption in the family dynamic creates conflict and causes the family to try to get back into balance. This conflict and rebalancing is normal. However, problems come up when these attempts to balance don't work or are blocked.

Satir placed great importance on the family in the process of therapy. In her sessions, Satir focused her efforts on the patterns in the family, instead of the events themselves that led to the problem. She felt issues were more likely to be resolved if the patterns of behavior were addressed and changed, rather than the event that caused the patterns.

Her work was also heavily influenced by the belief that all people have the potential to be good. She felt everyone had the capability to change and grow and that change is not just natural but essential.

Impact (Psychological Influence)

Satir was a dedicated teacher and trained other therapists during more than 430 workshops during her career. Charismatic and engaging, she wrote in a nontechnical style with commonsense advice, in a way that appealed to both professionals and laypeople. In 1987 the American Psychological Association made Satir an honorary member of its Division of Family Psychology.

The Satir model of family therapy continues to be taught and practiced by therapists working with individuals and families. At its core is the mission of therapists to help a client set positive goals in line with his or her whole self, as well as create a deep level of change, instead of just altering feelings or actions.

Satir and her teachings influenced the practice of family therapy around the world. Many therapists today draw from her teachings for their own family practices. As a result of her methods, patients can spend less time in therapy while achieving greater positive changes in their relationships and lives.

Savant Syndrome

Savant syndrome is a rare mental condition characterized by mental retardation but with very special abilities in memory, calculation, music, or art.

Definitions

- **Autism spectrum disorder** is a neurodevelopmental disorder characterized by difficulty learning, communicating, and repetitive bodily movements.
- **DSM-5** stands for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, which is a diagnostic system used by professionals to identify mental disorders with specific diagnostic criteria.
- **Traumatic brain injury** is an insult or injury to the brain from an external force. In DSM-5, this disorder is known as Neurocognitive Disorder Due to Traumatic Brain Injury.

Description

Savant syndrome is a rare condition in some individuals with severe mental retardation. Individuals with this syndrome exhibit many of the same inabilities in social skills, communications, and other arenas of functioning that are shared by others with the same mental disorders or injuries. However, they also exhibit a remarkable ability that is limited to a specific and narrow domain. These abilities may include incredible abilities to calculate numbers, recall facts, compose music, or create art. The savant's ability is referred to as an island of genius. It is an accurate description since their abilities are similar of those who are considered a genius or prodigy in a given field. One of the most common special abilities involves memory, with a high degree of idiographic (photographic) memory. While savants have considerable memory in a specific area, they tend to have limited memory in other areas.

Although this condition is rare, it is widely known in the United States. This recognition is in large part due to the popular 1989 movie *Rain Man*, starring Tom Cruise and Dustin Hoffman. The cause of savant syndrome is unknown. It occurs relatively frequently, but to differing degrees, in individuals with autism spectrum disorder. It is believed that up to 10% of individuals with autism spectrum disorder exhibit savant capability. This condition affects more males than it does females. However, this may be due to a similar disproportion in the number of males with autism spectrum disorder as compared to females. In addition, this condition has been diagnosed in individuals with other mental disorders and traumatic brain injuries. It should be noted that this syndrome is not a formal diagnosis in DSM-5.

Schema-Focused Therapy

Schema-focused therapy is a type of psychotherapy whose aim is to modify a client's maladaptive schemas, coping styles, and modes of being by addressing basic unmet emotional needs.

Definitions

- **Attachment theory** is a concept of developmental psychology which emphasizes the types of bonds developed between parent and child and their effect on future psychosocial interactions.
- **Behavioral psychology** is a form of psychology whose aim is to study behavioral adaptation to an environment and its stimuli.
- **Cognitive behavior therapy** is a form of psychotherapy that focuses on maladaptive (faulty) behaviors, emotions, and thoughts.

- **Cognitive psychology** is a form of psychology whose aim is to study thought and distorted patterns of thinking.
- **Cognitive therapy** is form of psychotherapy that focuses on changing maladaptive (faulty) cognitions and thinking patterns that lead to maladaptive behaviors.
- **Coping styles** are the behavioral reactions to schemas and maladaptive schemas.
- **Gestalt therapy** is a form of psychotherapy whose aim is to reduce cognitive distortions and increase a client's awareness of and centering in the present moment.
- **Maladaptive schemas** are self-defeating patterns of thought, beliefs, and values about self, others, and the world, which inform a person's negative observations and evaluations of life.
- **Modes of being** are the various states of consciousness, subjective emotional experience, or mind-set resulting from schemas and maladaptive schemas.
- **Pathology** is an experience of suffering or aspect of a disease incorporating cause, development, structure, and consequences.
- **Practice** is a method or process used to accomplish a goal or objective.
- **Psychotherapy** is a psychological method for achieving desired changes in thinking, feeling, and behavior. It is also called therapeutic counseling.
- **Schemas** are long-standing patterns of thought, beliefs, and values about self, others, and the world, which inform a person's observations and evaluations of life.

Description

Schema-focused therapy is a form of psychotherapy that can be utilized when other more common interventions are, or are predicted to be, ineffective. Typically, this involves severe and chronic mental conditions such as enduring depression and/or personality disorders. Schema-focused therapy addresses a client's maladaptive schemas, resultant maladaptive coping styles, and modes of being. Schema-focused therapy analyzes the client's essential themes of thought, affect, and behavior. Typically, these pathological themes are a result of years of unmet emotional needs. Schema-focused therapy utilizes practices from many theoretical orientations. Schema-focused therapy integrates the theories of behavioral psychology, cognitive psychology, cognitive behavioral therapy, object relations, attachment theory, and gestalt therapy. This integrative (combined) form of psychotherapy aims to create schema change in clients suffering from dysfunctional and pervasive patterns of being. It attempts to facilitate this change through empowering a client to honestly stay present with his or her feelings, and set limits to behavioral reactivity to these feelings. Schema-focused therapy also assists clients in identifying their central emotional needs and working with clients to plan ways to meet their core needs. It focuses systematically on problematic emotions, early childhood experiences, and the therapeutic relationship.

Development and Current Status

Schema-focused therapy was developed by psychologist Jeffrey Young (1950–) in the 1990s. It resulted from his experience treating clients with long-standing maladaptive thinking, feeling, behavior, and relational patterns. The primary roots of schema-focused therapy are in the cognitive therapy approach of psychiatrist Aaron Beck. Young has demonstrated that clients with pervasive pathologies experience more positive therapeutic outcomes when schema change, or even personality change, occurs. Over time, schema-focused therapy has been developed and refined. In 2003, research was published that identifies 18 different "early maladaptive schemas," each of which is paired with a proposed cause or origin and a typical presentation. In brief, the 18 early maladaptive schemas are Abandonment/Instability, Mistrust/Abuse, Emotional Deprivation, Defectiveness/Shame, Social Isolation/Alienation, Dependence/Incompetence, Vulnerability to Harm or Illness, Enmeshment/Underdeveloped Self, Failure,

Entitlement/Grandiosity, Insufficient Self-Control/Self-Discipline, Subjugation, Self-Sacrifice, Approval-Seeking/Recognition-Seeking, Negativity/Pessimism, Emotional Inhibition, Unrelenting Standards/Hypercriticalness, and Punitiveness.

Description

Schemas and maladaptive schemas are enduring patterns of thought. They are generalizations about the self, others, and the world. Schemas and maladaptive schemas assist people in making real or imagined meaning out of the enormous amount of information encountered in life. Only a fraction of the information available to the senses is integrated into an individual's consciousness. Schemas are preconceived notions about what information is important and what is to be ignored. The preconceived notions of the self, others, and the world are established early in life, often

childhood or infancy. Repetitive or intense experiences establish enduring configurations of thoughts, beliefs, and values that a person uses later in life to make meaning out of stimuli. Schemas are cognitive templates that shape experiences. They filter and distort information into biased and predictable patterns of experiencing and relating. Through schematic processing (patterns of thinking) reality is repetitively distorted into preconceived notions of what an individual believes reality to be. These distortions of perception effectively alter the way in which individuals experience themselves, others, and the world. Schemas do not only operate upon information that an individual is exposed to. They also affect how information is retrieved from memory. In fact, schemas govern nearly all human thinking and perceiving. A schema is the mental representation of a simple object or event and can even be the basis for a complex value system. Schemas are stereotypic thinking that prevent the honest experiencing of novel information. New information instead is compared against what has been previously learned. Then only the schema is experienced and the novel information is largely ignored. This schematic processing or stereotyping can be understood as a type of jumping to conclusions about the nature of reality. In other words, these patterns of thought called schemas selectively abstract (filter) information that a person is exposed to or remembers. Schemas tend to be effective across multiple situations and persist despite the presence of evidence that challenges the schemas. Schemas are core beliefs and are not easily altered.

Schemas are adaptive or maladaptive. Adaptive schemas are patterns of thinking that assist an individual in achieving health and well-being. An example of an adaptive schema might be, "I can overcome this." Adaptive schemas allow an individual to selectively ignore information that does not assist him or her in living a meaningful life. In contrast, maladaptive schemas are self-defeating patterns of viewing self, others, and the world. Maladaptive schemas often cause and perpetuate unhealthy patterns of living. An example of a maladaptive schema might be, "I can never do anything right." There are 18 categories of maladaptive schemas, each of which is developed as a result of unmet emotional needs in early childhood. In brief, the 18 early maladaptive schemas are Abandonment/Instability, Mistrust/Abuse, Emotional Deprivation, Defectiveness/Shame, Social Isolation/Alienation, Dependence/Incompetence, Vulnerability to Harm or Illness, Enmeshment/Underdeveloped Self, Failure, Entitlement/Grandiosity, Insufficient Self-Control/Self-Discipline, Subjugation, Self-Sacrifice, Approval-Seeking/Recognition-Seeking, Negativity/Pessimism, Emotional Inhibition, Unrelenting Standards/Hypercriticalness, and Punitiveness.

Development and Current Status

"Schema" is a term that was first used by the developmental psychologist Jean Piaget (1896–1980) in 1926. The concept was simultaneously being used by the educational and gestalt psychologists of the time. In the early 1930s, Frederic Bartlett conducted a series of psychological experiments which helped further the understanding of schema dynamics. His work with memory and memory recollections indicates that a person's memories are stored and subsequently altered according to the schemas that the individual maintains. Many years later, in the 1980s, researchers conducted similar studies that demonstrated that fake memories could be created as a result of schemas. These studies suggest that reality may be misperceived as a result of the individual's expectations and schemas. Schema-focused therapy was developed by psychologist Jeffrey Young in the mid-1990s. The most prominent influence of schema-focused therapy is the cognitive therapy approach developed by psychiatrist Aaron Beck and cognitive behavior therapy. The cognitive-based psychotherapies primarily help clients modify their distorted patterns of thinking. However, many clients with long-standing patterns of maladaptive thought, affect, and behavior, which include dysfunctional interpersonal relationships, are not responsive to simple thought or behavior change. Young demonstrated that clients with pervasive pathologies experience more positive therapeutic outcomes when schema change occurs.

Schizoaffective Disorder

Schizoaffective disorder is a mental disorder characterized by psychotic symptoms such as hallucinations or delusions along with a severe mood disturbance.

Definitions

- **Antidepressant medications** are prescription drugs that are primarily used to treat depression and depressive disorders. They are known as antidepressants.
- **Antimanic medications** are prescription drugs that are primarily used to treat bipolar disorder (manic depression). They are also called antimanics and mood stabilizers.
- **Antipsychotic medications** are prescribed drugs that are intended to reduce psychotic symptoms. They are also known as neuroleptics.
- **Bipolar disorder** is a mental disorder characterized by a history of manic episodes (bipolar I disorder), mixed, or hypomanic episodes (bipolar II disorder), usually with one or more major depressive episodes.
- **Cognitive behavior therapy** is a form of psychotherapy that focuses on changing maladaptive (faulty) behaviors, emotions, and thoughts. It is also known as CBT.
- **Delusions** are fixed false beliefs that persist despite contrary evidence.
- **Depressive episode** is a mental state characterized by sad mood, reduced ability to enjoy life, and decreased energy or activity occurring during the course of a bipolar disorder.
- **DSM-5** stands for the *Diagnostic and Statistical Manual of Mental Disorders, fifth edition*, which is a diagnostic system used by professionals to identify mental disorders with specific diagnostic criteria.
- **Family therapy** is a type of psychotherapy for families that focuses on improving relationships among family members.
- **Hallucinations** are false or distorted sensory perceptions that appear to be real perceptions that are generated by the mind rather than by an external stimuli.
- **Manic episode** is a mental state of expansive, elevated, or irritable mood with increased energy or activity. It is also called mania.
- **Mood disturbance** refers to various symptoms ranging from excessively happy (manic) to extremely sad (depressive) that are distressing or disruptive to daily life.
- **Psychotherapy** is a psychological method for achieving desired changes in thinking, feeling, and behavior. It is also called therapy and therapeutic counseling.
- **Psychotic symptoms** are a group of severe symptoms that include hallucinations, delusions, disordered thinking, or disorganized movement.
- **Schizophrenia** is a chronic mental disorder that affects behavior, thinking, and emotion, which make distinguishing between real and unreal experiences difficult. Symptoms include hallucinations, delusions, thought and communication disturbances, and withdrawal from others.
- **Schizophrenia spectrum and other psychotic disorders** are a group of mental disorders characterized by psychotic features. These disorders include schizophrenia, delusional disorder, and schizoaffective disorder.

Description and Diagnosis

Schizoaffective disorder is one of the schizophrenia spectrum and other psychotic disorders. Basically, schizoaffective disorder is a cross between schizophrenia (hallucinations or delusions) and a disturbance in mood (depressive or manic episodes). Both psychotic and mood symptoms occur simultaneously. But schizoaffective disorder is not schizophrenia, nor is it a depressive disorder or a bipolar disorder. Neither is schizoaffective disorder a depressive or a bipolar disorder with psychotic symptoms. DSM-5 criteria distinguish schizoaffective disorder from these other disorders.

The occurrence of this disorder is estimated to be relatively rare, affecting less the one-third of 1% of the U.S. population. It is considered to be more common in females than males, and it usually appears in late adolescence or early adulthood (American Psychiatric Association, 2013). For those with disorder, psychotic symptoms typically precede the mood disturbance.

According to the *Diagnostic and Statistical Manual, Fifth Edition*, individuals can be diagnosed with this disorder if they meet the following criteria. They must experience a long-standing, uninterrupted period of hallucinations or delusions along with a depressive or a manic episode. To distinguish schizoaffective disorder from a depressive or bipolar disorder with psychotic symptoms, the delusions or hallucination must last for at least two weeks in the absence of the depressive or manic episode at some time during the lifetime of the disorder. In addition, these symptoms cannot be attributed to substance use. There are two main specifiers of this disorder: bipolar type and depressive type (American Psychiatric Association, 2013).

The cause of this disorder is not fully understood. However, it is believed to be a combination of genetic and environmental factors. The genetic component has been suggested as a vulnerability to psychotic or mood disorders, as opposed to a single cause.

Treatment

Effective treatment of this disorder usually incorporates both medications and psychotherapy. Because of the presence of both psychotic symptoms and mood symptoms, medications are directed at both sets of symptoms. Antipsychotics are used to reduce psychotic symptoms. Antimanic medications are prescribed to treat manic symptoms. Antidepressants are used to treat depressive symptoms. Cognitive behavior therapy is often used with this disorder. It is focused on faulty beliefs and behaviors that underlie this disorder. Also, family therapy is used to help a family adjust to living with those with this disorder.

Schizoid Personality Disorder

Schizoid personality disorder is a mental disorder characterized by a pattern of detachment from social relationships and a limited range of emotional expression. It is also referred to as schizoids and schizoid personality.

Definitions

- ***Diagnostic and Statistical Manual of Mental Disorders*** is the handbook mental health professionals use to diagnose mental disorders. The current edition (fifth) is known as DSM-5.
- **Personality disorder** is a long-standing pattern of maladaptive (problematic) behavior, thoughts, and emotions that deviates from the accepted norms of an individual's culture.

- **Psychotherapy** is a psychological method for achieving desired changes in thinking, feeling, and behavior. It is also called therapeutic counseling.
- **Psychotic disorder** is a severe mental condition in which an individual loses touch with reality. Symptoms can include hallucinations (hearing or seeing things that are not there), delusions (fixed false beliefs that persist despite contrary evidence), and disordered thinking.
- **Schizophrenia** is a chronic psychotic disorder that affects behavior, thinking, and emotion, which make distinguishing between real and unreal experiences difficult. Symptoms include hallucinations, delusions, thought and communication disturbances, and withdrawal from others.

Description and Diagnosis

The schizoid personality disorder is a personality disorder characterized by a pervasive pattern of detachment and social isolation from others, a limited capacity for interpersonal relationships, and a minimal range of emotional expression. Basically, individuals with this disorder prefer to be alone and derive little or no pleasure, support, or meaning from relating to others. Accordingly, they gravitate to solitary occupations (like night watchmen and security guards), live alone, avoid dating, and have no real friends. Others find them to be awkward, distant, cold, and formal in all social contacts. Nevertheless, they can perform tasks well if left alone. They seem humorless and aloof, and they daydream excessively.

The clinical presentation of the schizoid personality disorder is characterized by the following: behavioral style, interpersonal style, thinking style, and feeling style. The behavioral pattern of schizoids can be described as lethargic, inattentive, and occasionally eccentric. They exhibit slow and monotone speech and are generally non-spontaneous in both their behavior and speech. Interpersonally, they appear to be content to remain socially aloof and alone. These individuals prefer to engage in solitary pursuits, are reserved and reclusive, and rarely respond to others' feelings and actions. They tend to fade into the social backdrop and appear to others as "cold fish." They do not involve themselves in group or team activity. In short, they appear inept and awkward in social situations. Their thinking style can be characterized as cognitively distracted. That is, their thinking and communication can easily become derailed through internal or external distraction. This is noted in clinical interviews when these patients have difficulty organizing their thoughts, are vague, or wander into irrelevance such as the shoes certain people prefer. They appear to have little ability for introspection, nor ability to articulate important aspects of interpersonal relationships. Their goals are vague and appear to be indecisive. Their feeling style is characterized as being humorless, cold, aloof, and unemotional. They appear to be indifferent to praise and criticism, and they lack spontaneity. Not surprisingly, their rapport and ability to empathize with others is poor. In short, they have a constricted range of affective response.

The cause of this disorder is not well understood. However, these individuals tend to have a characteristic view of themselves, the world, and others, and a basic life strategy. They tend to view themselves as misfit from life and indifferent to everything, and so they they tend to view the world as a difficult place and that relating to others can be harmful. Accordingly, their basic life strategy and pattern is to trust no one and to maintain physical and emotional distance from others.

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, individuals can be diagnosed with this disorder if they exhibit a pervasive pattern of detachment from others and restricted emotional expression. They do not desire nor enjoy close relationships, including family relationships. Except for first-degree relatives, they are unlikely to have close friends or confidants. These individuals typically choose solitary activities and have little, if any, interest in sexual relations. Not surprisingly, they seem indifferent to the feedback, including criticism, of others. They experience little, if any, pleasure in most activities. Instead, they exhibit emotional coldness, detachment, or flat affect.

Treatment

Unlike other personality disorders in which psychotherapy can be effective, the schizoid personality

disorder is less amenable to such treatment. Because of their relational style, these individuals rarely volunteer for treatment unless they begin to decompensate (get worse). Nevertheless, they may accept treatment if a family member demands it. Treatment goals are focused on symptom reduction rather than on restructuring of personality. Effective treatment interventions are those that focus on crisis resolution and provide consistency and support. Medications, such as antipsychotic drugs, are not useful with this disorder and should be avoided unless psychotic decompensation is noted.

Schizophrenia

Schizophrenia is a chronic psychotic disorder that affects behavior, thinking, and emotion, which make distinguishing between real and unreal experiences difficult. Symptoms include hallucinations, delusions, thought and communication disturbances, and withdrawal from others.

Definitions

- **Antipsychotics** are prescription medications used to treat psychotic disorders, including schizophrenia, schizoaffective disorder, and psychotic depression.
- **Delusions** are fixed false beliefs that persist despite contrary evidence.
- ***Diagnostic and Statistical Manual of Mental Disorders*** is the handbook mental health professionals use to diagnose mental disorders. The current edition (fifth) is known as DSM-5.
- **Hallucinations** are false or distorted sensory perceptions that appear to be real perceptions that are generated by the mind rather than by an external stimuli.
- **Psychoeducation** is a psychological treatment method that provides individuals with knowledge about the condition as well as advice and skills for reducing their symptoms and improving their functioning.
- **Psychotherapy** is a psychological method for achieving desired changes in thinking, feeling, and behavior. It is also called therapeutic counseling.
- **Psychotic disorder** is a severe mental condition in which an individual loses touch with reality. Symptoms can include hallucinations, delusions, and disordered thinking.

Description and Diagnosis

As a diagnostic label, schizophrenia includes a wide variety of clinical presentations. Symptoms can vary so greatly from one individual to another that to present a classic textbook picture of the disorder is difficult. For example, the diagnostic presentation could be that of a hypervigilant accountant who suspects that others are plotting against him, or the housewife who believes she is controlled by her dead mother's voice. Or, it could be that of a withdrawn and apathetic college student who broods incessantly about the reality of existence. Symptoms also can vary within the same individual over time so that the individual may be floridly psychotic and totally unable to function one week, and then be capable of adequate reality testing and reasonable performance in the workplace the following week.

Three phases of this disorder can be described. The first is the *prodromal phase*. It begins with a noticeable deterioration of functioning prior to the active phase and involves the presence of specific symptoms. The *active phase* is recognized by the presence of certain characteristic symptoms combined with gross impairment in the tasks of life: work, love, and friendship. These include primarily "positive" psychotic symptoms. The *residual phase* gradually follows from the active phase. It is manifested by the same symptoms already described for the prodromal phase along with "negative" psychotic symptoms. An individual with a diagnosis of schizophrenia who recovers fully is usually considered to be "in remission." If no recurrences intervene over a period of five years without medication, the diagnosis is then changed to that of "no mental disorder." Those in remission frequently experience an acute exacerbation of their symptoms, possibly requiring hospitalization. The so-called rule of thirds describes the course of this disorder and its treatment. According to this rule, approximately one-third of all those who meet the criteria for the diagnosis of schizophrenia will recover fully after a single episode. Another one-third will experience periodic exacerbations of symptoms and periods of remission. The remaining one-third will experience an ongoing, chronic form of the disorder.

Arriving at a diagnosis of schizophrenia can be challenging. The symptom pattern of this disorder consists of some combination of "positive symptoms" (delusions, hallucinations, disorganized thinking, or bizarre behavior) and "negative symptoms" (flat affect, reduced motivation, and limited relationships). But these symptoms are not necessarily specific to schizophrenia, since they can occur in other mental disorders. That means none of these symptoms are pathognomonic (specific and always present) for schizophrenia. Some individuals will be present with all or most of these diagnostic features, while most others will present with only some of them.

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, individuals can be diagnosed with this disorder if they exhibit the positive and negative symptoms and three phases: prodromal, active, and residual phases. Individuals who meet criteria for this diagnosis exhibit characteristic symptoms during the active phase. Positive symptoms include delusions, hallucinations, disorganized speech, and grossly disorganized behavior. Negative symptoms include flattened affect and avolition. Symptoms are experienced continuously over a period of at least six months. During this time, approximately one month involves active phase symptoms, while prodromal and residual symptoms are experienced the rest of the time. Negative symptoms are more likely to be exhibited in the prodromal or residual phases of this disorder. Besides displaying such symptoms, the individual's functioning is also greatly affected. This is noted by markedly impaired functioning in interpersonal relations, work, and/or self-care. The diagnosis of schizophrenia is not given if schizoaffective disorder, depressive disorder, or bipolar disorder with psychotic features is present. Nor can the diagnosis be made if there is evidence of the direct physiological effects of a medication, a drug of abuse, or a medical condition. When there is a history of a communication disorder beginning in childhood or autistic spectrum disorder, the diagnosis of schizophrenia can be added only if prominent delusions or hallucinations have been present for at least one month. Previously, the DSM had listed schizophrenia subtypes: paranoid, disorganized, catatonic, undifferentiated, and residual type. But these subtypes have been removed from DSM-5 because of limited diagnostic reliability and poor validity (American Psychiatric Association, 2013).

Treatment

Since the mid-1950s antipsychotic medications have been the treatment of choice for schizophrenics, particularly in the active phase. The introduction of these medications has had a powerful influence on the management of schizophrenia. Some believe that antipsychotic medication is the only proven mode of treatment and that psychotherapeutic interventions are of little use. On the other hand, advocates of psychotherapy for schizophrenia argue that medication alone is not sufficient and that the effectiveness of medication depends on the psychosocial context in which it is given. They also contend that medication only reduces psychotic symptoms but does not affect the patient's social or personality functioning. For all practical purposes,

talking about a single "correct" treatment is not useful since schizophrenia is a syndrome consisting of a number of disorders. The range of treatments and combinations of treatments used reflect the variability inherent in this disorder. Usually, the most effective treatment regimens combined psychopharmacology and psychosocial therapies. However, those with severe symptoms or who are at risk of harming themselves or others may also require hospitalization.

Schizophrenia in Youth

Schizophrenia in youth is a brain disorder in which children experience hallucinations, delusions, paranoid thoughts, and other psychotic symptoms.

Definitions

- **Delusions** are fixed false beliefs that persist despite contrary evidence.
- **Hallucinations** are false or distorted sensory perceptions that appear to be real perceptions that are generated by the mind rather than by an external stimuli.
- **Psychotic disorder** is a severe mental disorder in which an individual loses touch with reality. Symptoms can include hallucinations (hearing or seeing things that are not there), delusions (fixed false beliefs that persist despite contrary evidence), and disordered thinking.
- **Schizophrenia** is a chronic mental disorder that affects behavior, thinking, and emotion, which make distinguishing between real and unreal experiences difficult. Symptoms include hallucinations, delusions, thought and communication disturbances, and withdrawal from others.

Description

Schizophrenia is a condition where those who are diagnosed experience a break between their perceptions and the perceptions of others. To people with schizophrenia, hallucinations or delusions are persistent. They often see people and things, hear sounds and voices, or even smell things that are not experienced by others. It can at times be a mysterious and terrifying experience both for the person with schizophrenia and for their friends and family.

The younger the onset of schizophrenia, the more the person's cognitive or intellectual functions will be impaired. Fortunately, schizophrenia is rare in children but becomes more common with the onset of adolescence. It often manifests itself more clearly between the mid-teenage years and the mid-20s. It is estimated that about 1% of people around the world may suffer from schizophrenia. Slightly more men than women have been identified as experiencing the symptoms of schizophrenia.

Causes and Symptoms

The exact circumstances that cause schizophrenia are not clear. There is some research that genetics, environment, or a combination of both may give rise to the increased likelihood of a child being diagnosed with schizophrenia. Certainly a family history of schizophrenia increases the chances that a young person will suffer from it. But the question of why one family member gets it while another does not remains a mystery. Magnetic resonance imaging studies of the brain have shown that gray matter reductions in the

prefrontal area may indicate a familial risk for schizophrenia. Other factors that are being researched as possible causes of schizophrenia include prenatal exposure to viruses or toxins, inflammation or autoimmune diseases in childhood, having an older father, and experiencing certain traumatic head injuries.

Among the most common symptoms of schizophrenia are hallucinations. Hallucinations are defined as false sensory information, for example, seeing, hearing, or smelling things that others do not experience. The second warning symptom is delusions. Delusions are beliefs in things for which there is no evidence, for example, that your relatives are all aliens or that people want to poison you. Directly connected to delusions is the symptom of paranoia. This includes the belief that people are watching you, spying on you, or are out to get you.

The other major symptoms are radical changes in behavior, especially antisocial ones. Examples are refusing to bathe or brush teeth, hiding, refusing contact, adopting strange or new compulsive habits. When these behaviors are tied to strange and unverifiable ideas about themselves or people close to them, individuals should undergo clinical psychological examination.

Diagnosis and Prognosis

As a general rule, schizophrenia in youth can be reliably diagnosed using the same criteria employed with adults. But great care should be taken when examining teenagers for signs of schizophrenia because in adolescence young people typically experience emotional traumas and the struggles of making the transition to physical, social, and sexual maturity. Physicians need to be mindful of the difference between behaviors which may be considered acting out and something much more serious that may be a sign of possible schizophrenia and that should not be ignored.

Schizophrenia is a chronic mental disease, and therefore lifetime support and treatment is required for a child with the disorder to be successful later in life. A child's prognosis will depend on the early identification and management of symptoms through medication and therapy. People with schizophrenia who are able to manage their symptoms successfully can lead productive and successful lives.

Treatment

Schizophrenia is a complex mental disorder, and therefore, treating it requires a battery of different approaches. Those approaches include medication and psychosocial treatments. Certainly medication, principally antipsychotic medication, is an invaluable tool in helping the person with schizophrenia to effectively manage his or her delusions and hallucinations. At the present time, most people with schizophrenia are not institutionalized, and ensuring that schizophrenics get the necessary regular dosage of their medications can be a struggle and responsibility that falls on the shoulder of the family members or caregivers of a child with schizophrenia.

Families who have a young child with schizophrenia should develop a comprehensive plan for their family member. This needs to be done with the help and guidance of medical professionals, educators, and other caregivers. An effective plan will include not only medications but other treatment options such as cognitive behavior therapy, self-help and support groups, and family educational opportunities. These opportunities should be available over the course of the person's life in order to maximize positive behavioral outcomes and manage negative side effects.

Schizophreniform Disorder

Schizophreniform disorder is a psychotic disorder with the signs and symptoms of schizophrenia but with a total duration of less than six months.

Definitions

- **Antipsychotics** are prescription medications used to treat psychotic disorders, including schizophrenia, schizoaffective disorder, and psychotic depression.
- ***Diagnostic and Statistical Manual of Mental Disorders*** is the handbook mental health professionals use to diagnose mental disorders. The current edition (fifth) is known as DSM-5.
- **Psychotherapy** is a psychological method for achieving desired changes in thinking, feeling, and behavior. It is also called therapeutic counseling.
- **Psychotic disorder** is a severe mental condition in which an individual loses touch with reality. Symptoms can include hallucinations, delusions, and disordered thinking.
- **Schizophrenia** is a chronic psychotic disorder that affects behavior, thinking, and emotion, which make distinguishing between real and unreal experiences difficult.

Description and Diagnosis

Schizophreniform disorder and schizophrenia are exactly the same in presentation and differ only in duration, with schizophreniform disorder presentation lasting less than six months. In contrast, schizophrenia is a lifelong illness. The main reason for differentiating the two disorders is that those who are able to recover more quickly have a better lifetime prognosis (prediction of the course of the disorder). Indicators of good prognosis are an acute onset, the absence of prior episodes, the absence of bizarre behavior, the presence of specific stressors, or the presence of mood symptoms. The cause of schizophreniform disorder is not clear. However, it appears to involve genetic, imbalance brain chemistry, and environmental factors such as poor social interactions or highly stressful events that trigger the disorder in those with an inherited vulnerability to it. About 1 in 1,000 individuals develops this disorder, which occurs equally in men and women.

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, individuals can be diagnosed with this disorder if they exhibit the positive and negative symptoms and three phases: prodromal, active, and residual phases. Individuals who meet criteria for this diagnosis exhibit characteristic symptoms during the active phase. Positive symptoms include delusions, hallucinations, disorganized speech, and grossly disorganized behavior. Negative symptoms include flattened affect and avolition. Symptoms are experienced at least one month but no more than six months. Besides displaying such symptoms, the individual's functioning is also greatly affected. This is noted by markedly impaired functioning in interpersonal relations, work, and/or self-care. The diagnosis is not given if there is evidence of the direct physiological effects of a medication, a drug of abuse, or a medical condition.

Treatment

Treatment for schizophreniform disorder usually consists of antipsychotic medication and psychotherapy. Those with severe symptoms or who are at risk of harming themselves or others may need to be hospitalized. The goal of treatment is reduction of symptoms and return to one's previous level of functioning. If the symptoms do not improve within six months, the individual is likely to have schizophrenia. Unfortunately, about two-thirds of individuals with this disorder go on to develop schizophrenia.

Schizotypal Personality Disorder

Schizotypal personality disorder is a mental disorder characterized by a pattern of acute discomfort in close

relationships, eccentric behaviors, and distorted thinking and feeling. It is also referred to as schizotypal and schizotypal personality.

Definitions

- **Asperger's disorder** is a mental disorder characterized by severely impaired social skills, repetitive behaviors, and narrow interests. In DSM-5 it is known as autism spectrum disorder without language or intellectual impairment.
- ***Diagnostic and Statistical Manual of Mental Disorders*** is the handbook mental health professionals use to diagnose mental disorders. The current edition (fifth) is known as DSM-5.
- **Personality disorder** is a long-standing pattern of maladaptive (problematic) behavior, thoughts, and emotions that deviates from the accepted norms of an individual's culture.
- **Psychoeducation** is a psychological treatment method that provides individuals with knowledge about the condition as well as advice and skills for reducing their symptoms and improving their functioning.
- **Psychotherapy** is a psychological method for achieving desired changes in thinking, feeling, and behavior. It is also called therapeutic counseling.
- **Psychotic disorder** is a severe mental condition in which an individual loses touch with reality. Symptoms can include hallucinations (hearing or seeing things that are not there), delusions (fixed false beliefs that persist despite contrary evidence), and disordered thinking.
- **Schizoid personality disorder** is a mental disorder characterized by a pattern of detachment from social relationships and a limited range of emotional expression.
- **Schizophrenia** is a chronic psychotic disorder that affects behavior, thinking, and emotion, which make distinguishing between real and unreal experiences difficult. Symptoms include hallucinations, delusions, thought and communication disturbances, and withdrawal from others.

Description and Diagnosis

The schizotypal personality disorder is a personality disorder characterized by a pervasive pattern of disorganized speech, disorganized behavior, and emotional blunting. While similar to the diagnosis of schizophrenia, individuals with this disorder do not experience delusions or hallucinations. However, they do demonstrate eccentric thinking and behavior, weird beliefs, and strange perceptual experiences. These symptoms and behaviors are recognized early in life and remain stable throughout life. Sometimes, individuals with schizoid personality disorder are misdiagnosed as having Asperger's disorder because of some similarities between the two disorders.

This disorder shares some features with the schizoid personality disorder, but those with the schizoid personality disorder do not exhibit eccentric behavior and peculiar thought content. Rather, those with the schizotypal disorder describe strange intrapsychic experiences, think in odd and unusual ways, and are difficult to engage. Yet none of these features reach psychotic proportions. It has been suggested that the schizotypal personality is part of the schizophrenic spectrum since schizophrenia occurs with increased frequency in family members of the schizotypal.

The clinical presentation of the schizotypal personality disorder is characterized by the following: behavioral style, interpersonal style, thinking style, and feeling style. Behaviorally, schizotypals are noted for their eccentric, erratic, and bizarre mode of functioning. Their speech is markedly peculiar without being incoherent. Holding a job is difficult for those with this disorder. They tend to quit or are fired from jobs after short periods of time. As a result, they may become drifters and move from job to job and town to town. They tend to avoid long-term responsibilities and in the process lose touch with common social expectations. Interpersonally, they are loners with few, if any, friends. Their solitary pursuits and social isolation may be the result of intense social anxiety, which

may be expressed with apprehensiveness. If married, their manner of relating tends to be superficial and peripheral and leads to separation and divorce in a short period of time. Their thinking style is described as scattered and ruminative, and is characterized by cognitive slippage (disconnected thoughts). Talking about superstitions, telepathy, conspiracies, and bizarre fantasies is common. Their way of thinking and self-expression is strange and vague but does not reach the level of delusions or auditory or visual hallucinations. Their feeling style is described as cold, aloof, and unemotional with constricted affect. They can be humorless and difficult individuals to engage in conversation probably because of their general suspicious and mistrustful nature. In addition, they are hypersensitive to real or imagined slights.

The cause of this disorder is not well understood. However, these individuals tend to have a characteristic view of themselves, the world, and others, and a basic life strategy. They tend to view themselves as on a different wavelength than others. They commonly experience being as estranged and disconnected from the rest of life. They then view the world as strange and unusual and that some have special powers. Accordingly, their basic life strategy and pattern is to be cautious while also being curious about these special magical intentions and powers of others.

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, individuals can be diagnosed with this disorder if they exhibit a pervasive pattern of social and interpersonal deficits with significant discomfort and limited capacity for relationships as well as by perceptual distortions and eccentric behavior. They experience ideas of reference as well as unusual beliefs and thinking that influence their behavior, and which is inconsistent with their subculture. They also experience unusual perception, such as bodily illusions, and odd speech thinking. These individuals are prone to suspiciousness and paranoid ideation. They exhibit inappropriate or constricted emotions, and behavior that is odd, peculiar, or eccentric. With few exceptions, they lack close friends or confidants except for first-degree relatives. When they are around others, they experience excessive social anxiety that is not diminished by familiarity and is associated with suspicion and fears.

Treatment

Unlike other personality disorders in which psychotherapy can be effective, the schizotypal personality disorder is less amenable to such treatment. Because of their thinking and relational style, these individuals often find it very difficult to engage and remain in psychotherapeutic relationship. Typically, they are on medication and may be referred for psychotherapy that focuses on dealing with daily life issues. A realistic treatment goal for the schizotypal personality is to increase the individual's ability to function more consistently even though on the periphery of society. Specifically, successful management will likely incorporate psychoeducation. If these individuals can remain in long-term treatment, they may be able to increase their ability to function more consistently and with less dysfunction. In terms of medication, low-dose antipsychotic drugs have been found to be useful for the schizotypal personality even in the absence of psychotic features.

School Phobia (School Refusal)

School phobia, also referred to as *school avoidance* and more recently as *school refusal*, is characterized

by an aversion to attending school due to excessive worry, fear, or anxiety.

Definitions

- **Absenteeism** defines either an excused or unexcused absence from school.
- **Psychoneurotic truancy** refers to school absenteeism characterized by negative affectivity or symptomatology related to worry, anxiety, fear, panic, hysteria, depression, or compulsive behavior.
- **School anxiety** defines when students experience feelings of worry, fear, or anxiousness brought on by the act of going to school, being at school, or separating from parents in order to attend school.
- **School refusal,** an umbrella term now used in lieu of the term "school phobia," describes child-motivated noncompliance in attending school, remaining in class for the entire school day, or both.
- **School resistance** is a phenomenon that occurs when a child or adolescent reacts to what he or she perceives to be injustices or excessive demands placed on them at school.
- **Separation anxiety** describes experiencing significant worry or distress from having to part from a significant person or people, usually a parent or guardian, for a given period of time.
- **Truancy** refers to excessive absentee behavior due to choice, not associated with fear, anxiety, or distress at school.

Description

Absenteeism associated with a student's negative experiences, symptoms, or feelings with previous attendance is commonly referred to as "school refusal." This was previously termed "school phobia," or "psychoneurotic truancy," though this phrase usually accompanies severe worry, paranoia, or distress, as with separation anxiety, post-traumatic stress, or social phobia. School phobia and school refusal are different from regular absenteeism or truancy. Absenteeism is simply not attending school for any excused or unexcused purpose, but not necessarily because of any adverse experience. Students who are truant would be more accurately characterized as "school resistant" and often miss school excessively out of choice, typically because they don't like going or have found something better to do with their time.

School phobia or refusal is characterized by certain physical, psychosomatic, and emotional ailments. Students may complain of stomachaches, headaches, or "feeling sick" in order to escape school. Relaying dislikes or fears pertaining to teachers, peers, or subject areas is also possible. Screaming, crying, pleading, and temper tantrums are likely to occur if the child is pressed to attend. Parents may struggle to get their child up in the morning, out the door, out of the car, and into the school building. If parents are successful in getting their child to school, the child may be unable or unwilling to attend the full school day. Frequent trips to the nurse's office are common as are calls home.

Development

School phobia and/or refusal are not part of normal childhood or adolescent development. Most students who report school refusal behaviors are between the ages of 5 and 14. This problem can impact both males and females. Those living in urban areas are more likely to have this issue as well. Transition periods have been linked to school refusal. Students entering kindergarten for the first time, those moving from elementary to middle school, or those moving from middle to high school may start displaying nonattendance patterns, usually out of anxiousness or fear of the unknown. Having to separate from a parent/guardian, leave familiar settings, or make new friends can prompt negative feelings. Likewise, changes in routine or schedule can prompt school refusal. Weekends, holidays, and summer vacations can bring on school refusal as children become over-accustomed to life at home, a place that often represents comfort and safety. School nonattendance may also arise after a stressful life event such as a move, illness, or death of a loved one.

Current Status and Results

Though many youth struggle with school compliance related to attendance at one time or another in their school-age lives, true school refusal affects only a small number; however, it can have a significant impact on a child's emotional, psychological, and academic well-being. School refusal can result in academic struggles, retention, or dropping out. Students with attendance issues are also more likely to have social difficulties. This is of concern as research indicated that forming positive relationships with peers and teachers plays a critical role in school success. Generalized anxiety disorder, post-traumatic stress disorder, conduct disorder, and depression have all been linked to school refusal patterns. It is imperative that parents and school staff address attendance issues immediately in order to prevent long-term consequences.

School-Based Therapy

"School-based therapy" is a general term referring to a range of services, most commonly occupational and speech therapy, that are offered by certified or licensed professionals on school-based sites.

Definitions

- **Individualized Education Program/Plan (IEP)** is a written statement that outlines the present learning needs of a student who qualifies under the IDEA guidelines and addresses specific measurable academic goals to be attained annually given the accommodations, modifications, and services provided by a school in conjunction with outside support staff.
- **Individuals with Disabilities Education Act (IDEA)**, a federal law reauthorized and signed into law by President George Bush on December 3, 2004, ensures special education programs and support services to children and youth with disabilities.
- **Occupational therapy (OT)** refers to the treatment interventions that OT professionals employ with patients aimed at fine and gross motor skill development as well as improving overall physical, sensory, emotional, social, and academic challenges.
- **Speech-language therapy/speech-language pathology** is comprised of evaluation and treatment procedures to address communication disorders related to articulation, pronunciation, phonation, and intonation.

Description

"School-based therapy" is a broad term that covers the supplemental services offered to children with identified needs at local, educational settings during the regularly scheduled school day. Offering these services to students at school allows for treatment to be more consistently monitored and maintained. Though occupational therapy and speech-language pathology are the most common forms of school-based therapy, other services such as physical therapy and counseling support may also be provided. Occupational therapy focuses on improving fine and gross motor skills; handwriting difficulties are commonly referred to occupational therapists. Speech-language therapy assists students with communication problems. Supplemental services require that the student be properly identified

and evaluated and that proper consents be obtained prior to beginning treatment. Certified/licensed professionals who are contracted with school districts or specific schools schedule session times with students to work on skills both individually and in small groups. Students with disabilities are most commonly referred for these types of services, though students who are displaying difficulties in these areas who do not have a diagnosis might also be referred for treatment. For those diagnosed, the duration, frequency, and goals for treatment are typically outlined in the student's Individualized Educational Program/Plan, discussed and agreed upon by the school-based team comprised of administrators, teachers, counselors, Exceptional Student Education (ESE) coordinators, and support service professionals. This is a written, signed document that outlines the student's current level of functioning, the services that will be provided along with any additional accommodations/modifications to the general curriculum, and measurable goals to be attained. Students who qualify under Section 504 of the Rehabilitation Act of 1973 are also eligible for school-based therapies. Students with a 504 Plan do not require specialized instruction but do qualify for special services and accommodations that meet their specific circumstances.

Development (History and Application)

The Individuals with Disabilities Education Act (IDEA) was first enacted by Congress in 1975 to provide all students, including those with disabilities, a free and appropriate education. IDEA ensured that students who qualified for support services and required variations to the regular curriculum in order to be successful in school received them. On December 4, 2004, President George W. Bush signed a reauthorization of IDEA, the majority of regulations became effective July 1, 2005, and the final regulations were published on August 14, 2006. The new regulations include information related to identification, evaluation, notification and transfer of rights, monitoring and providing appropriate interventions, and transition. Students who would benefit from school-based therapies, regardless of diagnosis, were now eligible for services under the reauthorization.

Current Status

School-based therapies are regularly provided in K-12 educational settings. Students who require support services in order to be successful in school benefit from occupational therapy, speech-language therapy, physical therapy, and counseling support. Evidence suggests that early intervention is key in resolving difficulties that can impact a student's physical, cognitive, social, academic, and emotional development.

Seasonal Affective Disorder (SAD)

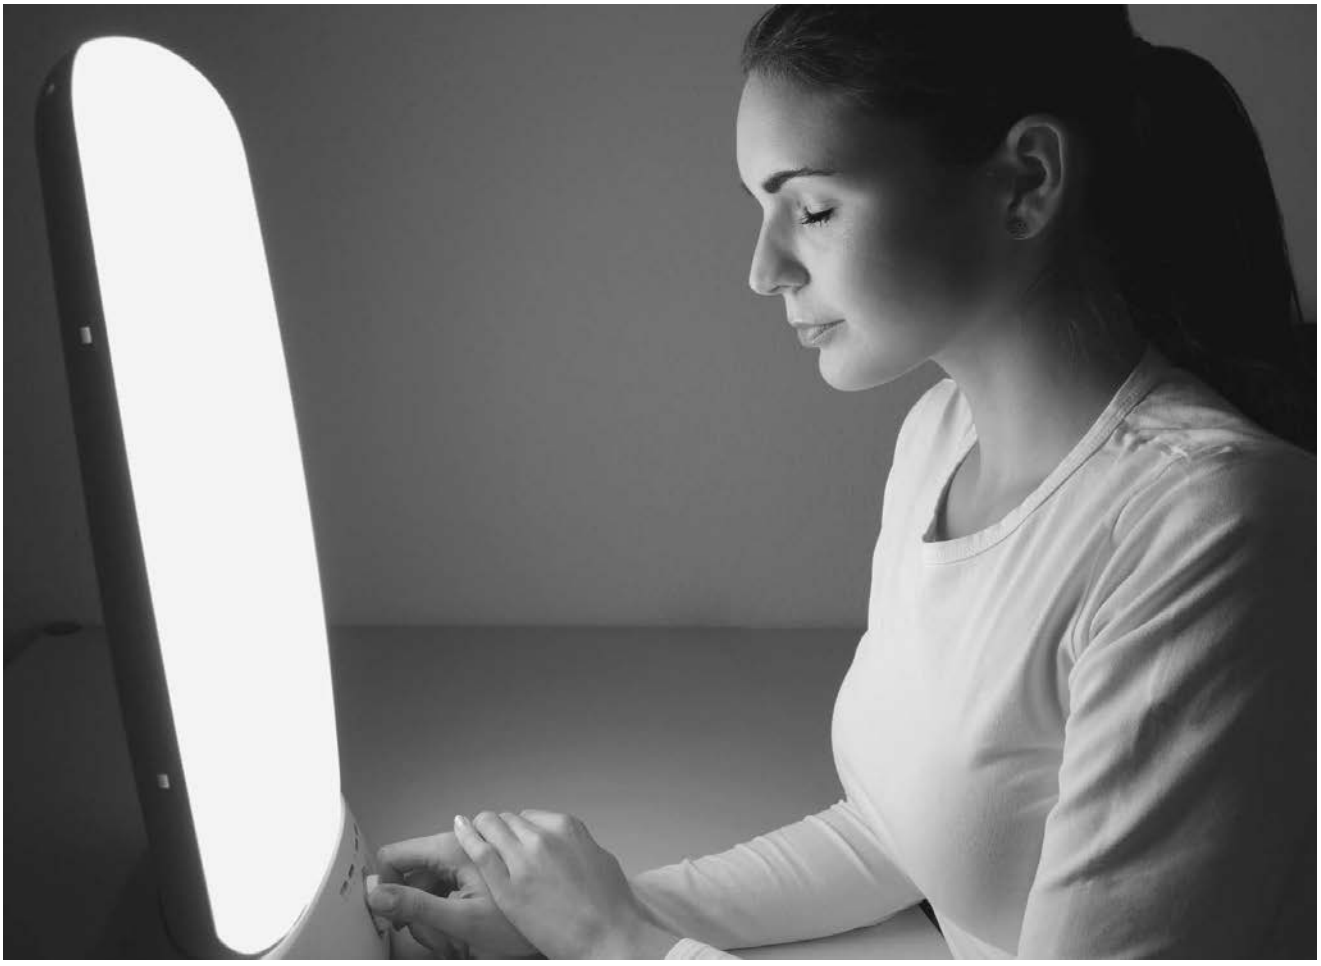
Seasonal affective disorder is a mental disorder in which depression comes on during the late fall and winter and begin to lift during spring and summer. It is also called SAD, winter depression, and winter blues.

Definitions

- **Circadian rhythms** are variations in biological activities that repeat during 24-hour intervals, which influence the amount and quality of sleep. It is also called a biological or internal clock.
- **Cognitive behavior therapy** is a type of psychotherapy that focuses on maladaptive (problematic) behaviors, emotions, and thoughts. It is also called CBT.
- **Depression** is a sad mood or emotional state that is characterized by feelings of low

self-worth or guilt and a reduced ability to enjoy life. It is not considered a mental disorder unless it significantly disrupts the individual's daily functioning.

- **DSM-5** stands for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, which is a diagnostic system used by professionals to identify mental disorders with specific diagnostic criteria.
- **Light therapy** is a medical treatment in which doses of bright light are administered to normalize the body's internal clock and treat depression. It is also called phototherapy.
- **Major depressive disorder** is a mental disorder characterized by a depressed mood and other symptoms that interfere significantly with an individual's daily functioning.
- **Melatonin** is a chemical messenger in the brain which regulates the sleep–wake cycle and promotes restorative sleep.
- **Serotonin** is a chemical messenger in the brain that regulates learning, sleep, mood, and appetite. It is involved in disorders such as depression and anxiety.
- **SSRI** stands for selective serotonin reuptake inhibitors. They are a class of antidepressant medications that work by blocking the reabsorption of serotonin in nerve cells and raising its level in the brain resulting in symptom reduction.



Seasonal affective disorder (SAD) is a disorder in which depression sets in during the late fall and winter and then lifts during spring and summer. Exposure to light therapy can be an effective treatment. (Rocky89/istockphoto.com)

Description and Diagnosis

Seasonal affective disorder (SAD) is a type of depression characterized by the onset of depressive symptoms during fall and winter when there is less natural sunlight. Symptoms generally lift during spring and summer as sunlight increases. Those with this disorder usually experience sadness, moodiness, irritability, and loss of interest in usual activities. They may eat more and crave carbohydrates, gain weight, sleep more, or have daytime drowsiness. These symptoms usually begin in September or October and end in April or May. Less often, SAD may cause depression in the spring or early summer.

This disorder is more common among those living in northern states. Women are twice to three times more likely to suffer from the winter blues than men. DSM-5 does not consider SAD to be a separate disorder. Rather, it is a specifier, "with seasonal pattern," for major depressive disorder (American Psychiatric Association, 2013).

The specific cause of SAD remains unknown. However, it is likely that circadian rhythms (biological clock) and brain chemistry are factors. The reduced level of sunlight in fall and winter appears to disrupt an individual's circadian rhythms that govern sleep and energy levels. This disruption can lead to depressive symptoms. An imbalance in two brain chemicals, serotonin and melatonin, also appears to be involved. Reduced sunlight can cause a drop in serotonin levels that may trigger depression. Also, a change in seasons can lead to lower melatonin levels, which can disrupt sleep patterns and mood.

Treatment

Treatment for this disorder can include light therapy, medication, and psychotherapy. Light therapy mimics natural sunlight and can increase brain chemicals and improve mood. Light therapy usually begins working in two to four days and causes few side effects. While it works for many, some do not get better with light therapy alone. For that reason, medication and cognitive behavior therapy (CBT) are used alone or in combination with light therapy. Antidepressants can be helpful, particularly if depressive symptoms are severe. These include Paxil, Zoloft, Prozac, and Effexor. Such medications may take several weeks to reduce most or all symptoms. CBT can be helpful in identifying and changing negative thoughts and behaviors that may be making you feel worse. It can also increase skills to better cope with SAD.

Second-Order Change

Second-order change involves changing a maladaptive pattern to a more adaptive pattern.

Description

Second-order change in psychotherapy involves assisting clients to change maladaptive patterns of thinking, feeling, and acting to a more adaptive pattern of thinking, feeling, and acting. Psychotherapy in its fullest sense is a psychological strategy designed to effect deep and enduring change. To appreciate the potential impact of psychotherapy, it is useful to conceptualize it in terms of orders of change. Three orders of change have been identified. "First-order change" refers to therapeutic efforts that resolve symptoms or situations without changing the causes of the problem. Here clients are assisted in making small changes, reduce symptoms, or achieve stability. Generally, career

counseling, crisis counseling, personal counseling, coaching, and case management can assist a client in achieving either symptom relief or resolution of a current life problem. This kind of change effects stability but does not result in transformation of the personality. In contrast, second-order change is transformative and results in a resolution of the causes of the problem. It is therapist-assisted pattern change wherein the therapist assists clients to alter their patterned thinking, feeling, and behaving within the situation in which their maladaptive pattern is occurring. The heart of second-order change is transformation, and specifically a transformation of pattern. In this order of change, a new and more adaptive pattern transforms or replaces the maladaptive pattern. In third-order change clients change patterns on their own without the assistance of a therapist. In essence, clients become their own therapists. This represents the ultimate goal of therapy wherein clients function "as their own therapists."

For example, an unemployed client with the diagnosis of social anxiety disorder might take medication that effectively reduces his anxiety symptoms but does not replace his maladaptive pattern of fearfulness and avoidance. Thus, he might fill out a job application online but out of fear decides he cannot tolerate the prospect of a job interview when it is offered. If medication reduces his symptoms, a degree of stability has been achieved. This represents first-order change. However, if the client is helped by a therapist to learn to face his fears and avoidance behavior directly so that he can be interviewed, offered, and starts the job, a more adaptive pattern is achieved. Such positive actions reflect a more adaptive pattern and constitute second-order change. If this same client is then able to disengage from excessive fearful and anxious feelings on his own, without the assistance of a therapist, he has achieved third-order change.

Developments and Current Status

The orders of change originated in the early family therapy literature. In the 1990s the orders of change were applied to change in organizational and institutional settings. More recently, the orders of change have entered the psychotherapy literature. The basic premise of psychotherapy is that when psychotherapy is truly effective, a transformation of current efforts is needed to effect change, called second-order change. This contrasts with psychotherapy that only produces stability or a return to baseline functioning, called first-order change. Deep, lasting change is not possible with first-order change. Rather, such change is the domain of second- and third-order change. Of these three, the first two are to be the focus of most therapists.

Secure Attachment

A secure attachment is an emotional bond between children and caregivers. Children with secure attachments trust their caregivers to meet their needs. These children also show minimal distress when separated and seek comfort when needed.

Description

Secure attachment is one of the two primary forms of attachment style—insecure and secure. A secure attachment is an emotional bond between children and caregivers. Children with secure attachments trust their caregivers to meet their needs. These children also show minimal distress when separated and seek comfort when needed.

Attachment styles are rooted in the theory first developed by John Bowlby, who also had significant contributions from Mary Ainsworth. Secure attachments developed in infancy, and childhood impacts the development throughout the life span, as well as how an individual interacts with others. John Bowlby was a key explorer of the concept of attachments, both insecure and secure. His belief was that a child's attachment to his or her mother was an indication for later

relationships and the child's ability to establish and maintain emotional stability. While there are four types of attachment styles, only one is secure in nature, with the others being various forms of insecure attachment.

The majority of babies are securely attached. Babies who are identified as securely attached display distress when they are separated from their mother. This results in crying and their attempts to go after her. When their mother returns they greet her happily and actively reach for her. Once securely attached babies are reassured by the presence of their mother, they are happy and comfortable to explore the room they are in. Mary Ainsworth did work where she identified that babies who are securely attached utilize their mother as a secure base for activity.

Attachment relates to the quality of the relationship between the child and the caregiver. It includes the interactions and the child's preference toward his or her caregiver. Attachment has been assessed using the strange situation paradigm, which was developed by Ainsworth. Children who are classified as securely attached have been explored and researched the most, especially since the majority of infants are identified as securely attached.

Secure babies are confident that the caregiver will return after an absence and meet their needs. The caregiver allows for safety to explore environments and to return to them when they are distressed. These infants are easily comforted by their caregiver when upset.

Secure attachments are formed when the caregiver is sensitive to the child's needs and appropriately responds to his or her needs. When children are securely attached, they can be separated from their parent. They can also comfortably seek support from their parents when frightened as well as utilize positive emotions when greeting their caregivers. As adults they can develop trusting relationships with others. They also have higher self-esteem and are comfortable with sharing their feelings with others and can seek out social support from others.

Secure attachments are identified by an individual being flexible with his or her interpersonal relationships. It allows for adaptive self-regulation and is key in continued positive psychology. The early experiences become internal models of the self and mold the individual's future social experiences, interactions, and relationships.

It is important to understand attachment styles as it impacts relationships in adulthood as well as development throughout the life span. Those who are securely attached tend to be more satisfied in relationships with others. In romantic relationships they feel connected to their partner but allow for movement within the relationship without experiencing great distress. They can actively provide and offer support to others and ask and seek comfort when distressed themselves. Someone who is securely attached can work well alone or with others. They have positive, flexible, reciprocal relationships with others. It allows for development of reliable social supports that they can utilize in times of need. With the confidence they have they can develop healthier coping mechanisms.

Current Status

Attachment styles are actively studied in psychology, counseling, and social work programs. About 60% of the population is identified as having secure attachments. This concept is important to be aware of due to its implications and impact throughout the lifetime on relationships and ability to maintain emotional stability.

Sedative, Hypnotic, or Anxiolytic Use Disorder

Sedative, hypnotic, or anxiolytic use disorder is a mental disorder characterized by stimulant use, which leads to significant problems for the user.

Definitions

- **Addiction** is a chronic disease of the brain, which involves compulsive and uncontrolled pursuit of reward or relief with substance use or other compulsive behaviors.
- **Alcoholism** is a general term for the compulsive and uncontrolled consumption of alcohol to the detriment of the drinker's health, relationships, and social standing.
- **Anxiolytics** are medications that relieve anxiety symptoms. They are also called antianxiety medications or tranquilizers.
- **Barbiturates** are a class of prescribed drugs that slow the nervous system and are prescribed primarily for sedation, general anesthesia, and for treating some types of epilepsy.
- **Benzodiazepines** are a class of drugs that slow the nervous system and are prescribed to relieve nervousness and tension, to induce sleep, and to treat other symptoms. They are highly addictive.
- **Depressants** are a group of drugs that are prescribed to reduce the symptoms of anxiety. They are addictive and can be abused. Benzodiazepines are a very common depressant.
- **Hypnotics** are substances that induce or cause sleep.
- **Sedatives** are substances that have a soothing, calming, or tranquilizing effect.
- **Stimulant** is a drug that increases brain activity and produces a sense of alertness, euphoria, endurance, and productivity, or suppresses appetite. Examples are cocaine, amphetamines, and Ritalin.
- **Substance-related and addictive disorders** are a group of mental disorders that include substance disorders characterized by physiological dependence, drug-seeking behavior, tolerance, and social withdrawal. This group also includes the non-substance disorder of gambling.

Description and Diagnosis

Sedative, hypnotic, or anxiolytic use disorder is one of the substance-related and addictive disorders. It is characterized by a problematic pattern of sedative, hypnotic, and anxiolytic use, which leads to significant distress or disrupted daily functioning. These drugs include barbiturates like Seconal and benzodiazepines like Xanax. Both are prescribed drugs used to control anxiety and aid in sleep. While effective in relieving anxiety in the short term, they become problematic for long-term use, or when used for every disappointment or frustration.

Benzodiazepines were introduced in the 1960s as a safer alternative to barbiturates. Since benzodiazepines are safer, this drug is much more common and has a tendency of being abused. The use of this drug leads to mild sedation, muscle relaxation, and lowered anxiety, and even when it is not abused, physiological addiction for this class of drug is common when used over several months. Problematic use of this drug occurs when it is combined with depressant drugs to counter the effect of stimulant drugs. Individuals have also been known to use these drugs during working hours when drinking alcohol would be too easily detected. Like alcohol, the effect of these drugs includes slurring of speech, difficulty with coordination, and poor judgment.

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, individuals can be diagnosed with this disorder if they exhibit a problematic pattern of sedative, hypnotic, or anxiolytic use, leading to significant impairment or distress. This must occur within a 12-month period. This includes taking the substance in larger amounts or for longer than intended. It means wanting to cut down or stop using the substance but not achieving this goal. It involves spending much time getting, using, or recovering from use of the substance. This disorder also involves cravings and urges to use the substance, and continuing to

Sedative, hypnotic, or anxiolytic use disorder is characterized by a problematic pattern of use of these substances, which can lead to significant distress or disrupted daily functioning. (istockphoto.com/James Brey)

use, even when it causes problems in relationships. It involves failure to meet obligations at home, work, or school because of substance use. It also means reducing or stopping important social, work, or recreational activities because of substance use. This disorder involves repeated substance use even when it is physically dangerous. Despite knowing the risks of the physical and psychological problems that are caused or made worse by the substance, use of it continues. It means develop tolerance (needing more of it to get the desired effect). Finally, it involves withdrawal symptoms, which can be relieved by taking more of the substance (American Psychiatric Association, 2013).

This disorder has some of the same root causes as other substance disorders. However, specific social and psychological factors may also be involved. Typically, those who will go on to develop this disorder begin use of this drug in their adolescent years or in their 20s. Their pattern of use escalates to the point at which they develop problems sufficient to meet criteria for the diagnosis. This pattern is particularly likely among those with other substance disorders. While use began intermittently, such as at parties, it progresses to daily use and increased levels of tolerance. Besides interpersonal difficulties, these individuals experience severe physiological withdrawal and difficulties with cognitive functioning. A less frequent pattern involves those who begin with a legitimately prescribed benzodiazepine for anxiety or sleep problems. Use is increased as tolerance develops, which they justify by their anxiety symptoms or sleep problems. It also happens that adolescents develop this disorder by experimenting with unused portion of a prescription found in the home.

Treatment

While it is rare for individuals to be addicted only to a single benzodiazepine, it does occur. More commonly, individuals are also addicted to another benzodiazepine or other central nervous system depressants such as alcohol, or opiates. When these drugs are used in combination with others, detoxification is complicated. Treatment for this disorder is similar to the treatment of other substance disorders. The goal of treatment is abstinence. Treatment approaches range from inpatient hospitalization and drug rehabilitation centers for detoxification to outpatient programs. Motivational interviewing is useful in identifying reasons to stop using and to increase motivation and readiness for treatment. Then, cognitive behavior therapy can be used to

identify the beliefs, behaviors, and situations that trigger use. From these they can develop a plan to reduce the likelihood of relapse. Treatment may also include a Twelve-Step Program like Narcotics Anonymous.

Seizures

A seizure is an episode of abnormal electrical activity in the brain that results in changes in the brain and in behavior.

Definitions

- **Computed tomography** is a medical diagnostic test in which computer-processed x-rays produced tomographs (cross-sectional images) of body areas. It is also referred to as CT scans.
- **Convulsions** are a medical condition during which time an individual's body shakes uncontrollably and rapidly.
- **Electroencephalography** is a medical diagnostic test that records electrical activity on the scalp to evaluate various brain functions and psychological disorders. It is also referred to as an EEG or brain wave test.
- **Epilepsy** is a medical condition when seizures reoccur. It is also known as seizure disorder.
- **Stroke** is a medical condition when there is deprivation of oxygen to the brain due to a lack of blood flow.

Description

A seizure occurs when sudden and disorganized electrical activity affects the brain. Seizures can come on unexpectedly and may be a one-time event or a series of multiple events. They vary in duration and severity. The symptoms that may occur include a brief blackout followed by a period of when an individual cannot remember a certain period of time. Other symptoms include drooling, body shaking, falling, mood changes, and twitching and uncontrollable muscle spasms. During such twitching and spasms, individuals lose control of their limbs. Symptoms may last from a few seconds to 15 minutes. The part of the brain that is involved will depend on the symptoms that occur.

Often an individual may exhibit some warning signs before a seizure occurs. Some of these warning signs include fear, nausea, anxiety, and visual problems. Some individuals may not be aware they have had a seizure and therefore it may go unnoticed. Others may go through such a significant change and lose consciousness. Those who lose consciousness may exhibit involuntary muscle spasms called convulsions. There are many different types of seizures. Some have mild symptoms and some have very severe symptoms.

Based on the type of behavior and brain activity, seizures are divided into two broad categories: partial and generalized. Partial seizures occur in a relatively small part of the brain. The most common symptoms of a partial seizure include muscle rigidity, spasms, head turning, unusual sensations affecting one or more of the five senses, memory or emotional disturbances, fidgeting, and other repetitive, involuntary but coordinated movements. Generalized seizures occur throughout the entire brain. The most common symptoms of a generalized seizure include convulsions, short loss of consciousness, jerking movements on both sides of the body simultaneously, stiffening of the muscles, and sudden loss of muscle tone.

There are many causes of seizures. These include drug abuse and dependency, alcohol use disorders, and withdrawal from certain drugs and alcohol. They can also include low blood sugar, head injury, heart disease, stroke, and brain infection. Sometimes a cause cannot be found. By the age of 80, about 5%–10% of

all individuals will have experienced a seizure, and 40%–50% of these individuals are likely to have a second seizure. If a second seizure occurs, the individual has developed epilepsy. Currently, epilepsy affects about 1% of the population. Men are more likely to develop epilepsy than women (Engel, 2013).

In most cases, seizures are not life threatening and generally easy to treat. If a seizure lasts for more than five minutes, the individual should seek medical treatment immediately. The medical care provider will attempt to diagnose the type of seizure the individual has had based on symptoms and medical tests that will be performed. Tests may be ordered to rule out other medical conditions that cause seizures or similar symptoms (e.g., stroke). Computed tomography and electroencephalography are two methods used when treating an individual who has had a seizure. Blood and urine tests may also be ordered. Treatment will vary depending on the type of seizure (e.g., first time seizure, epilepsy). For individuals who have been diagnosed with epilepsy, it will be important for the health-care provider to access the medication individuals are currently taking, as well as the dosage prescribed.

Selective Mutism

Selective mutism is a mental disorder in which children or adolescents fail to speak in some social situations although they have the ability to talk normally at other times. Previously it was called elective mutism.

Definitions

- **Anxiety disorders** are a group of mental disorders characterized by anxiety as a central or core symptom. The group includes specific phobias, social anxiety disorder, and generalized anxiety disorder.
- **Behavior therapy** is a psychotherapy approach that focuses on identifying and changing maladaptive behaviors. It is also referred to as behavioral therapy.
- **DSM-5** stands for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, which is a diagnostic system used by professionals to identify mental disorders with specific diagnostic criteria.
- **Separation anxiety disorder** is an anxiety disorder characterized by excessive anxiety resulting from separation from those to whom a child is attached.
- **Social anxiety disorder** is an anxiety disorder characterized by excessive and unreasonable fear in social situations of being judged or evaluated by others. Previously it was referred to as social phobia.
- **Specific phobia** is an anxiety disorder characterized by a marked and enduring fear of specific situations or objects.

Description and Diagnosis

Selective mutism is an anxiety disorder in which a child who is capable of speaking does not speak in specific situations. It must be distinguished from mutism in which the child cannot speak. Instead, those with selective mutism are fully capable of speaking and understanding language; they fail to meet the expectation to speak and respond. For example, a child with this disorder may be silent at school for years but speaks freely at home. It appears that the refusal to speak serves to control others and situations that the child fears. While the disorder may develop in early childhood at home, it is seldom diagnosed until the child is in school. This refusal to speak can lead to

impairment in school, work, or other areas of life. It is a rare disorder affecting less than 1% of children. It is most common in children under age five but not diagnosed until they begin school.

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, children can be diagnosed with this disorder if they exhibit consistent failure to speak in specific social situations despite the capacity to speak in other situations. It interferes with school, work, or social communication. This failure to speak is not the result of not knowing the spoken language, and it must continue for at least one month. Finally, it is not the result of stuttering or other communication disorder or a developmental disorder like autism (American Psychiatric Association, 2013). In addition, selective mutism is not diagnosed if there is a neurological problem with the child's speech or if the child has recently emigrated from a place where people speak a different language.

The cause or causes of this disorder are not well understood. Children with this disorder may inherit a tendency to be anxious and inhibited. Some have a family history of selective mutism, extreme shyness, or anxiety disorders, which may increase their risk for similar problems. Most children with selective mutism also have social anxiety disorder, separation anxiety disorder, or a specific phobia. Parents of children who use selective mutism are often overprotective and more controlling than the parents of children who have other anxiety. It may be that selective mutism is a purposeful choice made by a child to control anxiety or to control others who are placing demands on the child that are unwanted.

Treatment

Behavior therapy can be effective with this disorder. The goal of treatment is to increase speech. Treatment begins with the therapist performing an assessment that identifies the child and the settings in which the child refuses to speak. Then, a behavior change plan based on a reinforcement (reward) system is established. Its purpose is to reward appropriate behavior (efforts to speak). The behavior plan typically uses tokens (tickets) which the child receives for desirable behaviors. The child can then trade the tokens for toys, candy, or privileges. Working with the child's parents and teachers is another treatment approach. They learn about the disorder and how to address the child's power-control strategy for controlling individuals and situations by refusal to speak. They are helped to defuse this strategy and become calm and supportive encouragers. They learn that neither speaking for the child nor demanding that the child talk is effective. Instead, they can help the child by asking questions once and then allowing consequences to occur. For example, if a child likes a particular treat, the parent could ask if the child would like the treat in a situation where the child had not been talking. Getting the treat requires that the child speak or lose out on the opportunity. Or, a teacher can tell a child that she has a gift which the child can have if the child asks for it in a clear voice.

Self-Actualization

Self-actualization is a psychological concept referring to both the human desire and ability to fulfill one's potential.

Description

"Self-actualization" is a term used by a number of developmental psychologists over the years to describe the condition when human beings are able to strive toward and fulfill their highest potential. Abraham Maslow (1908–1970) and Carl Rogers (1902–1987),

both listed in the top 10 most eminent psychologists of the 20th century, considered self-actualization to be the highest level of human development. Maslow used the term to describe a motivating desire. Rogers described it as a fundamental driving force. Both Maslow and Rogers believed that to become self-actualized an individual needed to have several internal characteristics or attributes. These include being vulnerable to others, being willing to learn from painful experiences, desiring to be one's true self, and being fully human.

Maslow placed self-actualization at the top of his "hierarchy of needs." He theorized five levels of needs, which must be met before a person is able to move up to the level above until reaching self-actualization. The five needs are (1) physiological, which includes what is needed to sustain life such as food, water, and sleep; (2) safety, which includes physical and economic security; (3) love and belonging, which includes friendship, family, and intimacy; (4) esteem, which includes self-esteem, the need to be accepted and valued by others; and (5) self-actualization, which is the realization of a person's full potential.

Rogers believed that people were self-actualized when their view of themselves, their sense of self-worth, and their ideal self (what they wish they were like) were congruent, or in harmony. He considered self-actualized individuals to be "fully functioning persons" who were well adjusted, well balanced, and interesting people to know. Rogers identified five characteristics of self-actualized or fully functioning persons: (1) open to experience, able to accept and handle both positive and negative emotions; (2) existential living, able to live in and appreciate the experience of the present moment, not being judgmental of others; (3) trust feelings, able to trust one's own emotional experience and trust that people can make the right decision for themselves; (4) creativity, creative thinking and taking risk in life, able to seek out new experiences; and (5) fulfilled life, the person is happy and satisfied with life and seeks out new challenges.

Self-Concept

"Self-concept" is a psychological term referring to a person's set of thoughts, perceptions, and beliefs about oneself.

Description

Self-concept is a collection of beliefs about oneself formed in our interactions with the environment and significant others, and the value we place on others. It involves the perceptions, thoughts, and attitudes about oneself and is formed in childhood. Self-concept consists of an assessment of many individual characteristics, including personality, abilities, skills, talents, strengths, physical characteristics, and intelligence

Carl Rogers (1902–1987), listed as one of the 10 most eminent psychologists of the 20th century, was very important in the development of the theory of self-concept. He described self-concept as resulting from the totality of the experience of what is going on inside the individual. It is the perceptions one has of oneself, the perception of the self in relationship to others, and the values attached to those perceptions.

A person's self-concept consists of three components. The first component, self-image, is the view a person has of himself or herself. The second component, self-esteem (sometimes referred to as self-worth), consists of how much value a person feels he or she has. The third component, the ideal-self, is what a person wishes he or she were really like. Rogers believed that people feel and behave in ways consistent with

their self-image and reflect what we would like to be like. The closer our self-image is to our ideal-self, the higher our self-worth will be.

Roger's theory of self-concept teaches that a person's self-concept is the result of the conditional or unconditional positive regard of the parents. Individuals raised in a home in which they experienced unconditional positive regard would be fully self-actualized. A person who is self-actualized is able to reach his or her potential and be able to fully and confidently function in life. Those who were raised in homes where regard was conditional, meaning it had to be earned, only felt worthy when they met certain conditions.

Because people have the capacity for change and growth, a person's self-concept can be modified. Individuals who grew up in abusive, neglectful, or other adverse circumstances can develop a negative self-concept that can affect how they deal with life. For instance, a child who grew up in a home where she was never praised and was constantly told how stupid she was, or was never enjoyed by the parents, would develop a negative self-concept. She may believe and act as if she really is stupid and unworthy of recognition, or praise. Insight-oriented therapies, such as Adlerian therapy or cognitive behavior therapy, can provide assistance to individuals seeking to change negative and patterned ways of perceiving, thinking, feeling, and behaving.

Self-Efficacy

Self-efficacy is an individual's self-evaluation of his or her own ability to accomplish a particular task or engage in a particular process.

Definitions

- **Autonomy** is an independent and self-determining reliance on one's self and a resistance to social or peer pressures to think, act, or feel a certain way.
- **Behavioral psychology** is a form of psychology whose aim is to study behavioral adaptation to an environment and its stimuli.
- **Classical conditioning** is an involuntary process of neurological change in response to a stimulus that causes a reaction to occur automatically when the new stimulus is present.
- **Environmental mastery** is the ability to competently manage everyday affairs of living by making effective use of resources and opportunities while controlling external activities.
- **Evidence-based practice** is a form of practice that is based on integration of the best research evidence with clinical experience and client values.
- **Pathology** is an experience of suffering or aspect of a disease incorporating cause, development, structure, and consequences.
- **Psychotherapy** is a psychological method for achieving desired changes in thinking, feeling, and behavior. It is also called therapeutic counseling.
- **Social learning theory** is the aspect of behavioral psychology that states knowledge is acquired through observation, modeling, and imitation. It is also known as social cognitive theory.

Description

Self-efficacy is an individual's belief as to whether or not he or she will be capable of performing a specific

practice or completing a specific task. It is not a behavior. Rather, self-efficacy is a self-perception or thought process. It actually serves to impede an individual's engagement in practices that he or she considers to be outside of his or her skills and abilities. Conversely, self-efficacy can promote behaviors that an individual has confidence in. Self-efficacy theory states that a person's self-evaluation affects his or her expectations of practice outcomes and motivation to attempt accomplishing a particular goal or objective. Decisions are affected by self-efficacy. In addition, when self-efficacy increases, motivation typically increases as well.

Self-efficacy has profound implications for mental health practitioners. They should utilize psychotherapeutic interventions that do not deviate too far from a client's perceived self-efficacy. A client's self-efficacy will predict what change behaviors he or she is willing to engage in. Due to the relationship between self-efficacy and motivation, motivational interviewing is one technique that can be used in psychotherapy to increase a client's self-efficacy. As a client's self-efficacy increases, his or her likelihood to engage in therapeutic behavior change is also likely to increase.

Self-efficacy is a self-evaluative thought that ranges from a semipermanent core belief to an immediate and reactionary assessment of one's own ability. An individual's self-efficacy can be influenced by traditional behaviorism, observations of others, social and cultural persuasions, or the individual's own level of psychological arousal. Psychotherapy related to self-efficacy is empirically supported and can assist a client achieve environmental mastery.

Development and Current Status

Behavioral psychology evolved in the 1970s to include social learning theory, which is also known as social cognitive theory. This evolution was largely due to the work of psychologist Albert Bandura (1925–) and the various cognitive theories of the time. Bandura helped integrate cognitive and behavioral theories. Social learning theory states knowledge is acquired through observation, modeling, and imitation. This is a departure from the classical conditioning and other forms of traditional behavioral psychology. In the 1980s, Bandura offered the addition of the theory of self-efficacy to social learning theory. Self-efficacy is important in the history of behavioral psychology because it provides a theoretical framework for self-determined behavior. Historically, behavioral psychologists believed that all behavior was conditioned. A client's evaluation of his or her own capabilities affects his or her choice of, and ultimately his or her success in, self-management, self-control, and self-determination.

Self-Esteem

Self-esteem is a psychological concept referring to an individual's internal sense of self-value or worth. Self-esteem is a component of a person's overall self-concept.

Description

Self-esteem is a psychological concept that refers to an individual's self-appraisal of himself or herself. It is a judgment of one's inherent self-worth. Self-esteem consists of attitudes and beliefs about self (e.g., I am smart vs. I am stupid) and emotions (e.g., feelings of pride vs. feelings of shame). Self-esteem is a component of a person's overall self-concept. At the most basic level, self-esteem is a combination of what we believe and how we feel about ourselves. Self-esteem tends to be either positive or negative and fluctuates throughout the life span in response to events. For instance, when a student received an excellent grade on a school project,

he or she might feel especially good about himself or herself. Although short-term variations occur, levels of self-esteem tend to be consistent and are generally viewed as part of a person's personality.

Current Status and Impact (Psychological Influence)

Carl Rogers, listed as one of the 10 most eminent psychologists of the 20th century, was very important in the early development of the theory of self-concept and self-esteem. The hypothesis of self-esteem continues to be widely researched. Initial research focused on how self-esteem is developed in childhood. This early research indicated that positive or negative levels of self-esteem were related to how an individual was raised and the experiences he or she had as a child. There are two dimensions of parenting that affect self-esteem. One dimension is how demanding and controlling a parent is in imposing rules, consequences, and punishments. The other dimension is how warm, supportive, loving, and responsive parents are to the emotional needs of their child. Individuals with high self-esteem usually have parents who were demanding, had clear expectations for school and behavior, had rules and consequences for their children's behavior, and were loving, warm, caring, and responsive to their children's emotional needs. Individuals with low self-esteem had parents who either were overly demanding, harsh, and controlling with little warmth, or were overly permissive with few rules and consequences.

Self-esteem research has also focused on the impact of academic and social experiences during childhood and adolescence in the development of self-esteem. Academic achievement in school has a significant influence on self-esteem as children become very aware of differences between themselves and their peer group. In elementary school comparison with peers regarding who did better or worse on quizzes, tests, exams, and projects can impact how children think and feel about themselves. As children move into adolescence, social standing and comparisons of looks, athletic ability, and popularity can have a significant influence on how they feel about themselves and what they believe about themselves. Studies indicate that individuals who are extroverted, emotionally stable, and conscientious have higher self-esteem.

A recent meta-analysis (an analysis of a group of research studies) of 50 self-esteem studies indicated that levels of self-esteem vary throughout a person's lifetime. The authors found that the self-esteem of children aged 6 to 11 years was fairly unstable. Self-esteem increased for young adults and reached its peak at about age 60 and then began to decrease. Young adult women had lower self-esteem than men, with differences decreasing as they aged. Caucasians and African Americans have similar self-esteem stability, with self-esteem sharply decreasing for African Americans after age 60. The more education a person has, the higher his or her self-esteem. Negative changes in socioeconomic status result in decreased self-esteem, as did declining physical health.

Self-esteem is an important psychological concept that has been highly researched. The fields of psychology, counseling, social work, and education are professions that engage in self-esteem research in order to more fully understand human development. Understanding how to increase the development of self-esteem in individuals of all ages is an important aspect to increasing individual well-being and improving our society.

Self-Fulfilling Prophecy

Self-fulfilling prophecy is a concept that describes how a person's beliefs and expectations elicit actions or behavior to occur, which confirms his or her initial assumptions.

Definitions

- **Confirmation bias** refers to the tendency people have to pay attention or favor information that supports their beliefs or hypotheses.
- **Placebo effect** is a phenomenon that has been evidenced in the medical community whereby patients experience perceived or actual improvement in their condition after being given a placebo, or simulated, treatment.
- **Pygmalion Effect,** or Rosenthal Effect, describes a phenomenon discovered in a Rosenthal–Jacobson study confirming that when teachers placed higher expectations on their students it resulted in better performance.
- **Social perception** is the process by which we gather information to form impressions of people and what they are like.

Description

"Self-fulfilling prophecy," also referred to as the Pygmalion or Rosenthal Effect, refers to the notion of how preconceptions, whether accurate or inaccurate, impact resulting behavior and reinforce initial beliefs. Essentially, self-fulfilling prophecies are beliefs that come true because an individual acts in ways, directly or indirectly, that result in their coming true. A self-fulfilling prophecy follows some basic steps. First, the perceiver holds expectations, or false beliefs, about the target. Next, the perceiver acts in a manner that is likely to elicit the target's expected behavior. In response, the target indeed behaves in the expected way, thus confirming the perceiver's original belief. Finally, the perceiver sees (objective experience) the target behave in this predicted way. Experiments have been conducted in a variety of areas (education, relationships, multicultural studies) to confirm this phenomenon.

Though prophecies have been in existence since the time of Ancient Greece, sociologist Robert King Merton was the first to coin the term "self-fulfilling prophecy." He used the term to describe how a false definition of a situation can evoke a new behavior that makes the original conception true. He used an illustration of "a run on a bank" in which a rumor began that a bank was going to run out of money. Fearing this was true bank customers immediately went to the bank and withdrew all of their money. Banks are unable to keep all of their customer's cash on hand, it would be too much cash to store, and it is very rare that a person would take all of his or her money out of a bank. Because banks cannot keep enough cash on hand, the people who heard the rumor later in the day got to the bank after all of the cash was given to those who heard the rumor earlier in the day. Thus, the prediction of the bank running out of money came true but only because of the prediction.

The term was popularizing it in his book *Social Theory and Social Structure* (1968). His concept was based on the Thomas Theorem from the late 1920s formulated by sociologist couple William Isaac Thomas and Dorothy Swaine Thomas, which states, "If men define situations as real, they are real in consequences," meaning that a person's interpretation of a situation causes the behaviors that result. Merton expounded on this principle by applying it to various human social experiences. He further suggested that in order to change outcomes, one must alter one's perceptions/beliefs. The distinction is also made between prophecies and predictions; prophecies are predetermined and destined to occur, while predictions are estimations on what may happen given predicted events.

In a notable 1968 study, experimenters Robert Rosenthal and Lenore Jacobson demonstrated the self-fulfilling prophecy phenomenon. Their research examined how teacher expectations were impacted by economic, cultural, and ethnic differences among students. Teachers were told that certain students in

their class could be expected to make significant academic gains during the school year when in actuality the students were selected at random and their potential success was no more probable than any other student in the class. However, results pointed to higher IQ scores, increased reading levels, and more favorable teacher reports for those identified students even a year later. These findings suggest that the preconceptions held by teachers may have caused them to behave more attentively, academically nurturing, and encouraging toward these students, thus contributing directly to students' improved performance. This study provided evidence of how social perceptions could influence outcomes.

Current Status and Impact (Psychological Influence)

Applications from the research on self-fulfilling have been noted in education, sports, medicine, economics, psychology, counseling, and law. It has been the subject of extensive social research in the fields of sociology, psychology, counseling, social work, and education. Self-fulfilling prophecy and its impact on student performance have been highly studied. Parenting and self-fulfilling prophecy have also been the focus of numerous studies. As a result of the extensive research findings indicating that self-fulfilling prophecies do indeed exert considerable effects on behaviors, the concept is generally regarded as a psychological truth.

Racial and ethnic stereotypes can become self-fulfilling prophecies if members of minority groups are underchallenged or underrepresented. Educators, administrators, and politicians have sought solutions to address the "achievement gap" with minority students, with findings suggesting that expectations can have a profound impact on future success. Efforts made to increase multicultural sensitivity and measures including affirmative action attempt to even the playing field for these groups. In the field of medicine a phenomenon known as the "placebo effect" has been well documented whereby patients who receive innocuous treatment but believe show improved health benefits. Research supports a strong connection between a patient's mind-set and his or her life span. Psychologists, counselors, and therapists employ the principle of self-fulfilling prophecy when using cognitive behavioral, rational emotive behavioral, and solution-focused approaches that stress the link between cognitions and one's resulting actions. The *law of attraction* provides an additional example of self-fulfilling prophecy, holding that "like attracts like," that the energy one puts out into the world, positive or negative, produces corresponding results.

Self-Help Groups

Self-help groups are peer-led, volunteer groups of people who share a common concern, need, bond, or desire related to a problem in living.

Description

Individuals, organizations, hospitals, schools, and just about any other person or group that has a concern can form self-help groups (SHGs) to address issues related to a multitude of problems such as parenting, physical illness, or a mental health illness. They may be led by professionals but are most often formed and led by nonprofessionals. The focus of SHGs can include management of a specific mental health disorder such as depression or anxiety; education and support for people impacted by diseases such as diabetes; grief support;

substance abuse; or for those dealing with other life issues such as divorce recovery groups. SHGs also focus on coping and stress management for physical illness such as support groups for cancer victims and paralytic conditions. According to the Substance Abuse and Mental Health Services Administration there are hundreds, if not thousands, of different kinds of SHGs.

Self-help groups are the oldest and most widespread type of peer support and generally fall into either lifestyle/behavior-oriented groups or coping/stress-related groups. Lifestyle groups, such as Alcoholics Anonymous, are usually focused on a debilitating addiction or compulsion. Behavioral SHGs focus on issues such as anger management. Coping/stress-oriented groups, such as cancer patient support or divorce recovery groups, focus on stress management, education, support resources, and member compassion. Basic principles of SHGs include reciprocity, which is receiving help through helping others, the absence of professionals, the empowering nature of peer interaction, and non-bureaucratic organizational practices.

Self-help groups offer many benefits to members. Developing a deeper understanding of one's problems, spending time with peers who are in the same situation or have a similar problem, developing a network of supportive social relationships and strengthened family relationships, receiving understanding and support, learning from other people's experiences, and an improved sense of being normal are just some of the recognized benefits of SHGs.

Traditionally self-helps groups have met almost exclusively in face-to-face meetings. With the expansion of Internet technology, online support groups have become widespread. Communication is conducted via e-mail, virtual chat rooms, or live forums. Although

some Internet support groups (ISGs) are private and require some form of membership, most ISGs are public and open to anyone. ISGs offer greater anonymity where there is little chance of one's identity being discovered. Anonymity can be almost complete, allowing some members to "troll" in which an individual can read and benefit from all of the group interaction without ever revealing his or her presence.

Self-help groups addressing mental health and drug use are widely utilized in the United States. According to the National Survey on Drug Use and Health (NSDUH, 2009), approximately 2.4 million adults aged 18 or older receive support from mental health SHGs related to emotional or mental health difficulties. Of that group approximately 61% are females, 89% are over 25 years of age, and 47% were employed full-time. Approximately two-thirds of adults who participated in SHGs also received more traditional treatment consisting of inpatient treatment, outpatient treatment, or prescription medication. According to the Substance Abuse and Mental Health Services Administration, 5 million people attended an SHG for help with alcohol and illicit drug–related difficulties.

Self-help groups exist for virtually any diagnosable mental health disorder. There are multiple online sources for locating SHGs, including Mental Health America and the American Self-Help Group Clearinghouse.

Self-Medication Hypothesis

Self-medication hypothesis is a theory that explains drug use as an attempt to "solve" emotional and behavioral problems.

Definitions

- **Addiction** is a chronic disease of the brain, which involves compulsive and uncontrolled pursuit of reward or relief with substance use or other compulsive behaviors.
- **Addictive disorder** is a chronic disease of the brain which involves compulsive and uncontrolled pursuit of reward or relief with substance use or other compulsive behaviors.
- **Dependence** is the need for a drug to function normally. Dependence can be psychological and/or physical. Psychological dependence is dependence on a psychoactive substance for the reward it provides. Physical dependence refers to the unpleasant physiological symptoms if the drug is stopped.
- **Depressants** are a group of drugs that are prescribed to reduce the symptoms of anxiety. They are addictive and can be abused. Benzodiazepines, like Valium, are a very common depressant.
- **Opioids** are a group of drugs that reduce pain. They are highly addictive and include both prescription drugs like Percocet and illegal drugs like heroin.
- **Psychoactive** is a drug or substance that has a significant effect on mental processes. There are five groups of psychoactive drugs: opioids, stimulants, depressants, hallucinogens, and cannabis.
- **Psychopharmacology** is the study of drugs that affect thinking, feeling, and behavior.

- **Stimulant** is a drug that increases brain activity and produces a sense of alertness, euphoria, endurance, and productivity, or suppresses appetite. Examples are cocaine, amphetamines, and Ritalin.

Description

Self-medication hypothesis is a theory used to explain why individuals use alcohol and drugs. Uncomfortable emotions, unresolved trauma, mental illness, and social problems are often improved through the use of different psychoactive substances. The theory holds that individuals prefer specific drugs because of their unique psychopharmacological properties. For example, an individual who suffers from feelings of anxiety and is uncomfortable in social situations may use a depressant like alcohol to feel calm and interact with others. In this case, a stimulant like cocaine would not improve these problems and may make them worse. However, stimulants may be attractive to those who have other problems like depression or low energy. Another example is opioids like heroin. This category of drugs reduces the perception of pain and produces feelings of euphoria. Those who experience feelings of aggression and rage often find comfort with this type of

drug. The theory holds that individuals will experiment with many different substances until finally settling on the one that works. While the drug helps individuals feel better initially, continued use often develops into addiction and creates additional problems. These may include damaged social relationships, physical or psychological dependence, and legal troubles. Until the substance user finds some other way to meet his or her needs, the use will likely continue.

The self-medication hypothesis was separately proposed by Edward Khantzian, MD (1943–), and David Duncan, MD (1947–), in the 1970s. Khantzian focused on the psychological factors that explain self-medication, such as emotions and defense mechanisms. He believed that individuals use substances when they do not have the ability to manage feelings on their own. Duncan, however, considers self-medication as a behavioral issue. For him self-medication is a way of avoiding problems or responsibilities. When individuals are able to escape problems or responsibilities by using substances, their behavior is rewarded and they are likely to continue doing it.

Self-Mutilation/Self-Harm

"Self-mutilation" or "self-harm" refers to an intentional act of harm committed by mutilating one's own body but without the intent to commit suicide.

Definitions

- **Cutting** is a form of self-injury whereby one makes cuts on one's body, usually on the arms or legs, without the intent to kill oneself.
- **Deliberate self-harm,** or *self-inflicted injury*, refers to acts of harming oneself with non-suicidal intent.
- **Non-suicidal self-injury (NSSI) disorder** is the terminology used to describe the new diagnostic classification for self-damaging behaviors with the absence of suicidal intent.
- **Self-inflicted injury** is a term used to refer to a range of behaviors that encompass self-harm where one deliberately injures oneself but without suicidal intentions.
- **Self-injurious behavior (SIB),** often used interchangeably with *self-mutilation* or *self-harm*, refers to purposeful acts of self-harm that are free from suicidal intent.

Description

"Self-mutilation" is a term used in the literature to describe self-harm or self-injury (SI). These three terms are often used interchangeably. This behavior describes when a person causes deliberate or intentional damage to his or her body. Cuts, bites, burns, and picking are forms of self-mutilation. Self-mutilating behavior can be broken down into three different types: superficial or moderate, stereotypic, and major. Superficial self-mutilation is the most common form associated with people who cut, burn, or hit themselves. This type of self-inflicted harm is typically committed by those who are diagnosed with personality disorders. Superficial self-mutilation is often the result of experiences that happen early in life that impair normal development. Victims of sexual, emotional, verbal, or physical abuse or trauma may engage in this type of self-harm. Those characterized as stereotypic are more severe and engage in behaviors, including head banging, eye gouging, and biting, which are more typical of individuals who are diagnosed as mentally delayed. The most extreme and rare form of self-mutilation is

major self-mutilators, who attempt to amputate limbs or genitalia, seeking to permanently disfigure themselves. Self-injury is not just a human phenomenon; some animals that are kept in captivity also display these types of behaviors.

More recently, terms such as "self-cutting"/"cutting," "burning," "self-poisoning," "hair-pulling," and "skin-picking" have been used to refer to more specified forms of self-harm. Deliberate self-harm is most common in adolescents and young adults between the ages of 12 and 24, though people of any age can engage in these acts. The most common form of self-mutilation is cutting, or wounding, one's own bodily tissue with a sharp object such as a knife or razor blade. High incidence rates of self-poisoning, referring to the excessive use of dangerous or mind-altering substances, have also been noted in the literature.

It was previously believed that self-harm was done for attention-seeking purposes; however, research now indicates that the majority of sufferers attempt to hide evidence of these behaviors. For example, cutters may wear long sleeves or pants. Most sufferers who are properly diagnosed as self-injurers know exactly how far to go with their actions and do not want to commit suicide, though this group is at an increased risk. Those who are diagnosed incorrectly may use SI to explain away an unsuccessful attempt at suicide. Self-harmers may also unintentionally end up taking their own lives. This is most common in those who use substances to self-soothe (alcohol, illegal drugs).

Often those who self-harm are remorseful or ashamed of their actions. They may be unable to express their thoughts or feelings openly to others and turn rather to internalizing coping mechanisms like SIB. Self-harming is viewed as a form of depersonalization or dissociative behavior, meaning the person is unable to relate or connect directly to what he or she is experiencing or feeling in a healthy or appropriate manner. The individual may be either too numb or oversensitive; thus, self-harming provides a way to bring the person back to himself or herself, his or her physical body, and help him or her to feel connected or grounded again.

Self-injurious behavior is usually seen in conjunction with more complex problems or other forms of mental illness, including borderline personality disorder, depression, anxiety disorders, eating disorders, schizophrenia, or post-traumatic stress. Self-harm behaviors are also commonly associated with disabilities such as autism and mental retardation. Reduced levels of cognizance, self-control, or lack of awareness regarding possible consequences may be contributing factors. Those diagnosed with behavioral issues such as attention-deficit hyperactivity disorder, oppositional defiant disorder, low self-esteem, and poor social skills are also at higher risk for SI.

Impact (Psychological Influence)

Incidents of self-mutilation/harm have rapidly increased in terms of reported cases since the 1980s. Possible explanations for this include environmental factors, negative influence of media, increased social pressure, and earlier exposure to drugs/alcohol. Several therapeutic interventions have proven helpful in targeting SI; however, more research is needed in this area. Specifically, cognitive behavior therapy, solution-focused counseling, rational emotive behavior therapy, and the use of psychotropic/mood-altering medications have been evidenced as effective. As this issue most commonly plagues adolescents and young adults, school-based interventions, programs, and education should continue to be developed. In 2010, a formal proposal was offered to include Non-Suicidal Self-Injury as a stand along diagnosis in the most recent version of the *Diagnostic and Statistical Manual*, DSM-5. Prior to this, self-harm behavior was simply viewed as a symptom of other underlying disorders.

Seligman, Martin (1942–)

Martin Seligman is a psychologist, educator, and author who is best known as the founder of positive psychology, which is an approach to psychology that focuses on the best things in life, including positive emotions, traits, and institutions.

Description

Beginning in the late 1960s, Dr. Martin E. P. Seligman attracted attention within the psychological community with his theory of learned helplessness. This concept grew out of his experience with clients suffering from depression. Seligman observed that his clients had learned to act or behave in a helpless fashion even when they had the innate ability to improve. Seligman saw a clear link between their feeling that they had no control over their behavior or feelings and their clinical depression. From this initial theory Dr. Seligman developed positive psychology.

The psychological and psychiatric treatment of mental health after World War II was based on a disease model. In the disease model, practitioners were focused on their patients' lack of mental health, their problems, inappropriate behaviors, and deficits in personality. Seligman and his colleagues came to believe that this focus was too narrow. Rather than concentrate on problem behaviors and mental illness, positive psychology starts with a focus on trying to discover the things that make people happy, the things that bring them satisfaction in life. Working with Christopher Peterson, Seligman began to draw up a list of the strengths and character traits that enable individuals and groups of people to thrive.

Positive psychology focuses on tools and interventions that can help make people happy. It does this by asking questions like, which positive human strengths and virtues can be reinforced to help people achieve a better quality of life? Research shows that people who exhibit optimism and hope suffer less from adverse events and actually live longer with greater satisfaction than their pessimistic peers. One study of longevity in a community of nuns showed that the nuns who exhibited positive traits early in their lives lived longer than the nuns who did not.

Based on more mounting research, Seligman wondered whether it might be possible that people who did not seem to have a natural joyfulness or optimism could change their attitudes and behaviors. Seligman's conclusion is that optimism can be learned. Achieving optimism depends on the willingness of less optimistic people to become aware of their negative thinking and invest their efforts in how to counteract it.

In his most recent studies, Seligman concentrates on the idea of achieving psychological well-being, or the state of being happy, healthy, prosperous, or successful. This occurs through his identification of the five pillars of positive psychology. The five pillars of well-being are positive emotion, engagement, relationships, meaning, and accomplishment. Seligman believes that learning how to engage in these five areas of health is the foundation of a fulfilling and improved quality of life.

Impact (Psychological Influence)

Positive psychology helped supplement or counterbalance the disease model which had dominated the approach to and treatment of clients seeking counseling. This was accomplished in part by emphasizing the newly created classification of character strengths and virtues. Practitioners have been able to identify and develop psychological intervention tools that show significant increases in individual happiness measurements and a decrease in symptoms of depression. Interventions based on positive psychology utilize effective techniques and create a multifaceted treatment. Its results are the relief of suffering for those with mental disorders, especially depression, and the enhancement of their chances for living a happier life.

Dr. Seligman is presently director of the Positive Psychology Center at the University of Pennsylvania, where he continues to explore applications of positive psychology.

Seligman and his associates believe that complete mental health is not just the absence of mental illness. They emphasize that treatment needs to address the emotional, psychological, and social domains of clients in therapy. Mental health professionals have adopted Seligman's principles and developed other programs based on them, such as quality of life therapy.

The Dalai Lama and Martin Seligman on stage during a 2009 science of the mind conference in Sydney, Australia. Seligman, a psychologist, educator, and author, is best known as the founder of positive psychology. (Gaye Gerard/Getty Images)

Even though there are significant findings about the research and effectiveness of positive psychology, there are psychologists who remain critical of it. It has been criticized for what some consider a naïve concentration on the idea of happiness, and many are uncomfortable with its adoption of its own version of the law of attraction. The concern is that the reality and painful effects of mental illness may be ignored or underestimated. When it is applied in social or work settings, some fear that positive psychology may lead to a forced emphasis on being happy in the workplace which could actually be counterproductive.

Senior Mental Health

"Senior mental health" refers to the mental health status of older adults.

Description

Subjective overall well-being seems not to decline with age. Seniors, for example, report high perceptions of their health and of overall life satisfaction. However, older adults are more likely than younger members of the population to experience physiologically based comorbidities.

Mental decline like dementia and delirium are considered by many to be inevitable consequences of aging. However, normal aging does not inevitably include mental illness, such as depression and anxiety, and chronic mental illnesses like schizophrenia. While seniors experience the full spectrum of mental disorders, including anxiety, severe cognitive impairment, mood disorders, and schizophrenia, they often exhibit better mental health than younger adults.

Mental illness and decline are not inevitable consequences of aging. However, idiosyncratic aspects of mental illness add to the challenges of helping older adults manage these disorders. Although older adults tend to maintain their repertoires of coping skills as they age, the frequency of significant stressors associated with growing old increases. Thus, older adults need to manage the effects of multiple stressors simultaneously, so straining their capacity to successfully manage stress. The psychological strain of coping with these stresses, and with the consequences of physical illnesses, further stretches coping capacities and can affect mental health.

Some older adults experience subclinical depression and significant depressive symptoms. This can have devastating effects, including increasing the risk of mortality from physical illness, increasing the risk of suicide, and contributing to cognitive decline of the non-demented elderly. Although the prevalence of major depression appears to decline with age, there is some dispute as to whether or not there is undiagnosed depression among seniors. This makes depression particularly important among seniors because of the dangers of misdiagnosis, for example of dementia, when in fact the person is simply suffering from depression and is treatable.

Substance abuse, like heavy drinking, is known to occur in the senior population, although abuse of prescription and over-the-counter medications is considered more an issue of misuse rather than abuse. The use of illegal drugs is relatively low among this group; however, as the baby boomer generation floods into old age, it is believed that recreational drugs use/abuse will become more prevalent.

Older adults also experience chronic mental illnesses, like schizophrenia. Although typically associated with younger populations, schizophrenia can continue into older life. It can also emerge in older adulthood. Symptoms tend to be less severe in older adults. Delirium, also known as acute confusion, is a highly prevalent and serious mental health problem for older adults. In fact, it is considered a geriatric emergency.

Dementia is yet another mental illness prevalent in the older population. In fact, advancing age is a major risk factor for the development of dementia. The word is a broad term used to describe a cluster of symptoms that interfere with daily life by affecting intellectual function and cognitive skills. Dementia encompasses multiple cognitive deficits and impairments, including executive dysfunction, aphasia, apraxia, and agnosia. These changes significantly interfere with occupational and social functioning. The most common form of dementia is Alzheimer's disease, while vascular dementia has lower prevalence. While delirium and dementia are considered a common side effect of aging (i.e., physiologically based), depression and substance abuse are not.

Besides physiological impairments, the constellation of symptoms associated with a variety of physiological disorders tend to include physiological disturbances, such as sleep or appetite disturbances, and nonspecific complaints of pain. Unfortunately, older adults tend not to recognize that their symptoms can represent some underlying psychological issue, in part thanks to a long-held view that these symptoms are a normal consequence of aging. Also, historical stigma associated with mental illness is strongly ingrained in the older population, leading to a sense of shame and denial.

In considering mental health challenges in the senior population, Joan Erikson suggests there is a ninth stage to Erik Erikson's psychosocial development. The latter believed the eighth stage of psychosocial development to be one of ego integrity versus despair. The new ninth stage proposes to clarify the new demands, reevaluations, and daily difficulties that extreme old age brings.

Erik Erikson saw personality as a lifelong developmental process. Each of his eight stages of development resulted from the interplay of biological pressures within the individual and expectations from that person's social and cultural environment. At each stage, there is potential for crisis and conflict. The resolution of the eighth stage takes place when the individual can accept the past as inevitable and satisfying, and can also accept death without fear. The result is ego integrity. However, the negative outcomes of earlier stages would result in an adverse prognosis for the later ones, thus affecting mental health. Later in life, Erikson admitted that you couldn't find a person who has resolved all previous crises equally well.

Joan Erikson's theory suggests that living into old age and facing its challenges brings about a shift in meta-perspective from a materialistic and rational view to a more cosmic and transcendent one. This is reflected in the fact that senior adults continue to develop spiritually. It also highlights the need to better understand senior mental health and better manage it.

Current Status

Treatment approaches vary depending on the severity of symptoms. In cases of severe depression, pharmacotherapy in conjunction with psychotherapy is a treatment of choice. Selective serotonin reuptake inhibitors are recommended as the first-line pharmacological treatment. In cases where the severely depressed senior has not responded to other treatment, electroconvulsive therapy may be implemented. For milder symptoms of depression, non-pharmacological treatment approaches are preferred. These include interpersonal therapy, cognitive therapy, and reminiscence therapy. In treating substance abuse, the approach needs to be supportive and nonconfrontational. The focus should be on coping with depression, loneliness, and loss, and rebuilding a social support network.

Medication is particularly important in treating chronic mental illness, particularly schizophrenia. Because symptoms tend to be less severe in older adults, lower doses of traditional antipsychotic medications are often prescribed. However, older adults tend to be more susceptible to the development of side effects. Unfortunately, the mental health of seniors remains a neglected aspect of health-care services.

Sensory Processing Disorder

Sensory processing disorder is a neurological disorder characterized by an abnormal experience of one or more of the five senses. It is also known as sensory integrating disorder.

Definitions

- **Anxiety** is a negative emotional state characterized by feelings of nervousness, worry, and apprehension about an imagined danger.
- **Autism spectrum disorder** is a neurodevelopmental disorder characterized by difficulty learning, communicating, and repetitive bodily movements.
- **Depression** is an emotional state characterized by feelings of sadness, low self-esteem, guilt, or reduced ability to enjoy life. It is considered a mental disorder only when it significantly disrupts one's daily functioning.
- **DSM-5** is the abbreviation for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, which is the handbook mental

health professionals use to diagnose mental disorders.

- **Occupational therapy** is a type of therapy that focuses on helping individuals gain or regain abilities to engage in activities of daily living like dressing, eating, and walking.

Description

Sensory processing disorder is a neurological disorder whereby an individual's brain and nervous system do not receive and process sensory information correctly. The abnormal functioning that results is expressed as a hypersensitivity (higher than normal sensitivity) to one or more of the five senses (sight, smell, sound, taste, and touch). For example, an individual with this disorder may find his shirt to be very uncomfortable or that daylight is much too bright. In addition, sensory processing disorder may manifest as a lack of sensitivity. As a result individuals may excessively season their food or have to turn up the volume when listening to music. Currently, this disorder is not recognized as a diagnosis in DSM-5. Instead, it is considered to be the result of other disorders such as autism spectrum disorder. Although this point is debated, there are commonalities between symptoms of autism spectrum disorder and sensory processing disorder, specifically hypersensitivity to sensory information.

Sensory processing disorder is more common in children than in adults. The usual age of onset tends to be in early childhood. However, adults also can be diagnosed with this disorder. It is estimated that 1 in 20 children in the United States can be diagnosed with this disorder (Miller and Fuller, 2006).

The cause of this disorder is unknown. However, it has been suggested that genetics may play a significant role in the manifestation of symptoms. Individuals with this disorder often develop anxiety and depression as they age. They may also experience difficulty in learning, working, and interpersonal relationships.

Treatment

Treatment for this disorder is commonly provided by an occupational therapist. The goal of treatment is to help these children cope with and become accustomed to their hypersensitivity. Treatment may also include learning age-specific skills. These include earning an income or learning adaptive (healthy) ways to interact with others in uncomfortable circumstances. In addition, comorbid (occurring simultaneously) conditions such as anxiety or depression treatment may be treated. There is no known cure for this disorder.

Separation Anxiety Disorder

Separation anxiety disorder (SAD) is an anxiety disorder characterized by excessive anxiety resulting from separation from those to whom a child is attached.

Definitions

- **Anxiety** is a negative emotional state characterized by feelings of nervousness, worry, and apprehension about an imagined danger.
- **Anxiety disorders** are a group of mental disorders characterized by anxiety which tends to be intermittent instead of persistent. The group includes panic disorder, phobias, and generalized anxiety disorder.

Description

Separation anxiety disorder is defined by the American Psychology Association as the inappropriate and excessive display of fear and distress when faced with situations of separation from places, objects, or people to whom children are emotionally attached. Common examples include separation from home, blankets, teddy bears, or parents and other family members. Separation anxiety occurs often, especially with people to whom the individual has a strong emotional attachment. SAD may cause significant negative effects and emotions and hinder normal everyday life for the affected child.

SAD can present in many areas such as social and emotional contacts, family life, physical health, and school attendance and performance. The anxiety expressed needs to be more intense than the behavior expected for other people of the same age. The anxiety also must be present for about one month and occur in children before adulthood.

Causes and Symptoms

The causes of SAD are most often a combination of developmental and social factors. One important social factor influencing SAD is parenting style. Parent and child interactions that include confusing messages to the child about affection from their parent play a factor. So does the independence the parent gives and expects from the child. Parenting styles can range anywhere from neglect to smothering. The child's own temperament plays a role. If a child feels insecure in the world, he or she needs to find places, objects, or people who help him or her feel protected.

How children exhibit separation anxiety varies, but certain behaviors are common in SAD. Many children experience clear distress, worry, or even panic at the possibility of separation. This can be demonstrated by clinging to a person or object that represents security. It can also include crying, withdrawing, and screaming, which threatens physical distance from the object of security. Other common symptoms are sleep disturbance, including lack of sleep and night terrors. Physical sickness can also occur, including headaches, stomach aches, and nausea. Children may also exhibit a variety of resistant behaviors, such as avoidance and denial, when threatened with the loss of the person or object they are attached to.

Diagnosis and Prognosis

SAD is diagnosed when it happens frequently and consistently over time. There is some difference of opinion on the exact definitions of how much and for how long the behaviors need to occur to warrant a diagnosis. Usually children need to present with anxious behaviors during specific events. These events include actual separation or even the threat or worry of separation. A diagnosis also requires that a child refuse to do expected tasks, like sleep or go to school, or isolate himself or herself from others. It also requires that a child experience physical symptoms like nausea or headaches. Depending on the severity of symptoms and access to treatment, a child's prognosis will vary. A child's ability to tolerate separations should gradually increase over time when he or she is gradually exposed to the feared events.

Treatment

As children become more able to engage in self-reflection, it becomes important to help them identify the circumstances that make them anxious. This includes SAD. Exposure therapy and desensitization to separation are common behavioral therapy approaches on working with children with SAD. Encouraging a child with SAD to feel competent and empowered, as well as discussing feelings associated with anxiety-provoking events, helps promote recovery.

For the treatment of SAD several behavior therapies have proved very helpful. Among the most effective have been behavior therapy and cognitive behavior therapy. Behavior therapy can use a reward system to give children verbal or tangible reinforcement. When children show signs of independence, they are praised or given a reward. In working with younger children, behavior therapy, without a cognitive component, can be more effective.

Cognitive behavior therapy focuses on helping children reduce feelings of anxiety by exposing them to stressful situations and then helping them identify

different ways of thinking that can help them deal with their anxiety. It is more difficult to use cognitive behavior therapy with very young children. Cognitive behavior therapy requires some maturity because a child needs the communicative ability to express emotions or the self-control ability to cope with the separation anxiety on his or her own. The goals of the treatment are to help the child recognize the anxious feelings and behaviors and design a plan to help cope with them. Developing skills that will work for children and then applying them in an ongoing way and refining the techniques through evaluating their effectiveness are important parts of this treatment.

Serotonin

Serotonin is a chemical messenger in the brain that regulates learning, sleep, mood, and appetite. It is involved in disorders such as depression and anxiety.

Definitions

- **Selective serotonin reuptake inhibitors** are a class of antidepressant medications that work by blocking the reabsorption of serotonin in nerve cells and raising its level in the brain.
- **Serotonin discontinuation syndrome** results from the abrupt discontinuation of antidepressant. It is characterized by withdrawal symptoms such as anxiety, agitation, insomnia, nausea, vomiting, diarrhea, fatigue, vivid or bizarre dream, dizziness, and other sensory disturbances.
- **Serotonin syndrome** is a serious medication reaction resulting from an excess of serotonin in the brain. Severe symptoms include high blood pressure, high fever, headache, delirium, shock, and coma. Milder symptoms include diarrhea, shivering, and goose bumps on the skin.

Description

Serotonin is a chemical messenger made from tryptophan, an amino acid, plentiful in a normal diet. About 80% of the body's total serotonin is in the gut where it regulates intestinal movements. Another 10% is synthesized by neurons in the brain, where it functions as a neurotransmitter. Serotonin acts by transmitting nerve impulses across synapses (gaps) between neurons (nerve cells). High levels of tryptophan in the blood signal the brain to make serotonin. One such signal is carbohydrate consumption, which explains why many individuals experience feelings of contentment after eating a cookie or other sugary or starchy snack. The beneficial consequences of increased serotonin include a sense of contentment and happiness, relaxation, and a good night's sleep.

Serotonin is called the "happiness hormone" because it can enhance an overall sense of well-being. Because of its importance in regulating moods and feelings of well-being, serotonin is targeted by medications that affect the mood, particularly antidepressants. Serotonin receptors and serotonin transporters play key roles in serotonin transmission or signaling. Serotonin receptors are found on the surface of neurons and other cells that receive and respond to serotonin. Research shows that women have more serotonin receptors than men, and lower levels of the protein that carries serotonin back into the nerve cells that secrete serotonin. This may explain why women experience more depression and chronic anxiety than men. Besides regulating serotonin, these receptors also regulate the release of other neurotransmitters like dopamine, acetylcholine, and gamma-aminobutyric acid. These

receptors are identified in groups numbered 5-HT1 to 5-HT7 and are the targets of antipsychotics, appetite suppressants, street drugs like ecstasy, and antidepressants. Serotonin transporters (SERT) regulate the amount of serotonin in synapses between neurons. They recycle serotonin by transporting (moving) serotonin from the synaptic space back into the presynaptic (originating) neuron. SERT is the target of many antidepressants, particularly the selective serotonin reuptake inhibitors (SSRIs).

Most antidepressants work by increasing serotonin in the brain. A class of antidepressant medications called monoamine oxidase inhibitors (MAOIs) prevent the breakdown of neurotransmitters, allowing them to increase in the brain and relieve depression. Commonly prescribed MAOIs are Parnate, Marplan, and Nardil. Unfortunately, these medications have some serious side effects and have problematic interactions with other types of medication.

SSRIs are also used to treat depression, yet they have fewer side effects, and they tend to react better than other medications. Commonly prescribed SSRIs are Prozac, Celexa, Zoloft, and Lexapro. There is a class of antidepressants that does not increase serotonin in the brain, however. Some, like tricyclic antidepressants, such as Elavil, actually block neurotransmitter reuptake.

Precautions and Side Effects

Despite its contributions to well-being, too much serotonin can be problematic. Extremely high levels can be toxic and even fatal. Serotonin syndrome is the name for this condition. Such high levels can result from an overdose of serotonin increasing antidepressant. In can also occur when an SSRI is used in combination with an MAOI medication. Serotonin syndrome is not always fatal; it can occur in milder forms. For example, the drug ecstasy can cause symptoms of the syndrome, yet the levels rarely reach toxicity. Other street drugs, including cocaine, methamphetamine, and LSD, can cause it. So can herbal remedies like St. John's wort and ginseng. The symptoms of serotonin syndrome typically appear within minutes to six hours after taking the medications. Serotonin discontinuation syndrome can also occur if an antidepressant is abruptly stopped rather than slowly tapered. Finally, all antidepressants can increase the risk of suicidal behavior. There appears to be a much higher risk of suicide among users of SSRIs as compared to other types of antidepressants.

Seven Principles for Making Marriage Work, The (Book)

The Seven Principles for Making Marriage Work is a book written by clinical psychologist and marriage researcher John Gottman and Nan Silver and published in 1999.

Description

The book *The Seven Principles for Making Marriage Work* (SPMMW) is based on extensive research by John Gottman and others, and captures principles on what makes marriages work. The principles are as follows:

1. Enhance your love map. A love map is a person's knowledge of the inner world of his or her partner. How well a person knows his or her partner's history, worries, stresses, joys, and hopes denotes how detailed a love map is. Couples who make marriage work have a richly detailed love map of each other.
2. Nurture your fondness and admiration. According to Gottman happy couples have an admiration, fondness, and overall positive view of each other. Admiration and fondness are two of the most important dynamics in

successful marriages. If these are absent from a marriage, the marriage cannot be saved.

3. Turn toward each other instead of away. Gottman addresses the importance of real-life romance in marriages that work. Real-life romance is expressed in the everyday little things such as letting your partner know he or she is valued. Calling your partner and encouraging him or her, for example, or choosing to listen to your partner's difficulties can make the difference between a happy marriage and an unhappy one.
4. Let your partner influence you. This is the principle that happy couples work together and form a team based on consideration for each other's feelings and perspective. Allowing your partner to influence you is a sign of respect and shared control.
5. Solve your solvable problems. Some problems, according to Gottman, can't be solved but many can. Knowing the difference is crucial to good marriages. Some problems are solvable and some are perpetual. Solvable problems are less painful or intense than perpetual problems. Solvable problems are situational and are usually based in arguments about housecleaning, sex, or parenting. Perpetual problems are deeper and are often based on significant differences in personality, values, and lifestyle. Perpetual problems include feeling rejected by your partner; one or both partners being critical, harsh, belittling, and stubborn; feeling like nothing ever changes, and the couple finds themselves gridlocked.
6. Overcome gridlock. According to Gottman gridlock comes from unfulfilled dreams that are not being addressed or respected by each other. The goal is to begin discussing the issues underlying the unfulfilled dreams and helping the partner more toward making those dreams come true.
7. Create shared meaning. Gottman teaches that marriage is more than the tasks and goals of raising a family and living together. Couples in marriages that work create a shared inner life, develop a shared family culture, are open to each other's perspective, and share an appreciation for the roles and goals that link them together.

The Four Horsemen of the Apocalypse

One of the major contributions made by Gottman in *The Seven Principles for Making Marriage Work* is his articulation of the "Four Horsemen of the Apocalypse." The four horsemen are a reference to the New Testament Bible passages from the book of Revelations in which four angelic horsemen of conquest, war, hunger, and death usher in the end of days. Gottman uses the four horsemen as a metaphor for communication styles that predict the end of the relationship: Criticism, Contempt, Defensiveness, and Stonewalling. These horsemen come and go and can be expressed through verbal aggression or more subtly through nonverbal ques.

The first of the four horsemen is "Criticism," in which a partner's personality or character is attacked. A criticism is different from a complaint, which addresses a specific situation. Criticisms add blame and often contain generalizations such as "you always. . .," or "you never. . . ." For instance, a complaint might be, "We agreed that we would take turns cleaning the dishes." A criticism would include, "You never keep your word" or "you only think of yourself."

The second horseman is "Contempt," in which a partner is treated with disrespect, sarcasm, and ridicule, leaving him or her feeling despised and worthless. Contempt is fuel by long-held negative thoughts about the partner. Contempt is the single greatest predictor of divorce. A contemptuous response to the dish-washing conflict would be "whatever" as the partner rolls the eyes.

The third horseman is "Defensiveness." Defensiveness is very common in marriages that are heading toward divorce. When accused, the partner responds with excuses, so the attacking partner will back off. This rarely occurs though because defensiveness is essentially blaming the attacking partner. For instance, in the dish-washing conflict a defensive response to "you only think of yourself" would be "well you would only tell how bad a job I did anyway and redo the dishes." Defensiveness commonly escalates problems.

The final horseman is "Stonewalling." Once criticism, contempt, and defensiveness have become a

vicious repeating circle, one of the partners will tune out and withdraw from interacting. This unresponsive closing out of the partner allows him or her to be less exposed to criticism, contempt, and defensiveness.

The Seven Principles for Making Marriages Work by John Gottman is a significant contribution to strengthening marriages. One-day training is offered to clergy, educators, life coaches, community leaders, social workers, nurses, counselors, and others who may want to facilitate a couples group at a community center, church, home, and so on. Training is provided through the Gottman Institute, a for-profit training institute founded by Gottman and his wife, Julie Schwartz Gottman, PhD.

Sex and Gender

The terms "sex" and "gender" are often used interchangeably but are distinguishable in that sex refers to one's biological sex characteristics, while gender refers to how one personally identifies with being either male or female.

Definitions

- **Anisogamy** is what differentiates between the two sexes, male or female, referring specifically to size and form differences between sex cells, or gametes.
- **Gender identity** is the way in which one self-identifies one's gender, or personal sense of being male or female.
- **Gender/sex roles** describe stereotypical characteristics, preferences, aptitudes, and behaviors of being either masculine or feminine.
- **Intersex** is defined as when a person has a combination or mixture of male and female sex factors.
- **Sexual identity** refers to whether one identities oneself as predominantly homosexual, heterosexual, or bisexual.
- **Transgender** describes individuals who are experiencing gender dysphoria, who do not personally identify with the gender they were assigned at birth.

Description

Though the terms "sex" and "gender" are closely related, they are not synonymous as each describes different constructs. Sex defines the anatomical, physiological, or biological makeup that defines males or females at birth. Male or female sex is determined by chromosomal and hormonal differences, type of gonads, and the presence or absence of internal reproductive organs or external genitalia. There are two sex chromosomes in human beings, the X chromosome and the Y chromosome. The Y chromosome is responsible for determining one's sex. Females have two X chromosomes, while males have an X and Y chromosome. The Y chromosome is passed only from father to son. Male gonads are the testes and female gonads are the ovaries. Females have an internal reproductive sex organ, the uterus, while males have external genitalia, the penis. People can also be intersexed, or have a mixture of these sex factors.

Gender describes the traits, characteristics, and attributes associated with masculinity or femininity. Gender may be assumed or presumed by others, though this may not match what a person feels is his or her true identity (gender identity). Individuals who are trans- or cisgender may experience gender dysphoria. Often gender assumptions are based on societal norms for what is expected, deemed appropriate, or "normal" for males or females. Stereotypes such as these are referred to as gender roles. Gender roles can

influence an individual's thoughts, feelings, behaviors, and sense of self.

Current Status and Impact (Psychological Influence)

Historical views believed there to be only two distinct categories of sex and/or gender, male or female. However, additional categories are now recognized, including people who are intersexed and those who identify as transgender or transsexual. Research indicates that both sex and gender impact how an individual thinks, feels, acts, and perceives the world around him or her. Feminists in particular have argued against the traditional male/female dichotomy and have suggested that the emphasis society places on sex/gender results in inequity, bias, and undue pressure.

Sexting

Sexting describes electronic communication sent through text messages, e-mails, or social networking that involves the use of sexually explicit or sexually suggestive language, photos, or videos.

Description

Sexting is defined as the sending or receiving of sexually explicit or suggestive messages, images, or videos via cell phone, e-mail, or social networking sites. This term is most commonly used to describe incidents where teenagers take seminude (for girls, topless) or nude pictures of themselves and proceed to send those to others using their cell phone or by posting the items on Internet sites like Facebook. Sexting also includes transmitting sexually suggestive message content. This type of communication is typically meant for someone the person has a romantic interest in or attraction to. However, a major concern about sexting behavior is that the content often ends up in the hands of those it was not intended for.

Sexting appears to occur along a continuum, ranging from typical teenage behavior to intentional victimization of others. Depending on the circumstances, some acts may be considered "experimental," while other, more serious instances may be categorized as "aggravated." Although adolescents are known to test boundaries and explore their sexual identity as they approach adulthood, red flags are raised when private, intimate communications become public. Of even greater concern is the emotional and psychological damage one can endure after being exposed to a broad audience electronically. Some sexting cases have resulted in tragic outcomes, including suicide.

Impact (Psychological Influence)

There has been growing concern about the rates at which adolescents participate in sexting. Reports indicate that both males and females engage in sexting behavior at nearly equal rates. Several factors contribute to high incidence rates among this population, including increased access to technology, impulsivity, hormone changes, and peer pressure. A Pew Research Center survey found that 77% of teens owned cell phones and two-thirds reported texting as their preferred method of communicating with friends (Lenhart, 2013). Girls send a median of 100 texts per day, while boys the same age send 50. However, evidence also suggests that many adults engage in sexting types of behaviors. Access to technology and the popularity of social networking sites, and online dating sites such as Match.com, may be factors impacting the adult subset.

In 2008, the Sex and Tech Survey, commissioned by The National Panel to Prevent Teen and Unplanned Pregnancy in conjunction with Cosmogirl.com,

indicated that 20% of teenagers (aged 13 to 19) had reported posting nude or seminude photos or videos of themselves online (Sex and Tech, 2008). These numbers increased to 33% as teens became young adults (Sex and Tech, 2008). Sending sexually explicit or suggestive messages via text, e-mail, or post was reported at even higher rates by teens, 39% (Sex and Tech, 2008). Peer pressure has been cited as a major contributing factor, particularly with the adolescent population.

Sexual Abuse

Sexual abuse involves nonconsensual sexual contact of any kind in which individuals are forced to engage in sexual activity against their will.

Definitions

- **Anxiety** is a negative emotional state characterized by feelings of nervousness, worry, and apprehension about imagined danger.
- **Cognitive behavior therapy** is a form of psychotherapy that focuses on changing faulty behaviors, emotions, and thoughts.
- **Depression** is an emotional state characterized by feelings of sadness, low self-esteem, guilt, or the reduced ability to enjoy life.
- **DSM-5** stands for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, which is a diagnostic system used by professionals to identify mental disorders with specific diagnostic criteria.
- **Frotteurism** is a mental disorder characterized by deriving sexual pleasure or gratification from touching or rubbing against non-consenting individuals.
- **Grooming** refers to intentionally forming an emotional connection with someone in order to manipulate him or her psychologically in order to lower his or her resistance to sexual activity.
- **Psychotherapy** is a psychological method for achieving desired changes in thinking, feeling, and behavior.
- **V codes** are codes listed in the DSM-5 that are used to identify conditions other than a disease or injury and are used to report significant factors that may impact the treatment.

Description and Diagnosis

Sexual abuse is one of the conditions presented as a V code in the DSM-5 "Other Conditions That May Be a Focus of Clinical Attention" section. Sexual abuse is listed under the categories of "Child Maltreatment and Neglect Problems and Adult Maltreatment and Neglect Problems." Sexual abuse is the coercion of unwanted sexual behavior by one individual on another. Sexual abuse does not necessarily involve direct physical contact. It can include exposing of one's genitals, sexual harassment, stalking, and exposing pornographic material to the victim. Child sexual abuse typically involves coercion, although it can include violence. Often young children are defenseless when they are sexually abused. Older children may become vulnerable to bribes, threats, and lies. Abusers typically manipulate a child through grooming for the purpose of gaining a child's trust. Sexual abuse can overwhelm a child with disbelief, fear, confusion, shame, and horror. It can leave a child emotionally devastated. Adults who have been sexually abused can lead to a host of symptoms that negatively impact their lives. Some symptoms include fear, anger, guilt, low self-esteem, anxiety, depression, and being afraid of or avoiding sex.

The occurrence of sexual abuse reports that one out of three girls and one out of five boys under the age of 18 in North America has been sexually abused (Centers for Disease Control and Prevention, 2011). Approximately, 4.8 million women and 2.8 million men report being sexually abused each year in the United States (Centers for Disease Control and Prevention, 2011).

According to the DSM-5, a child should be given the V-code of "Child Sexual Abuse" if the abuse includes any sexual act involving a child in order to provide sexual gratification to the abuser. The abuse may include incest, penetration, indecent exposure, and fondling a child's genitals. The abuse also may not involve sexual contact. For example, the abuser may pressure a child to become involved in acts for the gratification of others, without having direct physical contact between the abuser and the child. An adult (spouse) should be given the V-code of "Spouse or Partner Violence, Sexual" when he or she has been forced into sexual acts during the past year. Physical force may be used by the abuser to engage in sexual acts against the victims will. An adult (nonspouse) should be given the V-code of "Adult Abuse by Nonspouse or Nonpartner" when the victim has been abused by a stranger or non-intimate partner. The acts may involve sexual, physical, or emotional abuse (American Psychiatric Association, 2013).

There may be several causes of this disorder. Abusers may differ in their motivations why they sexually abuse other individuals. Some may have a past history of trauma (e.g., being sexually abused themselves). Some abusers may engage in this form of abuse due to their current physical and mental health status. In addition, some may have diseases or disorders (e.g., loss of self-control) and may act inappropriately with adults as well as children.

Treatment

Treatment for victims of sexual abuse typically involves psychotherapy. Cognitive behavior therapy has been shown to be effective in changing the victim's beliefs about the abuse that may be contributing to his or her depression of anxiety, among other symptoms. Some other forms of treatment that may be helpful include mindful meditation, massage therapy, yoga, and relaxation techniques.

Sexual Addiction

A sexual addiction is a mental disorder characterized by compulsive sexual acts and thoughts.

Definitions

- **Antidepressant medications** are prescription drugs that are primarily used to treat depression and depressive disorders.
- **Cognitive behavior therapy** is a form of psychotherapy that focuses on changing maladaptive behaviors, emotions, and thoughts.
- **Depression** is an emotional state characterized by feelings of sadness, low self-esteem, guilt, or the reduced ability to enjoy life.
- **Exhibitionism** is the act of an individual exposing parts of his or her body that are normally not exposed in public.

- **Obsessive-compulsive disorder** is a mental disorder characterized by unwanted and unrepeated thoughts and feelings (obsessions), or behaviors that one feels driven to perform (compulsions).
- **Psychotherapy** is a psychological method for achieving desired changes in thinking, feeling, and behavior.
- **Twelve-Step Program** is a self-help group whose members attempt recovery from various addictions and compulsions based on the Twelve Steps.
- **Voyeurism** is an individual who seeks sexual gratification from secretly observing naked bodies or sexual acts of others.

Description

A sexual addiction is described as a mental disorder characterized by an escalating, continuous, and compulsive pattern of sexual behavior despite negative consequences to self and others. For some individuals with a sexual addiction, their behavior does not develop beyond the use of pornography, uncontrollable masturbation, or computer sex services. For other individuals with a sexual addiction, they often engage in illegal activities, such as voyeurism, exhibition, molestation, rape, or obscene phone calls. The sexual addict often intensifies the addictive behavior to achieve the same results.

Some symptoms of sexual addiction include an individual frequently having more sex with more people than intended, having a preoccupation with or frequently craving sex, and frequently engaging in excessive sexual activity despite the desire to stop. An individual with a sexual addiction can negatively impact many areas of one's life (e.g., work, family, school). Often times, when a sexual addict is unable to engage in his or her desired behavior, he or she becomes very frustrated and irritable.

There is no known cause for an individual with a sexual addiction. However, biological, psychological, and social factors are thought to contribute to sexual addiction. For example, certain areas of the brain elicit chemicals that cause compulsion. Depression, anxiety, and obsessive-compulsive disorders are potential psychological risk factors for sexual addiction. Furthermore, individuals tend to be socially isolated from others, impulsive, and insecure, and have difficulty dealing with their emotions.

Treatment

Psychotherapy is one form of treatment for individuals with a sexual addiction. Cognitive behavior therapy has been shown to be an effective form of treatment by helping an individual learn what triggers his or her sexually destructive behaviors. This type of therapy also helps the individual to evaluate his or her distorted thoughts, which control his or her behavior. Individuals with a severe form of a sexual addiction may require an inpatient or outpatient treatment program. Twelve-Step meetings can also be helpful for an individual with a sexual addiction. In addition, some individuals are prescribed antidepressant medications if they are suffering from depression during their sexual addiction.

Sexual Aversion Disorder

Sexual aversion disorder is a mental disorder characterized by strong dislike, fear, or disgust of genital contact with a sexual partner.

Definitions

- **Anxiety** is apprehension or worry about an imagined danger.
- **DSM-5** stands for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, which is a diagnostic system used by professionals to identify mental disorders with specific diagnostic criteria.
- **Exposure** is a cognitive behavior therapy intervention (method) in which a client is exposed to a feared object or situation. It is also referred to as flooding.
- **Fear** is an emotional response to a known danger.
- **Genito-pelvic pain/penetration** disorder is a mental disorder in women characterized by persistent fear, pain, or difficulty with vaginal intercourse. Previously this disorder was referred to as dyspareunia and vaginismus.
- **Other specified sexual dysfunction** is one of the DSM-5 sexual dysfunctions disorders, which is used to diagnose presentations where symptoms cause significant distress but do not meet the full criteria for one of the listed sexual dysfunction disorders.
- **Sexual and gender identity disorders** were a group of mental disorders in DSM-IV-TR. They were characterized by disturbances in sexual desire or functioning, or discomfort with one's assigned gender.
- **Sexual dysfunctions disorders** are a group of mental disorders in DSM-5 characterized by significant difficulty in responding sexually or experiencing sexual pleasure. They include female orgasmic disorder and other specified sexual dysfunction.
- **Specific phobia** is a mental disorder characterized by a marked and enduring fear of specific situations or objects. Previously this disorder was referred to as simple phobia.
- **Systematic desensitization** is a form of cognitive behavior therapy that gradually exposes individuals to their phobia (fear) while remaining calm and relaxed.

Description and Diagnosis

Sexual aversion disorder was one of the DSM-IV-TR sexual and gender identity disorders. It was characterized by a strong aversion to genital contact. This aversion is usually experienced as disgust, fear, or anxiety that is focused on genitalia, bodily fluids related to sexual activity. The aversion can also be toward kissing or intimate touching. The symptoms of specific fear and anxiety are similar to that of a specific phobia. However, there are differences. The main difference is that feelings of disgust in sexual aversion disorder are not common in specific phobia. However, this disorder is not included as a separate disorder in DSM-5. Instead, it can be diagnosed as another specified sexual dysfunction. The prevalence of this disorder is unknown because it is not well researched and individuals with such disorders do not report their symptoms.

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Addition, Text Revision*, an individual can be diagnosed with this disorder if he or she experiences distressing dislike and avoidance of genital contact with a sexual partner. For some, this disorder may have been present since they became sexually mature, while others may develop this disorder late (American Psychiatric Association, 2013). The cause of this disorder varies between individuals. It has been suggested that genito-pelvic pain disorder, adverse sexual experience and abuse, and the pairing of adverse stimuli with sexual activity may play a role in the manifestation of this disorder.

The cause of this disorder is not well understood. Several factors may contribute to it. These include partner factors, relationship factors, and individual factors such as history of sexual or emotional abuse, cultural and religious factors, and medical factors.

Treatment

Treatment for this disorder is very similar to that of specific phobia. Cognitive behavior therapy (CBT) is used

to reduce fear, anxiety, and pain. Specific CBT interventions (methods) include systematic desensitization and exposure techniques. If sexual abuse is a contributing factor, therapy may need to specifically address it.

Sexual Dysfunctions

Sexual dysfunctions are a group of mental disorders characterized by a significant disturbance in an individual's ability to respond sexually or to experience sexual pleasure.

Definitions

- **Antidepressant medications** are prescription drugs that are primarily used to treat depression and depressive disorder.
- **Depression** is an emotional state characterized by feelings of sadness, low self-esteem, guilt, or the reduced ability to enjoy life.
- **DSM-5** stands for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, which is a diagnostic system used by professionals to identify mental disorders with specific diagnostic criteria.
- **Opioids** are a class of narcotic drugs used to treat moderate to severe pain.

Description and Diagnosis

Sexual dysfunctions are a group of DSM-5 mental disorders characterized by a significant disturbance in an individual's ability to respond to sexually or to experience sexual pleasure. An individual may have more than one sexual dysfunction at the same time. If this is the case, each dysfunction should be diagnosed separately. A number of circumstances must be taken into consideration when making the diagnosis of a sexual dysfunction. Some of these circumstances include partner factors (e.g., partner's sexual difficulties), relationship factors (e.g., lack of communication), individual vulnerability factors (history of abuse), the presence of two disorders (e.g., depression and erectile dysfunction), and stress (e.g., financial problems). Other circumstances to be considered include religious or cultural factors (e.g., attitudes toward sexuality). Medical factors relevant to the prognosis (prediction of outcome), course of action, or treatment options for sexual dysfunction must also be considered. Aging may also be related to a decrease in sexual response in individuals. In many situations, the cause of a sexual problem is unknown.

There are several separate disorders that fall under the DSM-5 classification of sexual dysfunctions. They include erectile disorder, delayed ejaculation, female sexual interest/arousal disorder, female orgasmic disorder, male hypoactive sexual desire disorder, genito-pelvic pain/penetration disorder, premature (early) ejaculation, substance-/medication-induced sexual dysfunction, other specified sexual dysfunction, and unspecified sexual dysfunction (American Psychiatric Association, 2013). Most of these disorders are more fully described in their own entries in this encyclopedia.

Erectile disorder. Erectile disorder is a sexual function disorder in males who repeatedly fail to obtain or maintain an erection during sexual activity with a partner. Symptoms may occur in specific situations

(e.g., a certain partner or type of stimulation) or may occur in all types of situations. Several men who experience this disorder have low self-confidence, low self-esteem, and a decreased level in their masculinity. Individuals with this disorder may avoid or have a fear of future sexual encounters. Many individuals with erectile disorder experience significant distress as a result of the symptoms. The symptoms of this disorder must occur for at least six months.

Delayed ejaculation. Delayed ejaculation is a sexual function disorder in which males have a significant delay in ejaculation or the inability to achieve ejaculation. These symptoms must occur on nearly all or all occasions of sexual activity with a partner. This disorder occurs despite the presence of adequate stimulation and having the desire to ejaculate. Individuals engaged in sexual activity may report an extended period of thrusting to reach orgasm to the point of extreme tiredness or genital soreness. If this occurs individuals generally end efforts to reach orgasm. The symptoms of this disorder must cause significant distress in the individual and occur for at least six months.

Female sexual interest/arousal disorder. Female sexual interest/arousal disorder is a sexual function disorder characterized by a lack of or significantly reduced sexual interest and arousal. It is often associated with difficulties in having an orgasm, pain during sexual activity, very little sexual activity, and differences in sexual desire between partners. Some symptoms of this disorder include feelings of disconnection, isolation, or boredom during sex. These symptoms can interfere with sexual interest and arousal if a woman does not feel close to her partner and does not find sexual activity pleasurable. A woman who has self-image problems (with her body) is another symptom of this disorder. Women with histories of emotional or sexual abuse, rape, incest, or other traumatic experiences may also contribute to a lack of interest or arousal in sexual activity. The symptoms associated with this disorder must occur for at least six months.

Female orgasmic disorder. Female orgasmic disorder is a sexual function disorder characterized by a woman having difficulty experiencing an orgasm. An individual diagnosed with this disorder may have a significant delay in achieving an orgasm or the absence of having an orgasm. She may also have a reduced intensity in the feeling of an orgasm. Although women with this disorder may not experience an orgasm during sexual activity, many women report high levels of sexual satisfaction whether they rarely or never have an orgasm (American Psychiatric Association, 2013). The symptoms of this disorder must cause significant distress in the individual and occur for at least six months.

Male hypoactive sexual desire disorder. Male hypoactive sexual desire disorder is a sexual function disorder characterized by a low or absent desire for sex and inadequate or absent sexual fantasies or thoughts. Men who experience erectile or ejaculation problems may be associated with this disorder. For example, if a man continually has difficulty obtaining and maintaining an erection, he may lose interest in sexual activity. Many men do not initiate sexual activity and often prefer the partner to do so. Several factors that affect sexual functioning are taken into account when making this diagnosis. They include age and general and cultural situations in the individuals' life. The symptoms of this disorder must cause significant distress in the individual and occur for at least six months.

Genito-pelvic pain/penetration disorder. Genito-pelvic pain/penetration disorder is a sexual function disorder characterized by recurrent difficulties with at least one of the following conditions. They include genito-pelvic pain, difficulty having intercourse, pressure in the pelvic muscles, and fear of vaginal penetration or pain. This disorder is frequently associated with other sexual function disorders (e.g., female sexual interest/arousal disorder). Individuals who do have sexual desire and interest will engage in sexual activity as long as penetration is not required. Women with this disorder often experience difficulties in their relationships (e.g., marriage). In addition, women tend to feel a decrease in their level of femininity. The symptoms of this disorder must cause significant distress in the individual and occur for at least six months.

Premature (early) ejaculation. Premature (early) ejaculation is a sexual function disorder characterized by ejaculation that occurs prior to or shortly after vaginal penetration. A heterosexual male with this disorder will usually ejaculate within 60 seconds of penetration. In severe forms of this disorder ejaculation may occur within 15 seconds of penetration. Many men with this

disorder claim that they have a lack of control over ejaculation. They also worry about their anticipated inability to delay ejaculation on future occasions involving sexual activity. The symptoms of this disorder must cause significant distress in the individual and occur for at least six months.

Substance-/medication-induced sexual dysfunction. Substance-/medication-induced sexual dysfunction is a sexual function disorder characterized by the use of a specific substance or medication that is causing sexual dysfunction. For example, an individual may be using substances such as opioids or antidepressant medications that may interfere with his or her sexual function. In particular, it is commonly reported that individuals who use antidepressant medication have difficulty achieving an orgasm or ejaculating (American Psychiatric Association, 2013). Illegal substance use (e.g., marijuana and cocaine) has also been found to decrease sexual desire, and cause problems obtaining an erection and difficulty achieving an orgasm. Sexual dysfunction can also occur when an individual is withdrawing (not using) such substances and medications. The symptoms of this disorder must occur for at least one month after the withdrawal period and cause clinically significant distress in the individual.

Other specified sexual dysfunction. Other specified sexual dysfunction is a category under sexual dysfunctions where an individual exhibits some symptoms of a sexual dysfunction that causes him or her clinically significant distress. However, the individual does not meet the full criteria for any of the other sexual function disorders necessary to make a diagnosis. A clinician will use this category in situations to share information of the specific reason the individual does not meet the criteria for another specific sexual dysfunction.

Unspecified sexual dysfunction. Unspecified sexual dysfunction is a category under sexual dysfunctions where an individual exhibits some symptoms of a sexual dysfunction that causes him or her clinically significant distress. However, the individual does not meet the full criteria for any of the other sexual function disorders necessary to make a diagnosis. In this category, a clinician chooses not to give a reason that the criteria are not met for a specific sexual dysfunction.

Treatment

Treatment for sexual dysfunctions will depend on the cause of a specific disorder. Some forms of treatment may include psychotherapy and medications. Cognitive behavior therapy in particular can be very helpful with many of the specific sexual disorders. There are several medications available for men who suffer from erectile dysfunction. For individuals who are taking antidepressant medications that are interfering with their sex life, they may want to seek medical consultation. There are several antidepressant medications on the market today, and some do not affect sexual activity or performance.

Sexual Identity

A person's sexual identity describes how he or she thinks of himself or herself in terms of sexual behavior, attraction, or sexual orientation.

Definitions

- **Asexual** refers to the absence of a traditional sexual orientation, which may be considered a fourth category of sexual orientation.

- **Bisexual** describes the sexual orientation of an individual who is romantically, physically, or sexually interested in both females and males.
- **Heterosexual** describes the sexual orientation of an individual who experiences romantic, physical, emotional, or sexual attraction to a person of the opposite sex.
- **Homosexual** describes the sexual orientation of an individual who experiences romantic, physical, emotional, or sexual attraction to a person of the same sex.
- **Sexual orientation** describes an individual's ongoing pattern of sexual attraction toward persons of the same gender, opposite gender, or both genders.
- **Transgender** describes individuals who are experiencing gender dysphoria, who do not personally identify with the gender they were assigned at birth.

Description

Sexual identity can encompass both a person's sexual orientation and his or her sexual behavior. The term refers to a person's conception of himself or herself related to his or her sexual behavior, attraction, or orientation. Sexual orientation is defined as an enduring pattern of sexual attraction toward persons of the same sex, opposite sex, or both sexes. There are three commonly recognized classifications for sexual orientation: heterosexual, homosexual, or bisexual. Lesbian, gay, bisexual, and transgender are readily used to describe sexual orientation. A fourth category, asexual, has also been proposed, referring to individuals who do not identify with any of the three traditional orientations. "Sexual behavior" refers to actual sexual acts performed by the individual. These behaviors may or may not be aligned with one's sexual identity or orientation. Incongruence between these constructs can result in anxiety or stress for an individual and his or her loved ones.

Current Status and Impact (Psychological Influence)

Sexual identity can grow, change, and develop over the course of one's lifetime. Furthermore, most scientists agree that nature (biological and genetic factors) and nurture (environmental and social factors) both contribute to sexual identity. Though labels and categories exist, there is not one right way to define sexual identity. Professionals suggest that overall mental health and a positive self-concept are attained by finding alignment between one's sexual identity, defined sexual orientation, and performed sexual actions.

Sexual Masochism Disorder

Sexual masochism disorder is a mental disorder characterized by fantasizing about or engaging in being beaten, bound, or made to suffer, resulting in sexual satisfaction.

Definitions

- **Asphyxiophilia** is a form of sexual masochism that involves deprivation of oxygen to the brain and is controlled by suffocation or strangulation in order to enhance the pleasure of masturbation.
- **Cognitive behavior therapy** is a form of psychotherapy that focuses on changing maladaptive (faulty) behaviors, emotions, and thoughts. It is also known as CBT.
- **DSM-5** stands for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, which is a diagnostic system used by

professionals to identify mental disorders with specific diagnostic criteria.

- **Hypoxyphilia** is a form of sexual masochism that involves deprivation of oxygen to the brain and is controlled by suffocation or strangulation in order to enhance the pleasure of masturbation. It is also referred to as asphyxiophilia.
- **Masochist** is an individual who obtains pleasure from having pain inflicted on him or her by others.
- **Pain and suffering** is a physical and emotional condition that leads to mental, emotional, and bodily stress.
- **Paraphilia** is a mental condition in which individuals can only become aroused by inappropriate object, actions, or fantasies.
- **Paraphilic disorders** are a group of DSM-5 mental disorders characterized by unusual sexual preferences and behaviors that are distressing or detrimental to one's self or others. They include exhibitionistic disorder, pedophilic disorder, and fetishistic disorder.
- **Sadist** is an individual who obtains pleasure from inflicting pain on others.
- **Specifiers** are extensions to a diagnosis that further clarifies the course, severity, or type of features of a disorder or illness.

Description and Diagnosis

Sexual masochism disorder is one of the DSM-5 paraphilic disorders. It is characterized by the feeling of sexual arousal or excitement resulting from receiving pain, suffering, or humiliation. It may be self-inflicted or by the hands of another individual. The pain is real and can be physical or psychological in nature. In addition, those with this disorder experience significant distress or significant impairment due to their behaviors and fantasies (e.g., urges). Some masochistic acts include being restrained by ropes, handcuffs, chains, or cages. Other acts include spanking, burning, whipping, cutting, rape, and mutilation. Masochistic behavior can also occur in the context of fantasy role-playing. For example, a sadist can play the role of a prison guard and a masochist can play the role of a prisoner.

The occurrence of this disorder typically begins in childhood, and the onset of sexual masochism usually occurs during early adulthood (American Psychiatric Association, 2013). One particular form of sexual masochism is extremely dangerous and can result in death. This feature is known as hypoxyphilia and involves deprivation of oxygen to an individual during the act of being sexually aroused. This form of sexual masochism can be self-inflicted or by the hands of another individual. Sexual masochism is slightly more common in males (American Psychiatric Association, 2013). It has been estimated that in Australia 2.2% of males and 1.3% of females had been involved in this disorder within the last 12 months (American Psychiatric Association, 2013).

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, individuals can be diagnosed with this disorder if they engage in intense and recurrent sexual arousal for at least six months from the act of being beaten, bound, humiliated, and made to suffer, as indicated by urges, fantasies, or behaviors. The urges, fantasies, or behaviors must cause significant distress or impairment in social, occupational, or other important areas of the individual's functioning. If the individual engages in achieving sexual arousal by restricting his or her breathing, the diagnosis must include the specifier "with asphyxiophilia." If an individual is living in a controlled environment (e.g., institution) to restrict his or her masochistic behavior, the specifier "in a controlled environment" must be included in the diagnosis. If an individual has not had any distress or impairment for at least five years in social, occupational, or other areas of important functioning, the specifier "in full remission" must be included in the diagnosis. If an individual states he or she does not have any distress or hindrance due to paraphilic impulses, he or she should not be diagnosed with sexual masochism disorder (American Psychiatric Association, 2013).

The exact causes of this disorder are unknown. However, there are some theories that try to explain the presence of paraphilias in general. One theory is that

an individual becomes a paraphilia because of inappropriate sexual fantasies that are suppressed. Due to the suppression of acting out on these urges, when an individual eventually acts out on the fantasies, an individual exhibits considerable distress and/or arousal. There is also a belief that masochists want to engage in a dominating role. This belief can cause conflict and make them submissive to others. Another theory is that masochists use their behavior as a means to escape by acting out their fantasies and become new and different individuals.

Treatment

Treatment for this disorder typically varies depending on the individual and situation. Some medications may be useful in reducing fantasies and sexual impulses, particularly in individuals who prefer dangerous physical masochism. Psychotherapy is another option that has been found to be effective for this disorder. In particular, cognitive behavior therapy can help an individual to become aware of his or her patterns and help to reconstruct his or her feelings, thoughts, and behaviors, therefore preventing symptoms and initiating new and healthier options. Treatment may be complicated for individuals who have health problems as a result of their sexual behavior. For example, masochists may have sexually transmitted diseases and other medical problems. Individuals who engage in hypoxyphilia and other dangerous behaviors can suffer extreme pain that may result in death.

Sexual Orientation

An individual's sexual orientation describes an ongoing pattern of sexual attraction toward persons of the same gender, opposite gender, or both genders.

Definitions

- **Asexual** may be considered a fourth category of sexual orientation referring to the absence of a traditional sexual orientation.
- **Bisexual** describes the sexual orientation of an individual who is romantically, physically, emotionally, or sexually attracted to both men and women.
- **Heterosexual** describes the sexual orientation of an individual who is romantically, physically, emotionally, or sexually attracted to members of the opposite sex.
- **Homosexual** describes the sexual orientation of an individual who is romantically, physically, emotionally, or sexually attracted to members of the same sex.
- **Sexual identity** refers to a person's conception of himself or herself as predominantly homosexual, heterosexual, bisexual, or asexual.
- **Transgender** describes individuals who do not self-identify with their assigned birth sex.

Description

Sexual orientation describes one's enduring pattern of sexual attraction toward members of the same gender, opposite gender, or both genders. A possible fourth category, asexual, has been proposed by researchers, describing those who do not identify with one of the three traditional sexual orientation categories. In the United States, common terminology used to describe sexual orientation includes "lesbian," "gay," "bisexual," and "transgender." Rather than viewing sexual orientation

as a characteristic, it is suggested that it be defined in terms of behavior, as it depends on relationships with other people. It has also been proposed that one's sexual orientation can change over time. The Kinsey Scale, also known as the Heterosexual-Homosexual Rating Scale, developed by Kinsey, Pomeroy, and Martin in the late 1940s early 1950s, has provided much evidence supporting the fluidity of sexual behavior. Subsequent assessment tools have followed supporting this same concept. Sexual orientation is thus seen on a continuum ranging from exclusive attraction to members of the opposite sex to exclusive attraction to members of the same sex.

One's sexual orientation differs from one's biological sex, gender identity, or prescribed gender roles. Biological sex is defined as an individual's biological, genetic makeup of being either male or female. "Gender identity" refers to one's personal sense of being either male or female. Gender roles are assumed characteristics, behaviors, or preferences that are typically associated with masculinity or femininity. Early views on sexual orientation believed it to be connected to and prescribed by one's assigned sex; males were sexually attracted to females and vice versa. However, this became highly debated around the latter part of the 20th century as the concept of *gender identity* began to take root. Writers, theorists, and researchers have since offered evidence that one's sexual orientation was a separate component to one's gender identity.

Current Status and Impact (Psychological Influence)

There is ongoing debate regarding whether or not sexual orientation is genetically predetermined or develops over time from parenting, socialization, and other life experiences. Most scientists and practitioners agree both nature and nurture play a role in sexual orientation. Sexual orientation has been a topic of critical debate for decades. Those who identify themselves as something other than heterosexual have been misunderstood, shamed, ridiculed, underrepresented, overlooked, and ostracized in mainstream society. Some have been physically attacked and killed. Many religions still regard any sexual relationship outside of heterosexuality as morally wrong. Prior to 1973, homosexuality was even referred to as a mental disorder in the *Diagnostic and Statistical Manual of Mental Disorders* (DSM) by the American Psychiatric Association (APA). The prevailing view was that homosexuality was a chosen behavior or type of deviant lifestyle. Popular opinion further suggested that this sexual orientation was something that could be influenced with therapeutic and/or medical intervention. Since that time, APA has worked hard to change this social stigma and to foster more acceptance among people in terms of sexual orientation. In 2012, the Pan American Health Organization released a statement cautioning people against seeking out services or procedures that suggested they could change one's sexual orientation as they pose serious health and psychological risks.

Sexual Predator

A sexual predator is an individual who seeks sexual contact with another in a threatening manner. Sexual predators are also known as sexual offenders.

Definitions

- **Child abuse** is the physical, sexual, or emotional abuse of a child or minor, usually under the age of 18.

- **Psychotherapy** is a psychological method for achieving desired changes in thinking, feeling, and behavior. It is also called therapy and therapeutic counseling.
- **Sexual offender** is a label used for an individual who has been convicted of crimes involving rape, sex, molestation, pornography, and sexual harassment.

Description

A sexual predator is an individual who pursues or preys on other individuals for sex in a manner that is considered harmful or threatening. Individuals who commit sex crimes (e.g., child sexual abuse and rape) are considered sexual predators or sexual offenders. They prey on strangers, neighbors, friends, and even family members. Typically, sexual predators have an immature understanding of intimacy. For example, they may want to be close to others but lack the capability to feel trust and satisfaction. Often, they feel frustration that erupts into anger. When this occurs, a sexual predator can become dangerous.

Some common characteristics of a sexual predator include having deviant sexual behavior, a troubled childhood, a history of abuse, and a lack of empathy for other individuals. Often, sexual predators refuse to take responsibility for their actions and tend to blame others for their problems. Many sexual predators have a need for entitlement, power, and control. Many sexual predators are married and most are attracted to adults. They often offend when they think they will not get caught (e.g., misdirecting an individual's attention).

There is no known cause for what makes an individual become a sexual predator. One potential theory is that the individual was victimized sometime during his or her youth. The individual may have learned that it is better to have power than to be subjected by the power of others. Another potential theory is that a sexual predator acts out because he or she has low self-esteem. In order to make themselves feel better, sexual predators may use violent actions for control and power in order to boost their self-image and to dominate others.

Treatment

Psychotherapy is one form of treatment for individuals who are sexual predators. This can help assist a sexual predator to focus on learning new strategies for stopping his or her behaviors and actions, in addition to taking responsibility for harm done to others. There are also specialized treatment programs for sexual offenders. These programs help individuals become aware of and reduce their manipulative behavioral patterns, understand the impact of their harmful behaviors toward others, and develop healthy sexual behaviors and attitudes.

Sexual Sadism Disorder

Sexual sadism disorder is a mental disorder characterized by feelings of sexual excitement resulting from inflicting pain, humiliation, and suffering on another individual.

Definitions

- **Antidepressants** are prescription medications that are primarily used to treat depression and depressive disorders.
- **Antisocial personality disorder** is a mental disorder characterized by a pattern of disregarding and violating the rights of others.
- **Behavior therapy** is a form of psychotherapy that focuses on identifying and changing maladaptive (faulty) behaviors.

- **Cognitive restructuring** is a psychotherapy technique for identifying maladaptive (unhealthy) thoughts and changing them to present a more accurate view of a situation.
- **DSM-5** stands for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, which is a diagnostic system used by professionals to identify mental disorders with specific diagnostic criteria.
- **Paraphilia** is a sexual disorder in which individuals can only become aroused by inappropriate object, actions, or fantasies.
- **Paraphilic disorders** are a group of DSM-5 mental disorders characterized by unusual sexual preferences and behaviors that are distressing or detrimental to one's self or others. They include exhibitionistic disorder, pedophilic disorder, and sexual sadism disorder.
- **Psychopath** is an individual who engages in antisocial behavior, has a lack of empathy and remorse, and has unrestrained and disrespectful behavior.
- **Sexual sadism** is an act of inflicting pain on others for the feeling of sexual excitement or pleasure.
- **Sexual masochism** is an act of engaging in or frequently fantasizing about being beaten, bound, or otherwise made to suffer, resulting in sexual satisfaction.
- **Social skills training** is a treatment method that assists individuals to learn specific skills that are missing or those that will compensate for missing ones.
- **Specifiers** are extensions to a diagnosis that further clarifies the course, severity, or type of features of a disorder or illness.

Description and Diagnosis

Sexual sadism disorder is one of the DSM-5 paraphilic disorders. It is characterized by intense fantasies and/or performing acts of complete sexual, emotional, physical, or psychological domination over another individual. Individuals diagnosed with this disorder receive a feeling of sexual excitement from witnessing and causing suffering to another individual. An individual who engages in sexual sadism is referred to as a sadist. Those who experience sexual pleasure or excitement as a result of humiliation and of inflicting pain on another individual may experience significant distress and significant impairment in functioning resulting from sadistic behaviors and fantasies. Those who suffer at the hands of the sadist may or may not be a willing partner. Whether or not the partner is consenting, the suffering that occurs is real. When the sexual activity is consensual between both individuals, the consenting partner may be given the diagnosis of sexual masochism. The sadistic acts are often associated with dominating others. Some extreme acts performed by sadists may not be harmful, but they are humiliating to the other individual (e.g., being laughed at or urinated on). Other acts are criminal and can potentially result in death. In very serious cases, sexual sadism can lead to significant injuries or death. This is likely to occur when the sadism is diagnosed as very severe. Often in such cases there is an association with an individual who is a psychopath (e.g., antisocial personality disorder). Some examples of extreme sadism include cutting, rape, murder, mutilation, burning, whipping, and beating.

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, individuals can be diagnosed with this disorder if they engage in intense and recurrent sexual arousal from the psychological and physical suffering of another individual for at least six months, as indicated by urges, fantasies, or behaviors. In the absence of reported distress an individual can be given the diagnosis of sexual sadism as long as there is evidence that the individual has acted on sexual urges. An individual who has acted on sexual urges with a non-consenting individual or has significant distress and impairment in occupational, social, or other areas of important functioning can be given this diagnosis. For an individual who is living in an institutional-type setting where opportunities to engage in sadistic sexual behavior are restricted, the diagnosis must include the specifier "in a controlled environment." If an individual has not acted on the

urges with a non-consenting individual while living in an uncontrolled environment, and there has not been any significant distress or impairment in social, occupational, or other important areas of functioning for at least five years, then the diagnosis must include the specifier "in full remission" (American Psychiatric Association, 2013).

The exact causes of this disorder are unknown. Some researchers believe that paraphilias are related to schizophrenia, a brain injury, or other mental disorders. Some theories try to interpret the presence of paraphilias in general. One theory is that an individual becomes a paraphilia because of inappropriate sexual fantasies that are suppressed. Due to the suppression of acting out on these urges, when an individual eventually acts out on the fantasies, an individual exhibits considerable distress and/or arousal. Most individuals who are eventually diagnosed with sexual sadism usually begin with milder forms of sexual fantasies such as collecting pornographic material that portray sadistic acts or may draw ropes, chains, and handcuffs on models in magazines. These acts typically progress into hiring a prostitute or asking a partner to participate in their fantasy. The severity of sadistic acts tends to increase over time (American Psychological Association, 2013).

Treatment

Treatment for this disorder typically varies depending on the individual and situation. Some medications may be useful in reducing fantasies and sexual impulses, particularly in individuals who prefer dangerous physical sadism. Some of these medications include female hormones and antidepressants. Therapy is another option that has been found to be effective for this disorder. In particular, behavior therapy can help manage arousal patterns and reduce compulsive masturbation. Social skills training and cognitive restructuring can also be effective forms of treatment.

Shared Psychotic Disorder

Shared psychotic disorder is a mental disorder characterized by a shared belief in a common delusion that develops between individuals in a close relationship. It is also known as Folie à Deux and induced delusional disorder.

Definitions

- **Antipsychotic medications** are prescribed drugs that are intended to reduce psychotic symptoms. They are also known as neuroleptics.
- **Delusional disorder** is a mental disorder characterized by delusions. Previously this disorder was referred to as paranoia or paranoid disorder.
- **Delusions** are fixed false beliefs that persist despite contrary evidence.
- **DSM-5** stands for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, which is a diagnostic system used by professionals to identify mental disorders with specific diagnostic criteria.
- **Hallucinations** are false or distorted sensory perceptions that appear to be real perceptions that are generated by the mind rather than by an external stimuli.
- **ICD-10** stands for the International Statistical Classification and Related Health Problems,

10th edition. This is a publication of the World Health Organization that represents a comprehensive list of all known medical and psychological conditions affecting human beings worldwide.

- **Psychotic symptoms** are a group of severe symptoms that include hallucinations, delusions, disordered thinking, or disorganized movement.
- **Schizoaffective disorder** is a mental disorder characterized by severe disturbances in mood accompanied by psychotic symptoms such as hallucinations or delusions.
- **Schizophrenia** is a chronic mental disorder that affects behavior, thinking, and emotion, which make distinguishing between real and unreal experiences difficult. Symptoms include hallucinations, delusions, and withdrawal from others.
- **Schizophrenia spectrum and other psychotic disorders** are a group of mental disorders characterized by psychotic features. These disorders include schizophrenia, delusional disorder, and brief psychotic disorder.

Description and Diagnosis

Shared psychotic disorder is a rare mental disorder in which two or more individuals share a common delusion. Because one individual induces the other into the delusion, it is called induced delusional disorder in ICD-10. This disorder was formerly recognized as a separate diagnosis in DSM-IV-TR. While it is not recognized as a separate diagnosis in DSM-5, it can be diagnosed as a form of delusional disorder. The occurrence of shared psychotic disorder is unknown. However, occurrence of delusional disorder is believed to be approximately 0.2% of the U.S. population (American Psychiatric Association, 2013).

Although shared psychotic disorder is not a formal diagnosis in DSM-5, it can be diagnosed as a delusional disorder involving two or more individuals with the same delusion. According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, an individual may be diagnosed with delusional disorder if he or she experiences delusion(s) that last one month or more. The individual cannot be diagnosed with schizophrenia or schizoaffective disorder. If hallucinations are present, this diagnosis cannot be given. Also, the symptoms must not be attributable to other mental disorders or to substance use.

The cause of this disorder is not well understood but is believed to include genetic and relational factors. The genetic component is likely to be a vulnerability (predisposition) to a psychotic or a mood disorder (America Psychiatric Association, 2013). The relational component involves two or more delusional individuals who influence each other over time until they cocreate a common delusion. How the delusion is transmitted from one to another is unknown.

Treatment

Treatment for this disorder tends to be difficult and long term. Treatment usually includes both medications and psychotherapy. Antipsychotics are prescribed to reduce psychotic symptoms. In terms of psychotherapy, cognitive behavior therapy can be effective in the treatment of this disorder. Also, family therapy is often used to assist family members in adjusting to living with those experiencing delusions.

Shyness

Shyness is a type of social withdrawal that results from fear and anxiety. It is described as wariness when confronted with novel social situations and/or self-conscious behavior in a social setting.

Description

Shyness is a multifaceted concept that describes an individual's hesitancy to act in social situations. Anxiety and social fear are key components of the condition. Psychologists distinguish between shy people as those with social phobias and those without. Those with social phobia suffer more symptomatology, functional impairment, and a lower quality of life. Many view shyness as a subclinical condition or normal personality trait that is not pathological. For shy people, no task may be more difficult than developing new relationships. Not only do shy individuals take longer to form friendships, they also form fewer of them; and they take longer to form romantic relationships and typically get married later in life.

There is a clear distinction between those who withdraw from social interaction due to anxiety and fear and those who withdraw for other reasons. The concept of shyness encompasses the former, while psychologists refer to the latter as asocial.

Psychologists also distinguish between shyness and social phobia. The former is a less well-defined lay term, while the latter is a well-defined clinical disorder. That said, the defining features of both are strikingly similar and include somatic symptoms like trembling, sweating, and blushing; cognitive symptoms like fear of negative evaluation; and behavioral symptoms like the avoidance of social situations. Shyness and clinical symptoms of anxiety are related, but they are not synonymous.

There are several hypotheses about the relationship between shyness and social phobia. One places both conditions on a continuum, where social phobia is conceptualized as extreme shyness. Another proposes that shyness and social phobia are partly overlapping conditions, with shyness being a broader construct than social phobia.

Some empirical investigations have begun to define the boundary between shyness and social phobia. One study found that the rate of social phobia was significantly higher among a highly shy sample, providing support for the continuum thesis. However, only half of the highly shy people in the study had generalized social phobia, which was lower than expected.

A shyness mind-set construct is based on the belief that shyness is fixed rather than malleable. The construction of this concept is an application of the implicit mind-set theory, which has been studied extensively in the domain of intelligence and academic achievement. Psychologist J. S. Beer was the first to propose the construct. She reports that the combination of high levels of shyness and low levels of shyness mind-set predicted a greater preference for learning social skills. Also, the combination of high levels of shyness and the shyness mind-set predicted especially high levels of social avoidance and negative perceptions by others.

Some studies have found that there are no significant gender differences in shyness through childhood and adolescence, while others show that gender differences gradually become apparent across childhood, with girls appearing more fearful and anxious than boys in preschool and becoming clearly more anxious during adolescence. Children rated as shy are four times more likely to have anxiety problems in adolescence. Shy adults experience the worst levels of adjustment, thus indicating that being shy may impede important developmental tasks of emerging adulthood, such as settling on one's religious beliefs, developing an identity, and developing quality relationships with others.

There are several different factors associated with the development of shyness. Children whose parents have an anxiety disorder are at an increased risk for developing internalizing behaviors themselves. Mothers who have difficulty with stress and anxiety are more likely to have shy or anxious children. Shyness is more likely caused by the uncertain environment created by an anxious parent.

Single-Parent Families

Single-parent families consist of one parent who is not living with a partner and who is the residential parent of one or more children.

Description

The structure of the American family has changed considerably over the past four decades. As many as 35% of all children born in the United States live in single-parent families (SPF). Single mothers head approximately 80% of all SPF. Researchers have recently defined a new subgroup of SPF as "fragile families" defined as unwed parents and their children. Researchers have investigated the impact of growing up in an SPF, including fragile families, and have found that SPF children have lower levels of health and lower cognitive, behavioral, social, and emotional well-being when compared to children growing up in traditional two-parent families.

Impact (Psychological Influence)

Researchers have identified several factors that impact children of SPF. These include parental resources, parental mental health, parental relationship quality, parenting quality, and father involvement. Single-mother households have significantly less money available to spend on their children, and single mothers tend to make less money and live in poorer school districts and neighborhoods. Even with enforced child support single mothers and their children are at an economic disadvantage compared to traditional families. Conflict between parents is higher in SPF than married families, and the negative consequences of divorce on children have been well documented. Single mothers shoulder all of the work, household and childcare duties, leaving them with less time to invest in their children. It is understandable that depression and other psychological problems are higher among single mothers than married mothers.

Given that single parents have less time, face more mental health challenges, and are economically disadvantaged, it is no wonder that the quality of their parenting suffers. Studies indicate that single parents are less emotionally available and supportive of their children, provide less supervision, have fewer rules but harsher inconsistent discipline, and have more frequent conflicts with their children. These parenting difficulties have been linked to children's poor academic achievement, emotional problems, low self-esteem, and difficulties in forming and maintaining social relationships. Higher positive father involvement is very beneficial to children of SPF and has been linked to fewer emotional and behavioral problems and higher academic achievement. Positive co-parenting that is cooperative, supportive, and consistent is especially beneficial to children of SPF.

In response to the significant challenges associated with SPF there are numerous support groups, school programs, web communities, and self-help books readily available to assist single parents. Both policy

makers and mental health professionals continue to explore ways to assist single parents and their children.

Single-Photon Emission Computed Tomography (SPECT)

Single-photon emission computed tomography (SPECT) is a diagnostic imaging device that uses gamma rays to produce images of the body. It is also referred to as SPECT scan.

Definitions

- **Computed tomography** is a diagnostic imaging device that uses x-rays to produces cross-sectional images (tomographs) of the body
- **Gamma** is an extremely short-wavelength electromagnetic radiation released during the process of radioactive decay.
- **Gamma camera** is a device inside the SPECT scanner that generates images of gamma rays emitted by the radionuclides used in radioactive tracers.
- **Magnetic resonance imaging** is a diagnostic imaging device that uses electromagnetic radiation and a strong magnetic field to produce images of soft tissues.
- **Nuclear medicine** is the branch of medicine that uses radioisotopes to evaluate the rate of radioactive decay in diagnosing and treating various diseases.
- **Positron emission tomography** is a diagnostic imaging technique that uses radioactive substances to produce three-dimensional colored images within the body.
- **Prodromal** is the early stage or the start of a disease, before specific symptoms occur.
- **Radioactive tracer** is a substance containing a radioisotope that is injected and monitored as it progresses through the body.
- **Radionuclides** are atoms that emits gamma rays during the process of its radioactive decay. Also known as radioisotopes, they are used to make the tracers used in SPECT.

Description

Single-photon emission computed tomography is a diagnostic imaging method in nuclear medicine. SPECT uses radioactive materials injected through a vein that pass into the brain, or other organ, and generate high-resolution images. SPECT relies on two technologies: computed tomography (CT) and the use of a radioactive material (radionuclide) to label a compound known as a radioactive tracer. The SPECT scanner monitors the tracer's movement through body tissues. The rate of its radioactive decay allows the physician to obtain three-dimensional images of blood flow in the heart or electrical activity in different areas of the brain. It can also scan for tumors or bone disease.

The SPECT scanner contains a gamma camera, an imaging device that detects gamma rays emitted by the radioactive tracer. The scanner rotates around the individual, while the gamma camera records a series of two-dimensional images. A computer analyzes these images and produces three-dimensional images of the organs in question.

SPECT is used to diagnose head trauma, epilepsy, dementia, and cerebrovascular disease. Tracers like technetium-99 increase the resolution of brain images generated from SPECT that are very

accurate spatial with high-contrast resolutions. Other radioactive isotopes used in SPECT are iodine-123, xenon-133, thallium-201, and fluorine-18. The resulting sharp images permit the visualization of very small structures within the brain or other parts of the body.

Developments and Current Status

In 1971 the first computed tomography (CT) scan was administered. Shortly afterward, the positron emission tomography (PET) was introduced. In 1977 the first magnetic resonance imaging (MRI) scan was administered. At the end of the 1970s, SPECT was introduced. In 1999 the combined SPECT/CT was developed and introduced.

SPECT diagnostic indications are similar to other imaging techniques, particularly CT, MRI, and PET. SPECT imaging is a sensitive research tool for measuring blood flow through the brain (cerebral blood flow), in individuals with psychiatric (mental) disorder such as obsessive-compulsive disorder (higher blood flow) and alcoholism (lower blood flow). The accuracy of SPECT images makes it a useful clinical and research tool.

Sixteen Candles (Movie)

The film *Sixteen Candles* is director John Hughes's 1984 debut film. It was the first in a series of movies about the lives of teenagers who were called "the brat pack."

Description

The movie *Sixteen Candles* influenced other filmmakers, like Kevin Smith and Wes Anderson, who specialized in sympathetically representing the angst, preoccupations, and issues of youth. In this movie actress Molly Ringwald plays the central female character, named Sam, on the day of her 16th birthday. To her disappointment and sadness, all of her family and friends ignore or forget her special day. Eventually, Sam finds some comfort from identification with "the geek," a nerdy character who initially embarrasses her. Not being the most popular girl in school, Sam entertains his flirtations but her real affection lies with Jake, the best-looking and idolized guy in school. After many trials and tribulations throughout the day, Jake and Sam end up together in a birthday cake scene for which the film is well known.

Impact (Psychological Influence)

It is clear from the plot and approach to the characters that John Hughes, the writer and director of *Sixteen Candles*, understood and empathized with the traumas, challenges, and adventures of American teenagers in the 1980s. The movie accurately depicts some of the key factors that influenced life in a typical high school. It demonstrates the hierarchy of cliques among students and the constant pressure teenagers feel as a result of unwritten and often mysterious social codes. In addition, it addresses the natural separation and opposition that exists among teenagers, their parents, and teachers. The film highlights the terrors, heartbreak, and ecstasy of first love.

Several factors make *Sixteen Candles* important for teenagers watching it. Although it is a comedy, the subject matter is accurately portrayed. In addition the movie uses music and profanity in a realistic way that teenagers can identify with. One possible contributing factor is that the teenage actors were allowed to ad lib their lines. It is gender sensitive although the story is told from the teenage girl's perspective.

The movie had a huge impact at the time and for many years thereafter through a series of similar films.

In John Hughes's 1984 film, *Sixteen Candles*, actress Molly Ringwald plays the central character on the day of her 16th birthday. Hughes's movies about teenagers have been praised for respecting their problems and not condescending in dealing with their issues, although *Sixteen Candles* has also been criticized for its Cinderella aspects. (Universal/Photofest)

Several were written and produced by John Hughes himself, but other writers and directors came along and were also able to accurately depict and speak to an adolescent audience in a realistic and sympathetic way. There are two important psychological outcomes from this and similar movies. The first one is generally good and beneficial. Teenagers are treated realistically and with an appreciation for the important issues they are facing. These movies don't stereotype teenage problems nor condescend in dealing with their issues.

But the second effect, especially of *Sixteen Candles*, is that the central love story between the sophomore hero and her senior love interest is a fantasy that would tend to encourage the unrealistic dreams that often haunt teenage girls and some boys. The way both romance and young men are portrayed can feed delusion and false hopes. The special psychological challenges of adolescence are very hard for many teenagers and their parents and other responsible adults to handle. Bridging from threatened self-worth to self-confidence and independence often requires both role models and assistance.

Sixteen Candles. Directed by John Hughes. 1984. USA: Channel Productions, Universal Studios.

Sixth Sense, The (Movie)

The Sixth Sense is a 1999 American film starring Bruce Willis and Haley Joel Osment.

Description

The Sixth Sense is a highly successful 1999 American psychological and supernatural thriller starring Bruce Willis and Haley Joel Osment. *The Sixth Sense* was written and directed by M. Night Shyamalan and is rated PG13. The movie is a story about a relationship between a troubled young boy who sees and speaks with dead people and child psychologist Dr. Malcolm Crowe. The film is known for the surprise ending, supernatural material, depth of acting talents of the principal actors, and the line "I see dead people." The film established Shyamalan as a highly talented writer and director and was nominated for six Academy Awards. Themes include the supernatural, relationships, loss, and personal redemption.

The story opens with child psychologist Dr. Malcolm Crowe (Bruce Willis) and his wife (Olivia Williams) returning home and celebrating a prestigious award for his work with troubled children. Although their relationship is an obviously loving one, his wife expresses a fear that she feels second to his work. As they enter into their bedroom they are confronted by

Still from *The Sixth Sense*.The movie is a story about a relationship between a troubled young boy who sees and speaks with dead people and child psychologist Dr. Malcolm Crowe. (Buena Vista/Photofest)

a man with a gun. The man, Vincent Grey, is a former child patient of Crowe's and he accuses Crowe of breaking his promise of helping him, that he is still a freak, and that he doesn't want to be afraid anymore. Vincent is deeply disturbed and yells that Crowe failed him. He shoots Crowe in the stomach before turning the gun on himself.

The next scene opens the following fall, with Crowe beginning to work with nine-year-old Cole Sear (Haley Joel Osment), a young boy with similar problems, and of about the same age, as Vincent Grey when he was in therapy with Dr. Crowe. Crowe struggles with self-doubt and a deep sense of personal failure after Grey's suicide. Cole, a soulful and sad boy, tells Crowe that he is a freak and sees dead people. At first Crowe believes the boy to be delusional. Eventually Crowe comes to suspect that not only is Cole telling the truth but also perhaps Vincent may have had the same ability that Crowe was unable to understand at the time Vincent was in therapy. Crowe encourages Cole to try and find out what the dead may want or need from him. In spite of his fears Cole begins to engage the dead in order to understand what they need from him. He learns how to help them and their living loved ones. As Cole assists the dead, they are able to let go and move on to the afterlife. Cole comes to accept the significance of his gift and begins to excel in school even getting the lead in the school play, which Dr. Crowe attends as a final therapeutic act.

During this time Crowe's wife is becoming more and more distant, and he discovers she has developed a friendship with another man. Cole encourages Dr. Crowe to speak to her while she is asleep. Soon after this Crowe comes home to find that his wife has fallen asleep on the couch while watching their wedding video. As he looks at her, his wedding band falls from her hand and rolls across the floor. Crowe is surprised he has not been wearing the wedding ring and is hit with a sudden realization. The twist is revealed that Crowe was in fact killed by Vincent the night of receiving the award and has unknowingly been dead the entire time he has been treating Cole. Cole was not only receiving help from Crowe but was helping Crowe resolve his shame and guilt over Vincent's torment and suicide. Crowe then speaks to his sleeping wife telling her she was never "second" and that he loves her. Now with no more unfinished business, Crowe is able to move on to the afterlife.

Reception and Criticism

The Sixth Sense was highly accepted by the critics and public alike, spending five weeks as the number one film at the U.S. box office. Worldwide it has grossed over $674 million. *The Sixth Sense* was nominated for six Academy awards.

Skinner, B. F. (1904–1990)

Born Burrhus Frederic Skinner in 1904, "B. F." Skinner was an influential behavioral psychologist who explored the relationship between stimuli and behavior.

Description

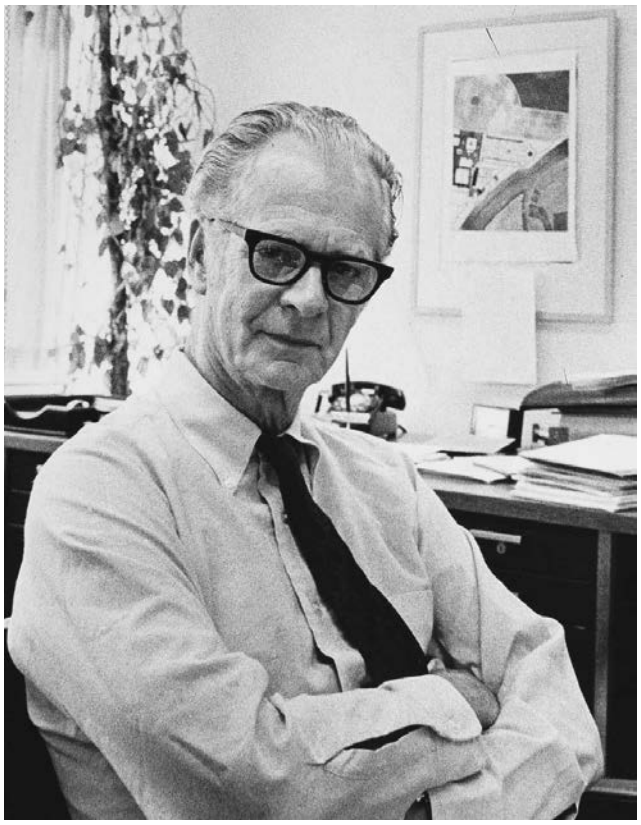
B. F. Skinner followed in the footsteps of John Watson and Ivan Pavlov in exploring human behavior. As a result of his experiments to find the roots of human behavior, he concluded that the notion of free will was a meaningless concept. His investigations seemed to show that in the stimulus-response-consequence model of behavior it was the consequences which were most determining of behavior. Skinner based many of his theories on his experimental work with rats and pigeons.

His research into behavior change showed that two things were important. First is that consequences,

rewards or punishments, tend to determine behavior. Second is that you can create behavior change more easily by breaking tasks into smaller parts and rewarding success on the parts not just the whole. He called this the principle of reinforcement, and it is influential in the fields of education, psychology, and more. Skinner was an advocate of behavioral engineering, which is also called operant conditioning. He thought that people could be controlled through the systematic allocation of external rewards, especially with the use of positive reinforcement.

Impact (Psychological Influence)

Skinner called his own philosophy of science radical behaviorism, and his investigation and experiments were presented in his work *Verbal Behavior*, as well as his philosophical manifesto *Walden Two*, both of which influenced not only scientists and educators but the whole culture. He extended his influence through a book called *Beyond Freedom and Dignity* where he advanced his idea that human beings are not truly free. Naturally this made him a target of controversy. Through his books and celebrity, his ideas became important in psychology, education, and training.



Born Burrhus Frederic Skinner in 1904, B.F. Skinner was an influential behavioral psychologist who explored the relationship between stimuli and behavior, building on the research of John B. Watson and Ivan Pavlov in studying human behavior. (AP Photo)

While Skinner's approach to behaviorism is no longer widely accepted today, his work remains influential, especially in the field of behavioral therapy where behavior modification and intervention of various kinds are used to change problem behaviors or reinforce positive new ones. His influence on fields as diverse as child rearing, management, education, and self-help continues; for example, the widely used concept of "time-out" with a child is based on Skinner's work. Mental health professionals often use operant techniques when working with clients; teachers frequently use reinforcement and punishment to shape behavior in the classroom; and animal trainers rely heavily on these techniques to train dogs and other animals.

Sleep

Sleep is the body's rest cycle, which is triggered by a group of hormones that respond to cues from the body itself and from the environment.

Definitions

- **Circadian rhythms** are variations in biological activities that repeat during 24-hour

intervals including the internal clock, which influences the amount and quality of sleep.

- **Non-REM sleep** is one of the two basic states of sleep consisting of stages 1, 2 (light sleep) and 3, 4 (deep sleep). It is also known as non-rapid eye movement and NREM sleep.
- **Polysomnography** is a medical test that records aspects of sleep (circadian rhythms, REM, NREM, number of arousals) as well as breathing patterns, heart rhythms, and limb movements.
- **REM sleep** is a stage in the normal sleep cycle characterized by rapid eye movement, dreaming, loss of reflexes, and increased brain activity. It is also known as rapid eye movement and REM sleep.
- **Sleep deprivation** is a condition characterized by insufficient sleep, which, if it is chronic, can cause fatigue, daytime sleepiness, and loss of concentration and productivity.
- **Sleep disorders** are a group of mental disorders characterized by disturbance in the amount and quality of sleep and that cause significant emotional distress or interfere with daily functioning.
- **Sleep stages** refer to five stages of sleep: 1, 2, 3, 4, and REM.

Description

Sleep is a basic necessity of life. It is as important for health and well-being as air, food, and water. When individuals sleep well, they wake up feeling refreshed, alert, and ready to face life's challenges. When they don't sleep well, every aspect of their lives can suffer. Jobs, productivity, health, and relationships are affected. Lack of sleep due to sleep deprivation or due to sleep disorders has taken its toll on Americans.

In 2002 the National Sleep Foundation (NSF) conducted a national survey called Sleep in America. It found that 80% believed they were not getting enough sleep. About 39% got less than seven hours of sleep each weeknight, and more than one-third were so tired during the day that it interfered with their daily activities. Also, 74% of adults reported that they experienced sleep problems. Over the years, data from NSF showed that Americans have increasingly reduced the amount of time they sleep. While society has changed, the human brain has not changed. Unfortunately, sleep deprivation has affected and continues to affect the health and well-being of Americans.

The amount and quality of sleep is regulated by two brain processes. The first is the restorative process when sleep occurs in response to how long an individual is awake. The longer one is awake, the stronger is the need for sleep. The second process controls the cycle of sleep and wakefulness. Timing is regulated by circadian rhythms, which act as an internal clock. This clock is influenced by exposure to light and darkness. The result is that individuals feel sleepy at night when it is dark and feel energetic during the day when it is light. Besides timing the sleep–wake cycle, the circadian clock regulates day–night cycles of other body functions. The result is that specific hormones that bring on sleep are secreted only at night, while other hormones that increase wakefulness are secreted only during the day. When this internal clock functions normally, individuals experience restorative sleep during the night and are refreshed and alert during the day (National Sleep Foundation, 2002).

This clock also influences sleep stages and cycles. There are five stages of sleep in a sleep cycle. These include stages 1, 2, 3, 4 of Non-REM, which are followed by REM sleep. Stage 1 is marked by drowsiness, stage 2 by light sleep, and stages 3 and 4 consist of deep sleep. Sleep begins with stage 1 and goes through each stage of the cycle until reaching REM sleep. The cycles are repeated, with each sleep cycle taking from 90 to 110 minutes. The brain acts differently in each stage of sleep. In some of the stages, there is movement of arms and legs, while in other stages there is no movement. These sleep stages and other biological patterns can be recorded with polysomnography.

Sleep Apnea

Sleep apnea is a temporary disruption or stoppage of breathing during sleep, which can result in daytime sleepiness.

Definitions

- **Central sleep apnea** is a type of sleep apnea in which the airway is not blocked, but the brain fails to signal the muscles to breathe.
- **Continuous positive airway pressure (CPAP)** is a device for treating sleep apnea that delivers air into airways through a specially designed face or nasal mask.
- **Non-REM sleep** is one of the two basic states of sleep consisting of stages 1, 2 (light sleep) and 3, 4 (deep sleep). It is also known as non-rapid eye movement and NREM sleep.
- **Obstructive sleep apnea** is a type of sleep apnea in which a blockage of the upper airway causes the body to snore and struggle for air.
- **Parasomnias** are a group of sleep disorders characterized by abnormal events that occur during sleep, such as sleepwalking, talking, or limb movement.
- **Polysomnography** is a medical test that records aspects of sleep (REM, NREM, and number of arousals) as well as breathing patterns, heart rhythms, and limb movements.
- **REM sleep** is a stage in the normal sleep cycle characterized by rapid eye movement, dreaming, loss of reflexes, and increased brain activity. It is also known as rapid eye movement and REM sleep.
- **Sleep disorders** are a group of mental disorders characterized by disturbance in the amount and quality of sleep and that cause significant emotional distress or interfere with daily functioning.

Description and Diagnosis

Sleep apnea is a sleep disorder in which breathing during asleep is interrupted by repeated pauses. This disorder can cause or worsen serious health conditions such as high blood pressure, stroke, obesity, diabetes, heart attack, and heart failure. It can also increase the risk for accidents since those with sleep apnea may fall asleep while working or driving.

There are three kinds of sleep apnea: obstructive sleep apnea (most common), central sleep apnea, and mixed sleep apnea. How does obstructive apnea differ from central apnea? Obstructive apnea results from an obstructed (blocked) airway. The result is the individual snores. Central apnea is caused by a problem in the brain sending proper signals to the muscles that control breathing. As a result, the individual gasps for air instead of snoring. Obstructive apnea is more common than central apnea. Both disorders are highly treatable, but obstructive apnea is curable. Obstructive sleep apnea affects 1%–2% of children, 2%–15% of adults in middle age, and over 20% of older adults. In contrast, central sleep apnea is relatively rare (American Psychiatric Association, 2013).

Obstructive sleep apnea. This disorder is characterized by shallow or complete disruptions of breathing during sleep. It is accompanied by snoring, gasping

for air, snorting, and pauses in breathing. Individuals with this disorder will often report daytime sleepiness, fatigue, and non-restorative sleep. According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, individuals can be diagnosed with this disorder if they exhibit excessive disruptions in normal breathing with excessive snoring, snorting, gasping, and prolonged pauses. It must result in daytime fatigues and sleepiness. It cannot be caused by another sleep disorder. The disorder must be demonstrated by polysomnography with 15 or more breathing disruptions per hour during sleep (American Psychiatric Association, 2013).

Central sleep apnea. This disorder is characterized by abnormally shallow breathing and complete cessation of breathing during sleep. Individuals with this disorder repeatedly engage in shallow breathing or simply stop breathing for short periods of time. Following the stoppage, they recover with a rapid deep breath. Those who also have heart failure, stroke, or kidney failure can have an atypical breathing pattern called Cheyne-Stokes breathing. This pattern consists of several deep breaths followed by a series of very shallow breaths or periods of several short, shallow breaths followed by a large, deep, recovery breath. This recovery breath usually results in an abrupt awakening. Those with this disorder are likely to be excessively sleepy and tired during the day. According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, individuals can be diagnosed with this disorder if they exhibit frequent episodes of abnormally shallow breathing or cessation of breathing during sleep. The episodes must last longer than 10 seconds and be followed by a sudden and rapid inhalation. Unlike obstructive sleep apnea there is no snoring, snorting, or gasping for air. This disorder cannot be caused by another sleep disorder and must be demonstrated by polysomnography with at least five episodes per hour of sleep (American Psychiatric Association, 2013).

Obstructive sleep apnea is caused by an obstructed airway. Several factors can lead to such obstruction. The most common factor is excess weight. Other factors include a narrowed airway (from enlarged tonsils or adenoids); gender (male to female ratios is 2:1); family history; smoking; and the use of alcohol, sedatives, or tranquilizers. The most common cause of central sleep apnea is heart failure. Less common causes are brain tumors and stroke.

Treatment

Effective treatment of sleep apnea begins with a professional sleep evaluation. The purpose of this evaluation, which includes polysomnography, is to determine the presence and type of the disorder. For those diagnosed with obstructive sleep apnea, several recommendations are made. The National Sleep Foundation recommends the avoidance of sleeping pills, alcohol, and nicotine. They also suggest losing weight and elevating the head when sleeping to reduce symptoms. If these measures fail to reduce symptoms or if the apnea is moderate to severe, surgery or the use of continuous positive airway pressure (CPAP) may be recommended. If the diagnosis is central sleep apnea, its cause, such as congestive heart failure, should be the focus of treatment. With obstructive apnea, CPAP may also be prescribed.

Sleep Disorders

Sleep disorders are a group of mental disorders characterized by disturbance in the amount and quality of

sleep and that cause significant emotional distress or interfere with daily functioning.

Definitions

- **Behavior therapy** is a form of psychotherapy that focuses on identifying and changing maladaptive behaviors.
- **Sleep deprivation** is a condition characterized by insufficient sleep, which, if it is chronic, can cause fatigue, daytime sleepiness, and loss of concentration and productivity.
- **Sleep hygiene** refers to the habits, practices, and nonmedical treatments for insomnia and which improve the quality of sleep.

Description and Diagnosis

Sleep is vital for good health and well-being. Getting sufficient quality sleep is necessary for mental and physical health as well as quality of life. It is during restful sleep that restoration and rejuvenation of all body systems occur. In children and adolescents, adequate sleep is essential to support growth and development. Without sufficient sleep, an individual's ability to perform even simple tasks declines dramatically. Sleep deprivation has become a major public health concern. Chronically sleep-deprived individuals are likely to experience impaired performance, irritability, lack of concentration, daytime drowsiness, decreased immunity, and sleep disorders.

There are several sleep disorders. The most common ones are insomnia, sleep apnea, restless leg syndrome, and narcolepsy. Less common sleep disorders include hypersomnia, nightmare disorder, sleep terror disorder, and sleepwalking disorder. Following are brief descriptions of these disorders. Each is more fully described in its own entry in this encyclopedia.

Insomnia. Insomnia is a sleep disorder characterized by difficulty falling or staying asleep. In addition, individuals with insomnia typically wake up during the night and then have trouble falling back asleep. Or, they may wake up too early in the morning. In either case, they often feel tired on waking. Insomnia can be short term (acute) or can last a long time (chronic). It can also come and go, with periods of time when an individual experiences no sleep problems. Acute insomnia can last from one night to a few weeks. Chronic insomnia is longer, lasting at least three nights a week for a month or longer.

Sleep apnea. Sleep apnea is a sleep disorder in which individuals stop breathing while asleep. Their breathing is interrupted by repeated pauses known as apneic events. There are three kinds of sleep apnea: obstructive sleep apnea (most common), central sleep apnea, and mixed sleep apnea. This disorder can cause or worsen serious health conditions such as high blood pressure, stroke, obesity, diabetes, heart attack, and heart failure. It can also increase the risk for accidents since those with sleep apnea may fall asleep while working or driving.

Restless leg syndrome. Restless leg syndrome is a sleep disorder characterized by an irresistible urge to move because of uncomfortable or painful sensations in the legs when attempting to rest and causing a compelling urge to move the legs. The movement makes it difficult or impossible to sleep restfully. Symptoms usually begin within 15 minutes and usually result in significant sleep loss, fatigue, and problems with daily functioning. If the individual is asleep, these involuntary leg movements, called periodic limb movements in sleep, begin and interrupt sleep.

Narcolepsy. Narcolepsy is a sleep disorder that affects the control of sleep and wakefulness. Those with this disorder experience excessive daytime sleepiness and uncontrollable episodes of falling asleep during the day. These episodes may occur during any type of activity at any time of the day. The normal sleep cycle involves light sleep stages followed by deeper sleep stages and then rapid eye movement (REM) sleep after about 90 minutes. But, for those with narcolepsy, REM sleep occurs almost immediately in the sleep cycle. It then occurs periodically during the waking hours, which leads to the symptoms of narcolepsy. This disorder usually begins between the ages of 15 and 25.

Hypersomnia. Hypersomnia is a sleep disorder that is more commonly known as excessive sleepiness. It is a condition in which an individual has difficulty staying awake during the day. Individuals with this disorder can fall asleep at anytime and anywhere. For example, they may nod off at work or even when

they are driving. Typically, they experience other sleep-related problems such as low energy and difficulty with concentration. The National Sleep Foundation estimates that 40% of adults experience symptoms of hypersomnia on occasion.

Nightmare disorder. Nightmare disorder is a sleep disorder characterized by repeated awakening from sleep or naps with detailed recall of extended and extremely frightening dreams. These dreams involve threats to survival, security, or self-esteem. On awakening from the frightening dreams, the individual rapidly becomes oriented and alert. The awakenings generally occur during the second half of the sleep period.

Sleep terror disorder. Sleep terror disorder is a sleep disorder characterized by repeated temporary arousal from sleep, during which the individual appears and acts extremely frightened. It is commonly confused with nightmares and nightmare disorder. Unlike nightmares, children with this disorder do not recall a dream after a sleep terror episode, nor remember the episode the next morning. Sleep terror symptoms are frequent and recurrent episodes of intense crying and fear during sleep, with difficulty arousing the child. Unlike nightmare disorder in which the individual is oriented and alert on awakening, those experiencing sleep terror disorder are confused and disoriented if awakened.

Sleepwalking disorder. Sleepwalking disorder is a sleep disorder that causes individuals to get up and walk around while still sleeping. These episodes typically occur while the individual is in the deep stages of sleep. Usually, the eyes of sleepwalkers are open with a glassy, staring appearance as they walk. They may talk incoherently while walking, and on questioning, their responses are slow or absent. If they are returned to bed without awakening, they seldom remember the event.

Circadian rhythm sleep–wake disorder. Circadian rhythm sleep–wake disorder is a sleep disorder characterized by a sleep pattern that is out of sync with normal circadian rhythms. Individuals with this disorder have trouble sleeping during the times that others typically sleep. Those with this disorder may not follow the typical circadian rhythms of others, but if allowed to follow their particular patterns, they can experience sufficient and otherwise normal sleep. To be diagnosed with this disorder, they must have recurrent difficulty adjusting their circadian rhythms to life demands. It must also cause sleeplessness, sleepiness, or both.

Treatment

The clinical treatment of these disorders varies depending on the disorder. Generally, treatment involves some combination of behavior therapy, sleep hygiene, and/or medication.

Sleep Terror Disorder

Sleep terror disorder is a sleep disorder characterized by repeated temporary arousal from sleep, during which the individual appears extremely frightened. This disorder is also known as night terrors and is often confused with nightmares and nightmare disorder.

Definitions

- **Cognitive behavior therapy** is a type of psychotherapy that focuses on maladaptive (faulty) behaviors, emotions, and thoughts.

- **Nightmare disorder** is a sleep disorder that is characterized by recurrent occurrences of troubling dreams.
- **Non-REM sleep** is one of the two basic states of sleep consisting of stages 1, 2 (light sleep) and 3, 4 (deep sleep). It is also known as non-rapid eye movement and NREM sleep.
- **Parasomnias** are a group of sleep disorders characterized by abnormal events that occur during sleep, such as sleepwalking, talking, or limb movement.
- **REM sleep** is a stage in the normal sleep cycle characterized by rapid eye movement, dreaming, loss of reflexes, and increased brain activity. It is also known as rapid eye movement and REM sleep.
- **Sleep disorders** are a group of mental disorders characterized by disturbance in the amount and quality of sleep and that cause significant emotional distress or interfere with daily functioning.

Description and Diagnosis

Sleep terror disorder is a sleep disorder seen in children and rarely in adults. It is characterized by repeated temporary arousal from sleep, during which the individual appears and acts extremely frightened. This disorder is often mistaken for nightmares and nightmare disorder. Unlike nightmares, children with this disorder do not recall a dream after a night terror episode, nor are they likely to remember the episode the next morning. In contrast, the symptoms of sleep terror are recurrent episodes of intense crying and fear during sleep, with difficulty arousing the child. In nightmare disorder the individual is oriented and alert on awakening. However, those experiencing sleep terror disorder tend to be confused and disoriented if awakened. It is important to note that in children sleep terror tends to be temporary and often resolves on its own in a few weeks or a month.

Sleep terror disorder is a parasomnia, which are sleep disorders that occur during arousals from REM sleep or partial arousals from non-REM sleep. They include nightmare disorder, sleepwalking disorder, and restless leg syndrome in addition to sleep terror disorder.

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, individuals can be diagnosed with this disorder if they exhibit repeated episodes of abrupt arousal from sleep, typically with a panicky scream. They also exhibit extreme fear and autonomic arousal systems. These include rapid heartbeat, sweating, rapid breathing, and dilated pupils during the episodes. They are also likely to be unresponsive to efforts to comfort them during these times. They have no memory of the episode and little or no dream imagery is recalled. The episodes must also cause significant distress to the individual or result in significant level of impaired functioning. In addition, the disorder is not the result of a substance, medication, other medical condition, or another mental disorder (American Psychiatric Association, 2013).

The cause of this disorder is not well understood. However, it appears that various factors can contribute to it. These include sleeping in unfamiliar surroundings, sleep loss, fatigue, lights or noise, and emotional stress. In children, a fever can trigger it. Certain medical conditions can trigger or exacerbate (worsen) it. These include sleep apnea, migraines, and head injuries In addition, alcohol and recreational drugs can trigger sleep terror episodes. Certain medications such as sleeping pills, sedatives, and antihistamines can also trigger the disorder.

Treatment

If the sleep terrors are associated with an underlying medical or mental condition or another sleep disorder, treatment is aimed at the underlying problem. If stress or anxiety seems to be contributing to the sleep terrors, psychotherapy may be useful. Cognitive behavior therapy and stress management may be useful. Medications are rarely used to treat sleep terrors, particularly for children. If necessary, an antidepressant like Prozac or Zoloft may help in reducing sleep terrors. For adults with severe sleep terrors, Klonopin may help.

If the disorder involves a child, the parents should be involved in therapy. Parents are helped to understand sleep terror disorders. They learn that during a

sleep terror episode, they should hold or rock the child or comfort the child in other ways, instead of trying to awaken the child. Parents are advised not to shake or yell at a child during a sleep terror as it can prolong the episode and further upset the child. Efforts to awaken the child will usually increase his or her disorientation. After a brief period of crying or screaming, the child will settle back into normal sleep mode and may not even remember the episode. Finally, parents can take comfort in knowing children generally outgrow night terrors within a matter of weeks or months.

Sleepwalking

Sleepwalking is a condition in which individuals get up and walk around while still sleeping. In DSM-5 it is a diagnosable sleep disorder called a non-rapid eye movement (non-REM) sleep arousal disorder. Sleepwalking is also known as somnambulism.

Definitions

- **Continuous positive airway pressure (CPAP)** is a device for treating sleep apnea that delivers air into airways through a specially designed face or nasal mask.
- **DSM-5** stands for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, which is a diagnostic system used by professionals to identify mental disorders with specific diagnostic criteria.
- **Non-REM sleep** is one of the two basic states of sleep consisting of stages 1, 2 (light sleep) and 3, 4 (deep sleep). It is also known as non-rapid eye movement and NREM sleep.
- **Obstructive sleep apnea** is a type of sleep apnea in which a blockage of the upper airway causes the body to snore and struggle for air.
- **Parasomnia** is a group of sleep disorders characterized by abnormal events that occur during sleep, such as sleepwalking, talking, or limb movement.
- **REM sleep** is a stage in the normal sleep cycle characterized by rapid eye movement, dreaming, loss of reflexes, and increased brain activity. It is also known as rapid eye movement and REM sleep.
- **Restless leg syndrome** is a sleep disorder characterized by an irresistible urge to move one's legs while attempting to rest.
- **Sleep disorders** are a group of mental disorders characterized by disturbance in the amount and quality of sleep and that cause significant emotional distress or interfere with daily functioning.

Description and Diagnosis

Sleepwalking is a condition and diagnosable sleep disorder where individuals get up and walk around while still asleep. These episodes occur while these individuals are in the deep stages of sleep. Usually, their eyes are open with a glassy, staring appearance as they walk. They may talk incoherently while walking, and on questioning, their responses are slow or absent. If they are returned to bed without awakening, they seldom remember the event.

This is classified as a parasomnia, which is a class of sleep disorders that occur during arousals from REM

sleep or partial arousals from non-REM sleep. They include nightmare disorder, sleep terror disorder, and restless leg syndrome in addition to sleepwalking disorder.

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, sleepwalking is listed as a non-rapid eye movement sleep arousal disorder. Individuals can be diagnosed with this disorder if they exhibit recurrent episodes of getting out of bed during sleep and walking around. During the episodes they stare blankly, are unresponsive when others attempt to communicate with them, and are only awakened with great difficulty. The episodes must cause significant distress to the individual or result in significant level of impaired functioning. In addition, the disorder is not the result of a substance, medication, other medical condition, or another mental disorder (American Psychiatric Association, 2013).

Various factors can cause this disorder. These can include genetic and environmental factors. Since sleepwalking runs in families, it may have a genetic basis. If one or both parents have a history of the disorder, it increases the likelihood of a child experiencing the disorder. Sleepwalking may occur when another medical condition that can affect sleep is present. These are obstructive sleep apnea, restless leg syndrome, migraines, or head injuries. In addition, alcohol, recreational drugs, and certain medications (antihistamines, sedatives, and sleep medications) can trigger sleepwalking.

Treatment

Treatment for sleepwalking may not be needed. A sleepwalker can often be gently lead back to bed. While it may not be dangerous to awaken the sleepwalker, it can be disorienting to them. If sleepwalking is caused by a medical or mental health condition, treatment is directed to that condition. For instance, if the sleepwalking is due to obstructive sleep apnea, the use of a continuous positive airway pressure device may be recommended. Should sleepwalking result in excessive daytime sleepiness, medication may be prescribed. Medications like Xanax or Prozac might be used with a continuous positive airway pressure device to stop episodes of sleepwalking.

Smoking Cessation

Smoking cessation is the process associated with discontinuing a nicotine-smoking habit.

Definition

- **Nicotine replacement therapy** is a type of treatment used to aid in smoking cessation that substitutes medications such as transdermal nicotine patches, lozenges, gum, inhalers, and other prescribed pharmaceuticals to help alleviate cravings, anxiety, and withdrawal symptoms associated with quitting.

Description

Smoking cessation describes the process one undergoes when trying to quit tobacco smoking. Tobacco contains an addictive carcinogen called nicotine that is a significant contributor in a multitude of health-related issues, including cancer, emphysema, and heart disease. Various interventions have been employed to assist those in quitting smoking, including nicotine replacement therapy, individual and small group counseling, and acupuncture. Many smokers though are reluctant to quit due to short-term side effects such as weight gain, headaches, stomachaches, and other withdrawal-related symptoms, including anxiety and irritability. However, research indicates that the benefits of discontinuing a nicotine habit greatly outweigh the costs. Studies have also found that it takes anywhere from 6 to 12 weeks

after one has quit smoking completely for the nicotine levels in the brain to return to levels of a nonsmoker. Health damage, though not entirely reversible, can be reduced if one quits smoking.

Cigarettes contain the chemical nicotine, which users can become addicted to. Nicotine acts on nicotine acetylcholine receptors in the brain causing them to release neurotransmitters such as dopamine, glutamine, and gamma-aminobutyric acid which causes cravings and withdrawal symptoms when ceased. Nicotine addiction is the most common form of addiction reported in the United States. Smokers generally increase the amount of cigarettes that they smoke per day over time, drastically increasing their risk of long-term health damage. The primary health concern for prolonged use is the development of certain types of cancer. Lung cancer is the leading cause of cancer deaths among both men and women, with approximately 90% of cases in men and 80% of cases in women being attributed to smoking. Nicotine use can also contribute to incidents of stroke, heart problems, and infertility.

Interventions to address nicotine addiction include both unassisted and assisted forms of treatment. Unassisted types refer to situations where users attempt to quit on their own volition, without the help of a health professional or the use of pharmaceuticals. Patients who attempt to quit "cold turkey" by eliminating all use or those who reduce their consumption on their own gradually over time would be classified as unassisted. The success rate for these individuals though is quite low, between 4% and 8%. Assisted types, on the other hand, include a range of treatments focused on emotional and psychological support and supplemental medication when necessary. Data further suggests that medical and dental providers who discuss health-care risks and encourage cessation readily with their patients are more likely to gain cooperation and yield higher success rates. Other beneficial forms of assisted treatment include nicotine replacement therapy, which makes use of medications, counseling, biofeedback, and even acupuncture. The American Cancer Society has projected a six-month success rate of around 30% for smokers who used other forms of assistance, referred to as nicotine replacement therapy, when trying to quit. Examples include transdermal nicotine patches, lozenges, gum, inhalers, and electronic cigarettes. Prescribed medications such as Bupropion, Varenicline, Moclobemide, Nortriptyline, and Clonidine, some of which are antidepressants, have also proven useful. Most smokers will attempt to quit several times throughout their lives, but most are unsuccessful, returning to the habit within six months.

Impact (Psychological Influence)

Cigarette smoking results in nearly 450,000 deaths each year, with approximately 49,000 of these due to exposure to second-hand smoke. Several forms of cancer, emphysema, coronary heart disease, stroke, and infertility have all been linked to smoking. Lawsuits have also been brought against Big Tobacco companies for their past failure in accurately informing and warning the public as to the dangers of cigarette smoking. Smoking cessation is a difficult process for many people and may require the assistance of health-care professionals or the use of medications. In the United States alone, it is estimated that some 60% of current smokers report that they would like to quit smoking. Studies are ongoing to determine not only the long-term health risks but also best forms of treatment for smoking addiction. Recent interventions have made use of web-based support groups and computer programs to assist addicts hoping to quit. Research indicates, however, that certain combinations of medications and nicotine replacement therapies have the highest rates of continued success. These include: (1) long-term nicotine patch and NRT gum/spray, (2) nicotine patch and nicotine inhaler, and (3) nicotine patch and Bupropion. A 2008 meta-analysis conducted by the U.S. Department of Health and Human Services on *Treating Tobacco Use and Dependence* also revealed that cigarette smokers were more likely to quit when they were informed about the risks and felt supported by their health-care provider, noting the importance of a positive relationship between doctor and patient.

Sobriety

Sobriety is the condition of complete abstinence from all mind-altering substances as well as increased mental, physical, and spiritual health.

Definitions

- **Abstinence** is the choice not to engage in certain behaviors or give in to desires such as alcohol or drug use.
- **Addiction** is a chronic disease of the brain, which involves compulsive and uncontrolled pursuit of reward or relief with substance use or other compulsive behaviors.
- **Alcoholics Anonymous** is a mutual aid or self-help fellowship that was founded in 1935 to help individuals struggling with alcoholism.
- **Mind-altering substances** are drugs or alcohol that can significantly influence perceptions, thoughts, and behaviors.
- **Recovery** is a series of steps individuals takes to improve their wellness and health, while living a self-directed (responsible) life and striving to reach their highest potential.
- **Twelve-Step Programs** are self-help groups whose members attempt recovery from various addictions based on a plan called the Twelve Steps.

Description

Sobriety requires the complete abstinence from any mind-altering substances. It also involves an increased level of health and balance in life. In this sense, sobriety involves a transformation in an individual's mental, physical, and spiritual health. An individual who has abstained from mind-altering substances but desires to resume use or engages in behavior patterns when he or she was using is not considered to be sober. In other words, sobriety requires much more than abstinence. Sobriety also includes repairing (making amends) to old relationships, as well as building new ones. Accordingly, sobriety is part of the process of recovery.

Overcoming addiction requires a huge commitment, and discovering how to get sober is the first step. Since sobriety can take a lot of time and effort, it may be helpful for addicts to find reasons to stop using and state these reasons with clarity. Some of the reasons may include an addict rebuilding damaged relationships with family, friends, and coworkers. Many individuals who suffer addiction may also have jeopardized their professional life and have legal issues to face. Whether an individual has been addicted to a substance for a short or long period, achieving

sobriety is possible when an addict takes the following steps. These steps include a commitment to stop using all mind-altering substances, setting short-term and long-term goals, and developing a treatment plan. Finding a support network (e.g., Alcoholics Anonymous) and planning to live a life free of mind-altering substances are also important steps in sobriety.

Treatment

The first step of sobriety is complete abstinence from mind-altering substances. Participating in psychotherapy and Twelve-Step Programs has been shown to be effective forms of treatment for individuals seeking sobriety. In many cases individuals cannot get sober by attending Twelve-Step Programs and psychotherapy alone. An individual may need additional help, such as participating in an inpatient or outpatient treatment program. Once an individual completes an inpatient or outpatient treatment program, becoming involved in a Twelve-Step Program and participating in psychotherapy is generally the best form of treatment for individuals achieving sobriety.

Social Anxiety Disorder

Social anxiety disorder is a mental disorder characterized by excessive and unreasonable fear of being judged or evaluated by others. Previously it was referred to as social phobia.

Definitions

- **Antianxiety medications** are prescribed drugs that relieve anxiety symptoms. They are also called anxiolytics or tranquilizers.
- **Anxiety** is a negative emotional state characterized by feelings of nervousness, worry, and apprehension about an imagined danger.
- **Anxiety disorders** are a group of mental disorders characterized by anxiety, which tends to be intermittent instead of persistent. The group includes panic disorder, phobias, and generalized anxiety disorder.
- **Behavior therapy** is a form of psychotherapy that focuses on identifying and changing maladaptive behaviors.
- **Cognitive therapy** is a type of cognitive behavior therapy that focuses on identifying and changing automatic thoughts and maladaptive beliefs.
- **Exposure therapy** is a behavior therapy intervention (method) in which a client is exposed to a feared object or situation.
- **Fear** is an emotional response to a known danger.
- **Phobia** is an intense fear of a person, place, or thing that significantly exceeds the actual danger posed.

Description and Diagnosis

Social anxiety disorder is one of the group of DSM-5 anxiety disorders in which an individual experiences distressing anxiety in social situations or in anticipation of social situations. More specifically, those with this disorder experience anxiety regarding the scrutiny of others that is abnormally severe. Often, their anxiety revolves around some sort of performance such as a presentation, dance, or speech. In more severe cases, simply attending a party or having a conversation with a stranger may be sufficient to induce significant anxiety. Social anxiety disorder can cause someone to become isolated or in severe cases unable to maintain relationships and/or become unemployed.

It is not uncommon for them to experience anxiety or fear regarding certain social circumstance. What characterizes this disorder from normal social functioning is that the anxiety almost always occurs as opposed to occasionally. The prevalence of this disorder in the United States is relatively common, affecting approximately 7% of the population. However, this disorder seems to occur far more frequently in the United States than it does in other countries. It is reported that it affects approximately 2% of European countries and less than 2% in the remainder of the world population. This disorder tends to affect roughly equal numbers of males and females. Also, it usually manifests during adolescence (American Psychiatric Association, 2013).

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, individuals must experience anxiety regarding social situations that is primarily focused on the critical scrutiny of others. They must fear that their own behavior will in some way be perceived as embarrassing. Also, they must experience anxiety in regard to almost all social situations. They must also actively avoid these situations as a direct consequence of their anxiety or experience intense anxiety while in the social situation. In addition, the anxiety experienced must be significantly disproportionate to the actual consequence posed by the situation. Also, the conditions and symptoms mentioned earlier must have been present for at least six months.

The exact cause of this disorder is unknown, but it is thought to result from the interaction of a number of factors. Like other anxiety disorders, it is believed that genetics, brain structure, and an individual's environment are factors. A family history of anxiety, depression, or neuroticism may predispose individuals to social anxiety disorder. Also, an overactive or sensitive amygdala, one of the brain structures involved in fear, may also influence the manifestation or experience of social anxiety. In addition, an individual's unique experience, especially adverse social experiences in childhood, may be a risk factor in the development of this disorder.

Treatment

This disorder is commonly treated with exposure therapy or cognitive therapy but may also be treated with medication. In exposure therapy of this disorder, individuals are slowly exposed to the specific social situation that causes them anxiety. The aim of exposure is to break the conditioned cycle of response. At first, the individual may be asked to perform a relaxation technique such rhythmic breathing. Once individuals have reached the relaxed state, they might be asked to imagine themselves entering a social situation that usually causes them a great deal of anxiety, but instead of avoiding the situation, they imagine themselves acting differently. Such exercises become progressively closer to the actual experience of the original social circumstances that were the focus of the individual anxiety. Eventually, such activities result in the extinction of the behaviors that were once associated with social anxiety.

Cognitive therapy is also used, often in conjunction with exposure therapy. The aim of this therapy is to help the individual uncover and understand his or her faulty beliefs about criticism of others and social situations. Self-help workbooks that incorporate both behavioral and cognitive techniques may also be used. In addition to these therapy techniques, medications are also employed in the treatment of this disorder. Both antidepressant medication and antianxiety medication may be utilized but serve different purposes. Antidepressants such as Prozac and Zoloft are used to reduce the severity and frequency of experienced anxiety, but do little to reduce acute symptoms once they manifest. This is in contrast to antianxiety medications such as Ativan or Klonopin, which are used to reduce acute symptoms.

Social Anxiety Disorder in Youth

Social anxiety disorder (SAD) in youth is a marked and persistent fear of social situations in which a person may feel shame or extreme psychological discomfort.

Definitions

- **Anxiety** is a negative emotional state characterized by feelings of nervousness, worry, and apprehension about an imagined danger.
- **Anxiety disorders** are a group of mental disorders characterized by anxiety which tends to be intermittent instead of persistent. The group includes panic disorder, phobias, and generalized anxiety disorder.

Description

Social anxiety disorder in children is one diagnosis within the category of anxiety disorders. The disorder is usually diagnosed in the period of a person's life between late childhood and young adulthood. Individuals who experience SAD are scared of performing in social situations. They often experience physical symptoms of discomfort when socializing with others. SAD is also known as social phobia. Social anxiety disorder is one of the most common of all anxiety disorders. Approximately 12% of the U.S. population is diagnosed with some kind of SAD (American Psychiatric Association, 2013). That rate of occurrence makes it the third most prevalent psychiatric disorder after depression and alcoholism.

SAD is characterized by intense internally generated fear in social situations. This fear causes considerable distress and can result in an impaired ability to interact with others in daily life. Often this can occur without any obvious signs or symptoms of anxiety. Individuals with SAD often think that others in social situations are passing unfavorable judgment on them. This makes the individual with SAD extremely self-conscious and fearful of being embarrassed by his or her own actions. These fears can be triggered by the misperception or the actual reality that the individual is being judged by other people.

Causes and Symptoms

As is true with many other mental health conditions, SAD probably arises from a complex interaction of genetics and environment. Some researchers have identified possible causes, which include a combination of genetically inherited traits that affect brain chemistry or structural problems with the amygdala that cause it to be overactive. Anxiety disorders in general often recur across generations of families. But it is not clear whether it is genetics alone, or the familial patterns of learned behaviors, or a combination of these things that influences this behavior more strongly.

Social anxiety disorder tends to develop early in life. About half of individuals who have this disorder have developed it by the age of 11 and almost all have developed it by age 20. It is understandable that children who are the victims of teasing, bullying, rejection, and humiliation are more likely to suffer from SAD. In addition to that, other negative events in life such as family conflict, death in the family, or abuse may be associated with SAD. Social anxiety disorder often occurs in combination with issues of low self-esteem and depression.

There are many physical symptoms that often accompany SAD. Some include excessive blushing of the face, sweating (hyperhidrosis), trembling, palpitations, and nausea. Panic attacks can also occur under intense fear and discomfort. Verbal stammering may also be present for those with social anxiety.

Diagnosis and Prognosis

In order to be diagnosed with SAD an individual must demonstrate several behavioral characteristics. These include persistent fear of one or more social situations, which may bind them to specific people and places. The person must recognize that his or her fear is excessive and that it negatively influences normal routines or daily activities. Lastly, in order to receive the diagnosis, the phobia cannot be caused by a substance or other medical condition.

An early diagnosis may allow those who are diagnosed with SAD to get both psychological and medication help. Both talk therapy and medication can minimize the symptoms of anxiety and the development of any other issues such as depression. Some people who suffer from SAD may use alcohol or other drugs to reduce their fears and inhibitions during social events. It is common for those who experience social phobias to self-medicate with alcohol or other drugs, especially when they are undiagnosed and untreated. While the fear of social interaction may be recognized by the person himself or herself and considered unreasonable, it can be difficult to overcome.

Treatment

A person with the disorder may be treated with psychotherapy, medication, or both. Psychotherapy or counseling can help people with SAD to recognize and change negative thoughts about themselves. Cognitive behavior therapy is the approach most favored for those with anxiety. This therapy helps deal with the role that your own thoughts, especially those about yourself, play in leading to your actions and behaviors. Group therapy, skills training, relaxation, and role-playing are also effective approaches for controlling stress in social situations.

If drugs are required, the patient will usually start with a low dose in order to reduce the risk of side effects. Remember in all cases, whether it is psychotherapy or drugs, that treatment is not a cure. Treatment can be brief or take some time for the symptoms to change and diminish. It is important to be patient when dealing with and treating anxiety disorders.

Social Communication Disorder

Social communication disorder is a mental disorder characterized by difficulties with the social language and communication skills.

Definitions

- **Attention-deficit hyperactivity disorder** is a problem with the inability to focus and concentrate, being overactive, and the inability to control behavior.
- **Autism spectrum disorder** is a neurodevelopmental disorder that impairs an individual's ability to interact and communicate with others. It also includes repetitive interests, behaviors, and activities, and causes significant impairment in occupational, social, or other important areas of functioning.
- **Developmental disabilities** is a diverse group of serious chronic conditions due to mental and/or physical impairments. They may cause an individual difficulty with language, mobility, learning, and independent living.
- **DSM-5** stands for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, which is a diagnostic system used by professionals to identify mental disorders with specific diagnostic criteria.

- **Global developmental delay** is a significant delay in two or more developmental areas of an individual.
- **Intellectual disabilities** are characterized by significant limitations in both adaptive behavior and intellectual functioning.
- **Language impairment** is a disorder in one or more of the basic learning processes involved in understanding or in using spoken or written language.
- **Learning disabilities** are neurological disorders that make it difficult for an individual to acquire certain academic and social skills. They affect the brain's ability to receive, process, store, respond to, and communicate information.
- **Linguistics** is the scientific study of language, including phonetics, phonology, morphology, syntax, semantics, and pragmatics.
- **Neurodevelopmental disorders** are a group of DSM-5 disorders characterized by impairments of brain function that affect language, learning ability, self-control, and memory that develop as an individual grows. They include intellectual developmental disorder, autism spectrum disorder, and social communication disorder.
- **Speech therapy** is treatment of speech and communication disorders, which is usually performed by a speech-language therapist.

Description and Diagnosis

Social communication disorder is one of the DSM-5 neurodevelopmental disorders. It is characterized by impairment in how meaning is created and understood, and delayed language development. Symptoms include limited variety in the use of language, and difficulty understanding the main point of a question, understanding what is socially appropriate. It may be a specific diagnosis or may occur within the circumstances of other conditions, such as specific language impairment, autism spectrum disorder, intellectual disabilities, learning disabilities, attention-deficit hyperactivity disorder, developmental disabilities, and serious brain injuries. Emotional and psychological disorders and loss of hearing may also affect social communication skills. A child or teenager with this disorder will have problems in following normal social rules of communication whether nonverbal or verbal. These individuals often have difficulty following the rules for conversations, that is, taking turns in a conversation. Changing language depending on the situation and needs of the listener is another difficulty for these individuals. These social communication difficulties result in problems participating in a social manner with others, communicating effectively with others, and performing academically. This disorder is most commonly diagnosed by the age of five, since most children possess adequate speech and language abilities (American Psychiatric Association, 2013). However, there are milder forms of this disorder that may not become recognizable until early adolescence. This is the period of when language and social interactions become more complex.

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, individuals can be diagnosed with this disorder if they have persistent difficulties in the social use of nonverbal and verbal communication. This is demonstrated by deficits in communication for social purposes (e.g., sharing information with another individual that is appropriate for the social context). The individual must have impaired ability to change communication to match the situation of the listener (e.g., speaking differently in a classroom than when playing with friends). Individuals must have difficulties with following rules during storytelling and conversations. Individuals may have problems rephrasing a statement when misunderstood, and difficulty knowing how to use verbal and nonverbal gestures to manage interactions with others. These individuals must also have difficulties grasping what is not explicitly stated. These deficits must result in functional limitations in social participation, effective communication, academic achievement, social relationships, or occupational performance. These deficits may occur individually or in combination with each other. The onset of symptoms of this disorder occurs in the early developmental period, and the symptoms are not a result of another medical or neurological

condition. The symptoms must not be derived from low abilities in the area of grammar and word structure, and are not better explained by global developmental delay, an intellectual disability, autism spectrum disorder, or another medical disorder.

The exact causes of social communication disorder are unknown. A family history of communication disorders, autism spectrum disorder, or a specific learning disorder appears to increase the risk for social communication disorder (American Psychiatric Association, 2013).

Treatment

Treatment for social communication disorder is tailored to the individual's need. Speech therapy is one form of treatment in which the goal is to help the individual recognize and correctly interpret verbal and nonverbal cues and expressions. It also assists individuals in differentiating between a sincere voice and a sarcastic one, or between an angry or mean voice. Speech therapists also help individuals to use verb tenses correctly and distinguish between singular and plural nouns. Role-playing is also used to assist individuals to practice taking turns in a conversation. The speech-language therapist will confront and assist the individual with social communication disorder when the individual is speaking far too long. The therapist can also work with the child's parents and teachers and help coach them on ways to improve the child's communication skills. The prognosis for this disorder depends on support of the family, the child's intelligence level, and whether he or she has any other medical or mental disorder.

Social Justice Counseling

Social justice counseling (SJC) is a multifaceted approach to therapy that incorporates collaborative social advocacy and activism to promote growth and development of individuals, families, and communities.

Definitions

- **Activism** refers to the actions and behaviors taken to promote social or political change.
- **Advocacy** is the act of supporting, recommending, asking, or pleading for a particular cause, policy, or need of a group or individual.
- **Social Inequality** refers to the existence of unequal opportunities or distribution of resources because of social position or status with a social group.
- **Systemic abuse** refers to the existences and maintenance of social inequalities due to a larger system such as the laws, policies, and practices of the land.

Description

Social Justice counseling is based in the belief that all people have a right to equitable treatment and access to services and resources. SJC focuses on issues of oppression, privilege, and social inequities of individuals and group that have been systematically excluded on the basis of race, ethnicity, age, gender, education, sexual orientation, socioeconomic status, physical or mental disability, and other aspects of group membership. SJC incorporates social advocacy and activism as a means to address inequitable social, political,

and economic conditions that impede academic, career, personal, and social development of individuals, families, groups, and communities. Social justice counselors operate from the belief that client problems must take into account the oppressive social and environmental barriers that impede development, growth, change, and harmony.

SJC requires mental health professionals to expand how they conceptualize client problems to include the impact of oppression and inequality on client outcomes. Social justice counselors empower and join clients in the active confrontation of injustice and inequality. The goal of SJC is to ensure that every individual has the opportunity to reach his or her potential free from oppression and other unnecessary external barriers to a quality education, health-care services, and employment opportunities. The process for achieving social justice is through a collaborative therapeutic experience in which clients become aware and knowledgeable of all external barriers that debilitate their development. Clients participate in skill building to address, change, and overcome those barriers.

SJC requires counselors to include advocacy as a core helping competency. Recognizing the critical role counselors play in assisting clients overcome oppression, the American Counseling Association (ACA) adopted an advocacy competencies model. This model identifies the extent of involvement of the client in the advocacy process and the level of intervention on an individual, systemic, or societal level. Counselors may choose to advocate with the client or on behalf of the client.

At an individual level social justice counselors work with clients to empower them. Empowerment includes facilitating the process of identifying, naming, and developing strategies to overcome oppressive barriers. This may also include assisting clients develop self-advocacy skills and locate resources that can help address social, political, economic, and systemic change.

At a systems level, counselors engage in community collaboration in which they work with a larger group to address an oppression or barrier impacting the community. This is similar to individual empowerment but at a group level. Systems advocacy is used by counselors on behalf of a group or community in which the group may not be aware that a systemic barrier exists; may fear repercussions from the larger system; or may not have the power, credibility, or voice to address the issue.

For example, during consultation two counselors at a university become aware that a particular college department has behaved in a discriminatory fashion toward a particular ethnic group. The individual client/students were unaware of the pattern or that other students had attempted to address it without results and that others had left the college because of it. Recognizing that an oppressive barrier exists, the counselors could empower the students on an individual level by assisting them in recognizing and naming the inequality, organize and unite them at the community collaboration level, and engage in systems advocacy by informing the department of the problem and organizing a safe process of resolution.

Other social justice advocacy competencies include counselors engaging in public information to raise awareness about an issue. Social or political advocacy occurs when counselors work directly with policy makers and legislators to address issues impacting client groups.

Development and Current Status

SJC has its roots in the multicultural counseling movement developed in the 1990s. A multicultural perspective led to a deeper understanding of cultural variables and the need to view client problems in the context of the external environment, including sociopolitical factors that impact client functioning. The growth of SJC can be attributed to the growing diversity of the American population and the recognition by counselors that not all personal problems can be solved in a counseling office with an individual client. In 2003, the ACA, drawing from the multicultural literature, adopted the advocacy competencies and by the mid-2000s counseling from a social justice perspective was emerging as another force in the field. SJC continues to be further developed and is included in many graduate counseling programs.

Social Learning Theory

Social learning theory is a way to understand how people behave and interact with others based on social contexts.

Description

Social learning theory was started and developed by psychologist Albert Bandura (1925–). The development of this theory moved beyond traditional behavioral theory. Instead the focus of social learning theory is to anchor the human learning process and new behaviors to human observation of other people's actions. Bandura, who is an emeritus professor at Stanford University, is recognized as one of the four great psychologists of the 20th century; he is included alongside Sigmund Freud, B. F. Skinner, and Jean Piaget.

Bandura showed that the social context of learning was key to thinking and behavior. This concept is most notably demonstrated in his Bobo doll experiments first conducted in 1961. The Bobo doll experiments used a five-foot-tall blow-up doll named Bobo. Bobo was weighted on the bottom so that when it was knocked over it would spring up again. Bandura set up experiments with nursery school children, aged three to six. He had half the children observe adults interacting aggressively with the Bobo doll. This included hitting it, knocking it over, and kicking it. The other half of the group were with an adult who simply played with other toys while ignoring the Bobo doll. Bandura exposed the children to these activities, one by one, so as to eliminate group pressure. There was also a control group who saw no modeling of behavior at all.

What Bandura discovered was that children who witnessed aggressive behaviors tended to demonstrate those same behaviors. This occurred more so than with the children who had not seen aggressive behavior. He also noted that boys who had seen an adult male act aggressive tended to be more aggressive themselves than boys who had seen the same behavior from an adult female. Although same-sex behavior modeling seemed to be more influential in terms of outcomes, girls in general tended to be almost 50% less aggressive than boys.

The Bobo doll experiments were criticized on many levels. Bandura conducted a revised version of the experiments in 1963. When adding a reward or punishment for the adult aggressive behaviors, things changed. He found that incorporating such consequences did impact whether or not the children themselves acted aggressively.

The main theme of social learning theory is that people learn by watching other people. This is true not only in terms of their motor behaviors, like hitting or kicking, but also in the way they may use language. But it seems clear that humans are not automatic copycats of behavior. Just because something has been observed or learned does not mean that behavior will change. As Bandura (1971) once wrote, "In the social learning view, man is neither driven by inner forces nor buffeted helplessly by environmental influences. Rather, psychological functioning is best understood in terms of a continuous reciprocal interaction between behavior and its controlling conditions."

Current Status and Impact (Psychological Influence)

Social learning theory moved beyond pure behavioral theories and practice, to see learning as part of a social process. It shows that learning can take place from observing behavior or the consequences of behavior. But learning is not passive observation; it requires gathering information and decision making. And while it is true that reinforcement plays a role in learning, it is not the only component necessary for learning. Social learning theory concludes that thinking, behavior, and environment all play an interactive role in the learning process.

Bandura's ideas have become a standard part of understanding human thinking and behavior. His theories helped people understand how anxiety could develop without having direct interactions with a triggering object itself. His work demonstrated that people can also learn from hearing about the experiences of other people.

The current empirical investigations of social learning strategies include a range of research from laboratory studies to observations in the natural environment. These studies consider factors big and small, from individual decision-making processes to observational work that seeks to explain population-level cultural and social issues. Such empirical studies build off the insight of social learning theory and the complexity of the human learning process.

Social Media

"Social media" refers to different forms of electronic communication, such as websites, blogs, and chat rooms, that people use to interact with one another to share information, exchange ideas, and establish online communities.

Definition

- **User-generated content** defines various types of media content generated by and accessible for use by the general public; some examples are videos, blogs, podcasts, social networking sites, wikis, and forums. Since 2005, user-generated content has had various applications, including circulating news and gossip, generating research and problem solving, and gauging public interest and opinion.

Description

Social media applications offer ways for people to interact with one another in the online environment. There are six different types of social media: collaborative projects, blogs and microblogs, content communities, social networking sites, virtual gaming sites, and virtual social worlds. Some social media may combine two or more of these types. The content that is created in these virtual communities is referred to as "user-generated content." A difference between social media and traditional forms of media is that social media is much more far-reaching, accessible, and permanent. Social media users are able to network, collaborate, share ideas, and socialize right from the comfort of their own computer, cell phone, or tablet. The development of social media has substantially impacted how people communicate with one another in today's world.

One of the first social media sites was created in 1994, known as Geocities. Social media became widely used in the early 2000s. Since then, social media sites have continued to explode. Nowadays, people use social media sites for a range of functions such as to gather information, post their opinions, catch up with friends, search career opportunities, and even seek out romantic relationships. The business world has benefited and uses social media to conduct market research, promote products and discounts, and foster brand loyalty.

Users cite the quality, immediacy, and accessibility that social media provides as some of the top benefits. The increase in this type of communication has resulted in unlimited access to information provided on the Internet. Many sites are open platforms and do not require registration or membership fees. People are able to connect and form relationships, both personal and professional, with individuals around the world. Answers are only a keystroke or mouse click away.

There are some drawbacks to social media as well. Experts argue that the increase in social media usage

The logos of some social media, showing the numerous popular online social network sites that people use to express themselves, keep in touch, and establish online communities. Researchers worry that social media usage has greatly cut the amount of face-to-face interactions and tends to encourage impulsive and inappropriate postings, often later regretted. (Roberto Giovannini/Dreamstime.com)

has drastically decreased the amount of face-to-face interactions that people engage in. Some even suggest that social media usage can be addictive. Many debate further that communicating via social media reduces the quality and personal nature of interactions. Furthermore, users who are not able to establish boundaries between their personal and professional selves may be subject to risk. Another limitation, given the ease of use, is the concern over exposure, particularly for minors. Without even trying, one can be subject to graphic images, videos, and even sexual predators. Monitoring minors' use of social media and setting up parental controls and privacy settings is recommended. Research has also cited a positive correlation between the use of social networking sites and cyber-bullying. In addition, one must question the reliability and validity of the information one finds on the Internet. Ownership and copyright issues are also an issue with social media content.

Impact (Psychological Influence)

These types of sites are extremely popular and are accessed by Internet users more than any other type of site. By July 2012, the total time spent on social media in the United States increased 37% to 121 billion minutes from 88 billion minutes just the year before. Facebook is an example of a popular social networking

site. With over 1 billion active users, it is the primary method for communication among college students in the United States. In addition, 93% of businesses employ Facebook as a marketing tool. Users aged 65 and older are also on the rise; one out of every four people in that demographic is a member of a social networking site.

Social Skills Training

Social skills training (SST) is a form of therapy used by teachers, therapists, and mental health professionals to help people with social challenges.

Definition

- **Social** means related to human society or its ways of being organized.

Description

Social skills training (SST) is a widely used treatment for different groups of people who struggle with interacting with others socially. Individual SST is effective when a trained therapist helps one child improve specific social behaviors. Examples of these include use of eye contact and taking turns during play. SST also includes group treatment, which has been effective because of the opportunity to practice with peers and learning from one another. Group SST has been overall proven more effective for clients and efficient for therapists and health-care systems.

The primary purpose of SST is to teach people how to overcome the problems they experience socially. In SST clients can be taught the interpersonal skills of how to start a conversation or have small talk, how to handle humor in groups, and what to do during a phone call. In most cases people who have trouble socially have not learned how to use and understand social cues. Social cues include verbal and nonverbal behavior. These cues let people know when someone else is bored or when to suggest changing an activity. SST helps teach specific social cues and rules for interaction based on social norms. These social norms can be complicated and require breaking down large concepts into smaller steps. If SST is effective, the people benefiting gain insight and successful experiences from socializing. This in turn positively affects their self-esteem and relationships overall.

There are various techniques and methods that are included in SST. These include teaching, modeling, rehearsal, and homework. People with social challenges often need to learn the rules or norms for socializing, which can be introduced and taught. Utilizing the method of Socratic questioning is a good way of engaging teens and adults in the learning process. After being taught it is important to provide a demonstration or real-life example of the skill. This can be done through live modeling or role-playing or through video. After learning and modeling are complete, a chance to practice or rehearse the skills and get feedback is important. During behavioral rehearsals, coaching from clinicians is critical for the delivery of corrective and positive feedback. Finally, having the opportunity to generalize the skills used in treatment outside of therapy is the last step to truly effective SST.

Understanding the effective methods of SST allows clinicians to provide a high standard of care with guidelines to help this population learn and grow therapeutically. It allows therapists to teach clients how to have friendships, manage emotions, become independent, and overall have a better quality of life. SST is an effective treatment for individuals with diagnosis such as autism, schizophrenia, and anxiety disorders.

Development

In the United States in the 1920s there was a major movement in the school system toward character education. During this movement, the introduction of teaching interpersonal and social skills happened in schools. A few decades later, psychologists became involved in SST through behavior therapy in children.

During the 1950s medication treatment for psychotic disorders became popular and psychologists were tasked with helping clients manage their bizarre behaviors. They were required to teach these patients how to interact successfully with others in the community. This is how SST became standard practice in treating individuals with chronic and acute social issues.

Current Status

In recent years the demand for SST has increased. Although SST has become popular, few of these have been formally researched and reviewed. Those that have been proven effective focus on changes in behavior and physiology. The advancements in functional magnetic resonance imaging measurements have allowed SST to be measured for changes in the brain after treatment. It is likely that the future direction of SST will continue to utilize physiological tests to identify effective social skills treatment.

SST can be used with other treatment to effective treat specific disorders. With disorders such as substance use or dependence, SST has been used with medication management and coping skills training. It is also commonly used alongside exposure therapy and behavior therapy to treat anxiety disorders. The incorporation of family education and therapy into SST has been extremely successful. Family education and therapy that works directly with the concepts being addressed in SST has the most effective, long-term outcomes. Current research suggests that if family treatment isn't involved, then follow-up support to SST is helpful.

There are many benefits of SST programs. One is that the treatment can be brief and structured, which allows clients to get maximum potential. Usually clients are placed in a group setting where they get support and resources from those whom they interact with. SST also focuses on new skills that are learned and built upon versus focusing on the history of struggles a client has experienced. This places a positive and concrete focus onto a psychological issue that can be more helpful to clients than analyzing its origins. More research needs to be done on SST, and SST is emerging as a standard best practice in treating those with social problems.

Social Workers

Social workers are professional individuals who work in human service settings assisting individuals, families, and communities.

Description

Social workers are highly trained individuals who most often work in human service settings to help people cope with challenges in their lives. The social work profession has a long and rich history of advocating and assisting underserved and minority populations. Social work core values include respect for the equality, worth, and dignity of human beings; civil rights; and social justice.

Social workers are represented by the National Association of Social Workers (NASW), the largest membership organization of social workers in

the world, representing over 140,000 members, in 56 states and local chapters. According to the NASW the social work mission is to "enhance the effective functioning and well-being of individuals, families, and communities through its work and through its advocacy" (NASW, 2013).

The profession of social work includes three levels of professional qualifications with distinct levels of service provision depending on education. Social workers may have a bachelor's degree in social work (BSW) or a master's degree in social work (MSW). Licensed clinical social workers (LCSWs) have an MSW and are licensed in the state where they work to provide mental health services. For those wishing to work in universities or colleges as social work educators, they must earn either a doctorate in social work or a PhD in social work. Over 650,000 individuals hold degrees in social work.

Social workers, those with either a BSW or an MSW degree who are not licensed, provide services in a wide range of social service settings. Service settings include family service agencies, childcare services, adoption and foster care settings, hospitals and community clinics, community mental health programs, disability support agencies, nursing homes and elder care, public health settings, criminal justice and correctional settings, community organizations, homeless organizations, programs for veterans, substance abuse treatment settings, and youth outreach programs. Master-level social workers also provide administrative leadership in social service settings.

Social workers are trained to assist individuals, families, and community organizations. On an individual/family level, social workers provide assessments of needs, identify beneficial resources such as community aid services and programs, develop plans to utilize resources, and provide assistance to individuals and families in need. On a community level social workers work with community and government service agencies in the development and provision of programs and policies to enhance individual and family well-being.

Licensed clinical social workers must have a master's degree in social work and hold state licensure to treat mental health disorders. Attaining state licensure is demanding and requires supervised clinical practice as a social work intern for a minimum of two years after graduating with an MSW. Although states vary somewhat in their requirements, licensure generally requires 1,500 hours of face-to-face psychotherapy experience while receiving clinical supervision from a state-qualified supervisor. LCSWs are qualified to diagnose and treat mental, behavioral, and emotional disorders such as depression, anxiety, trauma, and other mental disorders and conditions. They provide psychotherapeutic services to individuals, groups, couples, and families. LCSWs may also work in private practice, providing psychotherapeutic services for a fee.

The U.S. Bureau of Labor lists the following occupations as having job duties similar to social workers: health educators, mental health counselors, marriage and family therapists; probation officers and correctional treatment specialists; psychologists; rehabilitation counselors; school and career counselors; social and human service assistants, and substance abuse and behavioral disorder counselors. According to the U.S. Bureau of Labor as of 2010 the median annual wage of all social workers was $42,480, with half the workers earning more and half the workers earning less. The top 10% earned more than $70,000. Employment of social workers is expected to grow by 25% from 2010 to 2020, which is faster than the average for most occupations.

Social workers have a profound and far-reaching impact on our society. Social workers are found in every facet of community life and are employed throughout the mental health industry.

Socioeconomic Status

Socioeconomic status is a tool for identifying status based on individuals' income and occupation in relation to others.

Description

Socioeconomic status looks at how people relate to each other based on their income, background, and occupation. Socioeconomic status is often referred to as SES. In the fields of social sciences, it is one of the most widely studied constructs.

Socioeconomic status is measured by looking at family income, parental education, and parental occupation. This area is widely researched, as people want to know the impact and relation to physical health, mental health, and advantages or disadvantages for children based on the family's SES.

Socioeconomic status is generally broken down and referred to as high, middle or low. It is often used interchangeably with the term "social class." Families of low and high status tend to be focused on the most. Children born to low-status families tend to be considered behind those children of high status in relation to education and development. For instance, children of high-status families tend to learn words faster than those of low-status families, which is noticed in children as young as 18 months old.

Research dating back to the early 1900s highlights the connection between family life and SES. Those with low SES face more hardship, which impacts parent–child relationships and family life. Those who are considered to be in the ethnic minority are more often considered part of low SES in the United States.

In relation to child development, the focus on SES has surrounded the concern that those who come from low SES lack access to resources, education, and care, leading to developmental problems and limited better future prospects regarding education and occupation. Education is a large focus point in regard to exploring status, as many believe that education has a great influence on occupation and income later in life.

Studies have supported the idea that those coming from higher SES will have more opportunity for economic growth and occupation choices. Studies have also highlighted a connection that those of higher SES have decreased percentages of separation and divorce in their relationships as well as better parent–child relationships.

Sociopathic Personality

Sociopathic personality is a mental disorder characterized by amoral and criminal behavior and a diminished sense of moral responsibility. It is also known as sociopathy and sociopath.

Definitions

- **Antisocial personality disorder** is a mental disorder characterized by a persistent pattern of disregarding and violating the rights of others.
- **DSM** stands for the *Diagnostic and Statistical Manual of Mental Disorders*, which is the handbook mental health professionals use to diagnose mental disorders. The current edition (fifth) is known as DSM-5.

- **Personality disorder** is a long-standing pattern of maladaptive (problematic) behaviors, thoughts, and emotions that deviates from the accepted norms of an individual's culture.
- **Psychopathic personality** is a mental disorder characterized by amoral behavior, inability to love and understand another's feelings (empathy), extreme self-centeredness, and failure to learn from experience. It is also known as psychopathy and psychopath.

Description

Individuals with sociopathic personality tend to spontaneously act out in inappropriate ways without thinking through the consequences. They may be nervous, easily agitated, and quick to display anger. They will lie, manipulate, and hurt others, but will often avoid doing so to the select few individuals they care about. Most often they are able to form attachments and loyalties to others. This means that they are likely to experience guilt and remorse when they hurt someone they care about. While they are capable of committing heinous crimes, they are unlikely to commit crimes against family or friends.

In the past, the term "sociopathic personality" has been used synonymously with psychopathic personality and antisocial personality disorder. More recently, clinicians and researchers favor distinguishing them. There appear to be differences among the three in both behavior and etiology (cause). While antisocial behavior is common in antisocial personality disorder and sociopathic personality, it is less common in psychopathic personality. Also, there are specific deficits in psychopaths that distinguish them from sociopaths. These include interpersonal deficits, such as grandiosity, arrogance, and deceitfulness, as well as affective deficits, such as a lack of guilt. In addition, psychopaths are characterized with global deficits of empathy. As for etiology, it appears that the psychopathic personality is more influenced by genetic inheritance than environment. In contrast, the sociopathic personality seems to be more influenced by environmental factors such as poverty, exposure to violence, and overly permissive or neglectful parenting. It should also be noted that the second edition of the *Diagnostic and Statistical Manual of Mental Disorders* provided a description of the sociopathic personality. However, in subsequent editions, it has been replaced by a description and specific diagnostic criteria for the antisocial personality disorder.

Solution-Focused Brief Therapy (SFBT)

Solution-focused brief therapy is a talking therapy that focuses on solutions rather than on problems.

Description

Solution-focused brief therapy (SFBT), also referred to as solution-focused therapy, is a talking therapy that focuses on the development of solutions rather than on past problems. SFBT is an evidence-based practice that minimizes emphasis on past failings and problems, and focuses on client's strengths and previous and future successes.

Development

The development of solution-focused brief therapy was led by husband and wife Steve de Shazer (1940–2005) and Insoo Kim Berg (1934–2007) at the Brief Family Therapy Center (BFTC) in Milwaukee, Wisconsin. Finding that an excessive amount of time and energy was spent in thinking about, talking about, and analyzing problems, the team at BFTC developed a method to bring about

realistic change as quickly as possible. Since the conception of SFBT in the late 1970s, other therapists have added to its conceptual framework. Eve Lipchik, John Walter, and Jane Peller, have written extensively about solution-focused therapy. Michelle Weiner-Davis and Bill O'Hanlon, influenced by de Shazer and Berg's work, expanded their own work and created solution-oriented therapy, which shares many key concepts with SFBT. Both de Shazer and Kim Berg wrote extensively on SFBT. With the passing of de Shazer and Kim Berg, the BFTC was closed and all rights to their solution-focused training materials were bequeathed and transferred to the Solution-Focused Brief Therapy Association.

Solution-focused brief therapy is a collaborative process that works from the client's understanding of his or her concerns and what the client might want different. The therapeutic focus is on what the client desires for the future rather than on past problems or even current conflicts. One of the basic premises of SFBT is that there is no problem that happens all the time. SFBT uncovers "exceptions," which are times when the problem could have happened but didn't. The model assumes that exceptions are actually solution-oriented behaviors that already exist for the client. The nature of these exceptions is used by the client and therapist to co-construct future solutions. Clients are encouraged to increase the frequency of behaviors, which have led to solutions. Another key concept of SFBT is that small increments of change lead to large increments of change.

The therapist takes a positive, collaborative, and collegial position that assists the client in finding alternatives to current patterns of thinking, behaving, and interacting that are problematic. The focus of the therapist is on what is observable in the communication and social interactions between the client and the therapist. The mechanism of change is the dialogue between the therapist and client.

One of the main techniques utilized in SFBT is the "miracle question." When clients have difficulty articulating a goal, the miracle question can help the client what may occur if a solution was found. Although there are many variations to the miracle questions, the basic question is, "Imagine that sometime during the night a miracle takes place and while you are asleep the problem you are talking about is solved. But because you were asleep when it was solved when you wake up you don't know a miracle has taken place. So when you wake up how will you know the problem is no longer a problem?" The miracle question has been so effective in assisting clients in the change process that it has been adopted and used in many other models of psychotherapy.

Current Status

Solution-focused brief therapy has been found to be an effective form of psychotherapy and is included in Substance Abuse Mental Health Service Administration's National Registry of Evidence-Based Programs and Practices. It has been found to be helpful with both adult and adolescent populations and in both outpatient and inpatient treatment centers.

Somatic Symptom Disorder

Somatic symptom disorder is a mental disorder characterized by bodily symptoms that are very distressing and result in disrupted functioning. In the past it was called somatization disorder.

Definitions

- **DSM-5** stands for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth*

Edition, which is a diagnostic system used by professionals to identify mental disorders with specific diagnostic criteria.

- **External locus of control** is the core belief that individuals' decisions and life are controlled by external factors over which they have little or no influence.
- **Mindfulness practices** are intentional activities that foster living in the present moment and awareness that is nonjudgmental and accepting.
- **Somatic sensitivity** refers to the high level of sensitivity and attentiveness to bodily sensations in some individuals, leading them to overly focus on physical symptoms.
- **Somatic symptom and related disorders** are a group of DSM-5 mental disorders characterized by prominent somatic symptoms and significant distress and impairment. They include somatic symptom disorder, factitious disorder, and conversion disorder.
- **Somatization disorder** is a mental disorder characterized by multiple bodily symptoms that cannot be explained by a medical condition. This term is no longer used and has been replaced with somatic symptom disorder in DSM-5.
- **Stress management** is a set of psychological techniques for increasing the capacity to better cope with psychological stress. It usually includes relaxation methods.

Description and Diagnosis

Somatic symptom disorder is one of the groups of disorders known as somatic symptom and related disorders. Individuals with this disorder experience somatic (bodily) symptoms that are very distressing and that significantly disrupt daily functioning. The duration and severity of these symptoms and the pursuit of relief often become the focal point of their lives. Talking about their condition often becomes the primary focus and way in which they relate with others. Their suffering can also limit their ability to work or care for their children. Somatic symptom disorder is similar to but different from somatization disorder. Whereas somatization disorder required that symptoms could not be explained by a medical condition, somatic symptom disorder does not.

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, individuals can be diagnosed with this disorder if they exhibit one or more somatic (bodily) symptoms that disrupt their lives. The disruption and their response become problematic in that the person has excessive worry and anxiety regarding the seriousness of the symptoms regardless of the fact that medical evidence does not warrant it. These individuals may also expend considerable time and efforts focused on their symptoms. In addition, the symptoms must persist for more than six months (American Psychiatric Association, 2013).

The cause of somatic symptom disorder is not well understood. It may be that those with this disorder are more sensitive to their bodily sensations (somatic sensitivity) than others. They tend to amplify and interpret these sensations are indicators of physical illness. As a result, when they experience emotional stress, they are likely to interpret it as a physical symptom. They tend to view life as threatening and overwhelming. They are also likely to view themselves as unable to control and deal with overwhelming circumstances. These views reflect an external locus of control. This disorder not only confirms and perpetuates their suffering but also explains their reliance and overuse of medical treatment.

Treatment

Effective treatment of this disorder involves counseling or psychotherapy. Usually, these individuals are referred to psychotherapy by their physician. But, because they are likely to resist a psychological explanation and treatment for their condition, a team approach is essential if treatment is to be successful. Framing treatment as a team approach lets these individuals know that the therapist will work with their physician, as part of a team, to reduce their suffering. Psychological treatment should emphasize increasing functioning decreasing preoccupation with symptoms. Intervention strategies should target physical functioning by

teaching relaxation and other stress management skills. Such interventions can greatly help them feel better physically and increase their sense of self-efficacy. In addition, mindfulness practice can help in reducing their preoccupation with and acceptance of physical symptoms.

Len Sperry, MD, PhD

Somatizing Personality Disorder

Somatizing personality disorder (SPD) is a mental disorder characterized by a persistent and excessive preoccupation with bodily concerns.

Definitions

- **Alexithymia** is the inability to experience, express, identify, and describe emotional responses.
- **Cognitive behavior therapy** is a form of psychotherapy that focuses on changing maladaptive (faulty) behaviors, emotions, and thoughts.
- **Delusions** are fixed and false beliefs that persist despite contrary evidence.
- **Hypochondriasis** is a mental condition characterized by a preoccupation with having a serious medical condition based on a misinterpretation of bodily symptoms.
- **Personality disorder** is a long-standing pattern of maladaptive (problematic) behaviors, thoughts, and emotions that deviates from the accepted norms of an individual's culture.
- **PDM** stands for the *Psychodynamic Diagnostic Manual* and is a diagnostic framework that characterizes individuals in terms of their psychodynamics.

Description and Diagnosis

Somatizing personality disorder is a personality disorder characterized by an excessive preoccupation with bodily concerns that is ongoing and long-standing. Individuals with this disorder typically experience health concerns that doctors can't explain. As a result these individuals become frustrated and come to believe that others do not understand and accept their concerns. Being preoccupied with bodily concerns can lead individuals to experience a delusion. The delusion may involve a belief that a part of their body has been injured or altered in some way. Individuals with SPD often present a confusing combination of concerns. Other issues include having a diagnosable stress-related physical illness and bodily symptoms that express ideas and emotions that are too painful to put into words (PDM Task Force, 2006).

Individuals with SPD are also characterized by alexithymia. Children who cannot verbalize their feelings tend to either act out or complain they have body aches and pains. Individuals with this disorder have also been described as lacking the ability to fantasize and being incompetent in symbolic expression. They tend to invest more time in "things" than in the effects of the imagination (PDM Task Force, 2006). It is possible that early caregivers of individuals with this disorder did not encourage expressing feelings and emotions. Therefore, this left their bodies to communicate what their minds could not. Although they may at times receive some secondary gain from the sick role, the pain they suffer is real and debilitating. Individuals with this personality disorder often claim that they feel that nobody is listening to them. Others may tune out individuals with SPD as previous efforts to help them left them feeling frustrated due to a lack of resolving the problem. Individuals with this personality disorder may

also feel "unheard" because of the early experiences with caregivers who failed to respond to their communication. This personality disorder tends to significantly interfere with relationships, school, work, and social activities. It is important to distinguish SPD from hypochondriasis. Both involve a preoccupation with medical concerns. The lives of those with SPD are totally dominated by these concerns. However, it is less likely that hypochondriasis interferes with daily activities and relationships.

According to the *Psychodynamic Diagnostic Manual*, SPD is diagnosable by the following criteria. It is common for individuals with this disorder to have a developmental history that includes early sickliness. It might also include being physically fragile and early physical or sexual abuse. These individuals tend to be preoccupied with something being wrong with their bodies. They commonly exhibit distress and rage. Alexithymia prevents them from acknowledging their emotions. Their basic belief is they are vulnerable, fragile, and in danger of dying. Their view of others is that they are healthy, powerful, and indifferent. Furthermore, their main way of defending themselves is by regressing (returning to a previous or usually worse state) and continually expressing they have body aches and pains (PDM Task Force, 2006).

Treatment

Treatment of this disorder requires a supportive relationship with both a health-care provider (physician) and a mental health-care provider (therapist). Cognitive behavior therapy has been shown to be particularly effective for SPD. This approach can assist an individual in dealing with pain and helping him or her realize his or her health concern is not fatal. Effective therapy involves such individuals talking about their concerns and their therapists listening and acknowledging these concerns in a caring manner.

Somatopsychic

"Somatopsychic" refers to the influence of the body on the mind. It is the opposite of psychosomatic, which refers to the effect of the mind on the body.

Definitions

- **Depressive disorder due to another medical condition** is depression that occurs as the result of a physical illness. The depression causes substantial difficulty in social, occupational, and interpersonal areas.
- **DSM-5** is the *Diagnostic and Statistical Manual of Mental Disorders*. It is the handbook mental health professionals use to diagnose mental disorders.
- **Major depressive disorder** is a DSM-5 mental disorder characterized by a depressed mood and other symptoms that interfere significantly with an individual's daily functioning. It is also referred to as clinical depression.
- **Psychosomatic** refers to the effects of mental processes on physical health.

Description

Somatopsychic is the relationship of the body and mind. It refers to the effect that physical bodily conditions have on mental processes, in other words, how physical health impacts mental health. Mental disorders such as depression and anxiety may be symptoms of physical illness or mental dysfunction. For example, the underlying cause of depression may be attributable

to a physical illness such as cancer. According to the DSM-5, the depression will be diagnosed as depressive disorder due to another medical condition and not as major depressive disorder. One of the criteria for major depressive disorder explicitly states that the depressive episode cannot be the result of a medical condition. The depression is the direct result of the physical illness and cannot be attributed to another mental disorder.

The interrelationship between body and mind makes it difficult for a physician or clinician to determine whether the presenting problem is somatopsychic or psychosomatic. It may be that both body-mind and mind-body play a role in symptom development. It is important for mental health clinicians, and especially physicians, to keep in mind that psychological symptoms could potentially be the result of physical illness. Conversely, it is important to remember that physical symptoms may be caused by psychological illness. Attentiveness to these possibilities can lead to more accurate diagnoses.

There are many physical conditions that are expressed through psychological symptoms. This is why it is crucial for mental health clinicians to rule out organic conditions as possible causes for psychological symptoms. A thorough history assessment is necessary to determine if an individual needs to be referred for a physical examination. It is important to ask when an individual was last seen by a physician, what type of exam was performed, what lab tests were performed, and what the results indicated. When a diagnosis is not clear, it is important to maintain awareness of the possibility that organic causes may be at the root of the problem.

The effects of the body on the mind were originally explored by early psychiatrists such as Christian Friedrich Nasse (1778–1851), Carl Friedrich Flemming (1799–1880), and Pavel Ivanovich Jacobi (1841–1913). These physicians were part of the somatic school and contended that psychological dysfunction was a symptom of biological diseases in the body. They believed that physical illness created an imbalance in the relationship between the body and mind.

South Park (Television Program)

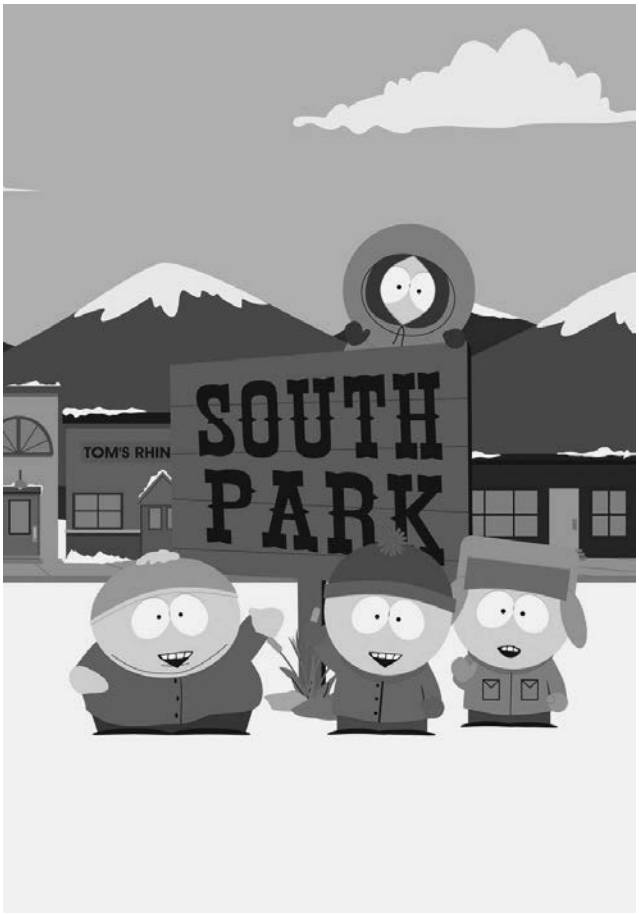
South Park is an American animated television program intended for mature audiences, televised on the Comedy Central cable network.

Description

South Park debuted in August 1997 and was created by Trey Parker and Matt Stone. Parker and Stone are the show's lead writers and producers and provide the voices of the main characters. Production took place at South Park Studios (SPS) in Culver City, California. *South Park* has received numerous awards and is known for its vulgarity, crude humor, strong profanity, dark satire, shock value, running gags, and pop-culture references. TV guide ranked *South Park* as the 10th greatest television cartoon of all time.

South Park is set in the fictionalized town of South Park Colorado and follows the strange adventures of four foul-mouthed boys in elementary school: Stan Marsh, Kyle Broflovski, Eric Cartman, and Kenny McCormick. Stan Marsh, described as the average fourth grader is modeled after Parker. Kyle, modeled after Stone, is described as the voice of reason, is Jewish, and is Stan's best friend. Eric Cartman is described as one of the worst human beings in the history of fiction and the most famous of the fourth graders. He is narcissist, self-centered, racist, and obese. Kenny is poor and, according to SPS, tends to frequently die and was killed in innumerable ways during the first five seasons.

South Park Studios has a staff of approximately 70 people. The use of cutout animation software allows for episodes to be produced the week of the airing. The production schedules allow for current events to be rapidly incorporated into episodes. Some episodes



South Park is an American animated television comedy about foul-mouthed elementary students. Its popularity, especially among teenagers, stems from its satirical representation of hypocrisy in religion, politics, parenting, and many other mainstream cultural topics. (Comedy Central/Photofest)

have featured events that had taken place just days prior to airing. For instance, the season 12 (2008) episode "About Last Night" included elements of President Obama's acceptance speech less than 24 hours after he won the election.

South Park has been an enormous ratings success and is credited with making Comedy Central a successful network. *South Park* has received numerous awards and has won the Emmy Award for Outstanding Animated Program four times as of the 2013 season.

South Park has been criticized for its crude humor and depiction of foul-mouthed elementary school-age children. It is known for its use of taboo subject matter and negative depiction of religion, politics, parenting, and most other main stream cultural topics. The show's portrayal of religion for comic effect is a frequent complaint, as is the use of profanity. Adding to the controversies, *South Park* frequently responds to criticism by producing shows containing more of whatever is being complained about. For instance, in response to complaints regarding the use of profanity, SPS released "It hits the fan" the first episode of season five (2005). During that episode the word "shit" is said 162 times uncensored.

Since its television debut in 1997 *South Park* has been the topic of countless college papers and has added many catchphrases to our cultural language. With its political incorrectness, satirizing of many of the world's most popular religions (Christianity, Mormonism, Islam, Scientology), and negative depictions of political leaders, *South Park* has generated worldwide controversy since its debut in 1997. *South Park* remains one of the most highly rated animated television programs of all time.

Special Education

Special education provides teaching instruction for students diagnosed with learning, behavioral, emotional, communicative, developmental, and physical disabilities, in specifically designed educational settings that meet their individual needs.

Definitions

- **Inclusion** is an educational approach that calls for students who are disabled to spend the majority of time in classrooms with nondisabled peers.
- **Learning disability,** or specific learning disability (SLD), is a neurological disorder that affects the brain and results in processing, reading, writing, reasoning, and recalling difficulties.
- **Mainstreaming** refers to the inclusion of students with special needs into regular, general education classrooms and activities.
- **Response to intervention**, also known as Multi-Tier System of Supports, is an approach used to provide students displaying academic and behavioral concerns with appropriate instruction and intervention.
- **Special needs** is a term used to describe persons who have been diagnosed with mental, emotional, and physical disabilities.

Description

Traditional classrooms, referred to as "general education" classrooms, provide education programs for typically developing students based on state standards as determined by state standardized achievement tests. Special education services are designed to supplement the regular curriculum and support the unique needs of students with qualified disabilities. Those disabilities include but are not limited to learning, emotional, behavioral, and communication disorders, physical impairments, and/or sensory needs. Students may become eligible for special education services after properly being diagnosed with one or more of these disorders. Those who receive special education support may be described as "special needs" or "learning disabled". The Individuals with Disabilities Education Act (IDEA), now the Individuals with Disabilities Education Improvement Act, mandates that children aged 3 to 21 with special needs receive a free and appropriate education in the least restrictive environment. Inclusion in general education classrooms with nondisabled peers should therefore be executed to the greatest extent possible. Evidence suggests that when disabled peers are mainstreamed, they experience positive outcomes. By providing proper support and services, educational systems seek to promote student well-being, self-sufficiency, and future success. Special education support can occur within traditional classrooms, resource rooms, self-contained classroom, or specialized schools. Reading and math instruction; speech-language, occupational, and physical therapies; small group counseling; and behavioral interventions may be offered.

Students who are born with noticeable disabilities or impairments (i.e., deafness, blindness, physical handicap) may be easily identified and thus begin their school careers with special support. However, other students, primarily those with specific learning disabilities (SLDs), require proper identification, evaluation, and diagnosis. The process for qualifying for special education support can be lengthy. Traditionally, a full psychoeducational evaluation by a licensed psychologist is required. Qualifying for an SLD is then determined based on the discrepancy model—whether or not there is significant difference, at least two standard deviations (30 points) between the individual's scores on an achievement test and his or her IQ. However, this model has been criticized as it does not provide a method for identifying children in primary grades, provides little information about the student's specific learning needs, and has resulted in disproportionate representation of minority groups. The recent introduction of an alternative approach, Response to Intervention, has placed heavy demands on educational

staff, primarily classroom teachers, to document and provide interventions aimed at meeting students' individualized needs. Each student with a documented disability is required to have an Individualized Education Plan/Program (IEP) on file outlining his or her specific needs, goals, and services received. IEPs are then tailored to each individual and describe both accommodations and modifications to the general curriculum. Accommodations are slight adjustments to the regular education that simply change the format in order to make it more palatable for the student, while modifications change or reduce the curriculum to bring it to a level that is obtainable for the student.

Development (Purpose and History)

Parents advocating for specialized schooling and support for their children can be traced back to the 1930s; however, over the next several decades slow progress was made toward advancing the rights of children with special needs. The 1950s and 1960s and the influence of the civil rights movement had a positive effect. Specifically, the landmark case of *Brown v. Board of Education* (1952) established precedence that segregating students based on race was unconstitutional, paving the way for other marginalized groups to follow. It was not until the 1970s that true educational reform benefiting disabled youth began. The federal Rehabilitation Act of 1973 was the first piece of legislation prohibiting discrimination on the basis of disability. In 1975, Congress enacted the Education for All Handicapped Children Act, mandating that specialized programs and services be made available to those who need them; that students who qualified for these services be guaranteed free, equal, and appropriate education; that specific monitoring procedures and policies for these programs be established; and that federal funds be allotted to support these efforts. This law has since became known as the Individuals with Disabilities Education Act after being signed into law by President George W. Bush on October 30, 1990. IDEA has been reauthorized several times, most recently in 2004. One of the key provisions calls for the creation of an IEP for every student who qualifies under the law for special services. Presently, increased emphasis has been placed on accountability standards, primarily in response to No Child Left Behind, and the required hiring of "highly qualified teachers" who are best able to meet the needs of those most vulnerable.

Current Status and Results

The Department of Education reports that over 6 million school-age children are receiving some type of special education support. This percentage has increased over the past several years mostly due to early intervention and proper identification. Debate continues over the disproportionate number of minority students who are targeted for services. Research suggests that the overrepresentation of certain ethnic groups may be attributed to lack of exposure to preschool foundational concepts, inadequate home support, and higher rates of reported behavior problems among these subgroups. In addition, reduced funding and a shortage of good teachers in underprivileged schools are also contributors.

Specific Learning Disorder

Specific learning disorder is a group of mental disorders characterized by specific deficits in the ability to understand and process information effectively and correctly.

Definitions

- **DSM-5** stands for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth*

Edition, which is a diagnostic system used by professionals to identify mental disorders with specific diagnostic criteria.

- **Learning disorders** are neurological disorders that can make it difficult for an individual to acquire certain academic and social skills.
- **Neurodevelopmental disorders** are a group of DSM-5 disorders characterized by early life deficits that produce impaired personal, social, academic, or job functioning. These include autism, attention-deficit hyperactivity disorder, and specific learning disorder.
- **Specifiers** are extensions to a diagnosis that further clarifies the course, severity, or type of features of a disorder or illness.

Description and Diagnosis

Specific learning disorder is one of the DSM-5 neurodevelopmental disorders. It is characterized by continuous and impairing problems with learning fundamental skills in writing, reading, or math. This results in academic performance that is well below average for their age. The disorder occurs when the learning demands or evaluation procedures (e.g., timed tests) create obstacles that cannot be overcome by their natural intelligence and compensatory strategies. Specific learning disorder results in lifelong impairments (e.g., job performance) for individuals affected by this disorder.

The occurrence of this disorder across the academic areas of writing, reading, and mathematics is 5%–15% among school-age children. This includes children who speak different languages and are from different cultural backgrounds. The occurrences of this disorder in adults are not exactly known, but estimates indicate being approximately 4% (American Psychiatric Association, 2013).

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, individuals can be diagnosed with this disorder if they experience problems with learning and academic skills with at least one of the following symptoms. These symptoms include inaccurate or slow word reading, problems understanding what the meaning of what is read, and problems with spelling and written expression. Additional symptoms include problems mastering sense of numbers, calculation, and number facts, and problems with mathematical reasoning. Symptoms of this disorder must occur for at least six months. In addition, academic skills must be significantly below what is expected for an individual's chronological age. Individuals with this disorder experience significant interference with academic and occupational performance. The learning problems must have begun during school-age years. The learning problems are not better accounted for by other neurological or mental disorders or a lack of skill in the language of academic or educational instruction. Specifiers must be included in this diagnosis if an individual has impairment with reading, written expression, or mathematics. The current level of severity of this disorder must also be specified in making this diagnosis. The levels include mild, moderate, and severe (American Psychiatric Association, 2013).

The exact cause of this disorder may be due to environmental and genetic factors. For example, individuals born prematurely have an increased risk for having this disorder. Individuals are more likely to have this disorder if their first-degree relatives have been diagnosed with this disorder. In addition, individuals who had a delay in speech or language during preschool years are likely to be diagnosed with this disorder.

Treatment

Children diagnosed with this learning disorder can qualify for special education services. Experts can help a child learn skills by building on the child's strengths and develop ways to make up for his or her weaknesses. Specific treatment techniques may vary depending on whether the individual is struggling with reading, writing, or mathematics. The earlier an individual receives help, the more likely he or she will be successful in school and later in life.

Specific Phobia

Specific phobia is a mental disorder characterized by a marked and enduring fear of specific situations or objects. Previously this disorder was referred to as simple phobia.

Definitions

- **Anxiety disorders** are a group of mental disorder characterized by anxiety as a central or core symptom. The group includes specific phobias, social anxiety disorder, and generalized anxiety disorder.
- **Behavior therapy** is a psychotherapy approach that focuses on identifying and changing maladaptive behaviors. It is also referred to as behavioral therapy.
- **Cognitive behavior therapy** is a type of psychotherapy that focuses on maladaptive (faulty) behaviors, emotions, and thoughts.
- **DSM-5** stands for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, which is a diagnostic system used by professionals to identify mental disorders with specific diagnostic criteria.
- **Exposure therapy** is a type of behavior therapy that involves repeated actual, simulated, or visualized exposure to a feared object, situation, or traumatic event that reduces fear and anxiety.
- **Social anxiety disorder** is an anxiety disorder characterized by excessive and unreasonable fear in social situations of being judged or evaluated by others. Previously it was referred to as social phobia.

Description and Diagnosis

Specific phobia is an anxiety disorder characterized by a persistent and unreasonable fear of presence or thought of a specific object or situation. However, it must be noted that the object or situation poses little or no actual danger. Yet exposure to the object or situation leads to an immediate reaction in which an individual experiences intense anxiety or avoids the object or situation entirely. This distress, or the need to avoid the object or situation, significantly interferes with the individual's ability to function. Adults with this disorder recognize that their fear is unreasonable but are unable to overcome it. Others may view those with this disorder as introverts or self-absorbed because of the amount of attention they put on the fear of either avoiding or having to engage in a situation that is causing the fear. A related disorder is social anxiety disorder in which the fear is of being judged or evaluated by other individuals.

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, individuals can be diagnosed with this disorder if they exhibit excessive anxiety or fear about an object or situation. Children with these disorders may express their fear in a multitude of flight or fight behaviors, including tantrums, crying, or clinging. The fear is avoided at multiple costs, is persistent, lasts at least six months, and is out of proportion to the actual risk or danger. Specific phobias are coded according to the feared stimulus (animal, natural environment, blood injection injury, situations, etc.) (American Psychiatric Association, 2013).

DSM-5 describes the following types of specific phobias.

- Animal phobias. These phobias involve a fear of dogs, snakes, insects, or mice. Animal phobias are the most common specific phobias.
- Natural environment phobias. These phobias involve a fear of storms, water, bridges, or heights.

- Blood-injection-injury phobias. These phobias involve a fear of medical procedures, such as blood tests or injections, of seeing blood, or of being injured.
- Situation-specific phobias. These phobias involve a fear of specific situations, such as flying, driving a car, riding in a car or on public transportation, going over bridges or in tunnels, or being in a closed-in place such as an elevator.
- Other phobias. These phobias involve a fear of choking or vomiting. Among children the fears are of loud sounds, of falling down, and of costumed characters, such as clowns.

The likelihood of experiencing this disorder in one's lifetime is about 8%. It is twice as common (16%) among those between the ages of 13 and 17, but much less common (4%) in the elderly. Women are twice as likely as men to report phobic experiences. Of the various phobias, women are more likely to experience animal, situation-specific, and natural environment phobias (American Psychiatric Association, 2013).

The cause of this disorder is not well understood. Often, there is no explanation for the development of a specific phobia. However, the cause may be traced to a traumatic experience or may develop from a general tendency to be anxious. It usually begins in childhood when exposure to a feared object or situation results in an immediate anxiety response. Experiencing a traumatic event, such as being bitten by a dog, could trigger the development of a phobia. Also, a child may learn phobias by observing a family member's phobic reaction to an object or a situation, such as a fear of dogs.

Treatment

The clinical treatment of this disorder usually involves exposure therapy. Gradual, repeated exposure to the feared object or situation helps individuals to conquer their fear and reduce their anxiety. Cognitive behavior therapy is also used to learn to view and cope with the feared object or situation differently. It focuses on developing a sense of mastery and control over one's thoughts and feelings.

Speech-Language Pathology

Speech-language pathology is a branch of medical treatment to assess, diagnose, treat, and help people who cannot produce speech sounds correctly or clearly.

Description

Speech-language pathologists (SLPs), sometimes called speech therapists, help people with a variety of communication or speech disorders. This includes those who suffer from speech delays and deficits or an inability to speak well because of physical speech limitations. Therapy will include a variety of strategies to improve speech, promote communication through alternative methods, and help with the motor movements of the mouth overall.

Speech-language pathology can be observed in both communication disorders and swallowing disorders. These difficulties are often medically linked to swallowing deficits, which also have their origin or effects in the throat region. When speech is the issue, the focus is on the elements of speech production, which include vocalizing or producing sound, tone, and pitch. When swallowing is the issue, the focus is on the physical components of respiration or breathing.

Speech-language pathologists are trained to screen and diagnose different types of speech-language disorders. They work with individuals and their families (especially those on the autism spectrum) to thoroughly understand the issues before helping choose appropriate intervention strategies and delivery models.

Development (History and Application)

As a distinct endeavor speech-language therapy has existed since the days of Annie Sullivan, who worked with Helen Keller, and Lionel Logue, who worked with King George V. Outside of education and general rehabilitation it became a specialty in the American medical field after George L. Larsen began to do important diagnostic work at the VA hospital in Seattle in the 1960s. He was especially skillful at relating swallowing problems to nervous system impairments, and he pioneered a team approach to speech and swallowing-related issues.

The original focus of speech-language pathology was on those with severe physical vocal restrictions and other language-related issues. The need for this occurred when war veterans after both World War I and World War II returned and required help. It has broadened to include individuals who suffer from the inability to use language with proper meaning as well as those who suffer from problems with the social aspects of communication. This latter group includes many individuals with a variety of developmental and learning disorders. The field of speech-language pathology became increasingly specialized, including formal certification. Today, certified speech therapist professionals work in both medical and educational settings.

Current Status

Today the field of speech-language pathology is well established. There are over 120,000 SLPs in the United States about equally divided between those who work in schools and those who work directly in clinical settings. SLPs who have been trained in the reliable and valid use of diagnostic and assessment tools are qualified to identify a variety of language and speech disorders. They are used frequently as independent or private practitioners who help plan a course of treatment to improve a variety of speech, language, and swallowing disorders.

Speech Sound Disorder

Speech sound disorder (SSD) is described as a difficulty with or delay in the development of speech.

Description

Speech sound disorder is a general category that includes many disorders such as articulation disorder, phonological disorder, and childhood apraxia of speech. They are also referred to as speech impairments or speech difficulties. Specifically, SSD affects children's ability to develop easily understood speech by the time they are about four years old.

In 2008, the American Speech Language Association created separate definitions for different SSDs. It described articulation disorders versus phonological disorders. Articulation disorder includes problems with developing speech sounds. This includes motor speech control issues so that the child will say "yeth" for "yes" where he or she does not yet have the muscle motor control to make the "s" sound. Phonological disorder is comprised of errors that develop into a pattern of speech problems. This disorder has an emphasis on the inability to grasp and apply differences in sound. One example is using "tat" for "cat." In the case of phonological disorder, it is not only articulation that is the problem; it is also the ability to understand and use words well. Other people usually have a difficult time understanding a child with phonological disorder.

If children have poor speech when they start school at about five or six years old, it is likely that their peers and teachers will have difficulty understanding them. It can also negatively impact their ability to learn reading and spelling. About 5% of preschool children are diagnosed with SSD. It is more common in boys than in girls.

Causes

Problems or changes in the structure or shape of the muscles and bones in the head and neck may cause SSD. These are the muscles and bones that are used to make speech sounds. These changes may include cleft palate and problems with the teeth. Another cause can be damage to parts of the brain or the nerves that control how the muscles and other structures work to create speech.

In some cases the cause of phonological disorder in children is unknown. Close relatives may have had speech and language problems. Multiple languages and poor pronunciation at home can complicate the issue.

Symptoms

Children with SSD will substitute, leave off, or change sounds. These errors may make it hard for other people to understand them. Only family members may be able to understand a child who has a very severe phonological speech disorder.

Commonly, children with this disorder have problems with words that begin with two consonants. "Friend" becomes "fiend" and "spoon" becomes "soon." There may also be problems with words that have a certain sound, such as words with "k," "g," or "r." They may either leave them out or not pronounce them clearly, or replace them with a different sound.

It is common for children to have problems pronouncing words while their speech is developing. However, by age three, it is thought that at least half of what a child says should be understandable by a stranger. By the beginning of school, age five or six, a child's speech should be mostly intelligible to everyone.

Treatment

Speech sound disorder should be diagnosed and treated by certified speech-language pathologists. The approach to treatment of SSD is based on principles that emphasize several things. It is important to look into the nature of the SSD with a focus on the person's language skills in combination with his or her motor abilities. It also includes the building of activities that support the child in developing a way to organize his or her speech. This aims to help the child generalize and apply what he or she has learned to other situations. To do this many other therapies may apply, which are core vocabulary therapy, cycles therapy, and imagery therapy.

Before any course of treatment is chosen, children should be examined for other problems. These problems include intellectual disabilities, hearing impairment, neurological problems, and physical conditions such as a cleft palate. In examining each case it is important to evaluate whether relatives have similar problems, and whether more than one language is spoken in the home. In all cases a comprehensive evaluation will help refine the treatment decisions and increase the likelihood of a child's success.

Spiritual Awakening

Spiritual awakening is a life-changing experience in the way an addicted individual thinks and acts. This experience often includes improved mood and increased spirituality.

Definitions

- **Abstinence** is the restraint of indulging oneself in bodily activities that typically gives an individual pleasure (e.g., alcohol and drugs).

- **Addiction** is a chronic disease of the brain, which involves compulsive and uncontrolled pursuit of reward or relief with substance use or other compulsive behaviors.
- **Addiction recovery** is the state of abstinence from addictive behaviors, usually achieved through self-reflection and spiritual exploration.
- **Alcoholics Anonymous** is a self-help fellowship that was founded by Bill Wilson and Dr. Bob Smith in 1935 to help people struggling with alcoholism.
- **Drug abstinence** is when an individual completely discontinues drug or alcohol use for a given period of time.
- **Higher power** is a term used in Alcoholics Anonymous to refer to a "power greater than ourselves." It can include a god, deity, nature, or anything beyond the individual.
- **Narcotics Anonymous** is a self-help and support group for those addicted to drugs to help them learn how to live without the use of mind- and mood-altering chemicals. It is a Twelve-Step Program.
- **Spirituality** is the sum of an individual's unique worldview and self-view, religious beliefs, attitudes, and behaviors.
- **Twelve-Step Program** is a self-help group whose members attempt recovery from various addictions based on a plan called the Twelve Steps.
- **Twelve Steps** refer to the 12 guiding principles on which Alcoholics Anonymous is based.

Description

Spiritual awakening is a major shift in the way an individual struggling with addiction thinks and acts. This change can include abstinence from drugs and alcohol, improved mood and physical health, heightened spirituality, and increased service to others. The term is used synonymously with spiritual experience. The experience is often triggered by a major conflict or "hitting bottom." As a result, individuals who have this experience often report reduced drug or alcohol cravings, abstinence, increased voluntary service, and increased positive mood states. In some cases, the experience can lead to an individual achieving complete recovery from addiction. This experience is clearly spiritual in nature and may or may not involve religion.

The term "spiritual awakening" was originally used in 1939 in the first edition of the Twelve-Step text called "the big book" of Alcoholics Anonymous, which is titled *Alcoholics Anonymous: The Story of How Many Thousands of Men and Women Have Recovered from Alcoholism*. The book was written primarily by Bill W., also known as William Griffith Wilson (1895–1971), who is one of the founding members of Alcoholics Anonymous. The book is for individuals who are working a Twelve-Step Program to manage their addiction to drugs or alcohol. Millions of individuals have sought help for their drug or alcohol addiction by entering Alcoholics Anonymous or Narcotics Anonymous to seek support. Participation in Twelve-Step support groups includes engaging in the Twelve-Step protocol, attending frequent meetings, volunteering for services, and believing in a "higher power." The term "spiritual awakening" is the 12th step of the Twelve Steps. The step is identified as "Having had a spiritual awakening as the result of these steps, we tried to carry this message to alcoholics and to practice these principles in all our affairs."

Research has studied the experience of spiritual awakening and examined traits that characterize the triggering event context and the common reactions of the experience of individuals who are in recovery from drugs or alcohol (Galanter et al., 2014). This concept is a significant component among the field of addiction, Twelve Steps, and spirituality.

Spiritual Bypass

Spiritual bypass is the process of avoiding uncomfortable psychological issues by focusing on spiritual matters.

Definitions

- **Addiction recovery** is the state of abstinence from addictive behaviors, usually achieved through self-reflection and spiritual exploration.
- **Defense mechanisms** are strategies for self-protection against anxiety and other negative emotions that accompany stress.
- **New Age spirituality** is a spiritual movement whose purpose is for individuals to reach their highest potential. It rejects religious doctrine and promotes individual ways of attaining truth.
- **Religion** is a spiritual belief system shared by many individuals that may include specific rules, practices, and institutions.
- **Spirituality** is the sum of an individual's unique worldview and self-view, religious beliefs, attitudes, and behaviors.

Description

Spiritual bypass is a way to avoid dealing with emotional, developmental, and relationship problems. The term "spiritual bypassing" was first used in 1984 by psychologist John Welwood (1943–) and has since been explored by others. Those who use spiritual bypass tend to focus on spiritual issues and practices rather than on the psychological or emotional problems that they experience as threatening. Spiritual issues include abstract ideas like "faith," while specific practices include prayer and meditation. Psychological issues that are avoided may include feelings of anger and sadness, relationship problems, or lack of direction.

Those who use spiritual bypass may appear to be psychologically healthy because of their focus on spirituality. In reality, spiritual bypass leads to underdeveloped coping skills with the result that individuals are less effective in dealing with everyday problems. An example of spiritual bypass is a wife praying about forgiveness in response to her husband's repeated verbal abuse. Rather than address her hurt feelings or the abuse directly, she "bypasses" them using spirituality. As a result, she misses the opportunity to develop new skills that may lead to a better relationship with him. Spiritual bypassing is like taking a shortcut to avoid traffic only to arrive right back where one started.

Interestingly, those using spiritual bypass are likely to have a simplistic and shallow sense of spirituality. In addition, they tend to have an exaggerated sense of detachment from "worldly" problems and blindly follow spiritual rules or practices without question. They may overemphasize positive feelings like happiness and well-being while fearing negative feelings. They are also likely to have relationship problems. These include isolation, people pleasing, and "holier-than-thou" behavior. Spiritual bypass has become increasingly common since the rise of New Age spirituality in the 1960s. It is also common in addiction recovery, which emphasizes spirituality.

This avoidance strategy can be difficult to recognize because spiritual development is generally seen as a healthy and desirable pursuit. What may appear as a positive behavior, such as volunteering at a homeless shelter, can be used to avoid negative feelings like inadequacy or guilt. The way to change spiritual bypass, once it is recognized, is to face difficult or unpleasant emotions and experiences. Counseling can be helpful in this process.

Spiritual Identity

"Spiritual identity" refers to how one relates to, experiences, and incorporates spirituality into their personal sense of self.

Definitions

- **Divine** refers to objects, practices, and experiences associated with God, gods, or a supreme being.
- **Deity** means a god or a supreme being.
- **Religion** refers to the beliefs, doctrines, and practices associated with membership in a specific religious institution.
- **Sacred** refers to revered objects, practices, or experiences that are considered holy or divine by religious individuals.
- **Transcendence** refers to the perception that there are extraordinary dimensions to life that go beyond the limits of our physical reality.

Description

The human experience consists of moral, social, physical, psychological, and spiritual dimensions. All individuals experience some form of spiritual hunger and a desire for self-transcendence that manifest in a search for meaning and purpose. This search results in the development of a spiritual identity that impacts all of the dimensions of life. An individual's spiritual identity will impact how events, experiences, and challenges are responded to. A person's spiritual identity may be expressed through an organized religion but may also be expressed in many other ways. Researchers have noted that in the last quarter of the 20th century Americans have been moving away from traditional religious expressions and seeking a spiritual direction outside of religious traditions to find meaning, purpose, and a sense of inner fulfillment to their lives.

There are multiple conceptions of just how a person's spiritual identity is formed. Douglas MacDonald, a psychologist and researcher of spirituality, conducted a large-scale analysis using data from 1,400 participants and identified five clear factors, or dimensions, related to spiritual development and identity. The first factor is a person's cognitive orientation, or beliefs about spiritual matters, the transcendent, and how personally relevant these beliefs are. The second factor is what kind of spiritual experiences the person has had. The third factor is a person's sense of existential well-being, or his or her sense of purpose and meaning, and how he or she copes with uncertainty such as the meaning of death. The fourth factor is belief in the paranormal. The fifth factor is religiousness and his or her belief in the existence of a higher power/intelligence and how sincere these beliefs are.

Other conceptions of spiritual identity view the process as a spiritual journey that shares common themes. Hope provides a sense that difficult or painful experiences have meaning and are not in vain. Hope allows individuals to endure hardship and look toward a better future. Virtue and character is the power to live a genuine life as a unique individual with a sense of social-minded obligation toward others. The search for the sacred or holy in an attitude of receptivity to what the future may bring and of how the divine within would emerge in wholeness of self is part of the spiritual journey. Spiritual identity involves reconciling polarities and ambiguity such as good and evil, happiness and sorrow, life and death. It also calls for balance of activity and patience, contemplation and action, self and others. Facing oneself by confronting the difference between the real self and the ideal self is an important part of one's spiritual identity. Compassion,

love, and forgiveness are vital spiritual themes that assist a person in being tolerant, empathic, helpful, and caring. The process of developing spiritual meaning in life is central to a sense of spiritual peace and well-being. Transcendence and going beyond ordinary or personal limits, feeling a sense of spiritual union and self-forgetfulness, is another characteristic of spiritual development and identity.

Spirituality is highly related to psychological well-being, and one's spiritual identity impacts how one interprets events and responds to stress. Spirituality and spiritual identity is related to a one's sense of meaning and purpose, hope and optimism, and social connectedness.

Spirituality and Practices

"Spirituality" refers to one's sense of awareness and connection with the divine, sacred, transcendent, Supreme Being, or higher power.

Definitions

- **Deity** means a god or a supreme being.
- **Divine** refers to objects, practices, and experiences associated with God, gods, or a supreme being.
- **Religion** refers to the beliefs, doctrines, and practices associated with membership in a specific religious institution.
- **Rituals** are a series or sequence of actions and behaviors performed in a specific order.
- **Sacred** is defined as those things that are holy, "set apart," and include objects, rites, and rituals.
- **Transcendence** refers to the perception that there are extraordinary dimensions to life that go beyond the limits of our physical reality.

Description

An individual's search for meaning, fulfillment, purpose, and ways of coping with problems often involves a spiritual journey. Interest in spirituality within the professional mental health communities has grown steadily over the past three decades. The role a person's spirituality plays in an individual's sense of self, well-being, and healthy functionality has been the focus of attention by both clinicians and researchers. Spiritual issues most often surface as a result of loss, conflicts, or health problems; because of events that cause a crisis in faith such as victimization, betrayal, or the sudden death of a loved one; or as a desire to increase well-being.

There are many perspectives on spirituality, and definitions continue to evolve over time. A person's spirituality should not be confused with being religious. The word "religion" is more frequently being associated with specific faith institutions and the beliefs, doctrines, and practices that express that religion. Religious practices include attending worship services, praying, reading holy text, singing, and other acts of devotion. A person's religious orientation, or religiousness, may be "intrinsic" or "extrinsic." A person with an intrinsic religious orientation participates in religious activities as a sincere form of worship in order to express his or her faith and devotion. The person's religion is a positive motivating force resulting in personal growth and increased well-being. A person with an extrinsic religious orientation may participate in religious practices but only because he or she gets something out of it, such as feeling good about

himself or herself, social gain such as meeting potential business clients, or the approval of others such as parents or teachers. Their religion is not a motivating or growth-promoting force. An example of this would be the politician who attends church in order to get the votes of religious people.

Spirituality is a complex concept, and although there is no consensus definition, it is possible to identify common components to most conceptualizations. Spirituality is universal and innate, spontaneous and developmental, private and highly personal. It is both an emotional and intellectual pursuit. Spirituality involves the capacity to seek out and transcend one's physical reality in order to experience the sacred in a search for meaning, purpose, and connectedness. Spirituality positively impacts a person's sense of well-being, as well as his or her mental, emotional, and physical health. Researchers have found that spirituality and intrinsic religiosity are linked to greater longevity, positive health outcomes, better coping skills, less depression, less anxiety, and higher quality of life even when coping with severe illness.

Spiritual wellness and a clear sense of spiritual identity can provide a consistent theme for one's life; a sense of connection to others as well as to the transcendent; and a sense of purpose, motivation, and vitality. Spiritual practices include prayer in order to express thoughts, needs, and attitudes toward the divine or sacred; meditation in order to reduce stress, find peace, or connect to the transcendent; use of ritual such as communion or purification ceremony; spiritual journaling providing a way to express, ponder, and develop spiritual insights; and bibliotherapy or reading spiritual texts. Practicing spiritual disciplines include forgiveness of self and others; confession in which one acknowledges one's wrongdoings or transgressions; and surrender that involves relinquishing the need to control others and acceptance of the direction of one's life.

Spirituality is an important aspect of an individual's search for meaning, fulfillment, and purpose. Developing a clear sense of spirituality can increase well-being, enhance abilities to cope, and provide a sense of connectedness to others and to the greater whole.

Spiritually Oriented Psychotherapy

Spiritually oriented psychotherapy is a form of psychotherapy that is sensitive to spiritual, religious, and life meaning considerations.

Definitions

- **Psychotherapy** is a psychological method for achieving desired changes in thinking, feeling, and behavior.
- **Religion** refers to the search for significance through the sacred. It typically involves dogma (belief system) and rituals, which often are communal.
- **Spirituality** refers to the search that reflects one's deepest desires and the ways in which individuals think, feel, act, and relate in their efforts to find, conserve, and transform the sacred in their lives.

Description

Believing that spirituality is vital for growth and essential for dealing with life's problems, many individuals are pursuing a journey of spiritual growth. Pursuing this

journey typically involves a commitment to engaging in spiritual practices such as prayer and meditation. As a result of this pursuit, some are finding their lives are more centered and fulfilling, whereas others are finding themselves trapped in old feelings, attitudes, and habits that appear to undo their progress. Even those who have made progress on the journey often encounter spiritual and psychological roadblocks to growth. For a number of reasons, many individuals are turning to psychotherapy rather than to ministers, rabbis, and other spiritual guides for spiritual advice. In addition, those who are already in conventional psychotherapy expect that therapy will focus on their spiritual concerns.

Spiritually oriented psychotherapy is psychotherapy that is sensitive to spiritual, religious, and life meaning considerations whether it is formally designed as spiritually oriented psychotherapy or not. Spiritual considerations include the individual's relationship with God or higher power, prayer life, and spiritual practices as well as involvement in a faith community. Religious considerations include one's beliefs about God, faith, doctrine, salvation, denominational affiliation, and the afterlife. Unlike psychotherapy, personality change is not usually a goal of pastoral counseling. Life meaning considerations include one's purpose or calling in life and one's sense of belonging and connection with others.

There are three clinical contexts in psychotherapy in which religious, spiritual, and life meaning considerations are likely to surface. The first context is a spiritual resource for coping with a serious health problem, personal or professional loss, or interpersonal conflict, for example, situations involving betrayal and death of a child. The second context is a sense of loss resulting in symptoms that reflect a crisis of faith or of meaning in life. The third context is the quest for increased well-being and spiritual growth. While a focus on spiritual growth may seem more consistent with traditional spiritual direction, clients today are increasing seeking out psychotherapists rather than ministers and other spiritual guides to foster their spiritual growth and development.

Developments and Current Status

Spiritually oriented psychotherapy is similar but different from pastoral counseling and spiritual direction. Basically, the primary goal of pastoral counseling is spiritual change, while psychological change is a secondary goal. As such, pastoral counseling can also address symptom relief, problem resolution, and the restoration of psychological health. The primary goal of spiritual direction is spiritual change and growth with a focus on prayer. It may also address crisis issues that impact the directee's spiritual life. Yet its primary emphasis is on developing the directee's relationship with God. Because prayer is critical to this relationship, the directee's prayer life is a major consideration. In contrast, the primary goal of spiritually oriented psychotherapy is psychological change and secondary goal is spiritual change or growth. Often, the focus is on the development and maintenance of psychological health and well-being and subsequent spiritual health and well-being.

Spiritually oriented psychotherapy is a broad characterization for a variety of psychotherapeutic approaches that are sensitive to the spiritual dimension. These approaches range from non-Christian approaches, transpersonal psychotherapies, and various Christian approaches. Despite considerable variability among these approaches, some general observations about typical clientele, goals and purposes, the nature of the relationship with the professional, and the type of interventions utilized in spiritually oriented psychotherapy are possible. Individuals seeking spiritually oriented psychotherapy range from relatively healthy spiritual seekers to disordered clients presenting with symptomatic distress and/or impairment in one or more areas of life functioning. The goals of treatment vary according to client presentation and need. They may include help with spiritual emergencies, the process of spiritual growth, increased psychological well-being, self-fulfillment or individuation, or the reduction of symptomatic distress and the restoration of baseline functioning. The therapeutic relationship typically involves mutual collaboration. Not surprisingly, those practicing spiritually oriented psychotherapy presumably will demonstrate respect for the client's spiritual values and concerns. Various psychotherapeutic and psychospiritual interventions are utilized depending on client need and indication. If indicated, referral for a psychiatric evaluation for medication or hospitalization may occur. Spiritual interventions may also

be involved. These include spiritual practices, such as prayer and meditation, and, when indicated, collaboration or referral to clergy or chaplain.

Split Brain

"Split brain" refers to the experiments that were conducted by Roger Sperry to learn about the left and right hemispheres of the brain.

Description

The split brain experiments began in an attempt to learn more about the brain as well as to gain a better understanding of epilepsy. In completing this study Dr. Roger Sperry (1913–1994) and his colleagues were able to learn about the differences between the right and left hemispheres of the brain and what happens when they don't or cannot communicate with each other. Sperry was an American neuropsychologist who earned a Nobel Prize in physiology or medicine in 1981 for his discoveries.

This study led to the realization that the two hemispheres of the brain control different parts of thought as well as action. This meant that the right and left parts of the brain had an area of specialization. The left brain for language and speech and the right for visual-motor tasks. This idea has translated into modern culture where people will casually refer to themselves as being right or left brained based on the areas of interest and skills. For instance, a writer may refer to himself or herself as being left brained as the basis of what he or she does is controlled by the left part of the brain.

The original study provided information about how the halves of the brain communicate to each other and how they do so if separation occurs. This revelation has been helpful in preparing doctors to better understand patients who come in with medical issues such as epilepsy or traumatic brain injury. The study provided information on language, attention, the organization of the brain and consciousness.

The study consisted of 11 participants whose hemispheres had been separated and all had a history of epilepsy. This case study provided in-depth investigations of each of the individuals. Participants were asked to complete tasks and with different tasks part of their vision blocked or covered.

The split brain experiment looked at patients whose hemispheres were already separated. The experiment provided evidence that when the brain had a disconnect it impacted the person on multiple levels. Conflicting demands from each of the hemispheres can have an impact on task completion and communication. However, these separated hemispheres allowed for Sperry and his colleagues to gain an understanding that had not existed previously to how each functioned and what tasks each controlled.

Sports Psychology

Sport psychology is a multidisciplinary field that focuses on psychological factors affecting the performance and well-being of athletes; systemic issues associated with sports settings and organizations; and developmental and social aspects of sports participation.

Definitions

- **Kinesiology** is the study of anatomy, physiology, and the mechanics of body movements.
- **Sport sciences** include fields such as kinesiology, biomechanics, sport management, sport physiology, sport nutrition, and athletic training.

Description

Sports psychology is a multidisciplinary field of study that focuses on health and exercise psychology, athletic performance psychology, and social psychology. The term "psychology" as applied to sports includes counseling, developmental, clinical, and social psychology. Sports psychology professionals include psychologists, social workers, mental health counselors, and industrial-organizational psychologists.

Health and exercise psychology focuses on psychological factors in sports and exercise related to athletic performance, disease development, and remediation; injury impact and recovery; health promotion; and sports related anxiety and stress. Areas addressed included exercise adherence, impact of exercise on mood and quality of life, and promotion and maintenance of health-enhancing behaviors over the life span. Use of sports and exercise in stress reduction and management as well as cognitive behavioral change strategies in treating performance and physique anxiety, disordered eating, exercise addiction, and movement disorders are also a focus of intervention by sports psychology professionals. Performance psychology focuses on the improvement of athletic performance in competition. Enhancing performance through mental strategies that target overcoming the pressure of competition and managing performance stress related to other's expectations such as coaches, teammates, and parents are frequently provided services. Social psychology focuses on individual and group dynamics in sport and exercise participation and settings.

Development

Coleman R. Griffith (1893–1966) is credited as the founder of sports psychology in North America. Griffith made numerous contributions to the field and in 1923 taught the first university course in sports psychology. The field expanded due to Griffith's pioneering work as other researchers began to contribute to the investigation of psychological processes at work in athletic performance. In 1979 the *Journal of Sports Psychology* became the first published professional journal. In 1986 a group of sports psychologists led by John Silva formed the Association for the Advancement of Applied Sports Psychology, later dropping the word "Advancement" and becoming the Association of Applied Sports Psychology (AASP). The AASP was formed in recognition of the need to emphasize the application of research knowledge to athletes and athletic groups. Also in 1986, members of the American Psychological Association (APA) formed Division 47: Exercise and Sport Psychology.

Current Status

AASP is an international, multidisciplinary, professional organization with over 1,600 members in 39 countries. It is the largest certification body designating qualified sports psychology professionals as "AASP Certified Consultants." Only Certified Consultants may use the letters CC-AASP after their names. Certification as a CC-AASP requires membership in AASP, a master's or doctorate degree with specific course work in sport and exercise psychology, 400 hours of mentored and applied experience, and an extensive evaluation process conducted by the AASP Certification Review Committee. Graduate degrees applicable to CC-AASP status include clinical psychology, educational and mental health counseling, clinical social work, industrial-organizational psychology, and sport and exercise psychology from a sport science field. CC-AASP is the only certification recognized by the United States Olympic Committee. It is important to note that CC-AASP is a credentialing

process and does not bar individuals without CC-AASP from practicing sports psychology.

Sports psychology is emerging as a distinct profession and has made steady progress over the past two decades. A growing number of professional athletes seek out and acknowledge working with sports psychology professionals, and both amateur and professional trainers are making increasing referrals to sports psychology professionals. In addition, university and high school coaches are increasingly drawing from the growing body of literature and research, which focuses on game preparation, teamwork, and psychological performance enhancement techniques.

St. John's Wort

St. John's wort is an herbal remedy used to treat symptoms of depression and various medical conditions.

Definitions

- **Immunosuppressants** are medications that lower the body's immune system. They are primarily used to help the body accept a transplanted organ.
- **Monoamine oxidase inhibitors** are a group of antidepressant drugs that decrease the activity of monoamine oxidase, a neurotransmitter found in the brain that affects mood.
- **Selective serotonin reuptake inhibitors** are a class of antidepressant medications that work by blocking the reabsorption of serotonin in nerve cells and raising its level in the brain.
- **Serotonin syndrome** is a serious medication reaction resulting from an excess of serotonin in the brain. It occurs when medications that increase serotonin are taken together. Symptoms

St. John's wort is an herbal remedy sometimes used to treat symptoms of depression and various medical conditions. (iStockPhoto)

include high blood pressure, high fever, headache, delirium, shock, and coma.

Description

St. John's wort is a perennial, yellow-flowering plant and is so named because it blooms about June 24, the birthday of John the Baptist. "Wort" is an old English word for plant. For centuries it has been used as treatment for depression, anxiety, inflammation, injuries, burns, muscle pain, high blood pressure, stomach problems, fluid retention, insomnia, hemorrhoids, and cancer. Research has proven the clinical effectiveness of St. John's wort in treating mild-to-moderate depression. It also shows promise in treating somatoform disorders, but the research on its treatment of anxiety is conflicting and inconclusive.

Hypericin and hyperforin are two chemicals in St. John's wort that play a role in relieving depressive symptoms. Both act on chemical messengers in the nervous system that regulate mood. St. John's wort is believed to work by balancing neurotransmitters (chemical messengers) in the brain in much the same way as SSRIs like Paxil and Celexa, and MAOIs like Marplan and Parnate

Precautions and Side Effects

There are a number of precautions to observe in using St. John's wort. Depression can be a serious, even life-threatening, condition. For that reason depressed individuals using St. John's wort must be carefully monitored. It can bring on mania in those with bipolar disorder and can increase cycling between depression and mania. St. John's wort could worsen symptoms of attention-deficit hyperactivity disorder, especially in those taking Ritalin. It might trigger psychotic symptoms in some with schizophrenia. St. John's wort can contribute to dementia in people with Alzheimer's disease. Pregnant or lactating women should never use it. Nursing infants of mothers who take St. John's wort can experience colic, drowsiness, and listlessness.

St. John's wort is generally safe when taken for the short term (three to four months). It can cause some side effects such as anxiety, diarrhea, dizziness, dry mouth, fatigue, headache, irritability, restlessness, trouble sleeping, vivid dreams, stomach upset, skin rash due to sun sensitivity, and tingling. It appears to be safe when used in children under 12 years of age for less than six weeks.

Dangerous interactions can occur when using St. John's wort with other antidepressant medicines. Of particular concern is serotonin syndrome. Several cases of serotonin syndrome have been reported in those taking St. John's wort in combination with MAOIs, SSRIs, Pondimin, or Serzone. John's wort may interfere with the effectiveness of birth control pills, increasing the risk of pregnancy. Also, women taking both birth control pills and St. John's wort may notice bleeding between menstrual periods. Other medications with reported interactions include amphetamines, asthma inhalants, decongestants, diet pills, narcotics, and the amino acids tryptophan and tyrosine. St. John's wort increases bleeding time in those under general anesthesia. Accordingly, its use should be discontinued at least two weeks prior to major surgery.

Stages of Change

Stages of change are sequential periods of time that describe clients' varying motivation, readiness, and process of engagement in change behaviors.

Definitions

- **Assimilative integration** occurs when one theoretical orientation primarily informs the psychotherapeutic process and techniques of other theories are deliberately adjunctive.

- **Common factors** are the similarities among theories of psychotherapy and the belief that these common factors are the real therapeutic factors.
- **Evidence-based practice** is a form of practice that is based on integration of the best research evidence with clinical experience and client values.
- **Motivational interviewing** is a form of psychotherapy that aims to enable, engage, and improve on a client's motivation to change.
- **Psychotherapy** is a psychological method for achieving desired changes in thinking, feeling, and behavior. It is also called therapeutic counseling.
- **Self-efficacy** is the belief in one's own abilities.
- **Technical eclecticism** is the psychotherapeutic use of intervention techniques from various theories without endorsing the theories themselves.
- **Theoretical integration** is the assimilation of two or more theories of psychotherapy.
- **Transtheoretical therapy** is an integrative approach to psychotherapy that identifies processes of change, stages of change, and levels of change to tailor treatment to the client.

Description

The stages of change are often conceptualized as a process that occurs over a period of time. Traditionally there are five stages of change: precontemplation, contemplation, preparation, action, and maintenance. The first stage of change, precontemplation, is marked by the client's absence of thought about change. After passing through precontemplation a client will enter the contemplation stage of change. In the contemplation stage a client will begin to think about his or her problems and imagine what he or she can do to change. After thinking about change sufficiently in the contemplation stage, a client will progress on to the preparation stage of change. The preparation stage of change is marked by the first attempts to actually change; however, the client still lacks a full commitment to the change process. Next is the action stage of change where clients are serious and committed to their change efforts. Finally, after a client has successfully made the change, he or she will enter the maintenance stage of change. In the maintenance stage of change, a client will strive to preserve therapeutic gains and prevent relapse.

It is important to note that the stages of change model is unique in that it allows psychotherapy to be personalized to the specific stage of change a client is operating from. Further, motivational interviewing is a commonly utilized technique to foster a client's movement through the stages of change.

Development and Current Status

The stages of change theory is the most well-developed approach to come out of the eclectic and integrative psychotherapeutic movement that began in the 1930s. The early years of the movement is famously discussed in a paper published by psychologist Saul Rosenzweig (1907–2004) in 1936. It examined the common factors among the diverse theories of psychotherapy. Over the years three other distinct approaches to eclecticism and integrationism were identified and named technical eclecticism, theoretical integration, and assimilative integration. The stages of change model is part of the theoretical integration approach to psychotherapy. It is also part of a larger psychotherapeutic theory called the transtheoretical model introduced by psychologists James Prochaska (1943–) and Carlo DiClemente (1940–) in 1983. In 2007, the stages of change model was expanded to include two additional stages of change, which are recycling and termination. Recycling alters the linear process of change to incorporate the common occurrence of relapse. When clients do not maintain change, they recycle to an earlier stage of change. "Termination" refers to a stage of client change that is stable enough to remove the threat of relapse. In the stages of change model, termination is the successful resolution of a problem through sufficient change.

Stanford Prison Experiment

The Stanford Prison Experiment, conducted by psychologists at Stanford University in 1971, demonstrated the influence of situational forces on changing the attitudes, values, and behavior of normal, healthy individuals.

Definitions

- The **"Lucifer Effect,"** a phrase coined by Stanford psychologist Philip Zimbardo, refers to the point in time when an ordinary, good person transforms into an evil one as a result of situational influences.
- **Obedience studies** ("Milgram's Experiments"), led by psychologist Stanley Milgram during the early 1960s, articulated the salience of real or perceived authority at influencing a human being's thoughts, values, and actions.

Description

In 1971, psychologists at Stanford University conducted an extreme study, now known as the Stanford Prison Experiment, with a volunteer group of college students using a mock prison setting to test the power of social and institutional influence on individual attitudes, values, and behavior. Lead researcher Dr. Philip Zimbardo, a former high school classmate of Stanley Milgram, sought to expand on Milgram's obedience studies, looking specifically at the impact of institutional factors. The primary question at hand is whether or not normal, healthy, well-functioning individuals would change under stressful, dehumanizing, and hostile circumstances. The results were alarming, causing the experiment to be called off early. Zimbardo summarized the findings in what he called the "Lucifer Effect," whereby ordinary, good people behave in evil ways if the situation perpetuates it. He wrote about the experiment and his subsequent impressions in the *New York Times* best seller *The Lucifer Effect* in 2007.

Development

The Stanford Experiment's research team included Dr. Zimbardo, Craig Haney, Curtis Banks, David Jaffe, and Carlo Prescott. Some more than 70 college students from the United States and Canada responded to an ad in the newspaper requesting participation in a study on prison life in exchange for $15 a day. Each potential participant was interviewed, subjected to a background check, administered a personality assessment, and examined for physical and mental health. Twenty-four males were selected and randomly assigned to be either guards or prisoners; 9 guards and 9 prisoners (18 total) were actively involved in the study, while the others remained on call if needed. The experiment was planned to last for a one- to two-week period. Researchers attempted to simulate a real incarceration setting in the basement of Stanford's psychology building. This mock prison consisted of three, six-by-nine-foot cells with three cots in each, a room for the guards, an office for the warden (Jaffe), a small room designated as "solitary confinement," and another small room deemed the prison yard. Prisoners were subjected to commonly experienced circumstances of incarceration: cell confinement, limited privileges, regulated meals, and verbal and physical degradation. They were not permitted to leave the prison at any time. The guards were assigned to three-man teams and required to work eight-hour shifts, but could return home when their shift was over. On day 6 the experiment had to be shut down after a graduate student, Christina Maslauch, raised concerns

about the behaviors she witnessed among the guards and prisoners. The guards were abusing their power, treating the prisoners in aggressive and dehumanizing ways. The prisoners were affected as well, and either rebelled or retreated, but actively displayed signs of stress, anxiety, and depression. Even the researchers themselves, Zimbardo and Jaffe included, who were videotaping the daily happenings became caught up in the simulation and neglected to stop the injustices. The Stanford Prison Experiment is a poignant example of how situational influences can alter a person's thoughts, feelings, and actions.

Current Status and Results

Critics of the study refer to concerns pertaining to generalizability, validity, and researcher bias. Though it would now be in violation of many ethical codes, the Stanford Prison Experiment has added valuable insight into the psychological and sociological study of obedience to authority and to the critical role that power plays in determining one's sense of control, freedom, and choice. The lessons of this experiment extend to the areas of education, social sciences, human rights, and national defense, and the study's findings have been applied to situations ranging from bullying among school children to abuse in the military to acts of terrorism. The incidences that occurred at Abu Ghraib Prison during 2003–2004 where Iraqi prisoners were subject to abuses by U.S. Army reservists articulate a recent example of the existence of this phenomenon. Instances such as these have created a national dialogue and spawned research into preventing these types of evils in the future.

STEP Parenting Program

STEP parenting program teaches basic skills to help parents relate more effectively with their children. It is also called systematic training for effective parenting program.

Definitions

- **Adlerian psychology** is an approach to psychology that understands individuals within their social context, particularly their families. Accordingly, parenting is emphasized.
- **Assumed inadequacy** is when a child gives up to be left alone so that others will expect little from him or her.
- **Attention seeking** is when a child keeps others busy through various behaviors to seek attention.
- **Parenting** is a process of educating and coaching parents to support children's development and change their problem behaviors.
- **Power** is when a child seeks power to feel in control and a sense of belonging.
- **Psychoeducation** is done by educating clients who are receiving counseling services through informative materials or verbally sharing information that has a psychological basis.
- **Revenge** is when a child seeks to get even or to retaliate for a previously perceived wrong doing of another person.

Description

The STEP parenting program teaches basic parenting skills such as communication, positive discipline, and boundaries setting. It is a seven-session course that teaches parents about dealing with conflict in the family and also enhancing communication. STEP is based on Adlerian psychology. The program is facilitated by

a designated facilitator and also includes reading materials and a parent survey. The seven sessions cover the following topics:

1. Understanding Yourself and Your Child
2. Understanding Beliefs and Feelings
3. Encouraging Your Child and Yourself
4. Listening and Talking to Your Child
5. Helping Children Learn to Cooperate
6. Discipline That Makes Sense
7. Choosing Your Approach

The program includes the following methods of instruction and learning: role plays, group discussions, analyzing videos, analysis of challenging situations, and homework. Some of the skills and content that are covered include reflective listening, using I-messages, utilizing family meeting, exploring alternatives for solving problems, using natural and creating logical consequences of an action, showing respect, and identifying the four goals of misbehavior. The four goals of misbehavior include power, revenge, assumed inadequacy, and attention seeking. There are four versions of the STEP program available: Early Childhood STEP for parents of children up to age 6; STEP for parents of children ages 6 to 12; STEP/Teen for parents of teens; and Spanish STEP, which is a complete translation of the STEP program for parents of children ages 6 to 12.

Developments and Current Status

This program was created by Adlerian psychology practitioners and authors: Don Dinkmeyer, Sr. (1924–2001), Gary D. McKay, and Don Dinkmeyer, Jr. STEP has been taught to over 4 million parents and has been translated into Japanese, French, Korean, Chinese, German, and Spanish. The STEP program is still utilized today throughout the world and is considered an evidenced-based program.

Stereotypic Movement Disorder

Stereotypic movement disorder is a mental disorder characterized by repeated and purposeless physical movements that cause distress or impairment.

Definitions

- **Antipsychotic medications** are prescription drugs used to treat psychotic disorders. They are sometimes referred to as antipsychotics or neuroleptics.
- **Autism spectrum disorder** is a mental disorder characterized by impaired social and communication skills, repetitive behaviors, and a restricted range of emotions and interests.
- **Behavior therapy** is a form of psychotherapy that focuses on identifying and changing maladaptive behaviors.
- **DSM-5** stands for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, which is a diagnostic system used by professionals to identify mental disorders with specific diagnostic criteria.
- **Neurodevelopmental disorders** are neurological disorders characterized by impairments of the growth and development of the brain or central nervous system.
- **Obsessive-compulsive disorder** is a mental disorder characterized by unwanted and repeated thoughts and feelings (obsessions), or

behaviors that one feel driven to perform (compulsions). It is commonly referred to as OCD.

- **Tourette's syndrome** is a neurological disorder characterized by recurrent involuntary movements and vocal tics such as grunts, barks, or words, including obscenities.

Description and Diagnosis

Stereotypic movement disorder is one of the DSM-5 neurodevelopmental disorders. It is characterized by repeated, rhythmic, and purposeless movements of the body. These may be harmless or cause harm (self-injury) to the individual. Examples of harmless behaviors include body rocking, hand waving, and head nodding. Harmful behaviors include head banging, face slapping, eye poking, and biting. Individuals typically develop a specific pattern of these movements. Movements may occur multiple times per day or there may be weeks in between episodes. They may occur generally or in specific situations, such as when individuals are under stress, bored, or excited. There are simple and complex stereotypic movements. Simple stereotypic movements are common during childhood development. These movements begin in the first year of life and generally disappear by age three. For example, infants often make repetitive sucking motions. This serves the purpose of getting food and developing motor skills. These types of movements are not considered harmful or purposeless and are not evidence of stereotypic movement disorder.

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, individuals can be diagnosed with this disorder if they exhibit repetitive and purposeless movements. The movements must cause harm or interfere with individuals' daily lives, such as in school, work, and social interactions. There must not be any other direct cause for the movements, such as the effects of substances like stimulants. Symptoms must also appear during early childhood development (American Psychiatric Association, 2013). Stereotypic movement disorder is different from other mental disorders that involve repetitive movement, like obsessive-compulsive disorder and Tourette's syndrome. These disorders occur later in development.

The exact causes of this disorder are unknown. It is believed that inadequate caregiving or social isolation during childhood can lead to these movements. This may be because movement relieves anxiety or produces self-soothing (activities that comfort and nurture). Stereotypic movement disorder is common in individuals who are institutionalized. Another possible explanation is the presence of other neurodevelopmental disorders like autism spectrum disorder. Movements may indicate underlying medical conditions such as infection and seizures.

Treatment

There is no cure for stereotypic movement disorder. Treatment usually focuses on decreasing harmful behaviors. This may involve behavior therapy and antipsychotic medications. In extreme cases, individuals are physically restrained to keep them from harming themselves. Occasionally, movements may disappear naturally as individuals age. Others may experience them throughout life. Currently, there is no way to prevent the development of this disorder.

Stigma

Stigma is a negative judgment made by an individual or group, which results in isolation or rejection of the persons being judged.

Description

Being excluded from a desirable social group is something that almost everyone experiences during the course of his or her life. From a therapeutic or psychological point of view, social stigma is of interest because of the extreme or lasting negative impact that rejection, exclusion, and marginalization can have on individuals. Stigma occurs among a variety of individuals and groups whose beliefs or lifestyles do not fit the norm. This can be based on ethnicity, religion, race, or other demographic factors. Stigma is often associated with those who suffer from mental illness. Stigma is usually applied because those with mental disorders may exhibit behaviors or characteristics that are found morally or socially unacceptable by the majority.

In the 1890s social scientists began to deal with the negative effect that the reactions of others can have on the excluded person's sense of identity. It was Canadian sociologist Erving Goffman's book *Stigma: Notes on the Management of Spoiled Identity* that brought this issue to international public awareness. Since that time many psychologists have explored the effects of social stigmatization on individual identity, subgroups, and those with mental health issues.

Stigma and shame are very closely connected because being judged negatively results in feelings of rejection, unworthiness, and embarrassment. This in turn leads some stigmatized people to try to hide their identity, known as concealment. Their values and feelings are often hidden from others. Concealment can be applied to someone's background, experience, or culture. It is damaging when people are forced to disguise themselves because they fear rejection or even physical and psychological personal threats. Stigmatization has demonstrated negative effects on one's self-esteem, academic achievement, and general health.

For many societies and cultures, mental illness is a stigma that means automatic rejection from others. This includes placing people into categories such as crazy or deranged. Society has a tendency to label those who suffer from more severe conditions as potentially dangerous. This kind of stereotyping can place added pressure on individuals with mental disorders who are already suffering from identity and inclusion issues. In some cases, the results of stigmatization can cause additional life stressors that challenge their already poor coping skills.

Current Status and Impact (Psychological Influence)

Although social norms and standards are constantly changing, counselors need to be aware that clients may not immediately be able to identify the effects of stigma in their life. Such diverse factors as ethnicity, sexual orientation, and socioeconomic status may lead to stigmas that affect clients psychologically. Clients may present with depression or other issues related to their self-identity. It is important for counselors to consider the issue of stigmatization for each client. The very event of seeking help or getting counseling can be a stigmatizing process itself. Most therapists can be trained on the different ways that the effects of stigma are expressed.

It is important for health-care professionals to be able to recognize the impact of stigma and its causative role in mental health and psychological problems. This is key to developing successful strategies for intervention. These interventions may take various forms from identifying and targeting stigma or stress-related health problems to helping the client decrease his or her vulnerability to being stereotyped. A focus on strengthening resilience for individuals so that they can overcome issues surrounding stigma is one effective tool. Not all the issues connected with stigmatization can be handled in clinical therapeutic settings. Many stigmatized issues require social action and political change.

The concept of stigma has been criticized for being too vague and overly focused on the individual. Nevertheless, the fact that individuals and groups are rejected and isolated socially or politically is a reality. This is especially true for those who have been diagnosed with and treated for mental health issues. Being diagnosed with a mental disorder can have negative effects on a person's life, including lower salaries, less access to housing, the potential for criminal involvement, and vulnerabilities to physical health problems. Many argue that the stigma associated with mental disorders puts people at a clear disadvantage and can negatively impact their prognosis and quality of life.

Stimulant Use Disorder

Stimulant use disorder is a mental disorder that is characterized by the use of stimulants leading to significant problems for the user. It includes stimulants such as amphetamine and cocaine, but not caffeine or nicotine.

Definitions

- **Addiction** is a chronic disease of the brain, which involves compulsive and uncontrolled pursuit of reward or relief with substance use or other compulsive behaviors.
- **Benzodiazepines** are a class of medications that slow the nervous system and are prescribed to relieve nervousness and tension, to induce sleep, and to treat other symptoms. They can be highly addictive.
- **Cognitive behavior therapy** is a type of psychotherapy that focuses on maladaptive (problematic) behaviors, emotions, and thoughts. It is also called CBT.
- **Detoxification** is a medical treatment for drug addiction that removes the physiological effects of the addictive substance and withdrawal from it.
- **Dopamine** is the chemical messenger in the brain responsible for coordinating the movement of voluntary muscle groups. It also regulates attention, pleasure, and coping with stress.
- **Stimulant** is a drug that increases brain activity and produces a sense of alertness, euphoria, endurance, and productivity, or suppresses appetite. Examples are cocaine, amphetamines, and Ritalin.
- **Substance-related and addictive disorders** are a group of mental disorders that include substance disorders characterized by physiological dependence, drug-seeking behavior, tolerance, and social withdrawal. This group also includes the non-substance disorder of gambling.

Description and Diagnosis

Stimulant use disorder is one of the substance-related and addictive disorders. It is characterized by a pattern of stimulant use that results in significant distress or disrupted functioning within a period of 12 months. This disorder includes amphetamine, cocaine, MDMA, ecstasy, and other stimulants but not caffeine or nicotine. Stimulants cause a buildup of dopamine in the brain, which leads to its many effects including intense pleasure and increased energy. The most often abused stimulants are of two types: amphetamine-like stimulants and cocaine. It is estimated that approximately 0.2% of the adult population are addicted to amphetamine-type stimulants and 0.3% are addicted to cocaine (American Psychiatric Association, 2013).

Amphetamines produce feelings of euphoria, provide relief from fatigue, increase mental alertness, and enhance mood. Negative short-term side effects include anxiety, confusion, paranoia, and aggression. Chronic use can result in side effects such as depression, psychotic behavior, and hallucinations. It can also lead to respiratory problems, cardiovascular problems, and extreme weight loss. Other dangers include infectious disease (due to shared needle use), intense cravings, and extremely poor oral hygiene. Cocaine produces feelings of profound well-being, enhanced alertness, and increased energy and strength. It also increases self-confidence, sexual drive, and a sense of mastery and power, while decreasing anxiety. Dangers include severe cardiovascular problems, irritability, nervousness, and agitation. Its long-term use leads to fewer dopamine (brain

chemical) receptors. That results in decreased ability to experience pleasure as well as nasal cavity irritation, problems swallowing, and lung damage.

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, individuals can be diagnosed with this disorder if they exhibit a problematic pattern of cannabis use, leading to significant impairment or distress. This must occur within a 12-month period. This includes taking the substance in larger amounts or for longer than intended. It means wanting to cut down or stop using the substance but not achieving this goal. It involves spending much time getting, using, or recovering from use of the substance. This disorder also involves cravings and urges to use the substance, and continuing to use, even when it causes problems in relationships. It involves failure to meet obligations at home, work, or school because of substance use. It also means reducing or stopping important social, work, or recreational activities because of substance use. This disorder involves repeated substance use even when it is physically dangerous. Despite knowing the risks of the physical and psychological problem that are caused or made worse by the substance, use of it continues. It means develop tolerance (needing more of it to get the desired effect). Finally, it involves withdrawal symptoms, which can be relieved by taking more of the substance (American Psychiatric Association, 2013).

Adolescents and adults use and abuse stimulants for various reasons. These include feeling good, getting high, relaxing, or relieving tension. Other reasons include reducing appetite and increasing alertness, and preventing withdrawal symptoms. These drugs are also used to be accepted by peers (amid peer pressure) or to be more social. Finally, they are used to improve concentration and work or academic performance. These drugs are also used by those with bipolar disorder. From a psychological perspective, stimulant use can also serve specific purposes. For instance, cocaine can be used to feel strong and empowered, while cocaine provides relief from discouragement.

Treatment

Treatment of this disorder usually requires detoxification and counseling or psychotherapy. Because withdrawal can be dangerous, detoxification should be done under medical supervision. This treatment involves tapering off the medication and relieving withdrawal symptoms, which typically includes sleep, appetite, and mood disturbances. Cognitive behavior therapy may be used to identify the beliefs, behaviors, and situations that trigger stimulant use and cravings. Therapy then focuses on developing a plan to reduce the likelihood of relapse. This may include a Twelve-Step Program. Other treatments may also be needed, particularly if depressant drugs (alcohol or barbiturates) were used to reduce anxiety and promote sleep. Detoxification will be needed for these substances. Treatment for stimulant addiction is often longer in duration when it causes depression or another mental disorder. Accordingly, these other disorders must be treated simultaneously. Finally, unlike marijuana and opiate drugs, the craving for stimulant drugs is much more intense and extended.

Stimulant-Related Disorders

Stimulant-related disorders are a group of mental disorders characterized by significant distress and disruption of daily life caused by the use of stimulants.

Definitions

- **Addiction** is a chronic disease of the brain, which involves compulsive and uncontrolled

pursuit of reward or relief with substance use and other compulsive disorders.

- **Amphetamines** are a class of stimulant medications that increase activity in the nerves and brain by increasing the amount of chemicals in the body.
- **Anxiety** is a negative emotional state characterized by feelings of nervousness, worry, and apprehension about imagined danger.
- **Attention-deficit hyperactivity disorder** is a disorder characterized by significant problems with attention, hyperactivity, or acting impulsively that are not appropriate for an individual's age.
- **Depression** is an emotional state characterized by feelings of sadness, low self-esteem, guilt, or reduced ability to enjoy life.
- **DSM-5** stands for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, which is a diagnostic system used by professionals to identify mental disorders with specific diagnostic criteria.
- **Hallucinations** are false or distorted sensory perceptions that appear to be real perceptions that are generated by the mind rather than external stimuli.
- **Narcolepsy** is a sleep disorder involving daytime sleepiness and uncontrollable episodes of falling asleep during the day.
- **Paranoia** is an unfounded or exaggerated distrust or suspiciousness of others.
- **Psychoactive** is a drug or substance that has a significant effect on mental processes. They include opioids, stimulants, depressants, hallucinogens, and cannabis.
- **Psychosis** is a severe mental condition in which an individual loses touch with reality.
- **Seizure** is an episode of abnormal electrical activity in the brain that results in changes in the brain and in behavior.
- **Stimulants** are drugs that increase brain activity and produce a sense of alertness, euphoria, and productivity, or that suppress appetite. Examples are cocaine, amphetamines, and Ritalin.
- **Substance-related and addictive disorders** are a group of DSM-5 mental disorders characterized by the continued use of addictive substances or behaviors despite significant impairment or distress. They include alcohol use disorder, opioid withdrawal disorder, and stimulant-related disorders.
- **Twelve-Step Programs** are self-help groups whose members attempt recovery from various addictions based on a plan called the Twelve Steps.

Description and Diagnosis

Stimulant-related disorders are a group of DSM-5 mental disorders characterized by significant psychological and physical distress and impaired daily functioning caused by the use of stimulants. This group of disorders is one of the 10 classes of disorders known as the substance-related and addictive disorders in DSM-5. Because stimulants are energizing, they may be prescribed to reduce sleepiness, decrease appetite, and reduce restlessness. They are also used to treat conditions such as narcolepsy, depression, and attention-deficit hyperactivity disorder. Some examples of legal stimulants include caffeine, nicotine, and prescription medications (e.g., amphetamines). Individuals also use stimulants for recreational use and abuse. They are often abused for the intense excitement that accompanies them. Some examples of illegal stimulants include ecstasy, cocaine, and methamphetamine. Illegal stimulants are extremely addictive. They cause mind racing and rapid heartbeat, and have the potential for overdose and death. Whether or not a stimulant is legal or illegal, they all may eventually lead to addiction.

There are five separate classifications of mental health diagnoses that fall under the category of stimulant-related disorders. They include stimulant use disorder, stimulant intoxication, stimulant

withdrawal, other stimulant-induced disorders, and unspecified stimulant-related disorder. Following are brief descriptions of each of these disorders. Stimulant use disorder is more fully described in its own entry in this encyclopedia.

Stimulant use disorder. Stimulant use disorder is a mental health disorder characterized by problems associated with the use of amphetamine-type substances, cocaine, or other stimulant drugs. Individuals with this disorder often lead to having significant distress or impairment as a result of taking larger amounts of a stimulant or over a longer period than intended. Individuals have a strong urge to use a stimulant and spend a great deal of time trying to acquire, use, and recover from the stimulant. Those with this disorder fail to fulfill obligations at home, work, or school. Stimulant use disorders lead to persistent or recurrent interpersonal and social problems, and important activities in one's life are reduced or given up as a result of continued use. Individuals continually use stimulants despite physical and psychological problems. Individuals who use amphetamine-type stimulants or cocaine can develop this disorder within one week. Tolerance of this disorder will occur with repeated use regardless of how the stimulant is administered (e.g., orally, injection, smoking, or snorting). One who has developed tolerance to a stimulant will need an increased amount of the drug in order to achieve the desired effect. Withdrawal symptoms can occur after an individual stops using or reduces the amount of a stimulant. They include excessive daytime sleepiness, increased appetite, depression, suicidal thoughts, irritability, and difficulty concentrating. Aggressive and violent behavior is common when large doses of a stimulant are smoked, ingested, or administered intravenously. Furthermore, those who use high doses of stimulants may experience extreme anxiety, paranoia, hallucinations, and psychosis.

Stimulant intoxication. Stimulant intoxication is a mental health disorder characterized by the presence of significant behavioral or psychological changes that begin during or shortly after the use of cocaine, an amphetamine-type substance, or other stimulant. Some of the behavioral and psychological changes include excitability, impaired judgment, anxiety, and anger. Hallucinations and paranoia may also be present. Stimulant intoxication usually begins with a high feeling and includes some of the following symptoms. They include hyperactivity, restlessness, talkativeness, alertness, grandiosity, and poor judgment. Signs and symptoms accompany these behavioral and psychological symptoms shortly after stimulant use. They include rapid heartbeat, pupil dilation, chills or perspiration, nausea, vomiting, difficulty breathing, chest pain, seizures, or coma. Stimulant intoxication can either be acute or chronic and is associated with impaired social or occupational functioning. Severe stimulant intoxication can result in death.

Stimulant withdrawal. Stimulant withdrawal is a mental health disorder characterized by withdrawal symptoms that usually develop within a few hours to several days after complete discontinuation or reduction of prolonged amphetamine-type substance, cocaine, or other stimulant use. The development of a distressed mood is an element of withdrawal, along with several other symptoms, which includes lack of energy, lack of sleep or excessive daytime sleepiness, increased appetite, unpleasant dreams, and agitation. A slower than normal heart rate is often present with the withdrawal of stimulants. Individuals experience significant impairment and distress in occupational, social, and other important areas of one's life. The signs and symptoms of stimulant withdrawal cannot be attributed to another medical condition and are not better explained by another mental disorder.

Other stimulant-induced disorders. Other stimulant-induced disorders, which include amphetamine, cocaine, and other stimulant disorders, are described in other chapters of the DSM-5 with disorders with which they share occurrences. Some examples of shared occurrences include stimulant-induced psychotic disorder, stimulant-induced anxiety disorder, and stimulant-induced obsessive-compulsive disorder. These stimulant-induced disorders are diagnosed instead of stimulate intoxication or stimulant withdrawal only when the symptoms are severe enough to justify independent clinical attention.

Unspecified stimulant-related disorder. Unspecified stimulant-related disorder is a category that is applied to the presentation of symptoms that are characteristic of a stimulant-related disorder. The one symptom that clearly occurs in this disorder is the

significant impairment and distress in an individual's occupational, social, or other areas of important functioning. The full criteria needed to make the diagnosis of a specific stimulant-related disorder are not met. Therefore, this is the diagnosis given.

Treatment

The clinical treatment of these disorders varies depending on the disorder. Generally, treatment involves a combination of participating in an inpatient treatment program, complete abstinence from any mind-altering substances, psychotherapy, attending Twelve-Step Programs, obtaining a sponsor, working the Twelve Steps of recovery, and medication management.

Stockholm Syndrome

Stockholm syndrome is a mental disorder characterized by an individual having positive feelings or sympathy toward his or her captor or abuser.

Definitions

- **Defense mechanisms** are strategies for self-protection against anxiety and other negative emotions that accompany stress.
- **DSM-5** stands for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, which is a diagnostic system used by professionals to identify mental disorders with specific diagnostic criteria.

Description

Stockholm syndrome is an uncommon mental disorder whereby an individual who has been exposed to severe stress by an abusive individual who feels positively or sympathetically toward that individual. The most common activities associated with the manifestation of this disorder are kidnapping, hostage situations, domestic or other abuse, prisoners of war, and cults. The occurrence rate of this disorder is not known because such situations occur rarely. Although this disorder is recognized, it is not induced in DSM-5 because it lacks sufficient research support.

The explanation given for the behavior of those exhibiting this disorder is the false sense of gratitude felt by those whose lives are acutely threatened but then spared. Another explanation is that it occurs as a defense mechanism or survival strategy. In the case of defense mechanism, the disorder may occur in response to the unbearable stress created by the life-threatening circumstance of the victim. Similarly, if the disorder is a strategy for survival, individuals are believed to act and feel positively toward their captor in the hopes that they will be sparred. The bonding that occurs between victim and captor occurs in a very short period of time.

This disorder was named after an extended bank robbery that took place in Stockholm, Sweden, in 1973. Hostages were taken and held captive for several days but began to support their captors and even defended them after the hostages were released. A similar situation occurred when Patricia Hearst, then a 19-year-old heiress of the Hearst publishing fortune, was kidnapped and held hostage in 1974 by a revolutionary group called the Symbionese Liberation Army. She participated in a bank robbery with them. Even months after her release, Ms. Hearst actively supported her captors, although she later condemned them for their treatment of her. This syndrome was also noted among some hostages in the 1985 hijacking of TWA

Patricia Hearst, an heiress to the Hearst publishing fortune, was kidnapped and held hostage in 1974 by a revolutionary group called the Symbionese Liberation Army, and participated in a bank robbery with them. Even months after her release, Ms. Hearst actively supported her captors, but she later condemned them. Hearst was thought to exhibit Stockholm syndrome behavior. (Bettmann/Corbis)

Strategic Family Therapy

Strategic family therapy involves the whole family unit in a brief therapeutic intervention designed to bring about rapid change. The therapist plays the leading role, with the family members completing various tasks to shift their systems of interaction toward the contracted outcome.

Description

Strategic family therapy is a form of brief therapy that involves the entire family unit. It was developed in California in the 1950s, rising to therapeutic prominence over the next several decades through the work of Gregory Bateson, Don Jackson, Jay Haley, Salvador Minuchin, Cloe Madanes, and Milton Erickson, among others. Though its popularity has waxed and waned in the subsequent years, strategic family therapy has been found to be a scientifically effective model appropriate for use with families from all cultures and ethnicities.

During strategic family therapy, the therapist takes a leading role. The goal of therapy is to address a specific issue or change a specific behavior pattern. It is not introspective, and the examination of the reasons behind an issue is given less emphasis than action to change the issue. Toward that end, the therapist may assign tasks to family members in session or give homework to the group to complete between sessions. The therapy is deemed successful when the targeted behavior or issue has been addressed or improved to the satisfaction of the family group.

Strategic family therapy aims to change family patterns of interaction in order to achieve a specific outcome. This might mean improved marital relations, a cessation of domestic violence, better school performance, or even a drug habit intervention. The overarching goal is the change in exhibited behaviors, and as such, introspection and understanding the roots of the problem are given less of a role in therapy sessions. It is not that the past is wholly irrelevant; it is simply that here, present and future outcomes have the leading role.

Designed as a brief therapy, strategic family therapy enrollment is typically triggered by a social services referral or specific event tipping point, such as an arrest, school suspension, or "last straw" moment from within the family. It begins with an evaluative assessment where group members meet with the therapist (individually or jointly, depending on the case) to discuss desired outcomes prior to beginning therapy.

While there may be multiple issues at place, the subsequent strategic therapy sessions will focus only on the contracted issue or change goals and not move beyond the immediate problem unless the family specifically requests this expansion.

The family attends sessions as a group, though the therapist may meet with individual family members separately in addition to the group sessions as needed. During the therapy sessions, the therapist takes a leading role and plays the part of interventionist. Role-playing, tests/ordeals, directives, and take-home assignments may all be used to try and shift family behavior patterns. Thus, the therapist must balance both a role as a trusted helper and a role as an antagonist challenging the existing system when leading the family through the sessions. Therapy ends when the contracted outcomes are reached, though some clients may transition to other forms of ongoing individual or family therapy.

Development and Current Status

Strategic family therapy grew from Bateson's cybernetics model. The first major institute championing its research and use was the Palo Alto Mental Research Institute, founded in 1958 by Jackson. Erickson, Haley, Madanes, and Minuchin, along with Virginia Satir, Richard Fisch, R. D. Laing, and Irvin Yalom, spent significant time there over the next decade developing aspects of the therapy and enshrining it as a key part of the marriage and family therapy canon.

However, the active, interventionist role played by the therapist in strategic family therapy became a source of tension as the different researchers theorized about different sources for family imbalance. Erickson, Bateson, and Jackson focused on systems and feedback loops, while Haley and Madanes focused more on power imbalances, believing shifts in hierarchical structures could both cause and repair family dysfunction. Difference in practice approaches led Haley to leave the institute, though he continued to be a major influencer in the strategic family therapy movement.

The interventionist model attracted additional negative attention in late 1970s and 1980s. At that time, shifting views on the appropriate roles for therapists in patient behavior change led some strategic family therapy practices—such as assigned tests or intentional deceptions to bring about change—to be accused of being manipulative by the broader psychological community. This led to a sharp decline in research and study in the strategic family therapy space, though it was still widely practiced.

Since 2000, there has been a resurgence in research and study, especially as long-term studies and field teams have continued to report on the effectiveness of strategic family therapy "in the trenches," particularly for treating complex cases. Emerging data in the dynamic systems field has justified many of the more controversial and "manipulative" practices of strategic family therapists, proving that these hands-on directives are in fact grounded in sound science within the context of treating complex systems, including families. Cross-cultural studies from the late 1990s and early 2000s have also shown that the short, action-oriented sessions can be extremely effective in treating families from diverse ethnic and racial backgrounds, especially as they seek to adapt to new environments.

Currently, the Mental Research Institute has regained its status as an active trainer and leader in the field of strategic family therapy. The therapy is increasingly popular in complex social services settings, particularly for dealing with adolescents. In that context, the therapy has proven to be effective both at changing behaviors in families with troubled adolescents and in containing costs of treatment where multiple agencies (schools, social welfare groups, and the legal system) are involved. As a result, strategic family therapy is likely to maintain a steady presence in the marriage and family therapy world for the foreseeable future.

Strattera (Atomoxetine)

Strattera is a prescription medication used to treat attention-deficit hyperactivity disorder. Its generic name is atomoxetine.

Definitions

- **Attention-deficit hyperactivity disorder** is a mental condition characterized by a lack of concentration, impulsive or inappropriate behavior, and hyperactivity.
- **Dopamine** is a chemical messenger in the brain that transmits nerve impulses that regulate attention, concentration, emotion, movement, impulse control, and judgment.
- **Neurotransmitters** are a group of chemical messengers in the brain that message to other nerve cells. Common neurotransmitters include acetylcholine, dopamine, norepinephrine, and serotonin.
- **Norepinephrine** is a chemical messenger in the brain that serves to transmit nerve impulses that regulate attention and power the "fight or flight" stress response. As such, it causes constriction of blood vessels. It is also called noradrenaline.
- **Selective serotonin norepinephrine reuptake inhibitors (SNRI**) are antidepressant medications that act on and increase the levels of serotonin and norepinephrine in the brain that influences mood. They differ from selective serotonin reuptake inhibitors, which act only on serotonin.

Description

Strattera belongs to a class of non-stimulating medications known as a selective norepinephrine reuptake inhibitors (SNRIs). It is used to treat children and adults with attention-deficit hyperactivity disorder (ADHD). Unlike ADHD medications like Ritalin, Strattera is not likely to be abused. Also, because it is not a controlled substance, the rules for prescribing it are much less strict. Strattera was the first non-stimulant medication approved for the treatment of ADHD. It is commonly used for those who develop multiple side effects from stimulants or who cannot tolerate stimulants because of coexisting anxiety or substance abuse. Since stimulants can worsen tics in those with Tourette's syndrome and ADHD, Strattera is particularly useful because it can treat ADHD without worsening coexisting tics. For those with ADHD and coexisting depression, Strattera is useful since it also has antidepressant properties. It is believed that a decrease in norepinephrine in the brain contributes to disorders such as ADHD and depression. As an SNRI, Strattera is thought to work by increasing levels of norepinephrine, while also regulating dopamine in certain brain areas.

Precautions and Side Effects

Strattera must be used with caution in those with uncontrolled hypertension, liver or kidney function impairment, glaucoma, heart conditions, and seizure disorder. Strattera must be used with care in those with bipolar disorder since it can trigger mania. Care should be taken to weigh the risks and benefits of Strattera in women who are or wish to become pregnant, as well as in breast-feeding mothers.

Common side effects include dry mouth, abdominal pain, nausea and vomiting, constipation, insomnia, vivid dreams, decreased appetite, erectile dysfunction, drowsiness, numbness and tingling in the extremities, dizziness, fatigue, hot flashes, increased blood pressure and heart rate, sweating, and palpitations. Rare but serious reactions include very high blood pressure, glaucoma, loss of consciousness, heart arrhythmias, heart attack, stroke, seizures, liver toxicity, and sudden death. Some develop increased aggressiveness, psychosis, mania, or suicidality in the first weeks of use. Children are especially at risk for these behavioral side effects. When starting treatment or after dose changes, those taking Strattera need to be monitored closely for behavioral changes.

Medications that may cause toxicity with Strattera include antidepressants such as Wellbutrin and Cymbalta; the antiulcer medication cimetidine; caffeine; and antipsychotics like Haldol and Mellaril. It is unknown which herbal supplements interact with Strattera. Since monoamine oxidase inhibitors (MAOIs) increase norepinephrine and dopamine, they cannot be used concurrently with Strattera. Switching treatment from an MAOI to Strattera may require a waiting period of up to two weeks. Ludiomil (an antidepressant) may also have additive effects with Strattera that cause toxicity.

Stress

Stress is the psychological, emotional, and physical state of strain resulting from negative appraisals of events, situations, and circumstances.

Definitions

- **Cognitive appraisals** are what a person thinks, believes, and concludes about events, situations, and circumstances.
- **Insomnia** is an inability to get to sleep or remain asleep during normal sleep times.

Description

Stress is the physical, emotional, and behavioral reactions to adverse events, situations, and circumstances. Stress can be acute or chronic. Acute stress is the most common and is short term in nature. Acute stress can result in emotional upset with some temporary physical manifestations such as headache or upset stomach. Not all acute stress is negative, such as the stress associated with riding a roller-coaster. Acute stress also has some positive effects as when it motivates people toward positive action. For instance, when an exam or deadline is in the near future, stress contributes to motivating a person to study or prepare. In extreme circumstances an automatic response to acute stress is a "fight or flight" reaction that serves to protect or defend an individual.

Physical symptoms of acute stress can include an increase in heart rate and blood pressure, sweating, dry mouth, stomach upset, and muscle tightening. Emotional reactions can include feelings of anxiety, anger, panic, and fear. Stress-related behaviors can include disturbed sleep patterns, overeating or undereating, social isolation, irritability, increased use of alcohol and drugs, or developing nervous habits such as nail biting or pacing back and forth.

Stress has been highly studied. Perhaps the best-known research on stress and coping was led by American psychologist Richard Lazarus (1922–2002). Lazarus and colleagues proposed that stress is an interaction between how individuals appraise, or assess, situations and its impact on their well-being. Individuals assess and categorize stressful events through primary and secondary cognitive appraisals. Primary appraisals evaluate the impact of an event or situation on one's life and well-being. Secondary appraisals evaluate what can be done to manage or cope with the event or circumstances. Secondary appraisals of coping options and primary appraisals of what is at stake interact with each other in shaping the degree of stress and the nature of the emotional reaction. For instance, a college student is assigned to a group project that will be worth half of her overall grade for the class. Her primary appraisal is that she could fail the class if her teammates perform poorly on the assignment. Her secondary appraisal is that she has no control over the assignment. This primary appraisal "I could fail" and the secondary appraisal "I have no control" result in a high level of stress and she becomes anxious and unable to sleep. Substitute

her secondary appraisal with the thought "I am pretty good at motivating people and working with a team" and the level of stress would be much less. Cognitive appraisals are very powerful in the formation and management of stress.

Prolonged or chronic stress has been shown to have many adverse physical effects on the body. Because stress can raise blood pressure, chronic stress can lead to heart attack and stroke. Chronic stress can manifest in specific areas of the body such as the head or stomach resulting in migraine headaches, irritable bowel syndrome, or ulcers, to name a few. Chronic stress can also lead to emotional debilitation through depression or anxiety disorders. Both acute and chronic stress can impact the immune system making people more vulnerable to illness.

Individual levels of hardiness and resiliency have a direct impact on perceived stress. Hardiness is the ability to withstand or tolerate stress, and resiliency is the ability to recover from stressful events. People who are hardy and resilient are able to cope with stressful events more effectively and with less emotional upset than are those who are less hardy and resilient. There are some events so stressful that they overwhelm a person's ability to recover. People who have experienced or witnessed life-threatening and horrific situations sometimes develop post-traumatic stress disorder and need the help of a mental health professional in order to recover.

Treatment for people who suffer from chronic stress, or are vulnerable to stress, is generally referred to as stress management. Stress management refers to a wide spectrum of treatments and includes exercise programs, self-relaxations techniques, biofeedback, guided imagery, meditation, and psychotherapy. The most common stressors are work, marital, and family related. Because stress is so common, there are a multitude of books, techniques, and seminars aimed at teaching people how to reduce and cope with stress. Most stress-related psychotherapies are cognitively oriented. The most common psychotherapy for addressing stress-related difficulties is cognitive behavior therapy (CBT). CBT focuses on changing and modifying an individual's primary and secondary cognitive appraisals in order to strengthen coping skills.

Stress Management

"Stress management" refers to a wide variety of techniques and methods used to reduce and manage acute and chronic stress.

Definitions

- **Acute stress** is the most common form of stress, is short term, and results in minor and temporary emotional and physical upset.
- **Chronic stress** is long-term stress that is emotionally and physically harmful to the health and well-being of the individual.
- **Cognitive appraisals** are what a person thinks, believes, and concludes about events, situations, and circumstances.
- **Stress** is the psychological, emotional, and physical state of strain resulting from negative appraisals of events, situations, and circumstances.

Description

Stress management refers to a wide variety of techniques used to assist individuals in reducing and managing stress. Stress occurs when situations are perceived as more demanding than a person's ability or resources to cope with the demands. Stress is the interaction between how individuals appraise, or assess, situations

and its impact on their well-being. Chronic stress has been found to have extremely negative health consequences, including hypertension and developing cardiovascular disease, obesity through emotional eating, and increased risk for heart attack and stroke, as well as developing chronic fatigue syndrome, depression, anxiety, and other mental health difficulties.

Because of the severity of stress impact on individual well-being, a multitude of preventative and stress management interventions have been developed. Stress management techniques are not only therapeutic but can also prevent the development of stress-related disorders. Evidence-based stress management methods include relaxation and breathing techniques, imaginal processing and mindfulness techniques, and cognitive-based techniques.

Muscle relaxation and breathing techniques are strategies that help clients attend to physical sensations in order to achieve periods of physical and mental relaxation. Muscle relaxation includes both a physical and a mental component. The physical component includes the sequential tightening and relaxing of muscles in the legs, abdomen, chest, arms, and face. Therapists instruct clients to tense muscle groups for 10 seconds and then relax the muscle group for 20 seconds before moving to the next group of muscles. Clients are instructed to practice the technique multiple times a day for short periods of time in order to produce a relaxed and peaceful physical and mental state. While tensing and relaxing the client concentrates on the difference between the tension and relaxation and learns to more quickly dissipate the physical symptoms of stress. Concentrating on muscles assists clients to block the cognitive processes associated with stress production. Outcome studies indicate that relaxation techniques help decrease blood pressure and heart rate, decrease headaches, and decrease levels of anxiety. Concentrating on deep breathing has long been used to produce states of relaxation. Diaphragmatic slow breathing in which individuals breathe from the diaphragm in the abdomen has been successfully used to decrease fatigue, reduce anxiety, manage aggressive behaviors, and reduce signs and symptoms of various health difficulties such as asthma.

Biofeedback is a technique in which individuals learn to control certain body functions by using electrical sensors and instruments to measure brainwaves, heart function, breathing, muscle activity, and skin temperature. The sensors provide instant feedback of body responses to changes in a person's thinking, emotions, and behaviors during biofeedback sessions. Trained therapists provide biofeedback training, and in three to six months an individual can learn to control functions such as heart rate and blood pressure. Biofeedback has been successfully used to reduce anxiety, blood pressure, headache, and other medical difficulties.

Stress management techniques include the use of guided imagery, meditation, and mindfulness techniques. Guided imagery is a method that focuses and directs the imagination in ways that are symbolic of a client's health and life issues. Therapists facilitate the development of personalized images and have clients create a script to follow that promotes relaxation and stress reduction. Engaging daily in these guided imaginal scripts have been found to reduce stress and promote health. Meditation in various forms has been found to be effective in reducing stress. Meditation has been practiced for thousands of years and involves focusing one's attention on a single activity such as a mantra. A mantra, as used in transcendental meditation, is a series of meaningless sequence of sounds and provides an activity that requires a person to disregard all other distractions such as thoughts and memories of stressful daily events. Other foci of attention may be body sensations, ambient sounds, images, and so on. Mindfulness is a type of meditation that focuses attention on moment-to-moment body awareness, and bringing one's complete attention to the present experience, thought, emotion, and sensation, but from a nonjudgmental distance. The goal is to assist clients learn to regulate emotions by awareness and reflection in a meditative state.

Cognitive behavior therapy (CBT) is a highly researched evidence-based psychotherapy that promotes changes in emotions, thinking, and behaving by helping clients modify their cognitive appraisals. CBT is based on the premise that thinking, feeling, and behaving are interconnected and a change in one will promote change in another. Clients are assisted in understanding and recognizing patterns of irrational or distorted thinking and restructuring the thoughts to promote

beneficial emotional states leading to increased health and well-being. CBT has been shown to be effective in stress reduction, management of cardiovascular disorders, chronic fatigue syndrome, diabetes, headaches, depression, anxiety, and many other health issues.

Chronic stress has many adverse effects on health and well-being. Stress management consists of a wide array of techniques and methods utilized in the reduction of stress-related emotional and physical difficulties.

Stroke

A stroke is damage or death of brain cells due to insufficient blood flow.

Definitions

- **Brain** is the organ at the center of the nervous system. It is responsible for a wide range of functions including learning, movement, and regulation of the body.
- **Computed tomography** is a medical diagnostic test in which computer-processed x-rays produce tomographs (cross-sectional images) of body areas. It is also referred to CAT scans.
- **Electroencephalography** is a medical diagnostic test that records electrical activity on the scalp to evaluate various brain functions and psychological disorders. It is also known as the brain wave test.
- **Magnetic resonance imaging** is a medical diagnostic test, which uses electromagnetic radiation and a strong magnetic field to produce detailed images of the brain and internal organs.
- **Physical therapy** is a method of treating of physical disability, malfunction, or pain by exercise, massage, and other nonmedication approaches.
- **Psychotherapy** is a psychological method for achieving desired changes in thinking, feeling, and behavior. It is also called therapeutic counseling.
- **Speech therapy** is a method of treating speech conditions with exercises and audiovisual aids that develop new speech habits.

Description

A stroke occurs when blood flow to the brain is blocked. This can happen when an artery bursts or closes due to a blood clot. Arteries carry blood from the heart to the brain. The area of the brain that was supplied by that artery does not receive blood, which contains oxygen and nutrients. Because of this, it becomes damaged or dies altogether. A stroke can result in paralysis, loss of vision, speech problems, impairment in memory and reasoning, coma, or death. This depends on the area of the brain that is affected and how much damage occurs. Individuals with other conditions like diabetes, heart disease, obesity, and high blood pressure have higher risk of stroke. Certain racial groups (African Americans, Asians, and Hispanics) have increased risk of stroke. Behaviors such as cigarette smoking, intravenous drug use, and lack of exercise also increase risk. Stroke is one of the leading causes of death in the United States. It is more common in men and in those over age 55.

There are four main types of stroke. *Cerebral thrombosis* is the most common. It occurs when a thrombus (blood clot) forms in the brain and blocks

incoming blood flow. This is generally the result of atherosclerosis (hardening) of the brain arteries. Atherosclerosis in the brain is caused by buildup of fatty deposits inside blood vessels. This type of stroke usually develops gradually. *Cerebral embolism* is another type of stroke. It occurs when a blood clot from somewhere else in the body breaks free and becomes lodged in an artery that supplies the brain. This also results in loss of blood flow to the brain. Cerebral embolism accounts for about 15% of all strokes. This type usually comes on quickly with severe symptoms. Both cerebral thrombosis and cerebral embolism are considered *ischemic* strokes because they result from restricted blood flow. Symptoms of ischemic strokes include dizziness; numbness of the face, arm, or leg; and blurred vision. The other two types of strokes are *hemorrhagic* strokes. These occur when a blood vessel bursts in or around the brain due to trauma or pressure. In a *subarachnoid hemorrhage*, blood spills into the space between the brain and cranium (skull). This is usually caused by hypertension (high blood pressure) or defective blood vessels such as an aneurism. Subarachnoid hemorrhages account for about 7% of all strokes. The final type of stroke is called *intracerebral* (inside the brain) *hemorrhage*. It occurs when there is bleeding in the brain itself. This deprives the tissue of blood and creates pressure on the brain. About 10% of all strokes are intracerebral hemorrhages. Symptoms of hemorrhagic strokes are loss of consciousness, severe headache, vomiting, and sensitivity to light (Levine, 2012).

A stroke is a medical emergency that requires immediate treatment. If individuals receive treatment quickly, then survival rates are high. Once a stroke is suspected, imaging technology is used to identify the type of stroke. Computed tomography scans and magnetic resonance imaging are two methods. Blood and urine tests and electroencephalogram are also used. Treatment varies depending on the type of stroke. For ischemic strokes, treatment involves trying to dissolve the blood clot with medications. Hemorrhagic strokes are treated with surgery to relieve pressure and repair ruptured blood vessels. Damage caused by a stroke usually requires rehabilitation therapy. Physical therapy is used to strengthen affected limbs and improve range of motion. Speech therapy is sometimes needed to help individuals improve communication ability. Psychological treatment involves psychotherapy to address emotions related to the stroke, such as depression. It may also be used to help caregivers manage stress and provide support. Strokes can be fatal, though improved medical treatments have reduced the number of deaths due to stroke. Measures to prevent stroke include quitting smoking, exercising, controlling blood pressure, and regular medical checkups.

Structural Family Therapy

Structural family therapy is a treatment approach developed by Salvador Minuchin (1921–) that focuses on restructuring the family organization to improve function and health.

Definition

- **Eco structural model** is a way of understanding the basic organization of the family, which includes the social impacts on the individual or family member.

Description

Structural family therapy uses a system-based treatment focus, which means that the whole family is considered as part of the therapeutic intervention. The focus of therapy starts with how the family system interacts, how it balances, any dysfunctional patterns, and their impact. The basic idea of structural family

therapy is exploring family rules, roles, boundaries, and organization.

The primary goal of this therapy is to restructure the family so that health and wellness can be attained. To achieve this, the therapist must first join the family as a leader. The therapist then can study the way in which the family interacts and the patterns that have a negative impact on the family. The therapist pays close attention to who says what to whom and how it is said. They also look at the impact of that and how the family members connect or disconnect. The therapist can then challenge the patterns that have made growth difficult.

Structural family therapy seeks to understand a family within the context of the presenting concerns. It looks at the family subsystems and the boundaries. It looks at how supportive, functional, and accepted the members are within the family unit. However, therapists using this treatment do not just look at the family unit alone but also the role that the community has in connection to the family.

The therapist has three functions: to join with the family in a leadership position, map the structure, and intervene allowing for a change to the ineffective structure. The assumption is that changing the organization and how it interacts will lead to symptom decrease and an increase in healthy functioning.

Structural family therapists use three key techniques. The first is family mapping where a diagram is drawn of the family connections and their boundaries. The mapping also looks at how engaged they are with each other. Enactments allow the family members to act out a common conflict that they experience at home. This allows an inside look to the family structure and communication patterns. Finally, reframing is used to allow for a different or new interpretation so that the family can understand the problems from different points of view.

Developments and Current Status

Structural family therapy was developed by Salvador Minuchin in the 1960s. At the time, Minuchin was working with juvenile delinquent boys in New York and found that the individual therapy was ineffective. Minuchin decided to include the family members to help gain a better understanding of the patterns and relationships and their impacts. Minuchin felt that studying the interaction patterns could allow the clinician to understand the symptoms the client was experiencing.

Including the families allowed Minuchin to see how the family members would interrupt each other and speak over one another. It was often unclear who the leader of the family was and each member's role lacked clarity. This allowed Minuchin the opportunity to redefine these roles, or the organization, to lead to appropriate boundaries and healthy communication.

Minuchin's work has been continued by Harry Aponte, who is considered to be a distinguished scholar. Aponte created an ecostructural model, which was designed to challenge oppression that is based on race, poverty, and culture.

Subjective Units of Distress Scale (SUDS)

The Subjective Units of Distress Scale (SUDS) is a short psychological measure for assessing levels of anxiety. It is also called the Subjective Units of Disturbance Scale and the SUDS scale.

Definitions

- **Anxiety** is a negative emotional state characterized by feelings of nervousness, worry, and apprehension about an imagined danger.
- **Behavior therapy** is a form of psychotherapy that uses basic learning techniques to modify maladaptive behavior patterns.
- **Eye movement desensitization reprocessing** is a psychological treatment for removing painful memories by providing a moving object for the eye to track in the therapy process.

Description

The Subjective Units of Distress Scale is a scale of 0 to 100 for measuring the subjective intensity of disturbance or distress currently experienced by an individual. Individuals can self-assess their level on the scale. The SUDS may be used as a benchmark for a therapist to evaluate the progress of treatment. It is a commonly used measure of anxiety in behavior therapy. It is a quick means of quantifying an individual's experience of anxiety and provides a way to monitor or assess an individual's responses and make comparisons with others.

The individual is asked to think of the worst anxiety and call it the maximum anxiety, or a rating of 100. Being absolutely calm is given a rating of 0. All other fears are ranked in between. The same scale is used later on during therapy to determine the strengths of the person's reactions during desensitization and after treatment. In clinical practice, asking the client or patient to rate his or her SUDS levels provides a quantitative index of progress. It also fosters a sense of accomplishment and empowerment in clients. In addition, it helps clinicians evaluate blocks and facilitators of the therapy process.

Developments and Current Status

This scale was published by South African psychologist Joseph Wolpe (1915–1997) in 1969. He developed it because there was no available quick measure for rating emotional distress or for monitoring change and evaluating progress in therapy. He called it the Subjective Units of Disturbance Scale. Originally, it was defined as a self-rated measure of current anxiety, with 0 being a state of absolute calmness and 100 as the worst anxiety ever experienced. It quickly became a standard measuring anxiety in exposure-based therapies. Later, it would be adapted for describing subjective alcohol urge and subjective level of sexual arousal. It has become a standard technique in eye movement desensitization reprogramming as a measure of distress before and after target memory processing. In 1990, Wolpe proposed the use of a more compact SUDS scale ranging from 0 to 10. SUDS has been criticized as lacking reliability and validity. However, recently published research has confirmed that SUDS does in fact have adequate psychometric properties. Overall, SUDS is a clinically useful and powerful assessment measure in psychotherapy.

Substance Abuse and Mental Health Services Administration (SAMHSA)

The Substance Abuse and Mental Health Services Administration (SAMHSA) is an agency created by the U.S. government to centralize efforts to help people struggling with drug abuse and mental disorders.

Definitions

- **Addiction** is a chronic disease of the brain, which involves compulsive and uncontrolled pursuit of reward or relief with substance use or other compulsive behaviors.

- **Substance abuse** involves the use of substances (drugs or alcohol) in amounts or with methods that are harmful.
- **Substance-related and addictive disorders** are a group of DSM-5 mental disorders that include substance disorders characterized by physiological dependence, drug-seeking behavior, tolerance, and social withdrawal. This group also includes the non-substance disorder of gambling.

Description

SAMHSA was created by an act of the U.S. Congress in 1992. As an agency of the government it is part of the Department of Health and Human Services. Its mission is to reduce the impact of substance abuse and mental illness on America's communities.

There are four beliefs that are the basis for the creation of SAMHSA. First is that behavioral health is essential to a healthy society. Second and third beliefs are that prevention efforts are worthwhile and that treatment is effective. The fourth belief is that people can recover from substance abuse and mental health problems. SAMHSA attempts to put these beliefs into effect through initiatives carried out by regional offices in collaboration with other state and local social service agencies.

The impact of substance abuse and mental illness on society was the reason for creating SAMHSA. Its continued funding and existence is justified by research and statistics produced by the agency. The agency estimates that in 2010 the total economic cost of substance abuse in the United States was over $510 billion annually. In the same period, over 23 million Americans aged 12 and older needed treatment for substance abuse. In addition, at least 10 million adults experience serious mental illness of some kind.

Impact (Psychological Influence)

Recently SAMHSA has devoted its efforts in multiple areas. These include people affected by trauma and the military. It is also aiming to improve access to culturally competent and high-quality services as well as to developing community, peer, and family support.

As with other government programs, SAMHSA collects and reports data, which shows the challenges and positive results from the programs it funds. One example of a statistic it tracks reveals the challenges faced by youth dealing with substance abuse. The problem society faces is the overall rate of treatment admissions for substance misuse among people. The age range group of 12 years and older in the United States was stable from 1999 to 2009. Yet during this same time period there was a 430% increase in the rate of treatment admissions for the misuse of prescription opioid drugs.

Not unlike other government agencies, SAMHSA struggles with budget cuts and an increasing need for social and government action. The agency often receives criticism for being ineffective and for the fact that some of its many programs may both be flawed and have conflicts of interest. The role of SAMHSA will continue to be important as long as the government needs to play a role in creating effective treatment for substance abuse and for people with other mental health and social issues.

Substance Abuse Treatment

Substance abuse treatment is the medical or psychotherapeutic method used to decrease or stop the abuse of psychoactive substances.

Definitions

- **Cognitive behavior therapy** is a type of psychotherapy that focuses on maladaptive (problematic) behaviors, emotions, and thoughts. It is also called CBT.
- **Disulfiram** is a man-made substance used to treat alcohol addiction. It is designed to create

very unpleasant side effects after alcohol consumption.

- **Methadone** is a man-made substance that is used to treat opiate addiction. It acts as a pain inhibitor and lessens the effect of withdrawal symptoms.
- **Psychoactive substances** are drugs or other substances that produce mood changes and distorted perceptions.
- **Psychotherapeutic** refers to a psychological method for achieving desired changes in thinking, feeling, and behavior. It is also referred to as therapy and therapeutic counseling.
- **Twelve-Step Program** is a self-help group whose members attempt recovery from various addictions based on a plan called the Twelve Steps.

Description

Substance abuse treatment is the process of assisting individuals addicted to drugs and/or alcohol to decrease or cease substance abuse. Substance abuse is usually a chronic condition that requires more than one treatment or continuing treatment over a long period of time. The type of treatment used depends on the individual's characteristics and the types of substances used. Typically, medical and psychological therapies are used to treat drug addiction. A very effective type of psychotherapy is cognitive behavior therapy. Cognitive behavior therapy helps an individual to identify, modify, and replace maladaptive thoughts and behaviors. Medical treatment may consist of medication. Certain medications are used to treat specific addictions. For example, methadone can be used to treat opiate addiction and disulfiram can be used to treat alcohol addiction. Other types of treatment include group therapy, and Twelve-Step Programs. Groups can offer social support to individuals. Substance abuse treatment may involve therapy alone or therapy in conjunction with medication.

There are several goals of substance abuse treatment. First, it engages individuals in the treatment process. It also teaches coping skills, relapse prevention, and effective response strategies if and when relapse occurs. Treatment also helps individuals develop or enhance communication and interpersonal skills. If necessary, it also addresses co-occurring disorders such as anxiety or depression. If appropriate, it will also include medication. Finally, substance abuse treatment provides individuals assistance with legal, occupational, medical, and family issues. These problems may be addressed during treatment, or the individual may be referred to an outside source. Substance abuse treatment can consist of a combination of different therapy modalities (i.e., individual, group, family) and medications. Treatment success requires tailoring treatment interventions and services to each individual's unique needs. It is also important to consider cultural factors and the role they play in an individual's life.

Substance-Induced Psychotic Disorders

Substance-induced psychotic disorder is a mental disorder characterized by hallucinations or delusions caused by the use of or withdrawal from substances like alcohol or cocaine. It is referred to as substance/medication-induced psychotic disorder in DSM-5.

Definitions

- **Antipsychotics** are prescription medications used to treat psychotic disorders, including schizophrenia, schizoaffective disorder, and psychotic depression.
- **Brief psychotic disorder** is a type of psychotic disorders characterized by a sudden onset, short duration, and the full return of functioning.
- **Delusions** are fixed false beliefs that persist despite contrary evidence.
- **DSM-5** stands for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, which is a diagnostic system used by professionals to identify mental disorders with specific diagnostic criteria.
- **Hallucinations** are false or distorted sensory perceptions that appear to be real perceptions that are generated by the mind rather than by an external stimuli.
- **Psychotic disorder** is a severe mental condition in which an individual loses touch with reality. Symptoms can include hallucinations, delusions, and disordered thinking.
- **Schizophrenia** is a chronic psychotic disorder characterized by hallucinations, delusions, thought and communication disturbances, and withdrawal from others.

Description and Diagnosis

Substance-induced psychotic disorder is a psychotic disorder that results from the use of medications or substances. These substances include alcohol and various recreational drugs like cannabis, cocaine, amphetamines, inhalants, sedatives, or hallucinogens. Hallucinations and delusions are the result of intoxication with the substance or, less often, in withdrawal from it. Experienced clinicians consider this diagnosis when evaluating adolescents and young adults who abruptly present with psychotic symptoms, particularly when visual hallucinations are involved. Laboratory testing, particularly drug screens, are invaluable in making this diagnosis. This disorder shares some common features, namely hallucinations and delusions, with brief psychotic disorder, schizophrenia, and other psychotic disorders.

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, individuals can be diagnosed with this disorder if they exhibit prominent delusions and/or hallucinations that are the physiological effects of a medication, drug of abuse, or toxic substance. This disorder is differentiated from other psychotic disorders by considering its onset and course. When the history, physical examination, or laboratory findings suggest that the cause of hallucinations or delusions is substance related, this diagnosis is highly likely. These symptoms must develop during or soon after intoxication by or withdrawal from the substance, and the substance must be capable of producing these symptoms. It must be determined that the disorder is not better accounted for by a non-substance-induced psychotic disorder. Finally, this diagnosis cannot be given if symptoms occurred primarily during the course of a delirium. This disorder can be further specified. The designation "with onset during intoxication" is given when symptoms occur during the period of intoxication. Likewise, the designation "with onset during withdrawal" is used with the substance and the withdrawal symptoms occur during the period of withdrawal. Finally, severity can be rated on a five-point scale ranging from 0 (no present) to 5 (present and severe) (American Psychiatric Association, 2013).

Treatment

The goal of treatment is the reduction and elimination of psychotic symptoms (hallucinations). If the disorder resulted from the effects of alcohol or a recreational drug, the focus of treatment is on relieving the intoxicated condition under careful medical supervision to control withdrawal symptoms. If the disorder resulted from the effects of a medication, the focus of treatment is reduction of the dose and withdrawal of the medication under close medical supervision. Antipsychotic medication may be used to quickly control psychotic symptoms. Usually, treatment takes place in an

inpatient medical or psychiatric setting to ensure the individual's safety and to provide life supportive measures. If the treatment is not successful, it may indicate that the diagnosis is actually brief psychotic disorder.

Substance/Medication-Induced Anxiety Disorder

Substance/medication-induced anxiety disorder is a mental disorder characterized by panic or anxiety as the result of a substance, medication, or toxin.

Definitions

- **Antianxiety medications** are prescribed drugs that relieve anxiety symptoms. They are also called anxiolytics or tranquilizers.
- **Anxiety** is a negative emotional state characterized by feelings of nervousness, worry, and apprehension about an imagined danger.
- **Anxiety disorders** are a group of mental disorders characterized by anxiety which tends to be intermittent instead of persistent. The group includes panic disorder, phobias, generalized anxiety disorder, and substance/medication-induced anxiety disorder.
- **Delirium** is a thought disturbance caused by a substance or medical condition.
- **Detoxification** is a process of purging the body of the toxic effects of a drug or substance. During this process the symptoms of withdrawal are also treated. Also called detox, it is the first step in a drug treatment program.
- **DSM-5** stands for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, which is a diagnostic system used by professionals to identify mental disorders with specific diagnostic criteria.
- **Intoxication** is a response to taking a substance. It involves changes in mental and physical functioning.
- **Panic attack** is an episode of sudden, intense, and debilitating sense of fear that is short lived.
- **Pharmacokinetics** is the body's reaction to a drug or substance.
- **Psychoactive** is a drug or substance that has a significant effect on mental processes. There are five groups of psychoactive drugs: opioids, stimulants, depressants, hallucinogens, and cannabis.
- **Withdrawal** is the unpleasant and potentially life-threatening physiological changes that occur due to the discontinuation of certain drugs after prolonged regular use.

Description and Diagnosis

Substance/medication-induced anxiety disorder is one of the DSM-5 anxiety disorders. It is characterized by panic attacks or anxiety as the result of using a psychoactive substance or being exposed to a toxin. Individuals develop symptoms soon after use or exposure to the substance (intoxication) or as it begins to leave the body (withdrawal and detoxification). Examples of substances that can produce these symptoms include stimulants like cocaine and caffeine. Individuals withdrawing from substances such as alcohol or opiates may also experience panic or anxiety. Some medications can also produce these symptoms. These include bronchodilators used to treat asthma and antihistamines used to treat allergies. Toxins such as insecticide and gasoline may also produce panic or anxiety symptoms.

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, individuals can be diagnosed with this disorder only if they have significant feelings of panic or anxiety. These feelings must arise during or soon after intoxication or withdrawal from the

substance or exposure to a toxin. The substance must also be capable of producing such symptoms based on its pharmacokinetics (the body's reaction to a drug). Individuals who have some other anxiety disorder, such as generalized anxiety disorder, do not qualify for this diagnosis. Symptoms must not be related to delirium, which is another response to a substance. In addition, the disorder must cause significant distress or disrupt daily life (American Psychiatric Association, 2013).

The cause of this disorder is the substance, medication, or toxin itself. Once individuals are no longer in contact with and detoxified of the substance, then symptoms decrease and eventually stop. There are no reliable statistics regarding how often substance/medication-induced anxiety disorder occurs in the population. It is believed to be rare and is more common in individuals who have other mental disorders (American Psychiatric Association, 2013).

Treatment

Treatment for this disorder depends on the specific types of substances used and symptoms experienced. It involves discontinuing use of or exposure to the substance responsible for the symptoms. Treatment may include antianxiety medications or behavior therapy, which are commonly used in treating other anxiety disorders. Since substances can remain in the body for extended periods of time, symptoms may continue even after use of the substance has stopped. This may last hours, days, or weeks. Substance/medication-induced anxiety disorder may be prevented by using substances in moderation or abstaining from them altogether.

Substance/Medication-Induced Depressive Disorder

Substance/medication-induced depressive disorder is a mental illness characterized by a depressed mood that results from the use of a substance or medication.

Definitions

- **Antidepressants** are prescription medications that are primarily used to treat depression and depressive disorders. They are also known as antidepressant medications.
- **Depressive disorders** are a category of mental illness that is characterized by depressed or lowered mood.
- **DSM-5** stands for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, which is a diagnostic system used by professionals to identify mental disorders with specific diagnostic criteria.
- **Mood** is an individual's subjective emotional experience and expression.
- **Psychotherapy** is a psychological method for achieving desired changes in thinking, feeling, and behavior. It is also called therapeutic counseling.
- **Substance** refers to chemical compounds that influence bodily processes. Typically this refers to alcohol and other drugs.
- **Substance-related and addictive disorders** is a group of DSM-5 mental disorders that are characterized by the problematic use of substances.
- **Twelve-Step Programs** are support groups that follow specific steps to help alcoholic and addicts stay sober. Such groups include Alcoholics Anonymous and Narcotics Anonymous.

Description and Diagnosis

Substance/medication-induced depressive disorder is one of the groups of DSM-5 depressive disorders. It is characterized by a depressed mood or decreased pleasure as a result of the use of a substance or a medication. It can also include symptoms similar to the other depressive disorders, such as a sense of hopelessness, fatigue, or listlessness. This disorder is relatively rare, occurring in less than 0.26% of the U.S. population (American Psychiatric Association, 2013).

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, individuals can be diagnosed with this disorder if they must experience a depressed mood or decreased pleasure as a result of substance or medication use. In addition, the individual must experience a significant distress related to the professional life, social relationships, or other important aspect of his or her life as a direct result of his or her symptoms. A key differentiator of this disorder and one of the substance-related and addictive disorders is that the depressed or lowered mood is the most significant symptom. The diagnosis cannot be given if the individual is only mildly depressed but has other symptoms that are more severe. Moreover, the individual is not considered to have this disorder if he or she is depressed independent of substance or medication use. As with the other depressive disorders, it is critical that a clinician assess the individual for suicide risk (American Psychiatric Association, 2013).

Unlike many mental disorders, the cause of substance/medication-induced depressive disorder is known. It is either a substance (alcohol or an illicit drug) or a prescription medication. Some of the medications known to cause this disorder include medication for smoking cessation, cancer, and oral contraceptives and antidepressants.

Treatment

Because this disorder is caused by a substance or medication, the initial goal of treatment is to remove the substance or medication—if present—and to reduce its effects. Usually treatment initially takes place in a hospital or clinic. This disorder is often treated similar to a substance-related and addictive disorders. This typically includes psychotherapy, group therapy, Twelve-Step Programs, and the use of drugs that reduce withdrawal symptoms. The symptoms of this disorder typically resolve as the effects of the medication or substance wear off. In the event that the depressive symptoms do not subside, an alternative diagnosis should be considered.

Substance-Related and Addictive Disorders

Substance-related and addictive disorders are a group of mental disorders characterized by the problematic use of substances or addictive behaviors.

Definitions

- **Addiction** is a chronic disease of the brain, which involves compulsive and uncontrolled pursuit of reward or relief with substance use or other compulsive behaviors.
- **Alcoholism** is a general term for the compulsive and uncontrolled consumption of alcohol to the detriment of the drinker's health, relationships, and social standing.
- **American Society of Addiction Medicine** is an organization of physicians whose purpose is to improve the care and treatment of individuals with addictions and to advance

the practice of addiction medicine. It is also referred to as ASAM.

- **Brain reward system** refers to brain circuits (pathways) that cause feelings of pleasure when activated (turned on) by something enjoyable (drugs, food, etc.). It reinforces addictive behaviors and explains the attraction of addictions over normal activities.
- **Cognitive behavior therapy** is a type of psychotherapy that focuses on maladaptive (problematic) behaviors, emotions, and thoughts. It is also called CBT.
- **DSM-5** is the abbreviation for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, which is the handbook mental health professionals use to diagnose mental disorders.
- **Motivational interviewing** is a counseling strategy for helping individuals to discover and resolve their ambivalence (uncertainty) to change. It is also referred to as MI.
- **Process addiction** is a term to describe non-substance-related disorders that are compulsive behaviors that have similar consequences to substance use disorders such as sex addiction, spending addiction, and gambling.
- **Psychological dependence** refers to reliance on an addictive substance for the effect it provides. It eventually leads to physiological (physical) dependence on the substance.
- **Tolerance** is the phenomenon in which the body requires increased amounts of the substance to achieve the desired effect.
- **Withdrawal** is the unpleasant and potentially life-threatening physiological changes that occur due to the discontinuation of certain drugs after prolonged regular use.

Description

Substance-related and addictive disorders are a group of DSM-5 mental disorders that activate the brain reward system. They are characterized by psychological dependence, drug seeking, tolerance, and withdrawal. This group includes alcohol use disorder; cannabis use disorder; opioid use disorder; sedative, hypnotic, or anxiolytic use disorder; stimulant use disorder; and gambling disorder. Non-substance-related disorders, such as gambling and Internet addiction, are called process addictions. The occurrence of these disorders differs greatly. For example, alcohol use disorder occurs in 4.6% of adolescents and 8.5% of adults. On the other hand, cannabis use disorder occurs in 3.4% of adolescents and 1.5% in adults (American Psychiatric Association, 2013).

These disorders have various conceptualizations regarding the cause and treatment of each substance use disorder. The biological perspective holds that addictions are a "brain disease" that has a genetic influence, while the psychological perspective views the cause of addiction to be a form of self-medicating other psychological conditions such as anxiety. Personality traits and issues such as self-esteem and self-worth are also psychological factors that predispose an individual to addiction. Social factors include easy availability of substances, stress, and hopelessness.

Treatment

Treatment methods vary among these disorders. However, generally, motivational interviewing and cognitive behavior therapy are commonly used in many of the substance-related and addictive disorders.

Suicide

Suicide is defined as the intentional or unintentional act of taking one's own life, of killing oneself.

Definitions

- **Euthanasia,** also known as "assisted suicide," refers to the practice of aiding another person in intentionally ending his or her own life in order to end pain and suffering.
- **Intentional suicide** occurs when an individual purposefully commits the act of killing himself or herself through the use of deadly weapons or behaviors.
- **Involuntary hospitalization** may be necessary for persons at imminent risk of harming themselves or others, referring to the reprimanding of persons into a hospital for psychiatric care without their consent.
- **Suicidal ideation** is the clinical term used to describe when an individual has preoccupied or persistent thoughts about suicide.
- **Suicide risk assessment** is an in-depth, thorough review of history, present situation, and future probability, which is conducted by a trained clinician to determine an individual's potential risk, plan, intent, and means for suicide.
- **Unintentional suicide** occurs when an individual feigns suicide but ends up killing himself or herself unintentionally.
- **Voluntary hospitalization** occurs when a person willingly agrees to enter a hospital for psychiatric care in order to ensure his or her own safety and the safety of others.

Description

"Suicide" refers to when an individual ends his or her own life, either intentionally or unintentionally. The term derives from the Latin word *suicidium*, from *sui caedere*, meaning "to kill oneself." Intentional suicide results when one uses deadly weapons (guns, knives, ropes, substances) or engages in lethal behaviors (jumping off a building/bridge, walking into oncoming traffic, drowning) in order to kill oneself. Unintentional suicide results when a person accidentally takes his or her own life but didn't intend to. Though the final decision to commit suicide lies with the individual alone, those surrounding victims can assist by noticing warning signs. Several risk factors are frequently cited as common characteristics of those who end up killing themselves, including having a mental health disorder(s), making previous suicide attempts, having a family history or of attempted or completed suicide, and suffering with a serious medical condition and/or chronic pain. If an individual experiences one or more of these at the same time, his or her suicide risk is even higher. Major depression has been closely linked with tendency toward suicidal behaviors. Suffering from schizophrenia, bipolar, anxiety, and substance abuse disorders also places a person at greater risk. However, simply being diagnosed with one or more of these disorders does not mean one will engage in suicide, particularly if one is seeking proper medical treatment and under the close supervision of a doctor. In addition to these commonly cited risk factors, additional forces at play in the environment may place an individual at greater risk for suicide. For example, stressful life events including job loss, financial pressures, the death of a loved one, trouble with the law, serious relationship conflict, bullying/harassment, and exposure to someone else who has taken his or her own life can increase one's susceptibility. These external factors may lead to anxiety, stress, extreme sadness, loneliness, hopelessness, and depression, which can contribute to suicidal ideation.

In addition to being under the care of an effective mental health professional, there are other protective factors, which assist in deterring suicide. Social and emotional support from loved ones is a key force in resiliency. Having a spiritual or religious connection

serves as another protective factor. Those with the ability to problem-solve and effectively navigate through life's pitfalls are also more likely to resist suicidal thoughts and behaviors.

Suicide statistics indicate that about 20% of people who die by suicide have a history of suicide attempts. Gender also plays a role in successful completions. While females are more likely to attempt suicide, they typically engage in less lethal means than males who are more likely to use deadly weapons and more drastic approaches. Persons at acute risk for suicide often display a host of behaviors that serve as warning signs. Talking about wanting to kill oneself or wishing one was dead should be taken seriously. Statistics indicate that the majority of people who attempt or commit suicide tell someone about their intentions. Having a suicide plan and means to carry out that plan is a glaring sign. Struggling with intense feelings of anxiety, sadness, anger, embarrassment, or hopelessness should be addressed. If an individual begins to pull away from others and social situations, or isolates himself or herself, this is a warning sign. Loss of interest in regularly engaged activities is also a warning sign. These signals should be noticed and addressed at once in order to prevent tragedy. Training professionals, educators, and laypeople in noticing warning signs and seeking out help for the struggling person is critical in reducing incidents.

Development

Beliefs about suicide have evolved throughout history. In ancient times, suicide was viewed as permissible and justified in cases where an individual was ordered by the state to commit the act for an indiscretion or crime, was suffering from a painful or incurable illness, or was compelled to because he or she was experiencing some intolerable misfortune in life. Greek philosopher Socrates was one of the first to publicly oppose suicide, stating that human beings had no right to take their own lives, as they were property of the gods. The Jewish and Christian religions contain examples of martyrs who were highly regarded for taking their own lives rather than being persecuted for their religious beliefs. It was not until the fourth century AD that the Church, persuaded by arguments made by St. Augustine, denounced suicide. Thomas Aquinas went onto support this position in the 13th century, concluding that it was an act against God. Those who committed suicide in the Middle Ages were subject to shaming, ridicule, and punishment. The Renaissance and Reformation periods evidenced more understanding views, particularly in situations where individuals were experiencing overwhelming pain or suffering. This trend continued into the next several centuries as the fields of sociology and psychology grew. French sociologist David Émile Durkheim's work did much to improve society's sensitivity toward suicide. In the 1897 book *Le Suicide*, he wrote about how societal and environmental stressors can contribute significantly to the problem. Psychologists Sigmund Freud, Alfred Adler, and Carl Jung approached the issue from a different lens, each offering views on the internal and external contributors to mental health and wellness. In 1938, American psychologist Karl Menninger published *Man against Himself*, tackling the delicate topic of suicide from a mental health perspective. As the shift regarding interest and compassion toward suicide victims and their families increased, laws and policies began to change as well. Suicide was no longer regarded a criminal act, though assisted suicide has remained under much debate. The establishment of task forces, online resource networks, nonprofit agencies, and support groups has continued.

Current Status and Results

Research on suicide has compared the brains of suicide victims to those of "normal" people. Findings indicate that there are key differences in specific cells called astrocytes contained within the brain's white matter. As suicide has been strongly linked to depression, scientists have noted that those with a history of depression have larger and more branched networks of astrocytes than those with no history of mental illness. Further studies have linked suicidal behavior with abnormalities in serotonin receptor subtypes located in the prefrontal cortex, hippocampus, and choroid plexus. Twin studies have also confirmed these neurological distinctions. Additional studies have associated suicidal behavior with traumatic life events, including sexual abuse and bullying.

Each year approximately 39,000 people commit suicide in the United States alone and about 1 million adults report making a suicide attempt. A recent report from the World Health Organization indicates that suicide is a global health problem. It is the 10th leading cause of death for Americans overall and the second leading cause of death among adolescents and young adults aged 15 to 29. Prevention efforts have focused on increasing understanding and education surrounding the causes and consequences of suicide and also on promoting support and intervention to those demonstrating warning signs, suicidal thoughts, or attempts. Evidence-based prevention programs that work to enhance protective factors and resilience have proven successful.

Suicide Assessment

Suicide assessment involves the process in which a qualified professional evaluates and determines a patient's level of risk for suicide through the use of screening tools, questionnaires, observation forms, checklists, and review health and medical history.

Definitions

- **Suicidal ideation** is the clinical term used to describe when an individual has preoccupied or persistent thoughts about suicide.
- **Suicide** is the intentional or unintentional act of taking one's own life.
- **Suicide contract,** also called a *suicide prevention contract* or *no-suicide contract*, is a written agreement initiated by a practitioner or health-care provider caring for a patient at risk of suicide that states that he or she will not commit suicide.
- **Suicide risk assessment** is an in-depth, thorough review of history, present situation, and future probability, which is conducted by a trained clinician to determine an individual's potential risk, plan, intent, and means for suicide.

Description

Assessing an individual's risk and taking the proper steps to provide intervention, treatment, and support is critical in reducing suicide incidence rates. Suicide assessment, also referred to as suicide risk assessment, is a complex process that involves the use of screening tools, observation forms, checklists, and questionnaires designed to gauge an individual's likelihood of suicidal behavior in the near future. Assessments such as these are conducted by properly qualified practitioners, usually mental health-care providers. Research has identified certain predictors strongly associated with suicide risk: demographics, existence of psychiatric and/or medical illness, and significant life stressors. In addition to these key areas, a comprehensive suicide assessment also examines prior suicide attempts, plan and means, presenting symptomatology, and protective factors. Acute (recent changes in circumstances and mental state) and chronic (diagnosed mental illness, social and demographic factors) patient risk are assessed on a continuum ranging from nonexistent to extreme. Several warning signs of suicidality exist: threatening to hurt/kill oneself, seeking out means to kill oneself, and talking, writing about death, dying, or suicide; displaying feelings of anger, despair, revenge, and/or hopelessness; engaging in risky behaviors; withdrawing from friends and family; excessive sleeping; and drastic mood swings. The more detailed and specified an individual's suicide

plan, the more likely he or she is to carry it out. The existence of a suicide note also increases one's probability. After assessing patients in threat of suicide, practitioners may recommend voluntary/involuntary hospitalization or outpatient treatment consisting of medication, behavioral intervention, and/or counseling support.

Development (Purpose and History)

Though informal means for gauging suicidality have existed for centuries, more formal tools were developed in the later part of the 20th century. Psychiatrist Aaron T. Beck released the Suicide Intent Scale in 1974, a questionnaire designed to measure aspects related to suicidal attempts and intent. In 1979, Beck went on to create the Scale for Suicide Ideation (SSI) with colleagues Maria Kovacs and Arlene Weissman, to assist practitioners in determining the intensity of suicidal thoughts in patients. A popular self-report measure, the Suicidal Behaviors Questionnaire (SBQ), was then published in 1981 by psychologist Marsha M. Linehan. The SSI and SBQ are often used in conjunction. Subsequent instruments were later developed, including the Reasons for Living Inventory (RFL) in 1983, also developed by Linehan and the Life Orientation Inventory by Kowalchuk and King in 1992. Other valid and reliable instruments recommended by researchers to determine suicidal risk are the Manchester Self-Harm Rule, the Re-ACT Self-Harm Rule, the Risk Assessment Matrix, and the Violence and Suicide Assessment Form. Brief assessments are also available through the American Counseling Association, the Substance Abuse and Mental Health Services Administration, the American School Counselor Association, and the National Institute of Mental Health.

Current Status and Results

Research on suicide assessment indicates that some practitioners refrain from using formal suicide-specific risk assessments, but rather rely on the information obtained during clinical interviews. Graduate programs should incorporate coursework, training, and practice in administering these assessments in order to increase practitioner exposure and confidence. Suicidality, though, is not definitive and can be prevented if addressed effectively. Therefore, suicide risk should be reevaluated and monitored on a continual basis until potential self-harm is no longer imminent.

Suicide in Youth

Suicide in youth, or youth suicide, is described as when a young person, between the ages of 10 and 24, engages in dangerous, lethal behaviors with the intent to end his or her own life.

Definitions

- **Suicide contagion,** also known as copycat suicide, refers to the phenomenon that occurs when, in the absence of protective factors, an individual chooses to kill himself or herself after being influenced by a prior person's suicide.
- **Youth suicide** is a term used to define adolescents or young adults, aged 10 to 24, who commit suicide.

Description

Suicide in youth is a serious public health concern, particularly in Western cultures. The term "youth suicide" focuses on the impact of this problem in young people aged 10 to 24. The Centers for Disease Control and the National Mental Health Association report that youth suicide rates have increased markedly over the past decade, resulting in thousands of deaths per year. Suicide

is the third leading cause of death for adolescents and the second leading cause of death for college students. Results from a national study of high school students from both public and private settings found that nearly 20% of youth have seriously considered suicide. Suicide contagion, or copycat suicide, is described as when a person kills himself or herself after experiencing the suicide of prior person. Unfortunately, this phenomenon is evident among youth suicide cases. As with adult suicide, youth suicide has been significantly associated with the presence of certain mental illnesses or psychological disorders; depression, substance abuse, and aggressive or disruptive disorders are the most prevalent. In addition to these risk factors, certain external events can contribute to youth suicide, including the loss of a loved one, trauma, bullying, poor grades, a breakup, arguing with parents, familial discord, separation, or divorce.

Demographic indicators suggest that while young females are more likely to attempt suicide, young males are more likely to succeed in their attempts, as they employ more lethal means. Youth who commit suicide most often do so through the use of firearms (approximately 45%), suffocation (approximately 40%), or poisoning (approximately 8%). Studies report that suicide rates are high among LGBTQ youth. Cultural differences also exist, with statistics indicating that Native American/Alaskan Native youth have the highest rates of suicide-related fatalities. Rates among Hispanic/Latino youngsters are also higher than their non-Hispanic peers.

Impact (Psychological Influence)

Though suicide among young people is prevalent, it is preventable. Research suggests that certain factors can serve as protective barriers to suicidal behavior in youth. Those with social support networks (family and friends), cultural/spiritual/religious/school connections, and access to effective medical and mental health resources fare better. In addition, youth who possess good communication skills, adaptive coping and problem-solving skills, positive self-esteem, and a general sense of life satisfaction are more resilient. Intervention should begin at an early age and consist of both prevention and postvention efforts. Creating school communities that are positive, caring, supportive, and safe is critical as is proper training for faculty and staff. Most districts now mandate that youth suicide be addressed in schools, requiring that educators become knowledgeable as to the risk factors, warning signs, and procedures to follow. Having a crisis response team/plan in place can alleviate stress and anxiety if and when a suicide occurs. Students and their parents should also receive information and be provided with resources to access if they or a loved one needs help. Seeking proper medical and mental health care in a timely manner is key. A trained professional can then conduct a thorough suicide risk assessment and outlay a treatment plan for the family. Ongoing services may consist of medication, individual counseling, support groups, family intervention, and school adjustments.

Support Groups

Support groups are a type of therapy group that provides emotional support and self-help to those willing to confront, discuss, and learn how to better cope with similar issues.

Definition

- **Support** means to help bear the weight of something such as the burden of disease or loss.

Description

Support groups are diverse. Some are self-help groups run by nonprofessionals, which are aimed at supporting behavioral change. One famous and highly attended example of this is Alcoholics Anonymous. In other support groups there is a gathering of people who come together for the purpose of giving emotional support and helping people cope in the face of common problems. One example of this is bereavement support groups, who help people deal with the loss of a loved one. A designated leader or professional therapist may facilitate these groups, but a licensed professional is not required. Psychotherapy support groups are the most intense since they usually focus on more complex interventions to help people learn about and cope with ongoing mental and physical health challenges. This last class of support group is almost always facilitated by a professional counselor and linked to a social service agency of some kind. One example of this kind of group is victims of domestic violence or people dealing with depression.

The great advantage of support groups is that the diversity of experience and background of the people involved provide the chance for a broad application of experiential knowledge to whatever problem the group is formed around. In other words, it is not just providing a shared chance to complain; it can help in real problem solving based on the accumulated wisdom of the group. Since they are so focused, membership in support groups is almost always restricted to those affected by a specific situation or problem.

Development

There are scattered examples of support groups historically. Jacob Moreno is considered the founder of group counseling. He discovered its importance when he facilitated a group of former prostitutes who were trying to reform themselves in Vienna before World War I. But the most famous self-help support group in history is Alcoholics Anonymous (AA), which started in the 1930s as a way for those struggling with alcohol dependency to get and stay sober. There has been a proliferation of groups modeled on AA, which have expanded to include groups for people with addictions to gambling, overeating, or other process addictions.

Within the field of psychology, the German American psychologist Kurt Lewin is responsible for much of the interest in and development of group work. He specifically had a concentration on group dynamics out of which grew training groups or sensitivity training groups. Lewin believed that groups were much more powerful than individual counseling due to the insight and support provided by others in the group. By the 1960s group work in therapy had become very popular throughout the United States.

During the 1960s and by the 1970s support groups were sometimes called encounter groups. In these groups psychological and personal issues could be discussed within a safe environment. The support group world has continued to grow exponentially with many reports that participation has led to good health outcomes for members, both in terms of physical and mental health.

Current Status

Support groups are common in the United States. Today there are many hospital and social service agency-based support groups for a wide variety of issues, topics, problems, diseases, and interests. Support groups for the mentally ill and for their family members have proven to be very helpful in providing education, information, and coping mechanisms.

In recommending support groups as a therapeutic tool, it is important that health-care professionals should encourage clients to seek out a support group where they can comfortably participate. Respect for personal boundaries, a skilled and experienced leader, and acceptance of differences between individuals' beliefs are some of the hallmarks of successful support groups. Online support groups have also become popular in recent years. Great caution should be taken in assessing the trustworthiness and seriousness of those participating in such groups before sharing private information.

Sybil (Book and Movie)

Sybil is a book and television movie that is best known for its controversial depiction of a patient suffering from multiple personality disorder, which is now known as dissociative identity disorder.

Description

Sybil is a 1973 best-selling book written by Flora Rheta Schreiber about the psychiatric treatment of Sybil Dorsett by her psychiatrist Cornelia Wilbur. The book was publicized as a true story about a woman suffering from multiple personalities. *Sybil* is also known for the 1976 television movie starring Joanne Woodward as the psychiatrist, and Sally Field who won an Emmy award for her portrayal of *Sybil*.

Sybil is the story of Sybil Dorsett, a young woman who seeks medical treatment for blackouts, disturbing memory image fragments, and memory lapses. She begins treatment with Dr. Cornelia Wilbur, who discovers that Sybil has suffered from her symptoms for many years. Dr. Wilbur tells Sybil she suffers from hysteria and begins treating her. After Sybil loses her job she becomes suicidal and calls Dr. Wilbur as "Vicky." Dr. Wilbur soon discovers that Vicky is just 1 of 16 personalities that will eventually be revealed during treatment. Both the book and movie chronicle Sybil's psychiatric treatment, the unveiling of Sybil's many personalities, and the traumatic and horrific childhood abuse she experienced that led to the splitting of Sybil's personality. The story closes as Sybil is able to merge and integrate the many personalities into a single whole individual.

Impact (Psychological Influence)

The book and movie led to a worldwide psychological phenomenon and fascination with multiple personality disorder (MPD). Prior to the book's release there was no official diagnosis of MPD. At the time, reported cases of MPD were quite rare, with less than a few hundred cases reported worldwide. Within a few years of the release of the book and movie, thousands of cases a year were being diagnosed. *Sybil* reportedly played a role in the diagnosis of MPD being included in the *Diagnostic and Statistical Manual of Mental Disorders III* in 1980.

Sybil also affected the psychotherapy profession. Use of hypnosis and regression therapy to reveal repressed and blocked memories became the psychological fad of the day. This eventually led to the phenomenon of false memories in which patients "recover" lost memories of terrible events in their lives but

Sybil is a 1973 book and 1976 television movie shown here with Joanne Woodward, left, as a therapist, and Sally Field, right, as Sybil, who is a patient suffering from multiple personality disorder, now known as dissociative identity disorder. In 2011, a biography of Shirley Mason (the real Sybil) suggested that Mason did not have "multiple personalities," and that the doctor was using unethical treatments on the patient. (NBC/Photofest)

in actuality are false memories rooted in the method of therapy used by the treating psychotherapist.

Shirley Mason is the name of the woman portrayed as Sybil Dorsett in the book and movie. Mason did receive treatment from Dr. Cornelia Wilbur, but considerable controversy surrounds Wilbur's diagnosis, methods, and motivations. The truth of Mason's condition and appropriateness of her treatment by Wilbur are also controversial. In 2011, journalist and writer Debbie Nathan published *Sybil Exposed*, detailing evidence of lies, fabrications, and significantly unethical treatment of Mason by Wilbur. According to Nathan, Wilbur was providing as much as 18 hours of therapy a week to Mason, was using shock therapy, and injecting Mason with Pentothal, a barbiturate commonly referred to as "truth serum."

Systematic Desensitization

Systematic desensitization is a form of behavior therapy and exposure therapy that gradually exposes a client to his or her phobia while teaching him or her to stay relaxed in the increasing presence of his or her phobia. It is also known as graduated exposure therapy.

Definitions

- **Behavioral psychology** is a form of psychology whose aim is to study behavioral adaptation to an environment and its stimuli.
- **Classical conditioning** is an involuntary process of neurological change in response to a stimulus that causes a reaction. Classical conditioning occurs when the involuntary reaction is associated (paired) to a new unrelated stimulus causing the reaction to occur automatically when the new stimulus is present. It is also known as Pavlovian conditioning.
- **Environmental mastery** is the ability to competently manage everyday affairs of living by making effective use of resources and opportunities while controlling external activities.
- **Evidence-based practice** is a form of practice that is based on integration of the best research evidence with clinical experience and client values.
- **Exposure therapy** is a therapeutic technique that encourages a client to confront a fear and refrain from reacting in his or her typical manner. It is also known as flooding.
- **In vivo** is a Latin term that means "in the living" and signifies therapeutically that an intervention is occurring in real life, as opposed to in an imagination or in a theory.
- **Pathology** is an experience of suffering or aspect of a disease incorporating cause, development, structure, and consequences.
- **Practice** is a method or process used to accomplish a goal or objective.
- **Psychotherapy** is a psychological method for achieving desired changes in thinking, feeling, and behavior. It is also called therapeutic counseling.
- **Reciprocal inhibition** is a therapeutic technique that obstructs the presence of one response through the introduction of an opposite response.
- **Relaxation training** is a progressive tensing and relaxing of specific muscle groups to teach acceptance and letting go of anxious symptoms.

Description

Systematic desensitization is a form of behavioral psychology that aims to create behavioral modification in clients suffering from phobic avoidance or other unwanted behaviors. Systematic desensitization aims to alter the involuntary response to a classically conditioned stimulus. It attempts to replace the fear response to a particular stimulus with a relaxation response to the same stimulus.

Systematic desensitization is similar to but different from exposure therapy. Both Exposure therapy and systematic desensitization are therapeutic techniques that focus on the extinction (removal) of a conditioned response. Exposure therapy (flooding) usually occurs in vivo. Sometimes it is impossible or impractical to expose a client to his or her feared stimulus in vivo, and in such cases imaginal exposure therapy is prescribed. Imaginal flooding requires the client to envision his or her phobia and refrain from becoming distressed. There is no subtlety to flooding. It is an all or nothing exposure to a phobia that teaches a client to tolerate the exposure. Therapists must be trained to assist the client through the distress that may result from exposure to a phobic stimulus. In contrast, systematic desensitization trains a client to tolerate progressive exposure to a phobia. In systematic desensitization a client is taught to stay relaxed when exposed to his or her phobia in increasing amounts. The gradual nature of systematic desensitization makes it a unique behavioral intervention.

Development and Current Status

Systematic desensitization was introduced by psychologist Joseph Wolpe (1915–1997) in the 1950s. It was a very common form of therapeutic intervention in the 1960s and 1970s. Wolpe coined the term "reciprocal inhibition" to describe the process of classically conditioning an opposite response to replace an automatic reaction to a stimulus. It was believed that a reaction and its opposite reaction could not exist simultaneously in a client. Systematic desensitization is fundamentally associated with reciprocal inhibition.

In systematic desensitization a client is instructed to rank all of his or her related fears on a scale of 1 to 100. Typically, the therapist ensures that there is no more than 10-point increments between identified fears. The fears are arranged in order of the amount of fear that the client experiences. After the fear hierarchy is created the client is trained in relaxation. Relaxation training, typically in the form of progressive muscle relaxation, is taught to clients so that they might utilize it in the presence of a feared stimulus. When the client has become proficient in relaxation training, the client is gradually exposed to his or her fears. This exposure can be imaginary or in vivo. During this exposure it is necessary for the client to remain as relaxed as possible. As distress returns, the stimulus is removed. This procedure is repeated until relaxation can be maintained for a sufficient amount of time prior to exposure to a more feared stimulus. Progressively a client learns to maintain relaxation in the presence of increasingly feared stimulus. Gradual repetition is essential to effective systematic desensitization.

The clinician works closely with the client to ensure that the client experiences no more than minimal fear during the entire systematic desensitization process. This is a critical aspect of the intervention as the conditioned response of fear must be replaced with relaxation. Research indicates that the process of successful systematic desensitization occurs within 10 to 30 therapeutic sessions.

Systems Biology

Systems biology is a new approach to the study of biology that seeks to understand how biological systems function.

Definitions

- **Biological system** is a group of cells, genes, and processes that work together to perform a specific task or function.
- **Genomic research** is the scientific study of the genes of an organism or a cell.
- **Metabolomics** is the scientific study of the chemical molecules of a cell, organ, tissue, or whole organism.
- **Proteome analysis** is the research of every protein found in a cell, organ, tissue, or whole organism at a particular point in time.
- **Proteomics** is the scientific study of proteomes. A proteome is every protein found in an organism.
- **Transcriptomics** is the scientific study of all the RNA molecules in a particular cell or group of cells.

Description

Systems biology is the integrative (putting together) approach to the study of biology. This is in contrast to the reductionistic (taking apart) approach of traditional biology. Systems biology facilitates the understanding of the larger system that biological subsystems are a part of. In systems biology the "sum of the parts is greater than the whole." Scientists strive to understand how the various subsystems combine to create the entire system, more specifically, how the different parts of a biological system interact and behave. Researchers collect data, process, and analyze it. Research analysis includes mathematical models, statistical tools, simulations, flow charts, and information processing. These computational techniques assist researchers in understanding complicated cellular and molecular processes.

Systems biology has been used to better understand the biochemical processes of the immune system and how it responds to infection and vaccination. Other uses include proteome analysis, genomic research, and cancer research. Systems biology utilizes different techniques such as transcriptomics, metabolomics, and proteomics to gather measurable data. The data is then used to construct and confirm mathematical models. Systems biology incorporates the use of computer science, statistics, and informatics. Specifically, it involves new ways to compute models, mine and combins data from empirical research literature, creates online databases for sharing information, and develops systematic methods for genomic data analysis.

The term "systems biology" was originally used by Mihajlo Mesarovic (1928–) in 1966 during an international conference entitled "Systems Theory and Biology." Mesarovic, a scientist and professor, is the forerunner of systems theory. Ludwig von Bertalanffy (1901–1972), a general systems theorist, made significant contributions toward systems biology before it was considered a field of its own. Alan Lloyd Hodgkin (1914–1998) and Andrew Fielding Huxley (1917–2012), both biologists, also made key contributions that set the stage for systems biology.

T

Tarasoff Decision

Informally, the *Tarasoff* decision refers to the result of the 1974 (reheard in 1976) landmark case of *Tarasoff v. The Regents of the University of California*, in which the Court ruled that it was a therapist's duty to warn potential victims of foreseeable danger arising from his or her patient's mental state.

Definitions

- **Confidentiality** defines the keeping private of information that is disclosed by a patient, client, or other protected party within the context of a safe, trusting relationship.
- **Duty to protect** refers to the responsibility of mental health professionals to protect their patients and other potential victims from foreseeable harm, established from the Tarasoff II decision of 1976.
- **Duty to warn** refers to the obligation of mental health professionals to warn third parties of potential harm if their client is deemed a threat to himself or herself or others that was established in the Tarasoff I decision of 1974.
- **Privileged communication** is the legal protection of any written or verbal correspondence that occurs within a confidential relationship.

Description

The Tarasoff decision refers to the landmark case of *Tarasoff v. The Regents of the University of California* that set the legal precedent of duty to warn and duty to protect for mental health professionals. In 1968, Tatiana Tarasoff and Prosenjit Poddar met at a dance and briefly dated while students at the University of California at Berkeley. Tarasoff was an undergraduate student and Poddar, who grew up in an elite caste in Bengal, India, was a graduate student in Naval Architecture. Poddar, unaccustomed to American dating customs, believed the relationship to be much more serious than Tatiana did. When Poddar discovered that Tatiana was romantically involved with other men, he became jealous and enraged, began stalking Tatiana, and telling friends and coworkers of his desire to kill her. He was urged to seek counseling and in 1969 became a patient of Dr. Lawrence Moore, a psychologist at UC Berkeley's Cowell Memorial Hospital, to whom he again relayed wanting to kill Tatiana, though he did not use her name as she was easily identifiable. Moore, believing Poddar was suffering from paranoid schizophrenia, notified police and recommended that his patient be civilly committed as he was a danger to others. Poddar was detained for a short period but then released. Dr. Harvey Powelson, Moore's supervisor, soon after ordered that Poddar not be subject to any further detainments. Neither Tatiana nor her parents ever received warning of the threat. While Tatiana traveled to visit an aunt in Brazil, Poddar befriended and moved in with her brother, though he also knew nothing of his intent. When she returned to school, Poddar carried out his plan, stabbing and killing Tarasoff on October 27, 1969, then calling the police himself. The Tarasoffs proceeded to sue Dr. Moore and several other university employees for negligence. The case went to trial but was dismissed, citing no cause of action and supporting prior precedence that a doctor's duty was to his

or her patient and not a third party. An Appeal's Court also dismissed the case and the case was then taken to the California Supreme Court. In 1974, the Supreme Court reversed the appellate decision, establishing it was a mental health professional's responsibility to provide reasonable care to patients but that this could not come at the expense of the welfare of others, who had the right to be warned of any foreseeable harm. This is commonly referred to as the Tarasoff I decision. In 1976, the case was reheard whereby the precedent of duty to protect was established, or Tarasoff II. Tatiana's family was awarded monetary damages and Poddar was sentenced to five years for manslaughter, of which he served four before his conviction was overturned due to faulty jury instructions and he was ordered to return to India.

Current Status and Impact (Psychological Influence)

Since 1976, Tarasoff has been the subject of much debate and has received increasing attention over the past few decades due to cases of school and mass shootings. The Tarasoff decision is now upheld in nearly every U.S. state where there are laws that require or permit mental health professionals to break confidentiality if they are concerned about the safety of the patient or others. Though a special, confidential relationship exists between a patient and his doctor/therapist, this cannot outweigh the safety of others. A regularly cited statement by Justice Matthew Tobriner, "*The protective privilege ends where the public peril begins*," summarizes this precedent.

Tardive Dyskinesia

Tardive dyskinesia is a neurological disorder characterized by abnormal and involuntary bodily movements. It sometimes occurs after taking antipsychotic medications.

Definitions

- **Antipsychotic medications** are prescription drugs used to treat psychotic disorders. They are sometimes referred to as antipsychotics or neuroleptics.
- **Dopamine** is the chemical messenger in the brain responsible for coordinating the movement of voluntary muscle groups. It also regulates attention, pleasure, and coping with stress.
- **Neurotransmitters** are chemicals in the brain that send messages between brain cells. There are many different types of neurotransmitters that regulate a variety of functions such as emotions and movement.
- **Psychosis** is a severe mental condition in which an individual loses touch with reality.
- **Psychotic disorder** is a severe mental condition in which an individual loses touch with reality. Symptoms can include hallucinations, delusions, and disordered thinking.
- **Schizophrenia** is a chronic mental disorder that affects behavior, thinking, and emotion, which make distinguishing between real and unreal experiences difficult.

Description

"Tardive dyskinesia" refers to abnormal bodily movements that result from taking antipsychotic medications

for a long period of time. Tardive means "late" and dyskinesia means "abnormal movements." It is not a mental disorder listed in the DSM-5 but rather a side effect of medication. Symptoms of tardive dyskinesia include involuntary movements of the face, such as frowning, blinking, mouth puckering, and clenching the jaw. Individuals may have involuntary twitching or tapping of the arms, legs, hands, or feet. Whole body movements like rocking or twisting can also occur. Some individuals may make grunting sounds or have difficulty speaking. This is due to involuntary movements of the diaphragm, the muscle that controls breathing and speech. Tardive dyskinesia progresses through stages and symptoms may be subtle at first. Subtypes of this disorder include tardive dystonia, which causes abnormal contractions of the neck and shoulders. Tardive akathisia is a general feeling of restlessness all of the time. A defining feature of tardive dyskinesia is the inability to stop these abnormal movements. This disorder is more common in the elderly. It affects between 16% and 43% of individuals taking antipsychotic medications.

Tardive dyskinesia is associated with long-term use of antipsychotic medications used to treat disorders such as schizophrenia. These medications block proteins in the brain that transmit signals from the neurotransmitter dopamine. One of dopamine's functions is coordinating movement of voluntary muscle groups. It is believed that nerves become overly sensitive to dopamine after a long period without it. This results in the abnormal and uncontrollable movements seen in tardive dyskinesia. There is no specific treatment for this disorder.

Because symptoms are caused by antipsychotic medications, discontinuing use of these medications leads to improvement. However, individuals with psychotic disorders have a high risk of psychosis returning if they do not take their medications. Tardive dyskinesia was very common in individuals taking "first-generation" antipsychotic medications. These are also known as neuroleptics. There are newer "second-generation" antipsychotic medications, which are known as "atypical" antipsychotics. These newer medications are believed to have a lower risk of tardive dyskinesia, though symptoms are still possible. Some individuals use "drug holidays" to control or prevent tardive dyskinesia. These are planned periods of time in which they do not take their medications before resuming use again. It is presently unclear whether or not drug holidays are effective. There is a better chance of eliminating symptoms of tardive dyskinesia the earlier they are identified. In most cases, they are not permanent and can be reversed.

Tattoo

Tattooing is a form of body modification in which permanent marks or designs are applied by inserting indelible pigments into the skin with a needle.

Description

The custom of permanently marking the body with pigments has been practiced across cultures for centuries as a normal and socially sanctioned custom. American attitudes have evolved over time, with tattoos, piercings, and other body modifications increasingly accepted as a way to mark a life experience, express identity, or collect as "body art." The number of Americans with a tattoo or body piercing is increasing, especially among college-age students, with genders equally represented. Recent studies indicate that 15%–25% of 15- to 25-year-olds have tattoos and 13% of the general population has a body piercing.

Formerly tattoos were associated with criminals, gang members, or members of the military who had gotten tattoos while on leave. Now, tattoos have become generally accepted. (Litwinphotography/Dreamstime.com)

American attitudes toward tattoos have vacillated between being regarded as fashionable and associated with deviance. In the 18th century tattooing was in vogue with the upper classes, but by the end of the 19th century criminologists began associating tattooing with criminal pathology and social attitudes began to change. With the invention of the electric tattoo machine, tattooing became more accessible, affordable, and popular among the less wealthy, and tattooing began to be associated with the lower-working classes and subcultures. By the beginning of the 20th century tattooing was closely associated with deviance, criminality, and socially undesirable behaviors. Having a tattoo was an indicator of low self-esteem, aggressiveness, impulsivity, sexual deviance, and psychopathology. Tattooing has also been closely associated with marginalized and stereotyped subculture groups, such as sailors, "savages," bikers, and motorcycle gang members, the incarcerated, and circus performers.

In response to the negative social connotations of tattooing, a vibrant subculture developed that provided support to the tattooed and began to redefine and change the negative social and intrapersonal connotations. In the 1960s public interest grew as the tattoo industry made advancements in technique, design, style, and sanitation standards. By the 1980s tattooist were redefining themselves as artist and more professionals and females were purchasing custom tattoos. By the 1990s tattooing was no longer singularly associated with social outcasts and was practiced by individuals from a wider range of socioeconomics, education, and occupations.

More recently, nationally representative research studies have been conducted, examining the social characteristics of those who are tattooed compared to non-tattooed, and the association to deviance. The research results have been mixed, with one study finding that having a tattoo was not associated with recreational

drug and alcohol use and another study finding a strong association. Younger respondents were more likely to have multiple tattoos than older respondents, and those with tattoos compared to non-tattooed individuals were more likely to have a body piercing and have a family member who was tattooed. People with tattoos, as a group, tend to be less educated and less religious than the non-tattooed. The research found that having a tattoo on the face, neck, hands, or fingers was associated with having spent three or more days incarcerated. This suggests that the area of the body which is tattooed can be stigmatizing and associated with deviance and criminality.

In spite of the positive change in attitudes toward tattoos, research suggests that the practice of tattooing continues to carry a stigma. Studies have indicated that in spite of evidence to the contrary teenagers with tattoos are often perceived as dropouts, drug users, and trouble makers, and medical professionals tend to attribute tattoos to gang affiliation. Ethnic and racial minorities are likely to be perceived as gang members and criminals by the non-tattooed. Others may easily misinterpret symbols that have a positive meaning for the tattooed, and tattooed individuals are frequently required to cover their body art by employers.

Tattooing is a form of body modification and is increasing in frequency especially among teenagers and college students, but also among adults of all ages. American attitudes are changing about the tattooed but continue to be stigmatizing. Tattooing and other body modifications are an increasingly popular form of self-expression, community, and social commentary.

Teen Pop Stars

Teen pop stars are a select group of young celebrities who become famous for their participation in music, movies, television, the Internet, and more.

Description

Music is a kind of universal language that speaks to people's emotions. As a genre, pop music has an especially

Singer Britney Spears, a child performer on the Mickey Mouse Club, and later a teen pop star in the late 1990s and early 2000s, was criticized for overly sexualized dress and performances. She also went through a period of erratic behavior and stayed in various treatment centers. Because she and other pop stars exert an enormous influence on impressionable young fans through their language, style, attitudes, and habits, there is always concern about fans imitating the less desirable traits of celebrities. (S. Bukley/ Dreamstime.com)

strong connection with teenagers and preteens. The musicians who create and play pop music often become the focus of young people's interest, admiration, and even obsession. Many of these musicians cross entertainment genres to play roles in movies and television.

Teen pop music is defined by the age and interests of its fans. The term "pop" comes from the more traditional or popular music and first came about in the 1950s and 1960s when representing the new music of the baby boomers. It especially came to public notice with the worldwide success of the Beatles and other bands in the early 1960s.

The music itself can be of many genres, from rhythm and blues, to hip-hop, country and rock and roll. The content of the music focuses on subjects and issues of interest to teenagers. This includes first loves, sexual relationships, finding yourself, friendships, independence, and the role of authority figures. The approach to these subjects ranges from serious introspection and self-pity to comedic and light-hearted awareness of the irony and humor in life. This musical form often includes a catchy beat and a repeated soaring chorus.

The stars and musicians who perform these songs often begin as teenagers themselves like Elvis Presley, the Beatles, and Michael Jackson. Every year there seems to be a new pop sensation, like Beyoncé, Taylor Swift, Justin Bieber, or Miley Cyrus, who attracts the passions and the pocketbooks of a new generation of fans. The best of these go on to long careers, and what begins in adolescent adoration can become a lifelong devotion and fandom that makes these teen pop stars enduring cultural icons. Teen pop stars today ride on a wave of reality television, auto-tuned vocals, dance, and special effects.

Impact (Psychological Influence)

If popular culture taste, styles, and the identification of its stars were once under the control of adults, this changed after World War II. When the baby boomer generation was growing up, they had unparalleled access to education, electronic media, and money. These three enabled them to exert an influence on the kinds of music that were produced and on the stars who would be successful.

Teen pop stars can often represent a world of freedom, success, and perfection to the young people who idolize them. They can inspire their fans to levels of fantasy involvement and style imitation that have an enormous influence not only on their attitudes but also on the way they spend their time and their money. Sadly some teen pop stars rise to success at a young age where their power combined with poor decisions means that in adulthood they are plagued with mental health and substance abuse issues.

Many teen pop stars exert an enormous influence on their fans through their language, style, attitudes, and habits. When these are problematic, as they were with Madonna in the 1990s and Britney Spears in the early 2000s, imitation can be dangerous to the life and health of the fans. Use of drugs, negative body image, and unhealthy sex habits are all areas where teens can be vulnerable because of observing and imitating the teen pop stars they follow.

When the influence of teen pop stars is more positive, they can reinforce good habits and attitudes in their fan base. In the future teen pop stars will continue to be imitated and influential. The symbiotic relationship between stars and fans will continue to change personal attitudes and set trends that will have a great effect not only during their own brief period of success but for many years afterward.

Tegretol (Carbamazepine)

Tegretol is a prescribed medication for the treatment of seizures and mania. Its generic name is carbamazepine.

Definitions

- **Anticonvulsants** are medications used to treat and to prevent seizures.

- **Mania** is the euphoric or irritable mood of bipolar disorder. It is characterized by mental and physical hyperactivity, disorganized behavior, and inappropriate elevation of mood.
- **Seizure** is a sudden convulsion or uncontrolled discharge of nerve cells that may spread to other cells throughout the brain.

Description

Tegretol belongs to a class of medications known as anticonvulsants. Tegretol is effective in the treatment of psychomotor and grand mal seizures and a type of facial pain called trigeminal neuralgia and, in combination with other drugs, for mental disorders such as mania and extreme aggression. Tegretol is also occasionally used to control pain in persons with cancer.

It is structurally related to tricyclic antidepressants such as Elavil and Tofranil. Tegretol is believed to work by increasing the levels gamma-aminobutyric acid (GABA), which is an inhibitory neurotransmitter. That means that as GABA levels increase in the brain, neurons (nerve cells) become less excitable. The result is a lessening of seizure activity, manic behavior, and aggression.

Precautions and Side Effects

Because Tegretol causes aplastic anemia, blood counts should be monitored in those using this medication. Tegretol should be used with caution in those other types of seizure disorders such as atypical absence seizures. Among such individuals, Tegretol usage has been associated with an increased risk of initiating, rather than controlling, generalized convulsions. This medication should not be discontinued abruptly since it may result in seizures. Tegretol use can increase the risk of birth defects when taken during pregnancy. Women who take Tegretol should not breast-feed, since it can pass into the breast milk. It also can decrease the effectiveness of oral contraceptives. Tegretol causes drowsiness and impairs alertness in some individuals, so care must be taken in driving and using machinery until they determine how the drug affects them. The sedative effects are increased in the presence of alcohol, so it should be avoided when taking Tegretol.

The most commonly reported adverse reactions to Tegretol are dizziness, drowsiness, unsteadiness, nausea, and vomiting. It may also cause a skin rash or sensitivity to the sun as well as blurred vision. Using Tegretol along with E-M erythromycin, Tagamet, Darvon, Laniazid, Prozac, and heart medications like as Procardia and Calan may increase the blood level of Tegretol to a toxic range. Using Tegretol and oral contraceptives may increase the possibility that they will not be effective in preventing pregnancy. Those taking Tegretol should not drink grapefruit juice as it can increase the concentration of Tegretol in the bloodstream.

Temper Tantrum

A "temper tantrum," or tantrum, refers to a bout of uncontrolled, angry, violent, or disruptive physical and/or verbal behavior.

Definitions

- **Attention-deficit hyperactivity disorder (ADHD)** is a behavioral diagnosis characterized by a combination difficulty sustaining attention, hyperactivity, and impulsivity.

- **Bipolar disorder** is a diagnosed disorder characterized by marked fluctuations in mood and emotional state, both manic and depressive.
- **Disruptive mood dysregulation disorder (DMDD)** is a mood disorder marked by disruptive outbursts indicative of severe impairment in one's ability to regulate temperament.
- **Oppositional defiant disorder (ODD)** is a mood disorder categorized by an ongoing pattern of defiant, uncooperative, hostile behavior.

Description

The term "temper tantrum" is used to refer to out-of-control behavior displayed by an individual, typically a child. Tantrums can be short lived, lasting only a few seconds, or continue for longer periods of time, perhaps up to several hours. Temper tantrum behavior is characterized by verbal outbursts, loss of bodily control, and/or physical aggressiveness. When one is in the midst of a tantrum, one may cry, scream, curse, hit, kick, punch, throw, and/or destroy things. Tantrums occur most commonly in small children between the ages of two and four, though older children, adolescents, and even adults can display tantrums. This type of behavior is often associated with the "terrible twos." When tantrum behavior continues into school age (past five years old), or outbursts become increasingly intense or excessive, then this may be indicative of other problems. Oftentimes temper tantrums result from feelings of anger or frustration with a situation, person, or thing. The individual displaying tantrum behavior may have been denied access to something he or she wants; may have been asked to do something he or she doesn't want to do; may be overtired, hungry, or ill; may be unable to express his or her feelings appropriately; may have been rewarded in the past for the tantrum, or may simply want attention.

Use of the term "temper tantrum" increased during the 1950s as mothers began expressing concerns over noticeable patterns of disruptive outbursts from their young children. Pressure to fit the perfect family mold lessened as psychologists, psychiatrists, therapists, counselors, and educators began to acknowledge the developmental prevalence of tantrum behavior. The term "terrible twos" followed noting the highest incidence rates between the ages of two and three years. Scientists later determined a neurological connection between this type of behavioral impairment and activity in the amygdala, part of the limbic system responsible for the flight or fight response.

Impact (Psychological Influence)

Multiple research studies, workshops, manuals, and parenting guides have been conducted to address the temper tantrum issue. An association has been made between children who are easily frustrated, emotionally oversensitive, impulsive, stubborn, or strong-willed and higher incidences of temper tantrums. Older children who exhibit a history of being unable to control their anger, regulate emotions, or manage their own behavior may be diagnosed with ADHD, bipolar disorder, ODD, or DMDD. DMDD is a new diagnostic term that may be used to categorize an excessive history of temper tantrums. There is an ongoing need to investigate and incorporate childhood behavior and mood-related disorders into diagnostic criteria and treatment protocol to further educate people on the difference between normal childhood stages and excessive incidences of tantrum behavior.

Terminal Illness, Psychological Factors

When a person is medically diagnosed with a terminal illness, this means that his or her condition will not respond adequately to treatment and will eventually result in death.

Definitions

- **Advance directives** are instructions outlined in a legal document that provide details for care that a person wants carried out on his or her behalf should his or her health, either medical or mental, become compromised; examples include living wills and do-not-resuscitate orders.
- **Anticipatory grief** is the type of grief associated with situations where the loss of a loved one is impending as with a terminal illness.
- **End-of-life care** refers to health care that is provided by nurses, hospice care professionals, or other medical practitioners to patients in the final days or hours of their life, commonly those who have been diagnosed with a terminal illness.
- **Euthanasia,** also known as "assisted suicide," refers to the practice of aiding another person in intentionally ending his or her own life in order to end pain and suffering.

Description

When a condition is deemed "terminal," medical professionals in charge of care have determined that the patient is not likely to benefit from further treatment interventions and that death is inevitable. A patient may be categorized as *terminally ill* or *terminal* when his or her life expectancy is approximately less than six months, though this is just an estimate and can vary depending on the progression of the disease. Common diseases for which there is no cure include some kinds of cancer, advanced heart disease, HIV/AIDS, and Alzheimer's disease. Being diagnosed with a life-threatening or terminal illness can result in psychological and emotional trauma for both patients and their loved ones.

A patient who has been diagnosed as terminal may experience a wide range of feelings, behaviors, and psychological reactions that can vary depending on his or her coping style, prognosis, support system in place, personality, and/or additional compounding factors. If a patient's prognosis is grim and he or she does not have long to live, then this can significantly impact his or her thoughts, feelings, and behaviors. Initially, the person may seek answers as to why this has happened to him or her. The person may also investigate the disease further in hopes of understanding how best to cure it. Some patients may pursue radical treatment options (strict nutrition regimens, supplements, acupuncture), while others may choose to stop treatments altogether. As time passes and the disease progresses, however, the patient may become more anxious and feel an impetus to get in as many experiences as possible while he or she is still able to do so. Spending time with loved ones and attempting to put one's affairs in order are behaviors that are also more likely to occur as death nears.

The ways in which one copes with a terminal diagnosis (anticipatory grief) is important. Negative coping behaviors include those in which the patient closes himself or herself off to others, emotionally and/or physically, becoming reclusive and increasingly depressed. In addition, someone who remains angry, hostile, and resentful may also be characterized as having a negative coping style. Those who remain in denial about their prognosis are not effectively coping with the terminal diagnosis either. On the other hand, positive coping behaviors may include seeking counseling from a mental health professional or support group, discussing the prognosis openly and honestly with loved ones, enjoying the remainder of life's experiences, and putting one's affairs in order.

Emotionally, those dealing with terminal illness may react in a variety of ways. In her 1969 book *On Death and Dying*, psychiatrist Elisabeth Kübler-Ross introduced five stages of grief that are commonly experienced by terminally ill patients: *denial, anger, bargaining, depression*, and *acceptance*. These stages have been applied to the emotional, psychological, and behavioral reactions of patients and their loved ones as well as those who are experiencing other forms of loss

including divorce, infertility, incarceration, and addiction. The five stages are not intended to be all encompassing or describe every possible emotional reaction of those who are grieving. Neither are they meant to be sequential; one can progress through each in a linear fashion or jump back and forth through different stages at any point in the grieving process. During the first stage, *denial*, patients are often in shock or disbelief and are not ready to accept the information as reality. They may seek alternative opinions that contradict the diagnosis in order to maintain hope. In stage two, *anger*, the patient may lash out, be hurtful to others, or react with envy or resentment toward those who are healthy. This can be an extremely difficult stage for loved ones of the patient to endure. Stage three, *bargaining*, is characterized by negotiating. The patient does what he or she can to sustain hope by trying to avoid or postpone the inevitable. The patient may bargain with a higher power for a miracle cure, more time with their loved ones, or a resolution to a problem. *Depression*, stage four, is one in which the patient experiences extreme sadness, fear, and regret about the impending death. At this point, the patient realizes that there is nothing he or she can do to change his or her situation and he or she begins to accept his or her fate. In stage five, *acceptance*, which is the goal of the grieving process, a patient may act more calm, retrospective, and peaceful as he or she has accepted death as an inevitable fate.

Current Status and Impact (Psychological Influence)

The majority of professionals in the medical and mental health fields support being up front, honest, and realistic with patients regarding their diagnosis. Research indicates that patients who are hopeful and optimistic experience lower rates of depression, anger, and anxiety. Longer survival rates are also noted in these types of patients.

There has been much controversy surrounding matters related to end-of-life care, euthanasia, and advance directives. Some regard the final stages of life as a natural progression that should remain free from medical imposition, while others argue that medical advancements exist to offer patients reduced pain and suffering during these times. Euthanasia, intentionally intervening to promote an individual's death, is outlawed in the majority of states nationwide. In addition to legal considerations, religious and moral implications exist for these acts. Another issue for debate is the creation of advance directives that allow for individuals to indicate their medical intentions legally in the event that they become incapacitated. *Do not resuscitate* orders in particular have been questioned in cases where brain activity remains. All of these issues pose difficult legal, moral, and ethical dilemmas for the majority of people.

Texting

"Texting" is a verb used to describe the action of sending a text message typically via a cellular phone application. It describes a process of communicating through typed word messages from one cell phone to another. Text messaging has become a preferred method of communication and has replaced phone calls and e-mail and is particularly popular with adolescents and young adults.

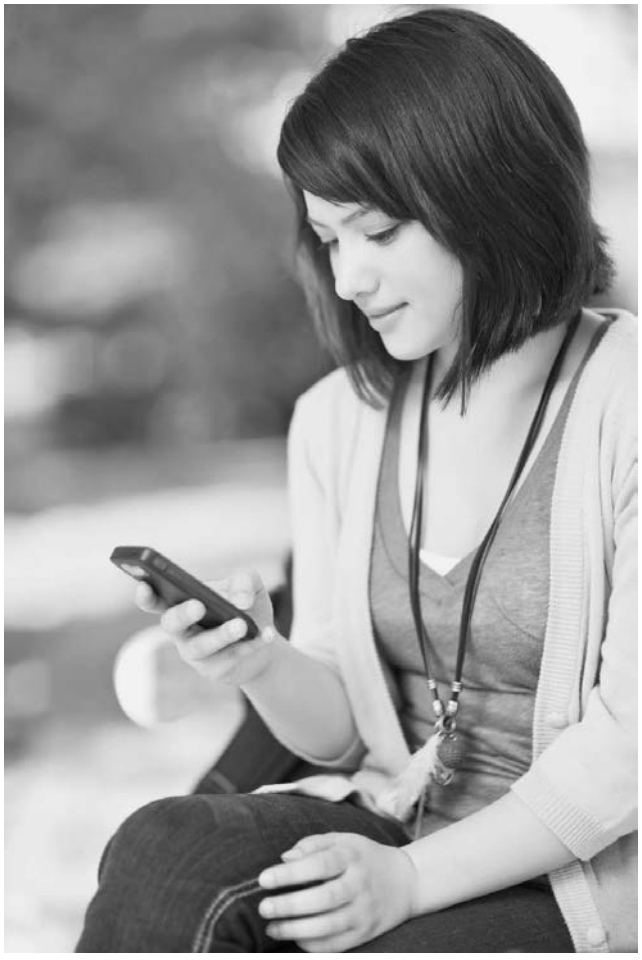
Definition

- **Short message service (SMS)** is another name for texting, sending a text message, or text messaging. This service describes the

process of sending brief texted script from one cell phone to another or from an Internet source to a cell phone. SMS has now grown to include images, video, and sound content (known as MMS messages).

Description

"Texting," or "text messaging," refers to a type of communication whereby a person (the texter) sends a message in typed text to another person (the receiver) via a mobile phone or portable device through a network. In the United States, or other locations where English is the predominant language, texts can be made up using all 26 letters of the alphabet, 10 numeric numerals, and any combination of the two.



Especially for young people, text messaging has essentially replaced phone calls or face-to-face communication. Texting or reading texts while driving has become a major safety issue for all ages and is considered as dangerous as driving while under the influence of alcohol or drugs. (Suprijono Suharjoto/Dreamstime.com)

Back in 1920, a New York company, RCA Communications (now Verizon Wireless), introduced the first "telex" service to transmit messages between New York and London. In the early 1970s, radiotelegraphy, the transmittal of alphanumerical messages sent by radio, was developed using a service known as ALOHA.net. Several contributions followed, including key ideas about function, operation, and technology from Matti Makkonen (regarded as the "father of text messaging"), Hillebrand and Ghillebaert, Finn Trosby, and Holley and Harris. All of these added to the eventual creation of SMS. The first SMS message, "Merry Christmas," was sent on December 3, 1992, by Neil Papworth, a young test engineer for the Sema Group. Finland was the first nation to offer SMS on a commercial basis. Omnipoint Communications was the first to provide text messaging services in the United States.

Today, texting is a common communication method used by people to interact with friends, family, and even coworkers. It is used all over the world but is particularly popular in Europe, Asia, the United States, Australia, New Zealand, and Africa. A study conducted by The Pew Research Center in May 2010 indicated that 72% of adult cell phone users in the United States send and receive text messages. These numbers are even higher for U.S. teens. Numbers indicate that American teens use text messaging over all other forms of communication, and reports cite that they send between 50 and 100 texts per day.

Communicating via text message can be quick and effective; however, content can also be misconstrued if it is read or interpreted incorrectly by the receiver. Largely, text messaging has replaced face-to-face contact or even voice contact over the phone. This has raised concerns about the value and authenticity of texting as a sole source of communication.

Impact (Psychological Influence)

Issues have been raised over the prevalence of text messaging and how it has essentially replaced verbal or face-to-face communication nowadays, particularly with the adolescent and young adult populations.

Of recent concern is the problem of texting while driving. Texting while driving has been proven to be more dangerous and even fatal than drinking and driving.

Proponents of texting argue that it is easier, faster, and more convenient to send a text than it is to pick up the phone; however, consideration must be given to how this can impact relationships and communication styles. When people do not readily engage in face-to-face or other forums of direct communication, much can be lost in translation. Voice tone, quality, inflection, sarcasm, and feelings are likely to be misconstrued if texting is the sole form of communication taking place between two people.

Regardless of the drawbacks, texting remains the most widely used mobile data service. Given this fact, it has been used across several areas: marketing, sales, research, and even politics. Companies and organizations have developed ways to use texting to gather information from the masses and drive sales, gauge product popularity, and predict voter trends.

Thematic Apperception Test (TAT)

The Thematic Apperception Test (TAT) is a projective test consisting of picture cards used to assess a person's major personality traits, underlying motives or concerns, and overall psychological well-being.

Definitions

- **Apperception** is the process of understanding something through associating it with a previous experience.
- **Projective test** is a type of psychological assessment that seeks to assess a person's true feelings, thoughts, and attitudes based on responses to ambiguous stimuli.

Description

The Thematic Apperception Test is a projective personality test that uses picture interpretation to gain insight regarding one's personality dynamics, hidden desires, and overall psychological wellness. Projective assessments, used commonly by Sigmund Freud, encourage one to freely express one's thoughts, feelings, and experiences. Practitioners make general impressions and insights based on the answers the person gives after being exposed to a series of ambiguous picture cards. The TAT was created for use with individuals 10 years of age and older.

The complete version of the TAT is comprised of a series of 32 picture cards. Pictures depict human figures, adults and/or children, in common social and relational situations; other pictures have no human figures at all. One picture card is completely blank, allowing for the client to develop his or her own original story. Respondents are asked to develop their own stories and share them aloud based on the scenes in the cards. Stories should contain the following four elements: (1) current situation, (2) thoughts and feelings of the characters, (3) preceding events, and (4) outcome. Answers are believed to reveal underlying themes, emotions, and conflicts about the person's inner world and interpersonal relationships. The test was designed for use with ages 10 and older, and any picture card can be used with these subjects though Murray proposed that scenes showing characters of similar age and gender may elicit more information from subjects. In order to gather the most information it is recommended that practitioners employ a variety of 20 cards, though generally most select 8 to 12 cards. Administration of the TAT takes approximately one and a half to two hours. However, there is no set time limit. There are no right or wrong answers, and no numerical scores are given on the TAT.

Development (Purpose and History)

The TAT was developed by American psychologist Henry A. Murray and psychoanalyst Christiana D.

Morgan at the Harvard Psychological Clinic at Harvard University during the 1930s and early 1940s. Murray and Morgan spent the latter part of the 1930s selecting pictures from illustrated magazines for the TAT. Three separate picture series (Series A, Series B, and Series C) were proposed before they decided on a final set, Series D. This version of the test was published in 1943 and is still in use today. Though Morgan was credited on the first publication citing the TAT in 1935, she was not listed as an author on the published version of the assessment tool itself. Psychoanalysts, clinicians, and therapists began readily using the TAT after World War II to assess the emotional stability of returning veterans. Increased use of the TAT came again later during the 1970s, and the Human Potential Movement as mental health practitioners used it as a vehicle to get to know more about its clients and promote their personal growth.

Current Status and Results

Administration of the TAT should be conducted only by a trained professional (psychiatrist, psychologist, licensed counselor, social worker, or teacher with specific training in this type of assessment). The results of this assessment alone should never be used to diagnose but should be included as part of a larger battery of tests. Thorough medical, familial, and behavioral histories should also be obtained. This way the assessor has a comprehensive picture of the examinee's overall psychological functioning.

Concerns have been raised as to the reliability and validity of the TAT as it lacks a standardized administration protocol, scoring system, and established norms. In addition, both inter-rater reliability and test–retest reliability are highly variable, indicating that there is no clear evidence to support that this test measures what it seeks to or that it measures constructs consistently from person to person. Finally, due to the subjective nature of the TAT, findings are likely to endure examiner bias and error.

Therapeutic Alliance

"Therapeutic alliance" refers to the relationship between a therapist and client that is a necessary component of effective psychotherapy.

Definitions

- **Bond** is the relational and emotional dynamic between the client and counselor.
- **Clinician credibility** is the client's perception that the therapist is effective and trustworthy.
- **Common factors** is the viewpoint that psychotherapy has common components or factors and that these effect change more than specific factors or techniques.
- **Goals** are objective and measurable outcomes that a client can achieve while in therapy.
- **Psychotherapy** is a psychological method for achieving desired changes in thinking, feeling, and behavior. It is also called therapy and therapeutic counseling.
- **Tasks** are the objectives or steps that support achieving a treatment goal.

Description

The therapeutic alliance is a crucial part of the change process in psychotherapy. It is also an important variable in psychotherapy research. The therapeutic alliance can have a significant effect on the process of therapy and the overall outcome. Research on common factors in therapy suggested that the therapeutic alliance accounts for 30% of the variance in client change and improvements (Sperry, 2010). Lambert identified

the following "common factors" that influence change and improvements among clients in therapy: the therapeutic alliance, the placebo or hope effect, therapeutic strategies, and client factors. The research on common factors contends that regardless of theoretical orientation, the therapeutic alliance and other factors effect change in the therapy process.

Psychologist Edward S. Bordin (1913–1992) is credited with proposing the commonly accepted understanding of the therapeutic alliance. Based on research, Bordin found that there were three components to a therapeutic alliance. The therapeutic alliance incorporates a bond between the client and counselor, and mutually agreed-upon goals and tasks to assist the client in achieving therapy goals. Both the therapist and client are responsible for setting an agenda for each session, while many of the tasks that occur in counseling are collaboratively determined by both individuals. The therapeutic alliance is an ongoing relational process that occurs throughout the duration of therapy. The initial contacts are typically facilitated by the therapist's rapport-building skills, while each encounter between the therapist and client influences the development of the alliance. The bond between the client and a therapist includes an emotional component, which could be called a "meeting of the hearts," and also a cognitive element called "a meeting of the minds" (Sperry, 2010). This process includes the client and therapist collaborating on what needs to occur in session for the client to attain treatment goals. The "meeting of the hearts" occurs when the client feels that the therapist cares about the client and wants to see him or her succeed. Therapists who incorporate active listening and responding, encouragement, and warmth will facilitate an effective therapeutic alliance. In such a relationship, clients will feel valued, supported, and accepted, and will believe that their therapist wants to see them succeed.

Psychologist Carl R. Rogers (1902–1987) identified three core conditions that he believed were the necessary and sufficient conditions for change in counseling. The core conditions include unconditional positive regard toward the client, genuineness of the therapist toward the client, and empathy. The majority of counseling theories articulate that the therapeutic alliance facilitates change, while some theories such as Carl Roger's person-centered theory articulate that the relationship is a primary mechanism of change in counseling. Many of the psychodynamic counseling theories also endorse the therapeutic alliance as a primary mechanism for change in counseling. Besides the importance of therapeutic alliance, the client's perception that the therapist is effective and trustworthy is called clinician credibility.

The client's perception of the therapist's effectiveness and trustworthiness influences the therapeutic alliance. The therapist will be seen as trustworthy if he or she is supportive; is sensitive to the client's needs; is accepting and caring; and instills confidence, hope, and faith that the client will improve. The therapist will establish effectiveness and interpersonal influence by showing evidence of multicultural competence, by displaying a sense of focus and direction in the treatment, by structuring sessions, and by fostering change among the client in sessions and between sessions.

Thorazine (Chlorpromazine)

Thorazine is a prescribed antipsychotic medication used to treat schizophrenia and the manic phase of bipolar disorder. Its generic name is chlorpromazine.

Definitions

- **Antipsychotic medications** are prescription drugs used to treat psychotic disorders. They

are sometimes referred to as antipsychotics or neuroleptics.

- **Bipolar disorder** is a mental disorder characterized by alternating episodes of extremely low mood (depression) and exuberant highs (mania). It is also known as manic-depressive disorder.
- **Deinstitutionalization** is the process of replacing long-stay psychiatric hospitalization with less isolated community mental health services for those diagnosed with a severe mental disorder or a developmental disability.
- **Extrapyramidal symptoms** are a group of side effects associated with antipsychotic medication use that are characterized by involuntary muscle movements, including rigidity, contraction, and tremor.
- **Neuroleptic malignant syndrome** is a potentially fatal condition resulting from antipsychotic use characterized by severe muscle rigidity (stiffening), fever, sweating, high blood pressure, delirium, and sometimes coma.
- **Psychosis** is a severe mental condition in which an individual loses touch with reality. Symptoms include hallucinations (hearing or seeing things that are not there), delusions (fixed false beliefs that persist despite contrary evidence), and disordered thinking.
- **Schizophrenia** is a mental disorder in which it is difficult to distinguish real from unreal experiences. Symptoms include hallucinations, delusions, thought and communication disturbances, and withdrawal from others. Tardive dyskinesia are involuntary movements caused by certain antipsychotic medications. They include tongue thrusting, repetitive chewing, jaw swinging, and facial grimacing.

Description

Thorazine is one of a class of antipsychotic medications known as "typical" or first-generation antipsychotics. It is in the subclass of phenothiazines along with Prolixin, Stelazine, and Navane. Thorazine was the first medication developed (1950) with specific antipsychotic action. It has been described as the single greatest advance in improving the prognosis of patients in psychiatric hospitals worldwide. Its use was a major impetus in achieving deinstitutionalization. Therapeutically, Thorazine is effective in treating "positive" symptoms of schizophrenia (abnormal thoughts and perceptions, such as delusions, hallucinations, or disordered thinking) and the manic phase of bipolar disorder. It is also used to manage behavioral symptoms such as aggression, combativeness, and excessive excitability. Thorazine is sometimes used as a sedative and to relieve nausea, vomiting, and persistent hiccups. It is thought to work by blocking dopamine receptors in the brain and interfering with dopamine transmission.

Precautions and Side Effects

The most common side effects of Thorazine include drowsiness, low blood pressure, constipation, decreased sweating, muscle spasms, dry mouth, and nasal congestion. Children may be especially susceptible to muscle spasms, while the elderly may be particularly sensitive to sedation and low blood pressure. Thorazine has the potential to cause extrapyramidal symptoms, tardive dyskinesia, and neuroleptic malignant syndrome. Other risks of Thorazine include liver damage, seizures, visual impairment, and tardive dyskinesia. Overdose symptoms include significant drowsiness, severe dizziness, significant breathing difficulties, severe weakness, trembling muscles, and severe uncontrolled movements. Thorazine should not be used by women who are pregnant, trying to become pregnant, or breast-feeding. Infants born to mothers who had taken Thorazine during pregnancy may develop extrapyramidal symptoms and withdrawal symptoms, including agitation, trouble breathing, and difficulty feeding.

Thorazine interacts with a number of other medications. Individuals who are starting this drug should review the other medications they are taking with their doctor for possible interactions. Thorazine should not be combined with other substances that depress the central nervous system, such as antihistamines,

alcohol, tranquilizers, sleeping medications, and seizure medications. Thorazine should not be combined with anticholinergic drugs because of the potential of decreased antipsychotic effects. Thorazine may enhance the effects of medications that lower the seizure threshold, such as steroid medications, asthma medications, and other psychiatric medications. Patients with epilepsy may require dosage adjustments of their antiseizure medications. The effectiveness of medications for Parkinson's disease may be reduced by Thorazine and other antipsychotics. The likelihood of changes in heart rhythm may be increased when the drug is taken with other medications that have the same effect, including other antipsychotic drugs, antidepressants, certain heart medicines, and erythromycin.

Three Faces of Eve, The (Movie)

The Three Faces of Eve is both a best-selling book and a major motion picture that is based on the biography of a woman diagnosed with multiple personality disorder, now called dissociative identity disorder.

Description

The Three Faces of Eve was both a best-selling book and a major motion picture. The movie, starring Joanne Woodward, first appeared in theaters in 1957 but remains a classic to this day. Based on the biography of a woman diagnosed with multiple personality disorder, the movie is chronicled in a book of the same name written by two psychiatrists, Corbett H. Thigpen and Hervey M. Cleckley. Woodward won a Best Actress Oscar and Golden Globe award for her role as Eve, a young, unassuming Georgia housewife suffering from multiple personalities, a term currently known in the DSM-5 as dissociative identity disorder. Nunnally Johnson was the producer and director of the movie, and also wrote the screenplay.

At the time, *The Three Faces of Eve* was considered a landmark film delving into the depths of what was once considered a mythical psychiatric illness. After displaying strange behavior, Eve White (played by Joanne Woodward) is taken to a psychiatrist (played by Lee J. Cobb) by her violent and abusive husband (played by David Wayne). Her husband reports she has been singing and dancing in bars and has purchased seductive clothing that is out of character for her. Her psychiatrist soon meets Eve Black, which is one of Eve's other personalities, or "alters." The psychiatrist realizes he is witnessing a rare case of multiple personality disorder and begins intensive psychotherapy with her to reclaim her missing memories. Through the course of her treatment, she leaves her unhealthy marriage and begins to uncover repressed memories of childhood trauma and abuse. Ultimately, in addition to Eve White (the good girl) and Eve Black (the bad girl), a third personality emerges—Jane (the mature intellectual). Jane slowly replaces the other two personalities and finds a new life with a loving husband.

Impact (Psychological Influence)

By today's standards, the book and movie seem old-fashioned and tame, but in 1957 it was considered groundbreaking. Never before had Hollywood tackled the true story of a patient with multiple personalities. The reason it resonated with the American public has much to do with the social climate at the time. At the end of World War II (1945), soldiers were coming home with post-traumatic stress disorder and other types of psychological distress. This, in turn, created a groundswell of curiosity among the general public in psychology and psychiatry.

Until the release of *The Three Faces of Eve* in book form, such well-documented (and well-distributed)

The Three Faces of Eve was both a best-selling book and a popular movie of 1957 starring Joanne Woodward, who won an Oscar for her performance. Based on the life of a woman diagnosed with multiple personality disorder, now called dissociative identity disorder, it also focused on her psychiatric treatment. (Twentieth Century Fox Film Corp./Photofest)

information by clinicians didn't exist on the topic. In 1951, Eve White (a pseudonym for the patient later revealed to be Chris Costner) was referred by her physician to the two psychiatrists. Three years later, Thigpen and Cleckley submitted a 17-page article that was published in the *Journal of Abnormal and Social Psychology*. The article was believed to be the first documented observation of documented multiple personality disorder that had been recorded in the 20th century. The response was so overwhelming by their colleagues that the two later expanded the article into a book, which soon afterward became a major motion picture.

Tic Disorders

Tic disorders are mental disorders characterized by rapid and recurrent body movements and vocalizations.

Definitions

- **Antipsychotic medications** are prescription drugs used to treat psychotic disorders. They are sometimes referred to as antipsychotics or neuroleptics.
- **Cognitive behavior therapy** is a form of psychotherapy that focuses on changing maladaptive (faulty) behaviors, emotions, and thoughts. It is also known as CBT.
- **Dopamine** is the chemical messenger in the brain responsible for coordinating the movement of voluntary muscle groups. It also regulates attention, pleasure, and coping with stress.
- **DSM-5** stands for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, which is a diagnostic system used by professionals to identify mental disorders with specific diagnostic criteria.
- **Neurodevelopmental disorders** are neurological disorders characterized by impairments of the growth and development of the brain or central nervous system.
- **Serotonin** is a chemical messenger in the brain that regulates learning, sleep, mood, and appetite. It is involved in disorders such as depression and anxiety.
- **SSRI** stands for selective serotonin reuptake inhibitors. They are a class of antidepressant medications that work by blocking the reabsorption of serotonin in nerve cells and raising its level in the brain resulting in symptom reduction.
- **Stereotypic movement disorder** is a mental disorder characterized by repeated and purposeless physical movements that cause distress or impairment.
- **Tics** are involuntary, compulsive, repetitive, and stereotyped movements or vocalizations. While they are experienced as irresistible, they can be temporarily suppressed.
- **Tourette's disorder syndrome** is a neurological disorder characterized by recurrent involuntary movements and vocal tics such as grunts, barks, or words, including obscenities.

Description and Diagnosis

Tic disorders are listed in the DSM-5 as neurodevelopmental disorders. They are characterized by involuntary, sudden, rapid, recurrent, and nonrhythmic body movements or vocalizations. Examples of movement-related tics include blinking, shoulder shrugging, and facial gestures. Vocal (or phonic) tics include coughing, barking, or repeated statements such as "Stop it!" Tics may be either simple or complex. Simple tics are only one movement or sound and last about one second. Complex tics involve longer and purposeful movements and sounds, such as *copropraxia* (obscene gestures), *echopraxia* (imitating another individual's movements), and *coprolalia* (obscene words, phrases, or slurs). These last many seconds and are usually a combination of multiple simple tics. Tics come and go over time, and may fluctuate in severity and type. They may also become more frequent or severe during times of increased stress or emotion. Many individuals with mild or moderate tics do not experience problems functioning in daily life. While temporary tics are common in children, only a small percentage develops a tic disorder. Tic disorders are separate from stereotypic movement disorder, which is a separate neurodevelopmental disorder that typically occurs before age three (American Psychiatric Association, 2013).Tic disorders usually develop between ages 4 and 6, with peak severity between ages 10 and 12. These disorders are more common in males.

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, there are four categories of tic disorders. These are Tourette's disorder, persistent (chronic) motor or vocal tic disorder, provisional tic disorder, and other specified or unspecified tic disorder. An individual's diagnosis depends on the severity and duration of symptoms. Tourette's disorder is the most severe form of tic disorder. Individuals must have both motor and vocal tics for more than one year. In persistent (chronic) motor or vocal tic disorder, only motor or vocal tics are present but not both.

A diagnosis of provisional tic disorder is given to individuals who have had symptoms for less than one year. The category of other specified or unspecified tic disorder refers to the presence of minimal symptoms that do not meet the criteria for the other tic disorders. For all of the categories, symptoms must be present prior to age 18 (American Psychiatric Association, 2013).

The exact causes of this disorder are unknown. It is believed that tic disorders are due to abnormalities in the brain. These include problems with the neurotransmitters serotonin and dopamine. There is some evidence that genetics influence tic severity. Environmental stress can also contribute to worsening symptoms. Problems in development such as low birth weight, maternal smoking during pregnancy, and birth complications similarly result in increased severity.

Treatment

Treatment for tic disorders involves a combination of cognitive behavior therapy and antipsychotic medications or SSRIs. There is no cure for tic disorders and no way to prevent their development. However, tics often disappear or diminish as individuals age.

Tobacco Use Disorder

Tobacco use disorder is a mental disorder involving a pattern of tobacco use, which leads to significant problems for the user.

Definitions

- **Addiction** is a chronic disease of the brain, which involves compulsive and uncontrolled pursuit of reward or relief with substance use or other compulsive behaviors.
- **Behavior therapy** is a form of psychotherapy that focuses on identifying and changing maladaptive behaviors.
- **DSM-5** stands for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, which is a diagnostic system used by professionals to identify mental disorders with specific diagnostic criteria.
- **Stimulant** is a drug that increases brain activity and produces a sense of alertness, euphoria, endurance, and productivity, or suppresses appetite. Examples are cocaine, amphetamines, and Ritalin.
- **Substance-related and addictive disorders** are a group of mental disorders that include substance disorders characterized by physiological dependence, drug-seeking behavior, tolerance, and social withdrawal. This group also includes the non-substance disorder of gambling.
- **Withdrawal** is the unpleasant and potentially life-threatening physiological changes that occur due to the discontinuation of certain drugs after prolonged regular use.

Description and Diagnosis

Tobacco use disorder is one of the DSM-5 substance-related and addictive disorders. It is characterized by the use of tobacco, which results in significant distress or disrupts daily functioning. Tobacco can be smoked in cigarettes or used in smokeless form as in chewing tobacco. A primary ingredient in tobacco is nicotine, which is a stimulant. While some individuals use tobacco on occasion, those with this disorder use it to excess. For example, individuals with this disorder may "chain smoke" cigarettes, smoking one right after the other. They may also engage in risky activities, such

as smoking in bed. In the past, this disorder was represented by the disorders of nicotine abuse and dependence. However, nicotine is only one aspect of tobacco use. Tobacco use disorder is a common disorder affecting approximately 13% of the adult population (American Psychiatric Association, 2013).

Tobacco use has both short- and long-term effects. Short-term effects include increased heart rate, alertness, and feelings of satisfaction. The sense of relaxation produced by tobacco use is associated with the elimination of withdrawal symptoms. Withdrawal occurs when tobacco's primary ingredient—nicotine—begins to decrease in the body of an individual who is physically dependent. This commonly leads to irritability, difficulty concentrating, insomnia, and restlessness. Individuals continue to use tobacco in an attempt to avoid these uncomfortable withdrawal symptoms. This is the basis for tobacco addiction. Long-term effects of tobacco use include medical problems like cancer, birth defects, and emphysema. Tobacco use also leads to cardiovascular illnesses such as stroke. Most medical conditions caused by long-term tobacco use are due to carbon monoxide, tars, and non-nicotine chemicals.

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, individuals can be diagnosed with this disorder if they use tobacco in larger amounts than intended and have a persistent desire to cut back or control tobacco use. Craving (a strong desire or urge to use tobacco) is another criteria, as is tolerance (increasing amounts needed to achieve desired effect) and withdrawal symptoms. These must occur within a 12-month period and lead to significant problems in functioning. The severity of this disorder can be diagnosed or specified on a continuum of severity. Those presenting with two to three symptoms are classified as "mild"; those with four to five symptoms are "moderate"; and those with six or more are "severe" (American Psychiatric Association, 2013).

The cause of this disorder involves biological, psychological, and sociocultural factors. While a majority of adolescents in the United States experiment with tobacco, only some go on to develop tobacco use disorder. Genetic factors and heredity contribute to tobacco use and other substance use disorders. In addition, individuals with certain personality traits such as impulsiveness and low self-esteem are at increased risk. This includes those with depression, anxiety, and other substance use disorders. Tobacco use is more common among individuals with low incomes and education levels. Cultural acceptability and peer approval are also factors.

Treatment

The goal of treatment for this disorder is abstinence (no longer using tobacco). Individuals may attempt to quit multiple times before finally remaining abstinent. Treatment may include nicotine replacements such as gum and transdermal patches. Individuals gradually decrease the strengths (doses) of these to wean themselves off nicotine without experiencing withdrawal symptoms. Prescription medications are also used in the treatment of this disorder. These include antidepressants to reduce withdrawal symptoms and medications that block nicotine receptors in the brain. Behavior therapy is also common in the treatment of tobacco use disorder. This may include support groups, counseling, or aversion therapy in which individuals intentionally make themselves nauseous.

Tofranil (Imipramine)

Tofranil is a prescription medication used to relieve symptoms of depression. Its generic name is imipramine.

Definitions

- **Selective serotonin reuptake inhibitors** are a class of antidepressant medications that work by blocking the reabsorption of serotonin in nerve cells and raising its level in the brain.
- **Tricyclic antidepressants** are an older class of antidepressant medications called tricyclic because of their three-ring chemical structure.

Description

Tofranil is the first of the class of medications known as tricyclic antidepressants. Like other tricyclic antidepressants it has long been used to treat depressive disorders but have largely been replaced by selective serotonin reuptake inhibitors. Tofranil is also used in the treatment of enuresis (bed-wetting). Tricyclic antidepressants are thought to work by changing the balance of neurotransmitters (chemical messengers) in the brain that regulate the transmission of nerve impulses between cells. Tofranil works primarily by increasing the levels of the neurotransmitters norepinephrine and serotonin in the brain. It also blocks the action of acetylcholine, another neurotransmitter. Tofranil shares most of the properties of other tricyclic antidepressants, such as Elavil, Sinequan, Anafranil, Nortriptyline, and Asendin.

Precautions and Side Effects

Those taking Tofranil should be closely monitored for signs of worsening depression or other risk factors such as difficulty falling asleep, irritability, planning to engage in self-harm, or abnormal excitement. Manic episodes and the reemergence of psychotic symptoms have been reported when Tofranil is started. The risk of suicide may also be increased when Tofranil is taken in overdose or combined with alcohol. Children and adults up to age 24 are at an increased risk of developing suicidal thoughts or behaviors when they first begin taking Tofranil or other antidepressants. Like all tricyclic antidepressants, Tofranil should be used cautiously and with close medical supervision in those with enlarged prostates, urinary retention, glaucoma, seizures, or heart disease. Those taking the monoamine oxidase inhibitors (MAOIs) like Parnate or Nardil should not combine it with Tofranil. Since fetal deformities have been reported with taking this drug during pregnancy, women should discuss the risks and benefits of Tofranil with their doctors. Breast-feeding should be avoided while using Tofranil.

Tofranil shares side effects common to all tricyclic antidepressants. The most frequent of these are dry mouth, constipation, urinary retention, increased heart rate, irritability, dizziness, decreased coordination, and sedation (drowsiness). The sedative effect is increased when Tofranil is taken with alcohol, sleeping medications, other sedatives, or antihistamines. Less common side effects include confusion, disorientation, delusions, insomnia, anxiety, seizures, ringing in the ears, nausea, vomiting, loss of appetite, diarrhea, and abdominal cramping.

Tofranil may decrease the effect of some medications used to treat high blood pressure. It should not be taken with other antidepressants, particularly MAOIs, or with Ritalin. It is important to check with one's doctor before taking Tofranil with Tagamet or Neo-Synephrine or other over-the-counter medications. Those taking Elavil should avoid the natural remedies like St. John's wort. Because it can increase the depressant action of alcohol, it should not be used by those taking Tofranil. The anticholinergic (drying out) effects of Tofranil are additive with other anticholinergic drugs such as Cogentin, Akineton, Artane, and antihistamines.

Tourette's Syndrome

Tourette's syndrome is a neurological disorder characterized by recurrent involuntary movements and vocal tics such as grunts, barks, or words, including obscenities. It is also known as Tourette's.

Definitions

- **Cognitive behavior therapy** is a type of psychotherapy that focuses on maladaptive (faulty) behaviors, emotions, and thoughts. It is also called CBT.
- **Dopamine** is the chemical messenger in the brain responsible for coordinating the movement of voluntary muscle groups. It also regulates attention, pleasure, and coping with stress.
- **DSM-5** stands for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, which is a diagnostic system used by professionals to identify mental disorders with specific diagnostic criteria.
- **Exposure and response prevention therapy** is the cognitive behavior therapy method that involves exposure to the anxiety that is provoked by the obsession and then preventing the use of compulsive behaviors to reduce the anxiety. This cycle of exposure and response prevention is repeated until the obsessions are less distressing and compulsions are reduced.
- **Habit reversal** is a CBT intervention for treating repetitive behavior disorders such as tics. It works by increasing tic awareness and developing a competing response to the tic.
- **Neurodevelopmental disorders** are neurological disorders characterized by impairments of the growth and development of the brain or central nervous system.
- **Tics** are involuntary, compulsive, repetitive, and stereotyped movements or vocalizations. While they are experienced as irresistible, they can be temporarily suppressed.

Description and Diagnosis

Tourette's syndrome is a neurodevelopmental disorder characterized by repetitive motor and vocal tics. Its symptoms include involuntary movements of the arms, legs, shoulders, and face. Along with these movements are often involuntary sounds or words. When the words are obscene or offensive, it is called "coprolalia." Tourette's syndrome is not a progressive nor a degenerative disorder. Instead, the symptoms tend to be variable and wax and wane throughout an otherwise normal life. These symptoms tend to vary greatly from individual to individual. For example, only some individuals exhibit coprolalia. Furthermore, an individual's can change even though the disorder itself persists. The combination of motor and vocal tics, while they may not occur simultaneously, is the hallmark symptom of this disorder (American Psychiatric Association, 2013). In DSM-5 this disease is listed as a neurodevelopmental disorder. Tourette's also commonly occurs with other disorders like obsessive-compulsive disorder, attention-deficit hyperactivity disorder, and anxiety disorder.

The onset of this disorder may not be obvious very early in life. The reason is that early tics, like repetitive eye blinking, may not be highly noticeable or may be covered up for some time. The DSM-5 indicates that tic onset usually begins between ages 4 and 6 years, but the peak severity of Tourette's symptoms may not manifest until ages 10 to 12. Also, tics may change over time and increase or decrease in severity over time due to factors such as fatigue, anxiety, or excitement (American Psychiatric Association, 2013). It should be noted that unlike other mental or neurological disorders, its symptoms may initially be interpreted as willful misbehavior or intentional disruptions. As a result, it is not uncommon for those with Tourette's, and who have not yet been diagnosed, to be mislabeled as defiant, rebellious, and impulsive in school setting.

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, individuals can be diagnosed with this disorder if they exhibit both motor and vocal tics at some time before the age of 18. Tic symptoms must be present for more than a year since the initial onset. Also, the tics are not due to another cause or condition. Individuals who have only

ever had motor tics or vocal tics, but not both in the course of the condition, would likely meet criteria for persistent motor or vocal tic disorder, rather than Tourette's syndrome.

The exact cause of Tourette's is currently unknown. However, it is an inherited disorder, meaning that it runs in families. The cause might involve abnormalities in certain brain regions, or it defects in specific brain circuits. It could also involve deficits in neurotransmitters such as dopamine.

Treatment

Tourette's syndrome is usually treated with a combination of medication and cognitive behavior therapy. The basic treatment goal for Tourette's is the reduction or extinction of tics. Commonly prescribed medications to reduce tics include clonidine, Haldol, and Risperdal. CBT interventions for Tourette's syndrome to reduce tics include exposure and response prevention, and habit reversal. Other CBT interventions are directed at increasing social skills and strengthening self-esteem.

Transgender

"Transgender," or "across gender," is a descriptive term that refers to individuals who do not identify with their assigned birth sex.

Description

Transgender individuals self-identify their gender (male, female, both, or neither) as different from the assigned sex they were at birth, or as determined by their genitals. The term "transgender" should be used as an adjective rather than a noun ("a transgender man" vs. "he is a transgender"). It describes the self-identification of a person's sex (gender), not his or her sexual orientation (heterosexual, homosexual, bisexual, pansexual, polysexual, or asexual). A transgender person identifies with the sex opposite from his or her birth sex, and thus, most would like others to perceive and address them accordingly. When speaking to a transgender person, it is appropriate and respectful to refer to he or she using the gender and pronouns to which they identify rather than by what appears on their birth certificate or other forms of identification.. "Transgender" is an umbrella term that encompasses various gender identities, including transgender women/men, transitioning women/men, transsexuals, transvestites, drag queens/kings, and gender queers.

A transgender person struggles with gender identity. This term, also commonly referred to as "gender variant," is descriptive rather than diagnostic. Certain procedures and surgeries for those persons seeking gender reassignment are available, from male-to-female (or trans-female) or female-to-male (or trans-man). This can be a lengthy, costly, and complicated process and may not resolve the psychological, emotional, and social difficulties experienced. Seeking psychological evaluation and counseling support is therefore recommended. People who are transgender can encounter significant mental health issues from feelings of distress, discomfort, sadness, and loneliness as they struggle to resolve their gender identities. Transgender persons who do not wish to pursue these more permanent means may choose to express themselves through their behavior or dress, while others keep feelings and thoughts private or suppressed.

Self-awareness regarding one's gender develops at a young age. Transgender individuals report feelings of discomfort and ambiguity about their assigned sex early on. Gender identity is often reinforced and supported by traditional gender roles. However, stereotypes further complicate the process for those who are transgender. This can have damaging effects on

one's emotional and psychological well-being as one's sexual identity plays a large part in overall development. Puberty can be an exceptionally difficult period for those who are transgender. As the body grows, matures, develops, and changes, male or female sex characteristics become more prominent (hair, breasts, Adam's apple, voice changes, etc.), making assigned sexual identities more obvious. This can lead to negative emotions, thoughts, and behaviors if a person does not feel he or she is what the world perceives him or her to be or treats him or her as.

Those who are transgender have been included in the LGBT (lesbian, gay, bisexual, transsexual) community for decades, having been rejected by the larger community. Misunderstanding about the transgender lifestyle caused paranoia, discrimination, and rejection. However, transgender individuals are deserving of the same inalienable rights as all people and should be treated accordingly.

The word "transgender" was first used during the 1950s by an American, Christine Jorgenson, a trans-woman, who was born George William Jorgenson, Jr. Jorgenson was the first woman in the United States to undergo sex reassignment surgery in Copenhagen, Denmark, after gaining special permission. Her struggles were highly publicized and she is revered for bringing attention, sensitivity, and understanding to the transgender community. The 1970s brought about further clarity to the distinctions between sex and gender identity. In 2000, Monica Helms, unveiled the transgender pride flag at a parade in Phoenix, Arizona. Consisting of five horizontal stripes, two light blue (traditional boy color), two pink (traditional girl color), and a white stripe in the middle (representative of those transitioning), the flag remains a symbol of the transgender community. Other symbols including the butterfly and light blue and pink yin and yang symbol have also been used as representations. At present, though transgender persons are still considered protected members of the LGBT community, they continue to work toward respect and acceptance.

Current Status and Impact (Psychological Influence)

Those experiencing psychological impairment resulting from conflicts over one's gender identity that results in distress or discomfort may be diagnosed by a mental health professional as having gender dysphoria, formerly termed gender identity disorder, by the DSM classification. Those experiencing the disorder experience significant emotional, psychological, and social consequences resulting from either living in secrecy or pursuing gender transition. In addition, persons who are transgender are subject to further discrimination if they are restricted access to certain health care and/or denied rights pertaining to religious freedom, marital unions, and adoption.

Transpersonal Psychotherapy

Transpersonal psychotherapy integrates psychological concepts and methods with spiritually transcendent personal experiences in order to assist individuals reach their highest potential.

Definitions

- **Mindfulness** is the practice of maintaining a present awareness and focus of one's thoughts, feelings, and sensations without judgment as to whether they are right or wrong, good or bad.

- **Trans** is a prefix that means to go beyond conventional or individual limits of experience.
- **Transcendent** means going beyond the physical realm and exceeding conventional limits of ordinary consciousness and personal identity.

Description

Transpersonal psychotherapy is grounded in transpersonal psychology (TP), which combines spiritual and transcendent human experiences in an understanding of human potential, wholeness, and transformation. The word "transpersonal" means to go beyond the physical realm of self. Transpersonal psychotherapy integrates psychological concepts with a variety of transpersonal and spiritual experiences such as mediation, mindfulness, and other spiritual disciplines. TP recognizes that individuals are spiritual beings and not just a self or psychological ego. A core principle of TP is that optimal individual well-being must address the spiritual dimension of life and focus on ways to enlighten, strengthen, and heal through spiritual pathways.

Transpersonal themes include nonduality, holism, beyond-person experiences, highest potential, and transformation. Nonduality is the recognition that each individual person is a fundamental part of the whole (sometimes simply referred to as the cosmos or universe), which extends far beyond physical reality. Holism is the belief that the parts of the whole are interdependent and cannot exist or be fully understood independent from the whole. Beyond person or beyond-ego experiences focus on personal connections to the whole made through mystical states of consciousness. As individuals are able to experience and identify with the deeper unified whole, they become less aware of self and more self-transcendent resulting in a deepening sense of connection, peace, and service to all parts of the whole. This is transformational not only on an individual level but also on a potentially global level as all parts of the whole (including individuals) experience unity, peace, and service.

TP is spiritual but it is also psychological. Transpersonal psychotherapy integrates the spiritual dimensions and practices with psychological insights, theory, and methods to help people overcome problems in living, behavioral health disorders, and suffering, while gaining enlightenment, peace, and well-being. Transpersonal practices include the use of meditation and mindfulness for self-exploration, emotional regulation, relaxation, stress reduction, finding peace, and connecting to the greater whole.

Development

TP was first developed in California beginning in 1969 and continues to be an emerging perspective. Carl Jung, Abraham Maslow, and William James, all of whom integrated some form of spiritual, humanistic, mystic, and/or religious thought into their theories of human functioning, influenced early proponents of the perspective. *The Journal of Transpersonal Psychology* was first published in 1969, and in 1972 the Association for Transpersonal Psychology was established to investigate and promote ultimate and mystical states of consciousness and how these experiences could be encouraged to change both personal and cultural perspectives. Various researchers and proponents of the field have worked to identify central themes and define TP but have yet to agree on a clear consensus definition.

Current Status

TP is continuing to develop. TP is receiving an ever-increasing level of investigation and research into its themes and assumptions and is being applied to many fields, including health care, education, business development, alternative medicine fields, counseling, and clinical psychology.

Transvestic Disorder

Transvestic disorder is a mental disorder characterized by transvestic behavior that causes distress or impairment.

Definitions

- **Behavior therapy** is a form of psychotherapy that focuses on identifying and changing maladaptive behaviors.
- **Behavioral addiction** is a form of addiction caused by the compulsion to repeatedly engage in a behavior that causes harmful consequences. It is also referred to as process addiction or non-substance-related addiction.
- ***Diagnostic and Statistical Manual of Mental Disorders*** is the handbook mental health professionals use to diagnose mental disorders. The current edition (fifth) is known as DSM-5.
- **Fetishism** is the sexual arousal an individual receives from a physical object or from a specific situation.
- **Paraphilia** is a mental condition in which an individual can only become sexually aroused by inappropriate objects, actions, or fantasies.
- **Paraphilic disorders** are a group of mental disorders characterized by paraphilias that cause distress or impairment or whose satisfaction involves personal harm. Included in this group are exhibitionistic disorder, fetishistic disorder, pedophilic disorder, and voyeuristic disorder.
- **Transvestic behavior** is wearing or fantasizing about wearing clothes associated with the opposite gender. This leads to intense sexual arousal. It is also called cross-dressing.

Description and Diagnosis

Transvestic disorder is one of the DSM-5 paraphilic disorders. It is characterized by transvestic behavior that causes distress or impairment. Those engaging in this behavior are sexually aroused by wearing or fantasizing about wearing clothes associated with the opposite gender. This may involve only one article of clothing or an entire outfit. For example, a man may wear women's underwear only. Others may wear a dress, makeup, and wig. Sexual excitement is achieved as the result of this behavior. Some individuals may masturbate to achieve orgasm. Others may avoid masturbation to prolong the cross-dressing session. Men with transvestic disorder sometimes exhibit autogynephilia (sexual arousal by imagining being female). Some also have fetishism and become aroused by certain fabrics, garments, or materials. The majority of males with transvestic disorder are heterosexual. Individuals may cross-dress in isolated episodes, or they may engage in this behavior continuously. Transvestic behavior is considered transvestic disorder according to DSM-5 only when specific criteria are met.

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, individuals can be diagnosed with this disorder if they experience intense sexual arousal from cross-dressing. This includes behavior as well as fantasies and urges. This behavior or fantasies must cause significant distress or disrupt daily life. Distress may be indicated by "purging and acquisition" behavior. This is when an individual discards cross-dressing items in an attempt to stop, only to purchase new ones later. The individual must be at least 18 years old and the behaviors must also last for at least six months (American Psychiatric Association, 2013).

The causes of this disorder are unknown. It may be that paraphilias are behavioral addictions, or they could reflect a problem with brain functioning. It is almost exclusively seen in men, although it occasionally occurs in women. Transvestic behavior usually begins in childhood with fascination regarding opposite-sex

clothing. This continues in adolescence and becomes associated with sexual arousal.

Treatment

There are no drugs to treat this disorder. Treatment for this disorder typically involves behavior therapy. The goal is to teach the individual to control the impulse and learn acceptable ways to achieve sexual gratification. The effectiveness of this treatment is unknown. This disorder is a chronic condition and there is little hope for change. The main reason is that individuals receive pleasure from this behavior and have little incentive to change. Since transvestic behavior is viewed as harmless to others, those with this disorder do not commonly seek treatment. However, relationship problems and demands for change from an individual's spouse may prompt treatment. Currently, there is no way to predict who will develop this disorder; however, it may be prevented through education about appropriate sexual behavior.

Trauma

"Trauma" refers to the deep emotional and psychological effects of a variety of extreme and negative experiences.

Description

The word "trauma" means wound, injury, or shock. The causes of trauma are many and include physical mistreatment and abuse such as a physical assault or domestic violence; terrifying disaster experiences such as being in a building fire or a tornado victim; emotional experiences and mistreatment such as being relentlessly ridiculed and bullied; or being a witness to traumatic events. Trauma can include physical neglect such as a young child being left alone all day; interpersonal violence such as being robbed or being physically abused; sexual assault such as molestation or rape; large-scale acts of violence such as terrorist attacks; small-scale acts of violence such as being held at gunpoint; man-made disasters such as car accidents and plane crashes; natural disasters such as tornadoes, earthquakes, and hurricanes; and war.

Trauma affects people in many ways depending on the context of the traumatic event, a person's age, development, his or her personality, and who was involved in the event either as victim or as perpetrator. Trauma can cause both emotional and psychological wounds but can also cause deep spiritual and existential wounds. A traumatic event is something that inflicts severe harm to a person's psyche.

Trauma is profoundly personal, and how traumatic an event is depends on many variables. For instance, a trauma that is personal in nature is different from a trauma that occurred due to a natural disaster. Someone who witnessed a loved one dying in an accident is different from witnessing a loved one being murdered. Another aspect of trauma that impacts its victims is whether the perpetrator of the traumatic event was someone personally known to the victim and the nature of the abuse. Being abused by a parent, a sibling, a relative, a member of clergy, or a teacher is an example of abuses that are traumatic partly due to the relationship between the victim and perpetrator.

Trauma refers to events that are extreme, often violent, emotionally overwhelming, and inherently difficult to cope with. The *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) lists diagnostic features, criteria, and symptoms that are commonly experienced by trauma survivors. Symptoms include distressing and intrusive memories, which means a person cannot get the memories of the event out of his or her mind; the person is always thinking about them even when he or she doesn't want to. Feelings of stress, fear, and/or anxiety when exposed to, or

reminded of, the traumatic event are another cluster of symptoms. These feelings may be intense and distressful, with physiological (body) reactions occurring such as a racing heartbeat and sweating profusely. Nightmares and dreams about the event are common. Going out of their way to avoid people or places that victims associate with the trauma such as not driving on a road where an accident occurred is another symptom. Flashbacks occur when a trauma victim feels or acts like the event is actually taking place in the here and now even though it may have occurred months or even years earlier. Symptoms can also include increase in "startle response," sometimes referred to as "jumpiness," self-destructive behavior, sleep disturbances, and other mood symptoms. Symptoms also include changes in a person's memory, personal relationships, and beliefs about oneself and the world around oneself.

The DSM-5 lists several disorders that are associated with trauma. Perhaps the best-known trauma diagnosis is post-traumatic stress disorder (PTSD) (American Psychiatric Association, 2013). In order to be diagnosed with PTSD an individual must have been exposed, in some way, to an event that involved actual or threatened death, serious injury, or sexual violence. The traumatic event may have been directly experienced, or witnessed in person as it occurred to someone else. PTSD can also apply to individuals who learn of the accidental or violent death of a close family member or loved one. People who are exposed to repeated and extreme details of traumatic events, such as first responders to catastrophic accident scenes, medical personnel, firefighters, and child abuse authorities,, can experience and be diagnosed with PTSD. Very similar to PTSD is acute stress disorder (ASD), with the main difference being how long symptoms have been present. If symptoms occur more than one month, the diagnosis would be PTSD; between three days and one month, the diagnosis would be ASD. According to the International Society for the Study of Trauma and Dissociation, approximately 10%–25% of adults who are exposed to an extreme event may develop ASD or PTSD.

Treatment of trauma is a multidimensional task that requires assessment, psychotherapy, and sometimes medication. The main goal of treatment is to assist clients in developing coping skills, increase self-awareness to assess intensity of symptoms, develop and maintain the ability to manage daily life responsibilities, manage symptom triggers rather than avoiding them, and increase a client's overall personal control. Common treatment approaches include exposure therapy, dialectical behavior therapy, cognitive behavior therapy, psychodynamic therapy, and eye movement desensitization and reprocessing.

Trauma Counseling

Trauma counseling includes a variety of psychotherapies provided to individuals suffering from traumatic experiences.

Description

Mental health professionals have been providing psychotherapeutic services to people suffering from the impact of traumatic experiences for over a century. "Trauma" refers to the deep emotional and psychological effects of extreme, often violent, and terrifying experiences. A person who is traumatized is debilitated, and his or her quality of life is diminished as compared to how he or she was prior to the traumatic event.

"Trauma disorders" is a general term describing a group of several specific disorders in which exposure to a traumatic event is listed as the cause of the person's difficulties. Perhaps the most well-known and researched trauma disorder is post-traumatic stress disorder (PTSD). PTSD is most often associated with war combat veterans, but war-related PTSD is only one of the causes of PTSD. There are many causes of trauma, including domestic violence, child neglect and abuse, natural disasters, catastrophic and deadly accidents, rape, and other acts of violence.

People who suffer from trauma reexperience the traumatic event in intrusive and debilitating ways. Common experiences include intrusive and horrifying memories, flashbacks, and nightmares. Emotional and physiological reactions are triggered by reminders of the trauma and can be severe and debilitating. For instance, someone who was held at gunpoint and robbed in a parking lot may experience extreme anxiety or panic attacks whenever he or she enters any parking lot. People who suffer from trauma disorders often go to great lengths to avoid anything that may trigger trauma reactions. This can become quite debilitating. Imagine how difficult life would be if a person was unable to go anyplace there was a parking lot. The person would be extremely limited to where he or she could go, whom he or she could go with, and what he or she could experience. The person would live a lonely and fearful life.

Development and Current Status

Since the 1980s trauma counseling has been the focus of considerable research and development. This has resulted in evidence-based practice guidelines and treatment methods known to be effective in the treatment of trauma disorders. These practices include exposure-based treatments, cognitive behavior therapy (CBT), and eye movement desensitization reprocessing (EMDR).

Exposure-based treatments include exposure therapy (ET) and prolong exposure therapy (PE), both of which have been the focus of significant research. Both ET and PE have been found to be effective in providing relief from trauma symptoms. The U.S. Department of Veteran Affairs considers PE to be one of the most effective treatments of PTSD and has initiated a national PE training program in order to provided needed services to combat veterans.

Prolonged exposure therapy is a type of counseling that decreases trauma-related distress by helping clients face the thoughts, feelings, and circumstances that have been avoided so as not to evoke memories of the traumatic event. Repeated exposure to these thoughts, feelings, and circumstances increases a person's ability to cope and decreases the debilitating effects of the trauma. Therapy involves educating the client about trauma and the therapy process. Relaxation and breathing techniques are taught in order to ground the person in the here and now as he or she talks about what happened to him or her in the past. Talking through the trauma and repeatedly telling and retelling his or her story and sharing the memories is called "imaginal exposure" and helps the client make sense of what happened to him or her. Imaginal exposure helps the client gain emotional control over the memories and learn to not be afraid of the memory. In vivo experiences are practiced in which clients are gradually exposed to real-world situations that evoke the trauma memories. In vivo experiences decrease trauma-related distress over time.

The goal of the therapy is to help the client process the experience, reduce stress and avoidance, and engage in enjoyable activities. For instance, treatment for the victim of the parking lot armed robbery would begin with educating him about trauma and PE. He would be informed that treatment would include him feeling anxious and distressed but that this is a reaction to the memories. He would be taught breathing and relaxation techniques and would be interrupted if he becomes too distressed to practice the breathing exercises. He would then be asked to tell his story. This

process of story, breathing, story, relaxing, would be repeated over and over. This may take several counseling sessions. As the client's distress decreases as he tells his story, the therapist helps him process situational triggers. The therapist may suggest that he drive by a parking lot that has evoked a strong emotional reaction and practice breathing. As the client is able to drive by the parking lot, the therapist may suggest entering the parking lot, parking for a moment without getting out of the car, and leave once the emotions are too negative, even if that means just a second or two. The in vivo experiences and the memories the experience evoked are discussed in therapy sessions. This process continues until the client is no longer debilitated by the feelings, thoughts, and situations associated with the traumatic event.

Cognitive behavior therapy and EMDR are two other therapies that have been found to be effective in decreasing trauma-related symptoms. CBT focuses on the distorted thoughts and beliefs associated with traumatic events and how to manage the residual emotions of the experience. EMDR is a relatively recent addition to trauma therapy and involves eye movements and body focus as clients talk about and recall traumatic experiences.

Trauma is highly treatable, and most victims are able to make a full recovery. Trauma counseling includes a variety of psychotherapies that are helpful to victims of traumatic experience.

Traumatic Brain Injury

Traumatic brain injury (TBI) is an insult or injury to the brain from an external force. In DSM-5, this disorder is known as neurocognitive disorder due to traumatic brain injury.

Definitions

- **Concussion** is a mild form of brain injury and is the most common type of traumatic brain injury. It involves a brief loss of brain function due to head trauma that resolves spontaneously without a loss of consciousness.
- **DSM-5** stands for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, which is a diagnostic system used by professionals to identify mental disorders with specific diagnostic criteria.
- **Neurocognitive disorders** is a group of disorders in DSM-5 that are characterized by a decline from a previous level of neurocognitive function. In DSM-IV this group was called delirium, dementia, and amnestic and other cognitive disorders.
- **Neurodegenerative disease** is a medical condition in which the nervous system progressively and irreversibly deteriorates.
- **Post-concussion syndrome** is a collection of symptoms that some develop as a complication of concussion, such as headache, disorientation, amnesia (inability to remember the injury), and memory and concentration problems, which usually clear within three months after the head injury.

Description and Diagnosis

Traumatic brain injury (TBI) is an injury to the brain from an external force. It is neither congenital nor degenerative. It can lead to temporary or permanent impairment of cognitive, physical, and psychological functions, and may involve a diminished state of consciousness.

TBI can range from mild (concussion) to severe and can last for hours, days, weeks, or longer. It results from a blow to the head, a fall, or anything that shakes the brain and leads to bruising, swelling, or tearing of brain tissue. Most individuals will fully recover from a mild brain injury. But severe or repeated injury to the brain can have long-term problems with learning, movement, or speech. Symptoms may include headaches, vision problems, dizziness, or trouble remembering new information. Occasionally, they include feelings of sadness, anxiety, anger, or disturbed sleep.

Traumatic brain injury is one of the groups of neurocognitive disorders in DSM-5. As the name suggests, this disorder requires clear evidence of TBI. Usually, this involves a head injury that has led to a change in cognitive functioning. The most common variation would be post-concussion syndrome.

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, individuals can be diagnosed with this disorder if there is evidence of a TBI. This injury must involve disorientation and confusion, neurological signs, post-traumatic amnesia, or the loss of consciousness. This diagnosis also requires that these symptoms and signs occur immediately after the brain injury occurs or right after recovery of consciousness. Criteria must also be met for either major or mild neurocognitive disorder. This disorder can be coded with or without behavioral disturbance (American Psychiatric Association, 2013).

As noted earlier, TBI is caused by a blow or other traumatic injury to the head. The degree of damage depends on several factors, including the type and the force of the impact. Common causes are falls, vehicle-related collisions, violence, explosive blasts and combat injuries, and sports injuries. For example, individuals who are hard driving and/or thrill seekers and are engaged in sports and related activities are prone to TBIs. This includes football players, race car drivers, and extreme sports enthusiasts, like skateboarders, who commonly experience TBIs.

Treatment

Most individuals with mild TBI require no treatment beyond rest and over-the-counter pain relievers for their headache. However, these individuals need to be observed and monitored closely at home for any worsening or new symptoms. Moderate to severe TBI may require treatment in an emergency room and/or hospitalization. The goal of such treatment is to ensure that the individual has an adequate oxygen and blood supply, to maintain blood pressure, and to prevent further injury to the head or neck. Those with significant brain injury will require rehabilitation. This may include relearning basic skills like talking and walking. The goal is to restore the individual's ability to perform daily activities. Other treatment interventions may include counseling, medication, psychiatric consultation, and family therapy.

Trichotillomania

Trichotillomania is a mental disorder characterized by the repeated pulling out of one's hair that leads to hair loss and significant distress or disruption in various areas of life.

Definitions

- **Obsessive-compulsive and related disorders** are a group of DSM-5 mental disorders marked

by preoccupations and repetitive behaviors that lead to personal distress or problems with daily functioning (e.g., obsessive-compulsive disorder). Other related disorders are characterized by repetitive behaviors that are fixated on the body. These disorders also result in personal, occupational, and/or social difficulties.

- **Obsessive-compulsive disorder** is a mental disorder that is distressful to the individual and is characterized by unreasonable obsessions or compulsions that are inappropriately time consuming or cause marked distress or impairment. It is commonly referred to as OCD.
- **Preoccupations** are thoughts, urges, or images that are undesirable and bothersome.
- **Selective serotonin reuptake inhibitors (SSRIs)** are antidepressants that boost serotonin levels in the brain. They are mainly used to treat depression, anxiety, and particular personality disorders. They are also used to treat trichotillomania.
- **Tricyclic antidepressants** are antidepressants that increase serotonin and norepinephrine levels in the brain. They have also been used to treat trichotillomania.

Description and Diagnosis

Trichotillomania is one of the DSM-5 obsessive-compulsive and related disorders. Individuals with this disorder experience the recurrent urge to pull out hair primarily from their scalp, eyebrows, and eyelashes. Other less likely places include hair from the face, pubic, and peri-rectal areas. The preferred location for hair pulling may change periodically. The duration and frequency of hair pulling also vary. An individual may engage in hair pulling intermittently but often during daily activity. Or the individual may pull out hair only for a concentrated period of time, such as one or two hours, during the day. Typically, hair pulling leads to hair loss, which is noticeable by others. However, in some cases the hair pulling is performed evenly over a particular region so it is less obvious. In other cases, an individual may try to hide hair loss by wearing a head scarf, hat, or wig; coloring in eyebrows; or wearing false eyelashes.

The occurrence of this disorder is low among the general population. Approximately 1%–2% of individuals meet the criteria for trichotillomania. Adult and adolescent females are 10 times more likely than males to develop the disorder. In childhood the occurrence is relatively equal in males and females (American Psychiatric Association, 2013). Trichotillomania typically begins in childhood or adolescence.

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, individuals can be diagnosed with this disorder if they pull out their hair frequently enough that it results in hair loss. This behavior results in negative emotions (e.g., shame and embarrassment) and problems in significant life domains. Any efforts to control or stop the behavior have been unsuccessful. There is no evidence of a medical condition or other mental disorder that may be the cause of the hair pulling or hair loss (American Psychiatric Association, 2013).

The cause of this disorder is considered to stem from difficulty with impulse control. It is also thought to have a genetic component. It occurs more often in individuals with obsessive-compulsive disorder. These individuals also are likely to have family members with obsessive-compulsive disorder. Other factors may include stress, trauma, anxiety, or boredom.

Treatment

Treatment may include psychotherapy and medication. Cognitive behavior therapy is instrumental in helping an individual develop awareness of hair pulling, identify and reframe negative thoughts and beliefs, and change maladaptive behaviors. Medication therapy may include SSRIs or tricyclic antidepressants, particularly clomipramine.

Truancy

Truancy is defined as any intentional, unexcused absence on the part of a student from his or her compulsory education.

Definitions

- **Compulsory education** is described as the required period of schooling for every person under law; in the United States this varies by state but typically begins at age 5 till approximately age 17.
- **Delinquency** is a general term used to describe the unlawful activity, wrongdoing, or misbehavior of young people.
- **Dropout** is a term that refers to a person who stops attending or withdraws from school prior to completing his or her degree (high school, college) or the equivalent to a degree.
- **Homeschool,** also termed home-based learning or home education, refers to the teaching or instruction of a student at home by a parent, guardian, or tutor, rather than at a traditional public or private school environment.
- **School refusal,** an umbrella term now used in lieu of the term "school phobia," describes child-motivated noncompliance in attending school, remaining in class for the entire school day, or both.

Description

Truancy is the unexcused absence of a student from his or her required attendance at school. Other terms or phrases commonly used to describe truancy are "skipping school," "cutting class," "ditching," and "playing hooky." Students who are truant do not miss class for acceptable (excused) reasons such as an illness, a medical condition, or a family emergency; rather, they choose to not attend at their own free will. Truancy is often identified and then reported by teachers or professional school counselors to administrators or school resource officers who may impose consequences, including detentions, in school suspensions, fines, or additional/remedial coursework (i.e., summer school). In the United States, truancy is considered a status offense, like alcohol consumption and curfew violations, because the perpetrator of the act is a minor. Furthermore, parents or guardians are charged with the responsibility to ensure that their child attends school. Laws, regulations, and policies regarding truancy can vary from state to state and even school districts.

Absentee rates are monitored on a daily basis and remain a part of the student's permanent educational record. Notification systems via phone call, e-mail, or text have been incorporated in recent times to help address truancy. Parents receive messages from their child's school that their child either has not arrived or has been marked absent from a class period or multiple class periods. Truancy officers have also been designated at school sites to assist in combating this problem. Some are authorized to ticket students directly or remand them into their parents' custody or directly back to their school site.

Current Status and Impact (Psychological Influence)

Truancy is a social concern as students who are truant are more likely to drop out of school, engage in delinquent behavior, and have a negative effect on their peers. Research indicates that truancy rates are highest in inner-city public schools where poverty rates are also high. Additional findings suggest that truancy peaks around 15 years of age and that males are slightly more likely than females to engage in this behavior. Truancy has also been linked to several factors, including poor academic performance (specifically in reading and math), specific learning disabilities (dyslexia, ADHD), friction with teachers and/or administrators, inability to make and keep friends, lack of family stability and parent involvement, and low

teacher expectations. Furthermore, studies suggest that there is a high correlation between students who were habitually truant during their youth and later criminal behavior. School personnel, in particular teachers and school counselors, can work together to improve truancy issues. Students who feel connected, safe, and supported during difficult times are more likely to remain in school. Likewise, parents who closely monitor their children's behavior, value education, and remain actively involved in the schooling process can also have a positive effect.

Twelve Traditions of Alcoholics Anonymous, The

The Twelve Traditions of Alcoholics Anonymous are principles and guidelines for relationships between Twelve-Step groups, members, other groups, the global fellowship, and society at large.

Definitions

- **AA Grapevine** is the international journal of Alcoholics Anonymous. It is written, edited, illustrated, and read by AA members and other individuals interested in recovery from alcoholism.
- **Addiction** is a chronic disease of the brain, which involves compulsive and uncontrolled pursuit of reward or relief with substance use and other compulsive behaviors.
- **Alcoholics Anonymous** is a mutual aid or self-help fellowship that was founded by Bill Wilson and Dr. Bob Smith in 1935 to help individuals struggling with alcoholism. It is also referred to as AA.
- **Sobriety** is the continued abstinence from any mood-altering substance (e.g., alcohol, marijuana, opiates, and tobacco).
- **Spiritual principles** are the concepts that correspond to each of the Twelve Steps of Alcoholics Anonymous.
- **Twelve Steps** refers to the 12 guiding principles on which Alcoholics Anonymous is based.
- **Twelve-Step Programs** are self-help groups whose members attempt recovery from various addictions based on a plan called the Twelve Steps.

Description

The Twelve traditions grew out of the Alcoholics Anonymous (AA) movement and outlined the means by which AA relates itself to the world and maintains AA unity. Questions regarding finance, authority, public relations, eligibility, anonymity, donations, outside opinions, and purpose are all addressed in the twelve traditions. The Twelve traditions contain the spiritual principles that keep Twelve-Step Groups focused on AA's primary purpose. The primary purpose of AA is to stay sober and to help others to achieve sobriety. Without such guidelines, it would be nearly impossible to maintain a worldwide fellowship and keep the AA message strong. The three legacies of AA include recovery, unity, and service. Each of these legacies is grounded on the foundation of spiritual principles. Each step, tradition, and concept is a principle (e.g., a rule of personal conduct).

Often, an individual in AA will extract a word or two from the Twelve traditions and formulate his or her own interpretation of the principle(s) rather than to

be positively informed by AA literature. Much can be gained from the Twelve traditions both in understanding and in results, when viewed as a whole instructive sentence. Each whole constructive sentence (tradition) can be viewed as a "principle." The Twelve traditions provide rules of personal conduct that are practiced in all of the affairs of those with addiction problems and as a way of developing a spiritual state that offers a daily reprieve from alcohol. The result is a gift called sobriety (e.g., freedom from alcohol). The gift of the traditions is "unity" (e.g., to keep the fellowship from destroying itself).

In 1939, several of the principles of what would become AA's Twelve traditions were first written in the beginning of the first edition of the *Big Book of Alcoholics Anonymous*. By 1944, several AA groups had some concerns of how to handle disputes caused by issues such as religion, publicity, and finances. They forwarded these concerns to AA headquarters. In 1946, Bill Wilson (1895–1971), the cofounder of AA, clearly developed the basic concepts for the Twelve traditions by collaborating with several AA groups. During this time, guidelines were set on how groups and members should interact with the public, each other, and AA in its entirety. The Twelve traditions were first published in April 1946 in the AA Grapevine under the title *Twelve Points to Assure Our Future*. In July 1949, during the first International AA Convention in Cleveland, Ohio, an estimated 3,000 attendees adopted the Twelve traditions unanimously by a standing vote. Bill Wilson's book *Twelve Steps and Twelve Traditions* was later published in April 1953. The Twelve traditions are not specifically mandatory in any AA group or groups. However, the overwhelming majority of its members have adopted the Twelve traditions as the foundation for AA's expanding internal and public relationships.

Twelve-Step Programs

Twelve-Step Programs are self-help groups whose members attempt recovery from various addictions based on a plan called the "Twelve Steps."

Definitions

- **Addiction** is a chronic disease of the brain, which involves compulsive and uncontrolled pursuit of reward or relief with substance use or other compulsive behaviors.
- **Addiction recovery** is the state of abstinence from addictive behaviors, usually achieved through self-reflection and spiritual exploration.
- **Addictive disorder** is a chronic disease of the brain, which involves compulsive and uncontrolled pursuit of reward or relief with substance use or other compulsive behaviors.
- **Alcoholics Anonymous** is a mutual aid or self-help fellowship that was founded by Bill Wilson and Dr. Bob Smith in 1935 to help people struggling with alcoholism.
- **Compulsions** are habitual behaviors, practices, or rituals that are impulsively engaged in to defend against perceived threats, to reduce fears, or otherwise to minimize distress.
- **Mutual aid fellowship** is a community in which individuals struggling with the same problem (e.g., alcoholism) help one another.
- **Spirituality** is the sum total of an individual's unique worldview and self-view, religious beliefs, attitudes, and behaviors.
- **Twelve Steps** refers to the 12 guiding principles on which Alcoholics Anonymous is based.

Description

All Twelve-Step Programs share the same model as Alcoholics Anonymous, which was established in 1935. The foundation for this model is the Twelve Steps, which focuses on the addiction recovery process. These steps include tasks such as admitting powerlessness, completing a moral inventory, making amends to those who were harmed, and helping other members of the Twelve-Step Group. While there is some variation depending on the specific focus of the Twelve-Step Group, most of the steps are the same. For example, Step 1 in Alcoholics Anonymous is "We admitted we were powerless over alcohol—that our lives had become unmanageable." In Narcotics Anonymous, "alcohol" is replaced with the words "our addiction." Other examples are Step 2: "We came to believe that a power greater than ourselves could restore us to sanity" and Step 5: "We admitted to God, to ourselves, and to another human being the exact nature of our wrongs." The ultimate goal of the Twelve Steps is to achieve a spiritual awakening that will help the individual continue to stay away from the problem substance or behavior. Twelve-Step Programs are based on the belief that addiction and compulsions are diseases for which spiritual development is the only cure.

Twelve-Step Programs are mutual aid fellowships intended for individuals who share the same problem to help one another. As with other self-help programs, lay members run meetings and activities rather than professionals such as physicians and counselors. Members participate in regular group meetings to discuss various topics. Other activities may include providing guidance through sponsorship, performing service work, and studying program literature. There are many different types of Twelve-Step Programs that address addictions to both different substances and compulsive behaviors. Narcotics Anonymous is the second-most popular program for substance abuse behind Alcoholics Anonymous. Other programs include Sex and Love Addicts Anonymous, Overeaters Anonymous, and Gamblers Anonymous. There are also Twelve-Step Programs that focus on relationships. These include Al-Anon and Adult Children of Alcoholics, and address family issues. Regardless of the specific focus, members of all Twelve-Step Groups are expected to maintain confidentiality, follow program guidelines, and support each other through the process of recovery.

Understanding Human Nature (Book)

Understanding Human Nature is a book written by Alfred Adler that explains the principles of Individual Psychology.

Definitions

- **Alfred Adler (1870–1937)** was an Austrian psychiatrist who developed the psychological system called Individual Psychology.
- **Family constellation** includes information about individuals' relationships with other family members, family values, and the way they found a sense of belonging in their family.
- **Individual Psychology** is an approach to psychology that understands individuals as social beings with a need to belong and to strive for significance. It is also known as Adlerian Psychology.
- **Inferiority feelings** are feelings that occur when an individual believes they are incompetent or inadequate.
- **Lifestyle and lifestyle convictions** are conclusions an individual makes about their inner world based on their interpretations of previous experiences.
- **Psychological birth order** is the perceived position or role that an individual takes or is given in a family system.
- **Rudolf Dreikurs** is an American psychiatrist and educator known for advancing Adlerian psychology through his writings and professional publications.

Description

Understanding Human Nature is a book written in 1927 by Alfred Adler (1870–1937). The book was Adler's effort to explain human behavior through a discussion of the principles of Individual Psychology. The book is written in a style that can be understood by lay citizens and mental health professionals. Content in the book is based on a year's worth of lecture material delivered by Adler at the People's Institute of Vienna.

Understanding Human Nature discusses various philosophical and psychological concepts from the theory of Individual Psychology. Adler believed that individuals seek to have a sense of power, belonging, and significance in the world. Individuals experience inferiority feelings and they compensate for those perceived inferiorities by having the courage to take risks, or by declaring bankruptcy through displaying weakness as an adult to seek help or attention. The book also explained that behavior is goal-oriented, and that individuals are always striving toward a conscious or unconscious goal. Additionally, psychological birth order, family constellation, and early memories influence our lifestyle convictions or personality.

Alfred Adler created Individual Psychology and was born in Austria. In 1911, Adler left the Vienna Psychoanalytic Society as a colleague of Sigmund Freud (1856–1939) due to differences in their explanations of human behavior. Freud believed that individuals experience psychological issues due to repressed

sexual feelings, while Adler believed that people's perceptions of their shortcomings and their difficulties with social belonging influenced human suffering. Rudolf Dreikurs (1897–1972) was an American psychiatrist and educator who also advanced the theory and practice of Individual Psychology. Dreikurs was a student and eventually became a close colleague of Alfred Adler. After Adler's death in 1937, Dreikurs went on to promote the use of Individual Psychology around the world. Individual Psychology is considered one of the most influential theories among the contemporary counseling theories. While the approach is criticized for having limited empirical research, it has thousands of active members in Adlerian societies around the world.

V

Vaginismus

Vaginismus is the inability to allow vaginal penetration in sexual intercourse because of anxiety and fear of pain that results in vaginal spasm.

Definitions

- **Anxiety** is a negative emotional state characterized by feelings of nervousness, worry, and apprehension about an imagined danger.
- **Cognitive behavior therapy** is a type of psychotherapy that focuses on maladaptive (problematic) behaviors, emotions, and thoughts. It is also called CBT.
- **DSM-5** stands for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, which is a diagnostic system used by professionals to identify mental disorders with specific diagnostic criteria.
- **Dyspareunia** is the experience of genital pain during sexual intercourse.
- **Exposure** is a cognitive behavior therapy intervention (method) in which a client is exposed to a feared object or situation. It is also referred to as flooding.
- **Fear** is an emotional response to a known danger. It is similar but different from anxiety.
- **Genito-pelvic pain/penetration disorder** is a mental disorder in women characterized by persistent fear, pain, or difficulty with vaginal intercourse. Previously this disorder was referred to as dyspareunia and vaginismus.
- **Pelvic floor muscle training** involves a series of exercises designed to strengthen the muscles of the pelvic floor. These exercises are used to treat problems with urine leakage, bowel control, and pelvic pain.
- **Psychotherapy** is a psychological method for achieving desired changes in thinking, feeling, and behavior. It is also called therapeutic counseling.
- **Sexual dysfunction disorders** are a group of mental disorders characterized by significant difficulty in responding sexually or experiencing sexual pleasure. They include female organismic disorder, and genito-pelvic pain/penetration disorder.
- **Specific phobia** is a mental disorder characterized by a marked and enduring fear of specific situations or objects. Previously this disorder was referred to as simple phobia.
- **Systematic desensitization** is form of cognitive behavior therapy that gradually exposes individuals to their phobia (fear) while remaining calm and relaxed.

Description and Diagnosis

Vaginismus is a sexual disorder in DSM-IV-TR but is not listed as such in DSM-5. It is characterized by vaginal spasm during or before vaginal penetration. This vaginal spasm is associated with anxiety and fear

related to penetration as opposed to a medical cause. This spasm, or the anxiety and fear of experiencing the spasm, tends to inhibit normal intercourse. For some individuals, these spasms may be associated with any form of vaginal penetration, including penetration by a finger or other objects. This disorder has been combined with dyspareunia in the DSM-5 diagnosis of genito-pelvic pain/penetration disorder. These two disorder were combined in DSM-5 because it was difficult for clinicians to distinguish between these two disorders and because they commonly occurred together.

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision*, an individual may be diagnosed with this disorder if they experience recurring vaginal spasms that inhibit intercourse. This spasm must cause the individual distress. These symptoms cannot be better explained by a medical condition or an alternative psychological diagnosis. This disorder may be present in an individual's entire life or it may begin after a period of normal sexual functioning. Symptoms may occur in a particular circumstance or in all situations involving intercourse. Also, some individual with symptoms of this disorder may also be diagnosable with a specific phobia related to sex.

The cause of this disorder is unclear. It is believed that sexual abuse, body-image issues, relationship issues, religious beliefs, and a history of vaginal infection may contribute to the manifestation of this disorder. However, for the majority of individuals, a combination of psychological, physiological, and social factors are likely to be present. For this reason, it is important for a clinician to be diligent in their assessment of this disorder.

Treatment

Treatment includes a comprehensive medical evaluation to identify any medical condition that might cause vaginismus. If one is found, than medical treatment is appropriate. If no such cause is identified, it is usually treated with a combination of physical therapy and psychotherapy. Physical therapy is necessary to help the individual learn how to train and control their pelvic floor muscles. The most common form of psychotherapy for this disorder is cognitive behavior therapy (CBT). CBT is used to reduce fear, anxiety, and pain. It emphasizes systematic desensitization and exposure techniques. If trauma issues are involved, it would also address them or refer for specialized treatment.

Valerian

Valerian is an herbal remedy used primarily for sleep problems.

Definitions

- **Flavonoids** are plant compounds that have anti-inflammatory, anticancer, or antioxidant effects.
- **GABA** (gamma-aminobutyric acid) is a chemical messenger in the brain that leads to relaxation, calmness, and sleep by reducing nerve cell excitement.

Description

Valerian (*Valeriana officinalis*) is a medicinal herb that promotes calmness and relaxation. It has long been used as a tranquilizer that acts without narcotic

effects. Because of its flavonoid properties, it has also been used as a pain reliever, antispasmodic, and sedative. Other uses include digestive problems, headaches, and arthritis. Valerian is thought to work by increasing gamma-aminobutyric acid (GABA), a neurotransmitter (chemical messenger) in the brain. To date there is limited research on the effectiveness of valerian. Based on a few small clinical trials valerian has been shown to have mild sedative and tranquilizing properties, but less than prescription sleep medication. There is not yet sufficient research evidence to support the use of valerian in the treatment of anxiety disorders. However, anecdotal reports indicate that regular use of the supplement promotes feelings of calmness and reduces stress.

Precautions and Side Effects

Unlike prescription sleep medications, valerian root is not believed to carry a risk of dependency. However, the supplement should only be used under the supervision of a qualified health-care professional. Caution should be exercised if taking the supplement over an extended period of time. Similarly, exercise caution in driving and in operating machinery particularly when using this supplement for the first time. Valerian should not be used in large doses or for an extended period. Individuals should not take valerian continuously for more than two to three weeks as they may become tolerant to its effects. Some research suggests that prolonged use could result in liver damage and central nervous system impairment. Increasing the dose of the herb to achieve desired effects may result in adverse (negative) effects. Women who are pregnant or breast-feeding should not use valerian, as its effects on the fetus or infant have yet to be tested. Those planning to undergo surgery should stop taking valerian at least two weeks before their procedure.

Side effects of valerian root are rare. They may include headache, upset stomach, daytime drowsiness, and dizziness. Large doses of valerian may occasionally cause headache, muscle spasm, heart palpitations, dizziness, gastric distress, sleeplessness, and confusion. Continuous, uninterrupted use of valerian may cause depression.

While valerian has been regarded as a relatively safe herb, it can interact with medications and other natural remedies. It can interfere with the effectiveness of medications broken down in the liver, such as allergy medications, cholesterol medications, antifungal medications, and cancer medications. Valerian root may also cause drowsiness if taken with prescription medications such as selective serotonin reuptake inhibitors, benzodiazepines like Valium, Xanax, or Klonopin. Drowsiness is also likely if used with narcotics such as codeine; barbiturates such as phenobarbital, over-the-counter cold and sleep remedies, or antihistamines; and alcohol. Long-term studies of valerian use are still needed to determine its safety.

Valium (Diazepam)

Valium is an antianxiety medication belonging to a class of drug known as benzodiazepines. Its generic name is diazepam.

Definitions

- **Antianxiety medications** are prescribed drugs that relieve anxiety symptoms. They are also called anxiolytics or tranquilizers.
- **Anxiety** is a psychological state of strong feeling of apprehension, distress, worry, or agitation, which is accompanied by physical symptoms of sweating, tension, and increased heart rate.
- **Benzodiazepines** are a group of central nervous system depressants that are used to relieve anxiety or to induce sleep.

- **Epilepsy** is a medical condition involving episodes of irregular electrical discharge within the brain that causes impairment or loss of consciousness, followed by convulsions.
- **Anterograde amnesia** is a type of amnesia in which new memories cannot be formed while existing memories remain intact.
- **Seizure** is a sudden convulsion or uncontrolled discharge of nerve cells that may spread to other cells throughout the brain.

Description

Valium is one of the class of antianxiety medications called benzodiazepines. Benzodiazepines help to relieve nervousness, tension, and other anxiety symptoms by slowing the central nervous system. They accomplish this by blocking the effects of chemical messenger that decrease the excitability of nerve cells in the brain. All benzodiazepines, including Valium, cause sedation, drowsiness, and reduced mental and physical alertness. Its primary use is in the short-term treatment of mild to moderate anxiety. Valium is also used to treat epilepsy, muscle spasms, nervous tension, and symptoms relating to alcohol withdrawal. Unlike Xanax and Ativan, which are short-acting benzodiazepines, Valium is a longer-acting benzodiazepines which makes it ideal for certain applications such as the treatment of epilepsy.

Precautions and Side Effects

Children, the elderly, and those with significant health problems should be carefully evaluated before been prescribed Valium. Children under the age of six months should not take Valium. In addition, those with a history of liver disease, kidney disease, or those with low levels of a protein in the blood called albumin need to be carefully assessed before starting this drug.

The sedative effects of Valium are cumulative and long-lasting. Because Valium can cause drowsiness, care should be taken while driving, operating machinery, or engaging in other activities that require mental alertness. Alcohol and other medications used in the treatment of mental illness should not be taken concurrently with Valium. Those who have had adverse reaction to any other benzodiazepines should not take Valium, neither should those with acute narrow-angle glaucoma. Valium, like other longer-acting benzodiazepines carries the risk of anterograde amnesia. As with other benzodiazepines, long-term use of Valium can be habit-forming. Because of its abuse potential, it should be used with caution in those with a history of substance abuse. Valium should not be discontinued abruptly as this can lead to withdrawal effects such as nervousness, confusion, depression, sensitivity to light, nausea, irritability, shaking, and abdominal cramps.

Common side effects of Valium include drowsiness, clumsiness, slurred speech, and dizziness.

More rarely reported are the following side effects: behavior changes, low blood pressure, muscle weakness, hallucinations, and jaundice or yellowing of the eyes or skin. Valium interacts with several medications, particularly other central nervous system depressant drugs such as alcohol, other tranquilizers, and sleeping pills. Therefore, in making the decision to use Valium, one's physician (and pharmacist) should review the other medications being taken for possible interactions.

Vascular Neurocognitive Disorder

Vascular neurocognitive disorder is a mental disorder characterized by loss of mental functioning that is caused by brain damage from impaired (blocked) blood flow. It is also known as vascular dementia.

Definitions

- **Alzheimer's disease** is a medical and mental disorder that causes a slow, progressive dementia usually late in life.
- **Dementia** is a group of symptoms including loss of memory, judgment, language, and other intellectual (mental) functions caused by the death of neurons (nerve cells) in the brain.
- **DSM-5** stands for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, which is a diagnostic system used by professionals to identify mental disorders with specific diagnostic criteria.
- **Neurocognitive disorders** are a group of disorders in DSM-5 that are characterized by a decline from a previous level of neurocognitive (mental) functions.
- **Vascular** refers to blood vessels. When blood flow through a vessel is impaired, (blocked) damage to the heart, kidneys, or brain can result.

Description and Diagnosis

Vascular neurocognitive disorder is one of the neurocognitive disorders listed in the DSM-5. It is characterized by a decline in mental processes caused by brain damage from impaired blood flow to the brain. Such damage results in significant distress or disrupted daily functioning. Those with vascular neurocognitive disorder have problems with memory and are unable to recall names or events. They also tend to have difficulty communicating, both verbally and in writing. Motor skills are also impaired in this disorder. Individuals may be unable to perform tasks that require hand-eye coordination, such as tying shoes. Some individuals experience physical symptoms like weakness of the arms and legs or abnormal reflexes.

Vascular neurocognitive disorder can also cause behavioral disturbances. Individuals may become aggressive or act impulsively. While the symptoms of vascular neurocognitive disorder resemble those of Alzheimer's disease, the two are different disorders. Vascular neurocognitive disorder occurs quickly with clear physiological causes. Alzheimer's disease generally begins slowly. Approximately 10%–20% of those who are diagnosed with neurocognitive disorders have the vascular form. It is the second most common after Alzheimer's disease. It is also more prevalent in men than in women. Vascular neurocognitive disorder typically occurs after age 60, and has a younger age of onset than Alzheimer's disease (American Psychiatric Association, 2013).

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, memory impairment must be present in individuals in order to diagnose this disorder. This may refer to problems learning new information or recalling previously learned information. An individual must also have one or more cognitive impairments. These may include aphasia (language disturbance), apraxia (motor skills disturbance), agnosia (inability to recognize objects), or problems in executive functioning (planning, organizing, etc.). They must also represent a decline from the individual's previous level of functioning. Neurological symptoms, such as weakness in limbs, or laboratory tests must point to cerebrovascular disease for this diagnosis. None of these symptoms can be caused by delirium, which is a separate diagnostic category (American Psychiatric Association, 2013).

Vascular neurocognitive disorder is caused by brain damage from impaired blood flow to the brain. A stroke or cerebrovascular disease ("cerebro"—brain; "vascular"—blood vessel) can block a major book vessel and cause this disorder. It is believed to be the result of small strokes that interfere with blood flow to the brain. Lack of blood flow depletes the brain's oxygen supply, leading to the symptoms described. Typically, this occurs after many small strokes over time rather than one large stroke. Strokes are the most common, but not the only cause of this disorder.

Treatment

There is no cure for vascular neurocognitive disorder and its effects cannot be reversed. Treatment is intended to slow or stop the progression of the disorder and improve symptoms. The most basic way to accomplish this is to prevent future strokes. This may be

done through changes in diet and drug treatments for high blood pressure. Lifestyle changes such as quitting smoking, avoiding heavy alcohol use, and reducing stress are usually prescribed.

Video Games

Video games (VGs) are a form of electronic interactive entertainment played by controlling images on a computer, console, or mobile-based video screen, including smart phones.

Description

Video games provide players with increasingly realistic and socially interactive experiences that deliver immersive emotional, social, and cognitive challenges. Players may play alone or with thousands; cooperatively or competitively; with other players physically present or located anywhere on the planet; and with people they know or with complete strangers. As many as 97% of children between the ages of 2 and 17 play VGs.

Impact (Psychological Influence)

VGs have been highly scrutinized with most of the research focused on the negative effects of VGs. Increased aggression, addictive gaming behaviors, negative mood states, and a decrease in empathy and prosocial behaviors (behaviors that benefit others) have all been linked to VG play. Findings however are disputed. While there is agreement that VG play has negative effects, some researchers argue that the actual magnitude of the effect is quite small and does not have any real predictive power. VGs are frequently cited as being connected to violence, mass killings, and school rampages but no research actually links these events to VG play.

Studies have identified many cognitive, emotional, and social benefits associated with playing VGs. VGs promote a wide range of cognitive benefits including the development of spatial skills. Spatial skills have been linked to achievement in science, technology, engineering, and mathematics, which in turn have been linked to long-term career success. VG play has also been associated with improved mood and increased positive emotions. Game play also evokes negative emotions but learning to control and regulate emotions for the sake of goal attainment is another emotional benefit to players.

Gaming is a social activity. Over 70% of gamers play with friends and some of the most popular games take place in virtual communities that contain millions of players. Acquiring social skills, engaging in prosocial behaviors, and learning to work cooperatively, even in violent VGs, carry over into positive offline behaviors. Emerging research indicates that playing violent VGs cooperatively in social groups verses competitively and alone increases prosocial behaviors while actually reducing hostility and aggressive thoughts. VG researchers acknowledge that more sophisticated and rigorous research models are needed in order to more fully understand both the positive and negative consequences of game play. There has been concern recently about sexism among gamers, including offensive criticism and cyberbullying of female VG developers. There is also concern about the addictive power of video and online games, which for some may create problems with school, work, or personal relationships.

Researchers agree that VGs are complex and sophisticated forms of entertainment that have tremendous potential in the fields of education and health care. Emerging data indicates that VGs can enhance both learning and health outcomes. VGs also represent a largely untapped potential for the promotion of well-being and the prevention and treatment of mental health problems. The future use of VGs in these fields has great promise.

Steven R. Vensel, PhD

While many researchers agree that video games are complex and sophisticated forms of entertainment with tremendous potential in the fields of education and health care, there are also concerns about video games leading to increased aggression, addictive gaming behaviors, and a decrease in empathy and in pro-social behaviors. Researchers are especially concerned about their impact on children and teenagers. (Gemenacom/Dreamstime.com)

Vocational Counseling

Vocational counseling is therapy for people looking to obtain or maintain work.

Definition

- **Vocation** is a person's employment, trade, or main occupation.

Description

Vocational counseling is also known as career counseling. This is because of its focus on helping people find jobs and be successful in those jobs. Vocational counseling is usually provided by mental health or rehabilitation counseling professionals. These services can be provided through schools, government agencies, and private practice.

Many centers that offer vocational counseling serve people with diverse backgrounds. Usually clients

are referred to the service when they are unable to find work independently or because they need special arrangements due to a disability. Vocational counselors will meet with clients to evaluate, improve, and develop skills. This includes teaching how to conduct a job search, build a resume, and practice interview skills.

The types of clients who seek out career or vocational counseling vary. A person who has difficulty keeping a job or who has skills that are no longer useful for work might need help getting a new job and could benefit from career counseling. Additionally, clients with disabilities or who are older might need these services in order to be employed. Before someone can qualify to receive government benefits, such as social security or unemployment, they often require an assessment from a vocational counselor.

One of the first steps of vocational counseling is to help identify the client's interests. This can be accomplished through tests and questionnaires that help produce lists of possible career options based on interests and strengths. These tests should be administered and interpreted by the career counselor as they help their client work through understanding the results. If a client does not have the skills required to seek out a career they have chosen during counseling, the counselor can provide recommendations for additional training and education.

Career counseling can be short in duration. Some clients simply need referrals or resources which could be obtained in one or two sessions. Others could require more visits as the counselor works through evaluations and coaching a client to improve their skills. A vocational counselor could help a client look at reasons why they have had difficulty getting or maintaining employment. When this is the case, the challenges that arise for some clients might indicate that they require help from other professionals who can support the client's particular needs. These clients' needs can range from housing issues to psychiatric or physical medical problems that need to be addressed in order for a client to be successful in work. For more complex cases that require more attention, the duration of vocational counseling can be longer. Rehabilitation counseling for people with disabilities can be longer in duration and includes vocational counseling.

Vocational counseling occurs in different places and phases throughout a person's lifespan. In middle and high school, school counselors and teachers will likely introduce career issues. At colleges and universities, vocational counseling also exists to help students identify their transition to employment after completing their degrees. Outside of these educational settings, government services that provide vocational counseling are usually provided at no cost. Lastly, vocational counseling can be provided through not-for-profit agencies and private services that are specifically geared to certain populations.

Development

In the early 1900s, the father of vocational counseling, Frank Parsons, published a book on this important topic. *Choosing a Vocation* is the first major work that discussed the need for children and adults to have professional guidance in their career choices. He stressed the importance of career guidance as early as possible.

As interest in the field of career guidance and vocational counseling grew, more developments were made. In the 1970s, Donald Super identified a lifespan approach to career counseling to help identify career characteristics at different ages. There were others who focused on matching values or traits to specific careers as well. From these concepts many theories of career counseling have been identified and are widely used today. Many of these models focus on investigating the individual person and their needs as they evolve throughout their lifespan and identify careers of interest that are the best match to their characteristics.

Over the years several pieces of federal legislation have supported the use of vocational counseling in educational and government-run agencies. These laws and regulations have helped to establish the national vocational rehabilitation programs that were initially targeted for veterans. Eventually these acts have evolved to include different populations including people with disabilities, young people, and generally people in need of or interested in career assistance.

Current Status

Vocational counseling continues to be a funded service of national and local governments. The professions of rehabilitation and career counseling are growing and anticipated to continue being a necessary service. The need can be attributed to economic challenges and an increased population of those being diagnosed with disabilities and mental health issues.

One of the major challenges associated with career counseling is encouraging participants to engage in the process. When career counseling is mandated or forced, it is often difficult for clients to engage. Likewise, when a client is receiving government assistance, there may be incentives not to take advantage of vocational counseling services. Career placement counseling depends on resources in the community and is faced with a serious challenge when there are no options for employment.

It is important to note that career advice is provided through a range of formal and informal roles. Some prefer to rely on family members or people in the community for more informal career guidance. Others seek out more formal support through teachers, therapists, managers, and other professionals who are officially trained. Many people rely on themselves and independently search for Internet-based resources for career advice. The resources available online include help with resume writing, virtual interview practice, and searching and applying for available jobs. Vocational counseling is still considered a formal process of seeking therapeutic services from a trained professional.

Voyeuristic Disorder

Voyeuristic disorder is a mental disorder characterized by voyeuristic behavior that causes distress or impairment.

Definitions

- **Behavioral addiction** is a form of addiction caused by the compulsion to repeatedly engage in a behavior that causes harmful consequences. It is also referred to as process addiction or non-substance-related addiction.
- **Behavior therapy** is a form of psychotherapy that focuses on identifying and changing maladaptive behaviors.
- ***Diagnostic and Statistical Manual of Mental Disorders*** is the handbook mental health professionals use to diagnose mental disorders. The current edition (fifth) is known as DSM-5.
- **Paraphilia** is a mental condition in which an individual can only become sexually aroused by inappropriate objects, actions, or fantasies.
- **Paraphilic disorders** are a group of mental disorder characterized by paraphilia that causes distress or impairment or whose satisfaction involves personal harm. Included in this group are exhibitionistic disorder, fetishistic disorder, pedophilic disorder, and voyeuristic disorder.
- **Voyeuristic behaviors** are behaviors that result in intense sexual arousal. These include watching others undress or engage in sexual activities, or secretly filming them. It is also called voyeurism.

Description and Diagnosis

Voyeuristic disorder is one of the DSM-5 paraphilic disorders. It is characterized by voyeuristic behavior that causes distress or impairment. Those engaging in this behavior are sexual aroused by spying on others engaged in intimate behavior. The term "voyeurism"

comes from the French word *voyeur* which means "one who looks." Common to voyeuristic disorder is that the individual observes but does not directly interact with those being observed. The term "peeping Tom" is associated with such behavior. Besides being sexually aroused by watching others, voyeurs may engage in masturbation. Many states consider voyeurism a crime. Voyeuristic behavior is considered voyeuristic disorder according to DSM-5 only when specific criteria are met.

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, individuals can be diagnosed with this disorder if they experience intense sexual arousal on a recurrent basis from observing a non-consenting, naked individual who is undressing or engaging in sexual activity. This behavior or fantasies must cause significant distress or disrupt daily life. The individual must be at least 18 years old and the behaviors must also last for at least 6 months (American Psychiatric Association, 2013).

The causes of this disorder are unknown. Voyeuristic behavior usually starts before age 15. There are no reliable statistics regarding how often voyeurism occurs in the population. It seems it is more common in men, although it occasionally occurs in women. It may be that paraphilias are behavioral addictions or it could reflect a problem with brain functioning.

Treatment

There are no drugs to treat this disorder. Treatment for this disorder typically involves behavior therapy. The goal is to teach the voyeur to control the impulse and learn acceptable ways to achieve sexual gratification. The effectiveness of this treatment is unknown. This disorder is a chronic condition and there is little hope for change. The main reason is that they receive pleasure from this behavior and most individuals have little incentive to change. However, legal problems such as arrests and court orders are the main reasons individuals seek treatment. Currently, there is no way to predict who will develop this disorder; however, it may be prevented through education about appropriate sexual behavior.

Vygotsky, Lev (1896–1934)

Lev Vygotsky was a Jewish Russian psychologist who applied Marxist thinking to the study of human development.

Description

Vygotsky is considered one of the most significant and influential educational psychologists of the late 20th and early 21st centuries. He has been credited as the key figure in developing a social constructivist understanding of psychological development. Vygotsky's goal was to solve the psychophysical problem and thereby the problem of the crisis in psychology. He also wanted to provide solutions to problems in education. His two main ideas are the notion of cultural "tools" and the "zone of proximal development." He argued that children's intellectual growth is not an autonomous, self-guided affair. Rather, it depends greatly on the tools that the culture provides for them. These tools include language (written and oral); mathematical procedures; and, today, computers.

Vygotsky also believed that whenever children undergo some significant developmental change, they must go through a period of time—or "zone"—when they make sense of what they've learned. At the beginning of this period, the child can usually copy only with the help of someone more skilled than him or her. By the end, he or she can manage by himself or herself. What goes on during that zone of proximal

Lev Vygotsky was an influential Russian psychologist whose two main concepts are the notion of cultural "tools" and the "zone of proximal development." He argued that children's intellectual growth depends greatly on the tools that the culture provides for them, which include language (written and oral), mathematical procedures, and, today, computers. (Heritage Images/Corbis)

development is the essence of human development, Vygotsky believes.

During his university years in Moscow (1913–1917), Vygotsky studied medicine before switching to law. Because he was Jewish, he was allowed into the university only through a lottery, because there was a quota. At the same time, he read for a master's degree in history and philosophy at a different university. His philosophy was influenced by the likes of Karl Marx, Friedrich Engels, and Vladimir Lenin. Benedictus de Spinoza also had an influence on his views, as did Ludwig Feuerbach and the linguist, Aleksandr Potebnya. He drew empirical data from the anthropology of Lucien Levy-Bruhl, and the psychology of Pierre Janet and Jean Piaget.

Vygotsky often held research meetings, called internal conferences, where his closest associates would discuss completed work and plan for the future. A deep interest and passion for the arts, especially literature, filled Vygotsky's personal and intellectual life. He turned to plays, poems, fables, and novels in his search for examples to illustrate and support his complex arguments. Vygotsky died of tuberculosis on June 11, 1934, at the age of 37. Much of his work and plans survived only in rough drafts and notes to himself. In 2006, a large quantity of his handwritten notes (unpublished) were found in the family archive.

Impact (Psychological Influence)

His influence had a deep impact on his colleagues. However, his approach seemed to suffer an eclipse during Stalin's time, apparently for political reasons. It was only after one of his main works, *Thought and Language*, was published and translated into English in 1962—after Stalin's death—that Vygotsky's contribution to psychology became widely known. A collection of his papers on child development and learning was later published under the title, *Mind in Society*.

Since then, enthusiasm for Vygotsky's ideas, and interest in his work, has steadily increased, but not uniformly around the world. There is a tendency for those in the United States and continental European countries to show more interest in Vygotsky's work than those in Britain.

There is some disagreement among Vygotsky's supporters about the interpretation of his work. For example, there is some debate about the use of "tools-and-results" versus "tools-for-results." Vygotsky uncompromisingly took the "tools-and-results" view, in which the tool is inseparable from the development in question. However, many Vygotsky followers misrepresent his view by simply arguing in "tools-for-results" terms, which means acquiring a tool to be able to do something (like using a calculator to do mathematical operations quickly).

Vygotsky's system was originally compared to that of Gestalt psychologists, Piaget and Pavlov. Now it is discussed in context of the school of literary Formalists, Bakhtin's theory of inner dialogue, and Habermas's

notion of communicative action. He is credited with making contributions to the fields of aesthetics, special education, history, linguistics, neuropathology, neuropsychology, and pedagogy. Still, his concepts and theories have been criticized for being unnecessarily obscure and cryptic. His psychological theory of aesthetics has largely been ignored or undervalued. His paper, *The Psychology of Art*, was only published in English in 1971.

Watson, John B. (1878–1958)

John B. Watson was an American psychologist who is considered to be the founder of behaviorism.

Description

John B. Watson, PhD, was born in South Carolina to a devout religious mother and an emotionally distant father. Watson's life and career is intriguing in that he began life immersed in poverty in South Carolina and as a student who struggled academically. He would go on to found behaviorism and by the time he was 36 years old he was the president of the American Psychological Association, as well as the head of the psychology department at John Hopkins.

In the 1920s, Watson left academia abruptly and turned to the world of advertising. He used his knowledge of psychology and behaviorism to influence marketing strategies. To this day, Watson remains a controversial figure in the field of psychology with some crediting him as a major contributor while others remarking that he is as an embarrassment to the field.

Watson believed that behaviorism was a branch of natural science. He identified the goal of behaviorism as being able to predict as well as control behavior. Watson felt that children could be raised with specific behavioral guidance to become the person he wanted or would choose for them to be. Watson also believed that the actual behavior of a person was the only way to understand the internal feelings and views of a person.

Watson believed that the environmental influence on behavior began prenatally. He felt strongly that there needed to be emphasis on understanding how learning and experience function. One of Watson's most famous experiments is now known as the "little Albert" experiment. Watson believed that emotional responses could be classically conditioned in humans. He also felt that there were three basic emotions present from birth—rage, love, and fear. To prove this theory, Watson and his colleague Rosalie Raynor used a child they called "Albert B." The child was exposed to various stimuli including white rats and loud noises. Albert had positive response to the white rat and would reach for it without fear. The rat was then paired with a loud noise, which would startle Albert. Eventually, after several pairings, when just presented with the rat, Albert still withdrew in fear. This study raised numerous ethical concerns in the care of the child used in the experiment both during and after the test.

Impact (Psychological Influence)

Watson's work had a great impact on the debate of nature versus nurture, especially in exploring what has a greater influence on people—the genetics or the environment that surrounds them. His work paved the way for other behaviorists such as the well-known psychologist B.F. Skinner (1904–1990).

Wechsler Adult Intelligence Scale (WAIS)

The Wechsler Adult Intelligence Scale (WAIS) is a test used for measuring intelligence (cognitive abilities) in adults and older adolescents

Definitions

- **Intelligence quotient,** or IQ, is a score derived from one of several standardized tests designed to assess intelligence.
- **Intelligence test** is a standardized method of assessing an individual's ability to form concepts, solve problems, acquire information, reason, and perform other intellectual operations.
- **Standard deviation** is a statistical measure of the difference to an arithmetical mean or average. The wider the spread of scores from the mean, the larger the standard deviation.

Description

The Wechsler Adult Intelligence Scale is a widely used standardized test for measuring intelligence. It is currently in its fourth edition (WAIS-IV) which has been available since 2008. It is one of a series of intelligence tests used to assess cognitive abilities n in children and/or adults. Included in this series are the Wechsler Preschool and Primary Scale of Intelligence for children from three to seven years of age, the Wechsler Intelligence Scale for Children for children from 6 to 16 years of age, and the WAIS for adults 16 years and older. All of these scales test cognitive abilities (intelligence) in children and adults by providing various index scores that indicate different verbal and nonverbal (performance) abilities. Distinguishing verbal from performance intelligence is the distinctive feature of the Wechsler scales.

The Verbal Scales measure general knowledge, reasoning, language, and memory skills, and the Performance Scales assess problem solving, spatial, and sequencing abilities. Verbal intelligence is most identified with academic achievement, while performance intelligence implies the ability to perceive relationships and integrate individual parts together logically into a whole. Scores on the performance section are particularly helpful in assessing the cognitive ability of non-native individuals and those with speech and language disorders. The specific subtests of performance section are used by psychologists in screening for specific learning disabilities.

The WAIS is administered by trained professionals, usually a psychologist. The current version of this test, WAIS-IV, consists of 10 core subtests and 5 supplemental subtests. It takes approximately 60 to 90 minutes to administer the core subtests, and about 10 to 15 minutes for each supplemental test that might

be given. Raw scores are generated and converted to standard scores with a mean and standard deviations from that average. Scores in on the verbal subtests are calculated and converted to a Verbal IQ score as are performance scores and converted to a Performance IQ score. The Verbal and Performance IQ scores are added together and are then converted to an overall Full Scale IQ score. A Full Scale IQ score higher than 130 indicates the highest intelligence category. Scores in the 120s are considered very high, those in the 110s considered above normal, while scores from 90 to 109 are considered normal average. Scores in the high 80s are considered low-average, while scores below 85 are considered low in mental functioning.

Developments and Current Status

The WAIS was developed by David Wechsler (1896–1981) an American psychologist. In 1939, Dr. Wechsler developed the Wechsler-Bellevue Intelligence Scale at the Bellevue Hospital Center in New York City. In 1949, he developed the Wechsler Intelligence Scale for Children; in 1955, the WAIS (Form I); and in 1967, the Wechsler Preschool and Primary Scale of Intelligence was published. These tests were originally developed by Wechsler as a way to learn more about his patients at Bellevue because of the shortcomings of existing intelligence tests such as the Stanford–Binet Intelligence Scales.

Wechsler's basic premise was that intelligence should measure performance instead of capacity, and that intelligence was the ability to solve problems. Accordingly, he defined intelligence as the global capacity to act purposefully, to think rationally, and to deal effectively with one's environment. He believed that general intelligence is composed of various specific and interrelated functions that can be individually measured. This belief guided his development of the WAIS with a specific subscale reflecting each of these functions. He assigned an arbitrary value of 100 to the mean intelligence, to stand for the average or expected value of intelligence. Wechsler then added or subtracted 15 points from 100 for each standard deviation above or below the mean, respectively.

Wechsler Intelligence Scale for Children (WISC)

The Wechsler Intelligence Scale for Children (WISC) is a test that was developed for use with children to provide a score that would describe their intelligence level.

Definitions

- **Intelligence** is the capacity a person has to learn and understand information and solve problems.
- **Intelligence quotient** is a measure of intellect to determine a person's level of cognitive ability.

Description

David Wechsler (1896–1981) was an American psychologist who developed WISC. The instrument is an individually administered intelligence test for children between the ages of 6 and 16. It can be completed without reading or writing. The WISC usually takes about an hour and ten minutes to administer and yields an intelligence quotient (IQ) score which represents a child's general cognitive ability.

Development (Purpose and History)

Intelligence has been shown to be predictive of a wide variety of important life outcomes. Therefore attempts to measure it have been occurring since the 1800s. One

of the first successful attempts that achieved great recognition in the world was the Stanford–Binet Intelligence Quotient test.

David Wechsler first became involved in intelligence testing while helping induct troops during World War I. This gave him an intimate knowledge of a range of previous intelligence testing. After 1932, when he became chief psychologist at Bellevue Psychiatric Hospital in New York City, he began to use and adapt some of the existing intelligence tests which he found lacking. David Wechsler developed his original tests (Wechsler–Bellevue) during the 1930s.

Wechsler's dissatisfaction with existing intelligence tests was based on his wartime experience. During this time he met recruits who had been successful and smart but who, according to the army group examinations, exhibited low mental-age scores. He was convinced that the discrepancy between their abilities and the test results was a factor of the excessive emphasis on verbal skills necessary to get high IQ scores on the Stanford–Binet scale.

Wechsler published his first widely used intelligence scale, the Wechsler Adult Intelligence Scale (WAIS) in 1939. WISC followed in 1949 after at least five years of development. This development included being thoroughly tested with school-age students who had been rated with average intelligence.

In his tests, Wechsler incorporated two very important innovations. The first was technical and involved replacing the ratio IQ result with a deviation score which yielded more reliable results. The second reflected his insight that task performance, not only verbal expression, should be a part of intelligence evaluation. The scales in his tests focused on a child's ability to do things rather than a concentration on their ability to speak about them.

Current Status and Results

The basic structure of the WISC has remained almost unchanged through the later revisions made over the years. Many studies have been conducted to test the scale's reliability and validity. Psychologists have embraced it because of its ability to measure intelligence without solely relying on verbal skills but by including performance skills, and it is one of the most widely used IQ tests.

Each successive version is thorough in its scientific rigor. This is accomplished through norming each version of the test to ensure that the norms do not become outdated. Also its revisions are designed to ensure that they are representative of the current population. The WISC distinguishes between a child's intelligence and their performance. This helps to identify differences and develop a plan of action when there are learning difficulties.

The WISC, like all tests, should be used and interpreted by experienced psychologists. Those interpreting the WISC results should apply contextual factors including elements from a child's background which can influence learning and the expression of intelligent behavior. Results of the WISC for individual children may produce the similar test scores as other children but each should be interpreted in different ways depending on the child's unique background.

There are two criticisms about the WISC and its popularity. The first is that it is based on tests originally designed for adults but applied to children. This is compared to the Stanford–Binet which was designed originally for children and later changed to include adults. The second criticism is that when educators rely on this test to make decisions, they are using a test with scales that do not reflect the many advances in the understanding of cognitive functioning that have been made over the years.

Well-Being

Well-being is the state of being happy, healthy, prosperous, or successful.

Description

Well-being is described as how individuals think about and experience their lives. Well-being is an indicator of how well individuals perceive their lives to be going. It reflects several health, job, family, and social outcomes. For example, higher levels of well-being are associated with decreased risk of disease, illness, and injury. It is associated with faster recovery, better immune functioning, increased longevity, and better physical and mental health. In addition, those with high levels of well-being are more productive at work, get along better with others, and contribute more to their communities. Accordingly, well-being is a key consideration for the Centers for Disease Control and Prevention (CDC) in tracking American's health.

The CDC indicates that while there is no consensus on the definition of well-being, there is general agreement that it includes the presence of positive emotions and moods, the absence of negative emotions, satisfaction with life, a sense of personal fulfillment, and positive functioning. In short, they describe well-being as judging life positively and feeling good. The CDC specifies various kinds of well-being. These include physical well-being, economic well-being, social well-being, emotional well-being, and psychological well-being. Finally, they state that while well-being can be attributed to heritable factors, environmental factors play an equally if not more important role. Proponents of positive psychology have made significant contributions to the theory and research on well-being.

Recently, researchers from Gallup, Inc. and Healthways have begun reporting results on the largest database on well-being in the world. Data was collected on two survey instruments: the Wellbeing Finder and the Gallup-Healthways Well-Being 5. Some 1.9 million individuals from 150 countries have reported on how they experience their days and evaluate their lives overall. Five distinct statistical factors emerged from this research. These factors are named the core elements of well-being.

Here is a brief summary of each of the five elements of well-being.

- **Purpose:** Liking what one does each day and being motivated to achieve one's goals.
- **Social:** Having supportive relationships and love in one's life.
- **Financial:** Managing one's economic life to reduce stress and increase security.
- **Community:** Liking where one live, feeling safe, and having pride in one's community.
- **Physical:** Having good health and enough energy to get things done daily.

Findings show that these elements are interconnected and that they can identify individuals on a continuum from thriving to struggling to suffering. For example, 66% of those surveyed were thriving in one of the five elements. However, only 7% were found to be thriving in all five elements. This ongoing research tracks and reports on the well-being of individuals and organizations. Much of this data is reported in the book *Wellbeing: The Five Essential Elements* and the Gallup website.

Well-Being Therapy

Well-being therapy (WBT) is a form of psychotherapy that focuses on developing greater autonomy, growth,

environmental mastery, self-acceptance, and positive relationships to improve one's personal well-being.

Definitions

- **Autonomy** is an independent and self-determining reliance on one's self and a resistance to social or peer pressures to think, act, or feel a certain way.
- **Environmental mastery** is the ability to competently manage everyday affairs of living by making effective use of resources and opportunities while controlling external activities.
- **Evidence-based practice** is a form of practice that is based upon integration of the best research evidence with clinical experience and client values.
- **Pathology** is an experience of suffering or aspect of a disease incorporating cause, development, structure, and consequences.
- **Positive psychology** is the sub-field of psychology whose aim is to understand the positive aspects of human thought, emotion, and behavior instead of focusing on pathology.
- **Psychotherapy** is a psychological method for achieving desired changes in thinking, feeling, and behavior. It is also called therapeutic counseling.
- **Third-order change** is change that results from an individual's own efforts rather than change that is mediated by a therapist or personal coach.
- **Well-being** is the presence of positive emotions and moods, the absence of negative emotions, satisfaction with life, fulfillment, and positive functioning.

Description

Well-being therapy is psychotherapy whose primary focus is to improve upon clients' subjective experience of psychological well-being and quality of life. It assists in the achievement of, or growth toward, clients' optimal human functioning (potential). WBT is commonly used to treat the anxiety disorders and mood disorders. Instead of focusing interventions on the reduction of the negative symptoms, WBT focuses intervention on increasing positive feelings and well-being. Heightening positive emotions is believed to interact with the negative symptoms of the anxiety disorders and mood disorders to promote balance within a client. A balanced lifestyle is considered to be a healthy lifestyle and an aspect of optimal human functioning.

WBT is a form of short-term psychotherapy. Typically, WBT involves between 8 and 12 sessions. In the initial stages of WBT, a structured diary is utilized. A structured diary helps a client learn skills related to self-observation. A client learns how to identify and document patterns of thoughts and ways of believing that may be inhibiting their access to well-being. Clients are also educated in ways to recognize and rank brief episodes of well-being. The structured diary develops clients' insight into their patterns of thinking and believing, as well as displaying clients' growth over time.

WBT typically begins with a focus on increasing self-determination and autonomy. For example, as individuals become increasingly autonomous and self-sufficient, they become increasingly able to analyze their own structured diary. Clients learn to think and act like a psychotherapist and discover ways to access well-being on their own. In time, they are able to function as their own therapists. This is called third-order change. Increasing self-determination and autonomy are significant aspects of WBT. Other essential aspects of well-being are personal growth, environmental mastery, self-acceptance, and positive relations with others.

Development and Current Status

In his 1998 presidential address to the American Psychological Association, psychologist Martin Seligman called on psychology to emphasize the positive: people's strengths and virtues. Seligman lamented that psychology had been overly preoccupied with

dysfunction (problems) and pathology. Instead of focusing on relieving mental distress, psychology should focus on nurturing well-being. Seligman's call resulted in sub-field of positive psychology. One of the most promising developments of positive psychology has been WBT.

Research evidence indicates that the remediation of pathology does not inherently produce well-being. Further, research has shown that well-being reduces the probability of relapse into symptomatic distress. WBT was originally developed as a relapse-prevention strategy for individuals rehabilitating from affective disorders, such as the anxiety or mood disorders. While it is still in its infancy, the value of WBT is becoming increasingly recognized by health and mental health-care professionals. Research interest in positive emotions and well-being has also increased. This research is imperative in establishing WBT as an evidence-based practice. WBT also appears to be effective with children and the elderly.

As the promised psychotropic "miracle pills" are failing to deliver a cure from anxiety and depression, more people are turning to interventions that foster well-being. Well-being does not only impact the lives of individuals, but it can also promote social advancement through the actualization of its individuals.

Wellbutrin (Bupropion)

Wellbutrin is a prescribed antidepressant medication used to treat depressive disorders and aid in smoking cessation (marketed as Zyban). Its generic name is bupropion.

Definitions

- **Antidepressant medications** are prescription drugs that are primarily used to treat depression and depressive disorders. These are known as antidepressants.
- **Dopamine** is the chemical messenger in the brain responsible for coordinating the movement of voluntary muscle groups. It also regulates attention, pleasure, and coping with stress.
- **Seasonal affective disorder** is a mental disorder characterized by depression weight gain and excessive sleep during the winter months.
- **Seizure** is a convulsion or uncontrolled discharge of nerve cells that may spread to other cells throughout the brain.

Description

Wellbutrin is in its own class of antidepressant medication because it is the one that increases dopamine. It is primarily used to treat depression and seasonal affective disorder. In addition, it useful in helping individuals quit smoking. It is also used in treating panic disorder and attention deficit hyperactivity disorder. Wellbutrin was developed as an alternative to the tricyclic antidepressants with their problematic side effects of sedation (sleepiness), dizziness, and weight gain. Wellbutrin is thought to work by balancing two neurotransmitters (chemical messengers) in the brain, norepinephrine and dopamine.

Precautions and Side Effects

While Wellbutrin is less likely to cause weight gain and lower blood pressure compared to other antidepressants,

it is more likely to trigger seizures. Those taking Wellbutrin should minimize alcohol use since consumption of it increases the chance of seizures. Increases in blood pressure have occurred in those taking Wellbutrin. When taken for smoking cessation, some patients have developed severe symptoms, including aggression, depression, mania, panic attacks, and suicidal thoughts and actions. As with other antidepressants, children and adults up to 24 years of age are at increased risk for developing suicidal thoughts and actions. It has not been determined whether Wellbutrin is safe to take during pregnancy. Pregnant women should take Wellbutrin only if the benefits outweigh its risks. Since it is secreted in breast milk, women taking Wellbutrin should consult their doctors about breast-feeding.

Some common side effects reported with Wellbutrin include insomnia, agitation, confusion, restlessness, anxiety, headache, dizziness, and tremor. Weight loss is more common than weight gain, but both have been reported. Less common side effects include blurred vision, constipation, decreased appetite, dry mouth, excessive sweating, nausea, rapid heart rate, sedation, sore throat, and vomiting.

Wellbutrin should not be taken with other medications that lower the seizure threshold. These include steroids, asthma medications like Theo-Dur, and monoamine oxidase inhibitors like Parnate and Nardil. Adverse effects may increase in those taking Wellbutrin and Parkinson's disease like L-dopa. Nicotine patches may be used concurrently with Zyban in smoking cessation treatment. However, blood pressure must be monitored since it can increase. Wellbutrin may delay the elimination of antidepressants, antipsychotic drugs, and heart medications, resulting in higher blood levels and potentially increased side effects.

Wellness Counseling

Wellness counseling focuses on the connection between physical and mental health and focuses on how they can be integrated to give a better quality of life to clients.

Definition

- **Wellness** is the state or condition of being in good physical and mental health and steps to promote it.

Description

A healthy lifestyle is an important aspect of mental health that is infrequently targeted, especially in outpatient mental health settings. Although the relationship of psychological and physical factors has often been acknowledged, interventions and treatment in the past frequently focused solely on mental functioning. When physical health was included as a factor at all, it was usually in the context of side effects from antipsychotics or other drugs.

Patients with psychiatric disorders have been shown to be at greater risk for comorbid drug, alcohol, or other substance abuse. Patients who are severely mentally ill are often on a regular regimen of antipsychotic drugs with the side effect of causing substantial weight gain which can endanger their physical health. This reality of multiple layers of problems is a challenge both for patients and for caregivers.

For wellness counseling, awareness of the interrelationship between the mental challenges patients face and its effect on their physical health is vital. Wellness counseling will differ depending on the patient's needs. Overall it aims to help people cope with their mental disorders in a different way. It focuses on enhancing the healthy aspects of clients' lives and improving those instead of simply focusing on reducing

problems. It seems clear that treatment and exercises that improve both psychosocial and physical functioning make a positive difference even for those who suffer from more severe mental issues. In one study, for example, war veterans who suffer from comorbidity between psychosis and alcohol/drug use were greatly helped by positively oriented group process activities and wellness counseling.

Development

Wellness programs are generally recognized to have begun in the 1960s based on an increasing awareness of human beings as integrated in mind and body. The start of this work was in Rogerian therapy with its emphasis on the wisdom of the client and concern for the whole person. Later, with the development of positive psychology, there was an emphasis on achieving happiness and the responsibility to work toward achieving a healthy life both physically and emotionally.

One of the results of the emphasis on wellness counseling is integrated health-care treatment versus fragmented treatment plans for the mentally ill. Interventions aimed at improving mental functioning must be conducted in the context of a healthy body and lifestyle. This means that both thinking and behavior need to be addressed. In addition, it is necessary to include the wider psychosocial environment. This includes working with the friends and family of someone who suffers from mental illness, so that they not only learn how best to cope with the mentally ill person but also can reinforce positive activities and be on the alert for signs of illness.

Current Status

There are several wellness models from which mental health professionals can learn how best to address the physical and social issues involved in treatment of mental illness. One example of the need for awareness is that when medications interfere with clients' ability to participate in physical activities that they value, there is a greater chance that they will change or stop following their drug protocol. This means clinical professionals should carefully regulate and track the effects of any prescribed drugs so that they do not interfere with the client's pursuit of physical activities which can aid in the coping or recovery processes.

In all of this it is important to have an integrative approach. Selecting and sequencing the appropriate interventions requires a careful assessment of the client's current functional levels. This includes both mental and physical aspects of a client's life and an awareness of the way the specific disorder is manifested or acted out, as well as the specific circumstances of the client's life. Above all, it is vital to involve the clients in making choices around their own treatment and activities because this will reinforce their sense of worth and their commitment to treatment. The range of treatments for issues that they are experiencing then becomes something they own, rather than something that is done to them.

Wernicke-Korsakoff Syndrome

Wernicke–Korsakoff is an alcohol-related medical condition characterized by severe problems with sight, memory, confusion, hallucinations, and loss of coordination.

Definitions

- **Alcoholism** is a general term for the compulsive and uncontrolled consumption of alcohol to the detriment of the drinker's health, relationships, and social standing. It is also called alcohol abuse.
- **Alcohol withdrawal** is the unpleasant and potentially life-threatening physiological changes that occur due to the discontinuation of alcohol after prolonged regular use.

- **Antipsychotics** are prescription medications used to treat psychotic disorders including schizophrenia, schizoaffective disorder, and psychotic depression.
- **Delirium** is a mental disorder characterized by rapid onset of extreme disorientation and confusion and is usually caused by illegal drugs, medications, or medical conditions.
- **Dementia** is a group of symptoms including loss of memory, judgment, language, and other intellectual (mental) function caused by the death of neurons (nerve cells) in the brain.
- **Family therapy** is a type of psychotherapy for families that focuses on improving relationships and understanding between family members.
- **Hallucinations** are false or distorted sensory perceptions that appear to be real perceptions that are generated by the mind rather than by an external stimuli.
- **Psychotherapy** is a psychological method for achieving desired changes in thinking, feeling, and behavior. It is also called therapy and therapeutic counseling.
- **Twelve-Step Program** is a self-help group whose members attempt recovery from various addictions and compulsions based on a plan called the Twelve Steps.

Description and Diagnosis

Wernicke–Korsakoff syndrome is a severe medical condition that results from long-term alcohol abuse. It is named after the German physician, Carl Wernicke (1848–1905). This syndrome is actually the combination of Wernicke encephalopathy and Korsakoff syndrome. Wernicke encephalopathy is characterized by delirium, inability or poor control of motor functions, severe vision impairments, and other symptoms associated with alcohol withdrawal. Alcohol withdrawal alone can be very difficult to bear as well as fatal. Korsakoff syndrome is a disorder causing memory problems and hallucinations. Individuals may become unable to form new memories or recall existing memories. They may also experience hallucinations. It is important to note that symptoms of Korsakoff syndrome mimic dementia and it is sometimes referred to alcohol-related dementia.

These two syndromes are combined because they often occur together. It is uncertain whether they are distinct but related disorders or if they are different evolutions of the same syndrome. Specifically, Wernicke–Korsakoff syndrome is caused by a severe deficiency of thiamine (vitamin B-1). However, this deficiency is most often the consequence of alcoholism. Wernicke–Korsakoff syndrome is also known to result from a failure to absorb nutrients (minerals and vitamins) from food. Regardless of specific cause, the symptoms of this syndrome are the consequence of brain damage. Consequently, the damage is not likely to be repaired and some symptoms may become permanent. Also, symptoms will continue to worsen if these individuals continue to drink and will ultimately result in death. Abstaining from alcohol use is the only way to stop the worsening of symptoms.

Treatment

Treatment for this condition usually begins with correction of the thiamine deficiency. This is accomplished by injecting this vitamin directly into the blood stream. Following the correction of this deficiency, both the harmful behavior of the individual and the symptoms will be treated. Treatments of alcoholism often includes 12-step programs, psychotherapy, group therapy (psychotherapy in small groups), and family therapy. Alcoholism can be a difficult disease to treat and individuals, even those with the severe symptoms of Wernicke–Korsakoff syndrome, may relapse. When severe, this syndrome can be treated with antipsychotic medication to control delirium or hallucinations. Other medical treatments to reduce other symptoms may also be used.

Whitaker, Carl (1912–1995)

Carl Whitaker was a physician, psychiatrist, professor, and family therapist best known for his pioneering family therapy work and controversial style of therapy.

Description

Carl Whitaker was born in Raymondville, New York, in 1912. He received his medical degree in gynecology and obstetrics before studying psychology at Syracuse University. Whitaker worked at the Syracuse Psychopathic Hospital in 1938 and began exploring family dynamics after observing that many of his psychiatric patient's symptoms would reappear after they were sent home. At the time, therapy was provided almost exclusively to individuals in private sessions. Whitaker created an approach that included all available family members and is considered a pioneer in experiential family therapy.

Whitaker was influenced by existential models of therapy and stressed freedom, choice, self-determination, self-actualization, and growth. He stressed the importance of the relationship between the family and therapist and believed that both would be changed by the encounter. Whitaker did not propose specific methods of therapy but encouraged therapist to use their intuition and spontaneous reactions to promote family interaction. He believed that through personal involvement a therapist could promote change and growth.

Whitaker was also known for being irreverent and outrageous in his methods and as a freewheeling, shoot from the hip therapist. Many stories are told of his humor and wit in both his approach to teaching and to therapy, sometimes bordering on the inappropriate. He believed the family should operate as an integrated whole not as a group of discrete individuals. He also believed that lack of emotional closeness and sharing led to interpersonal problems and family dysfunction. He used humor and spontaneity to creatively expose and confront emotions held by family members who were unable or unwilling to express them. Characterized as being confrontational his goal was to creatively promote realness in family relationships by developing autonomy for individuals and connectedness with family members.

Impact (Psychological Influence)

Whitaker was one of the first therapists to acknowledge the role of the family in the development and maintenance of an individual family member's difficulties. He believed that dysfunctional family members were symbolically expressing family dysfunction. Whitaker developed a unique approach to family therapy referred to as symbolic-experiential family therapy and is considered a founder of experiential family therapy. He also pioneered the use of co-therapists in which a pair of therapist would work with families. Whitaker served as chairman of the Department of Psychiatry at Emory University and then as professor of Psychiatry at the University of Wisconsin-Madison until his retirement in 1982.

White, Michael (1948–2008)

Michael White was an Australian social worker and family therapist who developed narrative therapy, which is an approach that connects identity as shaped by the individual's story and perception of those stories.

Description

Michael White was born and raised in Australia. He grew up in a working-class family. White has written about how he had limited access to information on how others lived and found himself fascinated by those worlds that were different from his own. On his 10th birthday he received a bicycle, which was his first opportunity to explore other worlds. He found himself intrigued with maps and the adventures that they held.

White felt his appreciation for maps and exploration directed him on his professional path. He viewed the journey as an opportunity to learn about what is possible for people to know about their own lives. White felt that the maps he loved provided an excellent metaphor for working with clients. He wrote of how sitting down with a client was the beginning of a journey with an unknown destination with routes that could not be predetermined. White felt it was important to not speak on behalf of others but instead to create opportunities where they would be able to speak for themselves. He felt it important to not make assumptions about other people's lives.

White first presented his idea of narrative therapy in 1990 in his book with David Epston, entitled *Narrative Means to Therapeutic Ends*. White gave credit to the clients he saw throughout his lifetime as providing the assistance and inspiration to the evolution of narrative therapy. He felt that the collaborative process with his clients was a learning opportunity and a motivation for new ways of therapeutic practice. White refused to engage in defining clients by their mental illness or even identifying what was normal for any individual. He felt it was important to maintain an open mind and work from a place of complete equal partnership with his clients. Michael White died from a heart attack at the age of 59 in 2008.

Impact (Psychological Influence)

White published numerous books and articles. He was the founding editor of the *Australian Journal of Family Therapy*, which would later be renamed the *Australian and New Zealand Journal of Family Therapy*. He is considered to be an innovator in the field of family therapy in Australia. He embraced each project with great enthusiasm, curiosity, and great humility.

Wide Range Achievement Test (WRAT)

The Wide Range Achievement Test (WRAT) is a measure of academic skills in the areas of reading, spelling, and math.

Definitions

- **Intellectual** refers to the ability to think and understand ideas.

- **Intelligence** is the capacity a person has to learn and understand information and solve problems.
- **Intelligence quotient** is a measure of intellect to determine a person's level of cognitive ability.

Description

The Wide Range Achievement Test is a short assessment tool that measures a person's ability to read words, comprehend sentences, spell, and solve math problems. The present version, the WRAT4, has two levels. The first level is designed for and provides consistent results for children between the ages of 5 and 11. The second level is normed for and covers a broader population from children 12 years old up to older adults in their 80s and 90s. It is important to note that the WRAT4 is not intended to identify cognitive disorders or learning disabilities. It is most useful for a simple, quick assessment of basic academic skills.

Development (Purpose and History)

In the 1930s, psychologist Joseph F. Jastak developed the first version of the WRAT. Jastak wanted to improve on Wechsler's cognitive performance tests by getting a more complete view of an individual's academic abilities. Later Jastak worked with pioneer child behavioral psychologist Sidney W. Bijou to refine the WRAT, which was officially published in 1946. Sara R. Jastak also contributed to the editing and development of revised versions of the WRAT. Since the 1940s several versions have been developed and the latest version, the WRAT4, was published in 2006.

Reliability ratings for the WRAT4 are strong. For the later teenage years through middle-adult years, the WRAT subtests are not as precise at the higher score levels. Nevertheless, clinical studies have shown that the WRAT4 can help distinguish between people with low and high cognitive ability. The WRAT's ease of application has continued to make it a popular choice for the assessment of reading comprehension and math skills.

Current Status and Results

As its title indicate, the WRAT4 currently is in its fourth revision and contains the four traditional subtests in the areas of word reading, sentence comprehension, spelling, and mathematical computation. For validity the first two tests need to be administered individually while the second two have the option of being administered in a group setting.

There are two different versions of the WRAT4 which gives administrators the advantage of being able to give the test a second time shortly after the first without impacting the results. The tests are also valued because they are relatively easy to score and take only between 15 and 45 minutes to complete. For these reasons, it remains a popular way of getting a lot of information about a person's cognitive abilities in a relatively simple and brief way.

Willpower

Willpower is the ability to resist a short-term temptation in order to achieve a long-term goal.

Definitions

- **Ego depletion** is the term used to describe the temporary exhaustion of self-control. It is also known as willpower depletion.
- **Psychoanalytic theory** is a psychological theory that explains behaviors and perceptions as the result of unconscious, sexual, and biological instincts. It was originally developed by Sigmund Freud.

- **Self-control** is the capacity for self-discipline. Some use this term interchangeably with willpower.

Description

Willpower is the ability to delay gratification and resist short-term temptations in order to achieve long-term goals. It is also commonly referred to as self-control. Willpower is the conscious and effortful regulation of the self to override unwanted thoughts, feelings, and impulses. It is also a limited resource capable of being depleted. Lack of willpower is the main reason most give for not achieving their goals whether it be eating right, exercising regularly, or saving for retirement. Actually, there are three necessary conditions for achieving goals. The first is a clear goal and the motivation for change. The second is monitoring one's efforts to achieve the goal, and the third is willpower. Of the three conditions, willpower is the most problematic for many.

Roy Baumeister (1953–) is the American psychologist credited with promoting scientific research on willpower. This research shows that willpower is correlated with various positive markers of health and well-being. It shows that those with a high self-control tend to have high grade-point averages, higher self-esteem, lower alcohol and substance abuse rates, better overall physical and mental health, and better relationship skills. Willpower is more important than intelligence quotient in predicting academic success. Even more remarkable is that one's capacity for self-control appears to persist throughout life. Children with a high capacity to delay gratification (an indicator of willpower) are found to have fewer criminal convictions, fewer cavities and other dental problems, better health and well-being, fewer traffic tickets, fewer divorces, and more savings and financial security as adults than those with less capacity to delay gratification.

Baumeister compares willpower to a muscle and likens ego depletion to energy depletion in a muscle. Just as a muscle's energy may be depleted slowly over many small actions or quickly in fewer large actions, so too can an individual's ability to exert willpower decrease with use. That is because individuals have only a limited amount of mental energy that they may utilize in a given amount of time. As the individual uses this energy for self-control, they deplete this energy and have less available for the next action. Furthermore, the more difficult a given decision is, the more mental energy is required to act on the decision.

Notions of limited willpower date back to Sigmund Freud's model of the psyche (mental) energy that became the basis of psychoanalytical theory. Freud suggested that drives associated with the pleasure-seeking id (unconscious and primitive instincts) conflicted with the superego (moral part of self) that represented societal rules and ideas of fairness. This conflict was resolved by the ego (decision-making part of self), but not always consistently. Freud used the analogy of a horse and rider whereby the rider is the ego and the horse is the remainder psyche; the rider controls the horse but at times, the horse acts without direction from the rider. As it pertains to ego depletion and Freud's structural model, this term indicates that the ego is able to control the action of the self as long as it has sufficient energy in reserve. If this energy is low or completely exhausted, it follows that the ego has far ability to dictate the actions of the self.

Baumeister's research shows that ego depletion has a physical basis and those with low self-control show differing brain patterns when presented with temptation (Baumeister and Vohs, 2004). Individuals whose willpower has been depleted have decreased activity in a brain region involved in thinking and planning, and have lower blood-glucose (sugar) levels than do individuals whose willpower has not been diminished. Fortunately, the effects of ego depletion can be lessened in various ways. These include eating a healthy diet; getting regular exercise and sleep; and maintaining positive moods, beliefs, and attitudes.

Wolpe, Joseph (1915–1997)

Joseph Wolpe was a South African Psychiatrist who is best known for his contributions to development of behavior therapy.

Description

Joseph Wolpe, MD, was born in Johannesburg, South Africa, in 1915. He was the son of Michael Salmon Wolpe and Sarah Millner. Wolpe received his medical degree from the University of the Witwatersrand in Johannesburg. During World War II, he was assigned to a military psychiatric hospital in South Africa. There he worked with soldiers diagnosed with what was then called "war neurosis." Today, this diagnosis is called post-traumatic stress disorder, a mental disorder characterized by nightmares, irritability, anxiety, emotional numbing, and recurrent flashbacks of a traumatic event that an individual experienced or witnessed. Wolpe created psychological treatments to treat the soldiers who experienced significant symptoms due to their traumatic experiences.

Impact (Psychological Influence)

Joseph Wolpe's practice, research, and publications have had significant influence in the field of behavioral psychology and behavior therapy, which espouses that maladaptive behaviors are learned and can be unlearned. He was most known for developing and researching reciprocal inhibition and systematic desensitization. Wolpe's work laid the foundation for the treatment of individuals living with significant anxiety by teaching them to relax by using a gradual exposure to an anxiety-producing object or situation. His other behavior therapy technique reciprocal inhibition involves an individual practicing a desired behavioral response in the presence of a stimulus that triggers an undesired response.

Wolpe was a professor of Psychiatry at Temple University's Medical School in Philadelphia from 1965 to 1988. He was also the director of the behavior therapy unit at the Eastern Pennsylvania Psychiatric Institute. He was a prolific author and received many awards in the fields of psychology and behavioral sciences. He received the American Psychological Association's Distinguished Scientific Award for the Applications of Psychology and a lifetime achievement award from the Association for the Advancement of Behavior Therapy. Wolpe's involvement in the field of psychology was a lifelong endeavor; even a month before his death he was attending conferences and giving lectures. Additionally, his theories and research have lasted beyond his death at the age of 82.

Women's Mental Health Issues

Women are at higher risk of experiencing certain mental health disorders such as depression, anxiety, self-inflicted injury, and eating disorders.

Definitions

- **Eating disorders** are mental health conditions that involve extremes in eating patterns that lead to serious physical and mental health complications; two of the most common eating disorders are *anorexia nervosa* and *bulimia nervosa*.
- **Generalized anxiety disorder** is a mental health condition characterized by uncontrollable, exaggerated, and chronic bouts of worry and tension.
- **Major Depression** is a clinical psychological diagnosis that persists over time and is characterized by overwhelming feelings of sadness, hopelessness, and difficulty engaging in normal everyday activity.
- **Self-inflicted injury** is a term used to refer to a range of behaviors that encompass self-harm where individuals deliberately injure themselves but without suicidal intentions.
- **Suicide** is the intentional or unintentional act of taking one's own life.

Description

Mental health disorders are a public health concern with estimates suggesting that nearly 500 million people are affected worldwide. Deaths resulting from mental health conditions are second only to cardiovascular disease. Though psychological disorders affect both men and women, women are at a greater risk of experiencing certain types of conditions including major depression, generalized anxiety disorders, post-traumatic stress disorder, self-injurious behaviors, attempted suicide, and eating disorders.

High depression rates have been linked to hormonal changes in women. Reports suggest that these rates are double that of men from the time a female reaches puberty onward. Statistics also indicate that these numbers are highest in white/Caucasian and Hispanic females as opposed to other ethnic groups. Major depression coincides with additional disorders including self-injurious behavior and suicide. Furthermore, women are at greater risk of experiencing anxiety-related disorders, which also have a biological connection, though societal and social factors contribute as well. Additionally, the prevalence of eating disorders in women has been evidenced. Oftentimes, women cite anxiety, stress, and lack of control as reasons for engaging in these extreme behaviors. Comorbidity further complicates matters as several mental health illnesses have been linked with substance abuse issues. Women who use illicit drugs, drink alcohol in excess, and who smoke cigarettes are at greater risk of experiencing mental health problems.

Biological, environmental, and psychosocial factors contribute to higher incidence rates of mental illness in women. All can impact women's mental health risks, rates of the disorders, and their progression. Biological contributors include hormone differences and variations in brain structure. Female hormones, estrogen and progesterone, drastically increase during premenstrual, postpartum, and perimenopausal periods, experiences distinct to women. These hormonal shifts result in physical symptoms (bloating, weight gain, cramping, nausea, headaches) and accompanying mood fluctuations in women. Estrogen and progesterone levels effect how the female brain reacts and subsequently responds to stress-related situations. Male and female brains also differ structurally. While male brains are larger, female brains are more complex. Specifically, female brain comprises a larger frontal lobe, the part of the brain that is responsible for regulating judgment, language, problem solving, and socialization. Environmental and psychosocial factors impact women's mental health as well. The majority of people who seek medical and therapeutic treatment for psychological distress are women. In particular, individual counseling and small group counseling are interventions that are primarily sought out by women. Psychosocial factors include the influence of gender roles, sexism, lower socioeconomic status, and differences in coping styles. Feminine social expectations and prejudices toward women can add to stress and anxiety levels. Women are not financially compensated equally to men and most bear the majority of the burden of caretaking tasks. Media also places added pressure on women to look and act in certain ways. Additionally, varying coping styles between men and

women can contribute to the onset of mental disorders. While most men tend to externalize problems, most women internalize them, which may result in self-blame, doubt, and negative thought patterns.

Current Status and Impact (Psychological Influence)

Much of the research over the past decade has focused on gender-based differences and success rates for various treatment interventions. Critical importance has focused on overall mental health and wellness over the lifespan. With early and proper diagnosis, most mental health disorders are highly treatable. However, certain protective or resiliency factors can prevent the onset of mental health illnesses. These include proper self-care and adequate social support. The literature has noted the effectiveness of comprehensive, holistic, and family-based interventions with female clients. Women also respond positively to culturally sensitive, strength-based approaches. Identifying cultural pressures that may be contributing to the deterioration of a woman's mental health is advised. Medical and mental health professional are also advised to properly educate and routinely screen for any evidence of trauma, violence, and/or abuse as these problems are also much more commonly experienced by women. Recovery is possible with proper and effective intervention.

Work Orientation

Work orientation is an individual's overall attitude toward work.

Definitions

- **Higher power** refers to a greater being or some form of God.
- **Intrinsic motivation** is the internal desire to engage in an action or activity.

Description

Work orientation is the view and attitudes individuals have toward work and their drive to work. It is influenced by personal values, beliefs, and work experiences. It also involves how individuals get along with co-workers, subordinates, and supervisors. Three work orientations that have been extensively researched in the United States are job, career, and calling orientations. Each orientation is associated with job satisfaction, attitude toward work, and motivation to work.

Job orientation means that an individual views work as the means to obtain material goods and services. He or she is motivated by outside interests and activities. Activities outside of work have greater personal value and provide greater satisfaction than work.

Career orientation means that an individual's primary focus is work and career advancement. Personal satisfaction is derived from career status, promotions, and pay raises. Individuals with career orientation are motivated to work and strive to improve their professional standing. In calling orientation, individuals find their work meaningful because it serves to provide services for others and the greater community. Promotions and pay raises are not as important as contributing to the well-being of others.

Vocation orientation is sometimes used synonymously for calling orientation but, technically, it is not the same. Individuals with a vocation orientation deem their work important for the well-being of others but do so for personal reasons. In comparison, individuals with a calling orientation consider their work meaningful and are motivated to work for the good of

others and the community. Both vocation and calling orientation involve working to serve others. However, with vocation orientation the motivation to work stems from internal reasons. Finding personal life meaning is the usual reason. With calling orientation individuals work for external reasons such as the greater good of humanity or for a higher power.

The term "work orientation" was originally used by Mihaly Csikszentmihalyi (1934–) a psychologist who teaches, researches, and writes about happiness, flow, and intrinsic motivation. According to Csikszentmihalyi, individuals with a desire to improve work performance, through continuous practice, will become intrinsically motivated. Work then becomes a way for the individual to express himself or herself. Even though the individual may receive monetary compensation and job benefits, what matters most is the sense of identity and purpose derived from work. Work becomes intrinsically motivating and develops into the individual's calling in life.

Working with Emotional Intelligence (Book)

Working with Emotional Intelligence, published in 1998, is an influential book by Daniel Goleman that investigated and expanded the concepts of social and emotional intelligence (EI).

Definition

- **Emotional intelligence** is the ability to accurately identify and respond to emotions in oneself and others.

Description

Daniel Goleman (1946–) began his career as a psychologist and science writer for *The New York Times* but is best known for this book and others on EI all of which became bestsellers. In the book *Working with Emotional Intelligence* (1998), Goleman highlights the research which challenges the effectiveness of using classical intelligence measures to predict a person's abilities and success.

The idea of EI and social intelligence was first noted by Edward Thorndike in the 1930s. In the work of others such as David Wechsler, Abraham Maslow, and Howard Gardner, they also recognized the important role that the emotions play in the concept of intelligence.

Goleman researched dozens of successful business people and exceptional individuals in society to conclude that they achieved their prominence not simply because of their measurable intelligence quotient but also because of the key factor of EI. EI comprises a set of skills that help people manage how they deal with feelings, interactions, and communication. Based on the research, he identifies two areas of vital skills: self-mastery and relationship skills. Self-mastery is based on 12 personal competencies such as accurate self-assessment, self-control, initiative, and optimism. Relationship skills involve 13 aptitudes such as service orientation, developing others, conflict management, and building bonds.

Many of Goleman's findings in the book came from research others conducted. These include the works of Peter Salovey and John Mayer published in their influential article *Emotional Intelligence*. In this scholarly work, the authors define EI as the ability to use the emotions one experiences with discrimination to help determine the most healthy thoughts and actions.

Impact (Psychological Influence)

The book brought the concept of EI to the forefront of public attention and pop culture. Several other books and articles preceded and followed this book to help educate

people about the concept of EI. This helped to create more interest in the topic and the development of ways to measure the concept. Over the years different tools have been developed to try to provide an objective measurement of EI. Among them are the Emotional Quotient Inventory, the Multifactor Emotional Intelligence Scale, the Seligman Attributional Style Questionnaire, and the Emotional Competence Inventory. These instruments are qualitative and descriptive in nature. They are used primarily to help identify and improve ways of expressing oneself and working with other people.

In working with clients, mental health professionals would do well to know and utilize the five elements that Goleman found to be crucial to EI. The first is encouraging self-awareness or knowing oneself including strengths and weaknesses. Second is self-regulation or the ability to control impulses and emotional responses. The third is motivation in order to embrace the challenge of ignoring short-term gains for long-term results. The fourth is empathy or the ability to identify and understand the needs and feelings of others. The last is social skills or the ability to engage with others on teams, communicate clearly and build lasting relationships.

Worldview

Worldview describes the individualized experience of how one perceives the world around him or her.

Definitions

- **Collectivism** is a psychological construct that stresses that survival and betterment of people in any given society depend upon their interrelated dependence and mutual effort.
- **Emic** describes a type of worldview that is specific to an individual person or culture, one that does not pertain to the collective group.
- **Etic** describes a type of worldview that is commonly shared or widely accepted by members of all cultures.
- **Individualism**, the opposite of collectivism, is a psychological construct that stresses that the overall good and/or survival of members in any given society depend upon their individual freedom and self-reliance.

Description

A person's worldview describes the way in which they perceive the world around them based on their values, beliefs, opinions, and life experiences. Worldview can also refer to the collective assumptions of a particular group, subgroup, or culture. An *etic* worldview describes one that is universally accepted by all cultures while an *emic* view pertains to a worldview that is held by an individual or by members of a specific cultural group. Several factors can influence worldview including family of origin, parenting style, socialization, education, culture, ethnicity, gender, time, and location. Understanding a person's worldview is important as this provides the basis for how one interprets reality. Mutual understanding can also help to promote a collaborative working relationship. Being knowledgeable and respectful of others' worldviews is critical in counseling relationships. Maintaining a level of openness and inquiry regarding cultural differences is an integral part of a counselor's ethical practice.

Current Status and Impact (Psychological Influence)

Derald Wing Sue was the first to introduce the concept of worldview in late 1970s. He wrote about the importance of maintaining culture competence within the counseling relationship and stressed how a client's worldview should be incorporated into the client's therapeutic goals. Sue suggested that the

manner in which individuals view the world is critical to how they think, feel, and subsequently behave. For example, a person who maintains a collectivist view of the world will operate quite differently than a person who holds and individualistic view. In the 1990s, Ibrahim referred to four specific worldview types: optimistic, traditional, pessimistic, and here and now, and offered that every person has both a primary and secondary worldview type that determines how they navigate the world around them. Assessing for one's worldview type and responding with an appropriate counseling style at the onset of therapy is advised.

Wundt, Wilhelm (1832–1920)

Many consider Wilhelm Wundt to be the father of experimental psychology.

Description

Wundt began his professional career at the University of Leipzig in Germany where, in 1879, he opened the Institute for Experimental Psychology. There, he attracted students from Germany, the United States, and Britain to what was the first institute that focused exclusively on psychology. His institute became the model for many other psychological laboratories that opened afterward.

Wilhelm Wundt, a German psychologist, was a pioneer in experimental psychology; much of today's research and experimental methods in cognitive psychology can be traced back to Wundt's work. (Corbis)

Perhaps Wundt's most notable achievement was to demonstrate that psychology can be a valid experimental science. His research was highly structured using carefully controlled experimental methodology. His focus was focused on three main parts of cognitive functions, namely thoughts, images, and feelings. Wundt founded voluntarism, which is a school of thought that looks at the process of organizing the mind.

Development and Impact (Psychological Influence)

In 1874, Wundt published an influential work entitled *Principles of Physiological Psychology*,— the first psychology textbook and one that many place among the most influential in the history of the field. He also is credited with establishing the first psychology journal, *Philosophical Studies* in 1881.

Today's research in cognitive psychology can be traced back to Wundt's work. In addition, his work

set the stage for researchers in behaviorism, many of which still use his experimental methods today.

Wundt was a prolific writer, authoring numerous articles and books. However, one of his greatest contributions came from mentoring more than 100 graduates students in psychology—many of whom went on to become well-known, influential psychologists in their own right.

Xanax (Alprazolam)

Xanax is a prescription medication used to treat anxiety symptoms and anxiety associated with depression. Its generic name is alprazolam.

Definitions

- **Antianxiety medications** are prescribed drugs that relieve anxiety symptoms. They are also called anxiolytics or tranquilizers.
- **Benzodiazepines** are a group of central nervous system depressants used to relieve anxiety and to induce sleep.
- **Epilepsy** is a medical condition involving episodes of irregular electrical discharge within the brain that causes impairment or loss of consciousness, followed by convulsions.
- **Seizure** is a sudden convulsion or uncontrolled discharge of nerve cells that may spread to other cells throughout the brain.

Description

Xanax is one of the group of antianxiety medications called benzodiazepines. Xanax is primarily used to induce sleep and to treat anxiety, panic disorder, and anxiety associated with depression. It works by slowing the central nervous system and blocking the transmission of nerve impulses in the brain. This decreases the excitability of nerve cells and results in decreased anxiety. While all benzodiazepines cause sedation, such as drowsiness and reduced mental alertness, Xanax causes less drowsiness than other benzodiazepine drugs.

Precautions and Side Effects

Because Xanax is a nervous system depressant, it should not be taken with other depressants, such as alcohol, other sedatives, sleeping pills, or tranquilizers. Xanax should not be taken by those who are pregnant, have glaucoma, or liver or kidney disease. Nor should it be taken with other medications used for treating other mental disorders. Because its use can be habit-forming, Xanax should be carefully monitored by a physician.

The most common side effects of Xanax include sedation, dizziness, drowsiness, insomnia, and nervousness. The intensity of these side effects gradually declines over eight weeks or so. A drop in blood pressure and an increase in heart rate may also occur in those taking Xanax. Decreased sex drive, menstrual disorders, and weight gain or weight loss have also been reported. Less common side effects include diarrhea and constipation, as well as tremor, muscle cramps, vision disturbances, rash, and amnesia or memory loss. Those who experience stomach upset, nausea, vomiting, and dry mouth should eat frequent, small meals or chew sugarless gum.

Y

Yoga

Yoga is a physical and mental practice of mindfulness that involves a sequence of body postures, breathing, and visualizations.

Definitions

- **Mindfulness** is the moment-by-moment awareness of one's thoughts, feelings, sensations, and environment without evaluating or judging them.
- **Mindfulness practices** are intentional activities that foster living in the present moment and awareness that is nonjudgmental and accepting.
- **Well-being** is the state of being happy, healthy, prosperous, or successful.

Description

Yoga started as a physical and spiritual discipline centuries ago in India. It is aimed at training the consciousness in order to achieve a state of perfect spiritual insight and tranquility. In order to achieve this, yoga uses a complex system of physical and mental exercises. The exercises promote balance in body and mind through removing ego and unconscious desires. Research has shown that yogic techniques can facilitate physical balance, psychological equanimity, and good health even apart from any spiritual aims. Yoga is used as a technique in achieving mindfulness and in some practices it is a common therapeutic recommendation for clients who are in therapy.

It has been said that yoga is a process of physical and mental exercises that enable us to become more aware of who we are and to be peaceful about that. Most yogic practices include postures and controlled breathing as essentials. Related practices include exercise for control of subtle forces, cleansing of the body-mind, visualizations, chanting of mantras, and many forms of meditation.

Yoga was first introduced in the United States in 1893 through the teachings of Swami Vivekananda. Vivekananda was an Indian monk who electrified American audiences through the simplicity of his teaching based on Indian sacred literature and traditions. He stressed the spiritual aspects of his Hindu traditions but inevitably the other physically based practices of the yogic tradition also gained attention and became popular.

Current Status and Impact

Yogic awareness of the dark side of human nature had a great influence on the psychiatrist Carl Jung and through him on Western psychotherapy. Part of the continuing fascination with yoga is that it offers a different, nonreligious, way of encountering the unconscious. Today about 20 million people in the United States report that they are regular practitioners of the many different kinds of yoga; breathing and exercise being among the most popular. There has been a major increase in the number of those certified as yoga teachers. It is clear that the influence of yogic ideas and practices have physical and mental health benefits that have contributed to its popularity and growth.

Yoga focuses on aligning the inner being and obtaining spiritual peace. Its practices align very well

Yoga, a physical and mental practice of mindfulness involving a sequence of body postures, breathing, and visualizations, aligns well with newer psychological theories that move away from a medical model and toward focus on building health and well-being. (Antonio Guillem/Dreamstime.com)

with newer psychological theories that move away from a medical model and focus on building health and well-being. Wellness counseling focuses on a holistic approach to both physical and mental health that is consistent with yogic ideas as well. Within the psychological community yoga has become an accepted recommendation based on research that demonstrates its therapeutic effectiveness in achieving mindfulness. The ultimate goal of mindfulness therapy and yoga is to provide an integral view of human nature that will support healing, growth, and individual transformation.

Yohimbine

Yohimbine is a prescription medication that increases blood flow and is used to treat sexual dysfunction. Its brand name is Yocon.

Definitions

- **Alkaloids** are plant compounds composed of carbon, hydrogen, and nitrogen which are pharmacologically active. Examples are caffeine, morphine, nicotine, and Yohimbine.
- **Erectile dysfunction** is the inability to achieve or maintain an erection long enough to engage in sexual intercourse. It is also known as impotence.
- **Selective serotonin reuptake inhibitors (SSRI**) are medications that act on and increase the levels of serotonin in the brain that influences mood.

Description

Yohimbine is an alkaloid with stimulant and aphrodisiac (sexual arousal) effects, found naturally in the bark of the Yohimbine tree. Yohimbine is used to arouse sexual excitement, for erectile dysfunction, for sexual problems caused by selective-serotonin reuptake inhibitor (SSRI) medications, and for other sexual problems in both men and women. It is also used for athletic performance, weight loss, exhaustion, chest pain, high blood pressure, low blood pressure that occurs when standing up, diabetic nerve pain, and for depression. Yohimbine is a prescription medicine in a pure form for the treatment of sexual dysfunction. It is also available as an over-the-counter medicine in an herbal extract form. This form is much weaker than the prescription form, which means it has limited therapeutic effect and fewer side effects. What follows pertains only to the prescription form. Yohimbine is believed to work by increasing peripheral blood flow and nerve impulses to the penis or vagina. An erection occurs because blood flow into the penis is increased and then prevented from flowing out. It also helps counteract the sexual side effects of SSRIs used for depression.

Precautions and Side Effects

Yohimbine should not be used in those with kidney disease or prostate problems. It can worsen the symptoms of benign prostatic hyperplasia and slow or stop the flow of urine. Neither should Yohimbine be used in those with liver disease. Since it can interfere with insulin and cause low blood sugar, Yohimbine should not be used in diabetic patients. Yohimbine can significantly affect blood pressure. While small doses of it can increase blood pressure, large doses can cause dangerously low pressure. Since Yohimbine can damage the heart, it should not be used in those with chest pain or heart disease. Yohimbine should not be used in those who are, or plan to be, pregnant as it can affect the uterus and endanger the pregnancy. It should not be used in those breast-feeding. Yohimbine should be used with caution in those with schizophrenia since it can trigger psychotic symptoms. It can also worsen the symptoms of anxiety and post-traumatic stress disorder. Yohimbine use can trigger manic-like symptoms in those with bipolar disorder, and suicidal tendencies in those with depression.

When taken orally in typical doses, Yohimbine can cause stomach upset, excitation, tremor, sleep problems, anxiety or agitation, high blood pressure, a racing heartbeat, dizziness, stomach problems, drooling, sinus pain, irritability, headache, frequent urination, bloating, rash, nausea, and vomiting.

Taking high doses can also cause other severe problems, including difficulty breathing, paralysis, very low blood pressure, heart problems, and death. Yohimbine has been reported to negatively interact with a number of medications. These include Abilify, Advil, Adderall, Klonopin, Paxil, Wellbutrin, and Zoloft.

Young Man Luther: A Study in Psychoanalysis and History (Book)

Young Man Luther: A Study in Psychoanalysis and History is a book about Martin Luther. It uses psychological concepts to analyze Luther's life. It was written by Erik Erikson.

Definitions

- **Psychoanalytic theory** is a psychological theory that explains behaviors and perceptions as the result of unconscious, sexual, and biological instincts. It was originally developed by Sigmund Freud.
- **Indulgence** is the belief that those who say certain prayers, do good deeds, or pay a fee will have some or all of their punishment for their sins reduced.
- **Psychobiography** is a biography written from a psychoanalytic point of view.
- **Psychosocial** refers to the impact of social environment and relationships on psychological development.

Description

Erik Erikson (1902–1994) was a psychoanalyst who developed a system of eight psychosocial stages to understand how individuals change throughout life. These stages are related to age. In each stage, there is a specific "crisis" that must be resolved. If individuals are successful, they move on to the next stage with no problem. However, if they do not respond to the crisis effectively, then problems will carry over into the future. Erikson coined the term "identity crisis" to describe the choices that individuals face at each stage of development. The complete order of Erikson's psychosocial stages and their ages are as follows: Trust versus Mistrust (0–2), Autonomy versus Shame (2–4), Initiative versus Guilt (4–5), Industry versus Inferiority (5–12), Identity versus Role Confusion (13–19), Intimacy versus Isolation (20–39), Generativity versus Stagnation (40–64), Integrity versus Despair (65–death). For example, Erikson believed that children between the ages of two to four experience a crisis of "Autonomy versus Shame." This occurs in their relationship with parents and through experiences such as toilet training. Those who have a supportive environment will develop a sense of autonomy (independence) and will feel good about themselves. Those who do not will feel ashamed and doubt their abilities. During adolescent years (around 13 to 19), the crisis is "Identity versus Role Confusion." Teenagers seek an identity and look to peers for approval. They are between childhood and adulthood, and must begin coming to terms with who they will be as adults. Those who successfully resolve this crisis will have a strong sense of self and a clearly defined purpose in life. Those who do not will lack direction as adults. They may have difficulty making important decisions, such as what type of job to pursue. These individuals will look to others to create an identity for them. Erikson believed that individuals define themselves throughout life. The adolescent identity crisis is one of the most important points in this process. He writes that societies should let young people take time out to "find themselves" before going into adulthood. When individuals are forced into roles, then they are unable to reach their full potential and experience problems.

In *Young Man Luther: A Study in Psychoanalysis and History*, Erikson applies his psychosocial stages to the life of Martin Luther (1483–1546), the leader of the Protestant Reformation. This book is considered a "psychobiography" because psychological concepts are used to examine an individual's life. Luther was born in a humble family in Germany. His father wanted him to become a lawyer and improve the family's standing. After graduating from university, Luther enrolled in law school. However, he was not committed to this path and instead decided to become a Catholic monk. This greatly upset his father. While Luther enjoyed life in the monastery, sexual temptation led him to doubt his vows. In his interpretation, Erikson writes that this was a classic identity crisis. Luther was caught between two different paths and did not feel comfortable in either one. Despite his doubt, Luther remained in the Catholic Church and studied theology. However, his studies led him to question the power of the Church and some of its practices. In 1517, Luther

publicly proclaimed his disagreement by posting his "95 Theses" on the door of the Castle Church in Wittenberg. These theses (arguments) spoke against practices such as selling forgiveness for sin in the form of "indulgences." Luther's writing inspired others to rebel against the Church and formed the beginning of the Protestant Reformation.

Erikson interprets Luther's behavior using psychoanalytic theory. He writes that Luther's disobedience to the Church represented his own conflict with his father. Luther rebelled against one authority figure and then another in his search to find an identity. However, he still questioned his choices throughout his life. Even after many years, Luther tried to defend his decisions to his father. This final crisis was one of Integrity versus Despair. Erikson called this the mature adult crisis in which individuals ask themselves if their lives were meaningful.

YouTube

YouTube is a website that provides access to videos online in a user-friendly format. It is one of the most popular video web portals on the Internet.

Description

Although registered as a corporation in 2005, YouTube, which is owned by Google, only began business in 2006. It became an Internet phenomenon because it allows users to easily upload, share, and view videos. The revolutionary aspect of YouTube is the fact that it allows anyone who visits the site to view the videos for free, without being a registered user.

There are several key features of YouTube which have made it so popular. One is that the visitor can browse videos based on content and popularity. Another is that videos play as soon as the webpage opens and files do not have to be downloaded. Third, all kinds of videos can be posted from the tacky and tasteless to the inspiring and educational, and from the professionally created to the homemade. Music videos are extremely popular. Upon viewing videos, visitors can rate the videos they have watched. Users who are registered have more features such as uploading their own videos and commenting on other users' videos.

Impact (Psychological Influence)

YouTube has had phenomenal success. In 2006, about 20 million visitors used the site each month. By 2013, that had grown to 1 billion visitors per month. The impact is also global as 70% of YouTube usage takes place with users who live outside of the United States. YouTube's auto-speech recognition technology makes it available in more than 50 languages.

YouTube's audience is broad-based. Most users are in the 18- to 54-year age range and have the equivalent of a high school education. There are few controls over the videos posted on YouTube. This has created some political problems in societies with more authoritarian governments, such as China. In countries with even more authoritarian governments, such as Cuba and North Korea, YouTube is banned entirely.

In addition to its success, YouTube has been the subject of criticism because of its impact on society. Due to its open platform, YouTube videos have both positive influences, through educational content, and negative influences through dissemination of violent content. A number of legal, ethical and social issues have surfaced. It has been the cause of lawsuits, primarily over copyright problems with illegal pirating of movie, television, and music content. YouTube has faced legal trouble with pharmaceutical companies and in high-profile divorce cases. Parents and educators have raised questions about its content, especially the violence, due to its open access to users of all ages including children.

Video content websites where users can upload free material have become popular on the internet

With more than 1 billion users on the Internet, and millions of videos submitted from around the world, YouTube, owned by Google, has enormous influence, especially on young people. (Sebastian Czapnik/Dreamstime.com)

and social media. Following the creation of YouTube, other video content sites have followed like Vimeo, Vevo, and Flickr. YouTube, like other popular internet video websites, will continue the momentum toward a shared global information base for entertainment and education.

Z

Zimbardo, Philip (1933–)

Philip Zimbardo is an American psychologist who is considered one the most influential psychologists of the 20th century, particularly for his Stanford Prison Experiment (SPE).

Description and History

Philip Zimbardo has a long and prolific body of work, including publishing more than 50 books and 400 articles, serving as president of the American Psychological Association (APA), and creating, in 1990, a 26-part PBS series entitled *Discovering Psychology*. After receiving his PhD in psychology from Yale University, Zimbardo spent more than 50 years teaching psychology and is professor emeritus at Stanford University. In fact, in 2012, he received the APA's prestigious Gold Medal for Lifetime Achievement in the Science of Psychology.

According to an interview with Zimbardo, he credits much of his dedication as a reaction to degrading experiences he had as an impoverished immigrant child. Zimbardo is well known for published works on topics such as shyness, terrorism, madness, evil, and post-traumatic stress disorder and is currently researching heroism.

He is probably best known, however, for the controversial SPE, a social experiment that gained national attention following a 1973 article on the results in *The New York Times Magazine* and a documentary aired on *Chronolog*—an NBC documentary television program. The SPE was initially intended to be a follow up to his deindividuation experiment he performed at New York University based on the Nobel Prize-winning novel *The Lord of the Flies*. The premise of the deindividuation experiment was that by changing a person's external appearance it would lead to a change in morality. This, in turn, was a follow up to Stanley Milgram's experiments.

The SPE involved testing the reactions of roles of two dozen male volunteers recruited for the roles of either guard or prisoner in a simulated prison environment. With the flip of a coin, the young men were divided into two groups—prisoners and guards. Zimbardo's aim was to offer an explanation for dehumanizing conditions of the penal system.

Originally planned to last two weeks, Zimbardo stopped the experiment after six days as a result of emotional breakdowns of four of the prisoners in reaction to guards' increasing sadistic treatment of the prisoners that included humiliation and degradation. The prisoners experience depression, crying, rage, and acute anxiety. The experiment itself became well known; Zimbardo even notes its status as "virtually an urban legend" (Drury et al., 2011, 161) and has been the inspiration for two feature films, including the German thriller *Das Experiment* (2001) and an American version, *The Stanford Prison Experiment*, first shown at the Sundance Film Festival in January 2015 and to be commercially released later.

Impact (Psychological Influence)

The experiment is considered one of the most famous psychological experiments of all time. More than 40 years after the experiment took place, controversy still clings to the SPE. Most articles that criticized the SPE were in top tier peer-reviewed journals, whereas the articles on the experiment were relegated to publishing in lesser respected venues. Notably, only a

Philip Zimbardo, shown in 1971, is a prominent American psychologist perhaps best known for the Stanford Prison Experiment in 1971, which showed that in certain situations normal, healthy people could become sadistic in their treatment of others. Zimbardo is also known for his work on shyness, PTSD, terrorism, evil, and, currently, heroism. (Duke Downey/San Francisco Chronicle/Corbis)

portion of the findings of the SPE were published and, as stated in his best-selling book *The Lucifer Effect: Understanding How Good People Turn Evil* (2008), which explores how group dynamics and situations can elicit harmful behavior in individuals, the full story has never been told.

Zinc

Zinc is a mineral that is essential for a healthy immune system and normal physical, mental, and emotional functioning.

Description

Zinc is an "essential trace element" because very small amounts of zinc are necessary for human health. It is found in nearly every cell of the body and is the key to the proper functioning of more than 300 enzymes. Normal growth and development cannot occur without zinc, and it is vital for healthy mental and emotional functioning. It has been shown to sustain intellectual (cognitive) function and mood control. Zinc is also important in promoting mental health and has increasingly been found to reduce symptoms of certain mental disorders. Research has found that symptoms of schizophrenia, autism, attention deficit hyperactivity disorder, Down's syndrome, Wilson's disease, and other mental health problems may be reduced with zinc supplementation.

Zinc is also vital for healthy physical functioning. It has been shown to sustain healthy skin, strong vision, blood-clotting ability, cell division, wound repair, and proper taste and smell.

Zinc is used for treatment and prevention of zinc deficiency and its consequences, including stunted growth and acute diarrhea in children, and slow wound healing. It is also used for boosting the immune system, treating the common cold and recurrent ear infections, and preventing lower respiratory infections. Some use zinc for an eye disease called macular degeneration, for night blindness, and for cataracts. It is also used for asthma; diabetes; high blood pressure; acquired immunodeficiency syndrome (AIDS); and skin conditions such as psoriasis, eczema, and acne. Other uses include treating attention deficit hyperactivity disorder, blunted sense of taste, ringing in the ears (tinnitus), severe head injuries, Crohn's disease, Alzheimer's disease, Down's syndrome, ulcerative colitis, peptic ulcers, and promoting weight gain in people with eating disorders such as anorexia nervosa. Some use zinc for benign prostatic hyperplasia, male infertility, erectile dysfunction, weak bones (osteoporosis), rheumatoid arthritis, and muscle cramps associated with liver disease.

Precautions and Side Effects

General symptoms of zinc deficiency include depression, impotence in men, low fertility in men and women, poor growth in infants and children, along with delayed sexual maturation in adolescents, night blindness, pale skin, acne, eye sores, lowered alertness levels, hair loss, lack of menstrual period, reduced ability to taste or smell, and poor wound healing. Symptoms of too much zinc in the body include nausea, vomiting, loss of appetite, abdominal cramping, diarrhea, headaches, and low levels of high-density lipoprotein cholesterol—the so-called good cholesterol.

The absorption of vitamin A is improved by zinc supplements, but these supplements may interfere with the absorption of other minerals taken at the same time, including calcium, magnesium, iron, and copper. Supplements of calcium, magnesium, and copper should not be taken as along with zinc supplements. Iron should only be taken if a known deficiency exists. Drinking coffee at the same time as taking zinc can reduce the absorption by as much as half. Some diseases increase the risk of zinc deficiency. Sickle cell anemia, diabetes, and kidney disease can all affect zinc

metabolism. People with Crohn's disease, sprue (celiac disease), chronic diarrhea, or babies with acrodermatitis enteropathica (a metabolic disorder affecting the absorption of zinc) also have an increased need for zinc. Those who are anorexic also are at increased risk of having insufficient amounts of zinc within the body, as are people with hookworm, cirrhosis, chronic renal disease, and severe trauma.

Zoloft (Sertraline)

Zoloft is a prescribed medication used for treating depression and various anxiety disorders. Its generic name is sertraline.

Definitions

- **Antidepressant Medications** are prescription drugs that are primarily used for treating depression and depressive disorders. They are known as antidepressants.
- **Selective Serotonin Reuptake Inhibitors (SSRIs)** are antidepressant medications that act on and increase the level of serotonin in the brain that influences mood.
- **Serotonin discontinuation syndrome** results from the abrupt discontinuation of SSRIs. It is characterized by withdrawal symptoms such as anxiety, agitation, insomnia, nausea, vomiting, diarrhea, fatigue, vivid or bizarre dream, dizziness, and other sensory disturbances
- **Serotonin syndrome** is a serious medication reaction resulting from an excess of serotonin in the brain. It occurs when a number of medications that increase serotonin are taken together. Symptoms include high blood pressure, high fever, headache, delirium, shock, and coma.

Description

Zoloft is an antidepressant medication that belongs to the class of medications known as SSRIs. It is used for treating major depression, obsessive-compulsive disorder, panic disorder, post-traumatic stress disorder, premenstrual dysphoric disorder, and social anxiety disorder. Depression and some other mental disorders are thought to be caused by low levels of serotonin, a chemical messenger (neurotransmitter) that is released and transmitted in the brain. Like other SSRI medications such as Celexa, Luvox, and Paxil, Zoloft is believed to work by increasing the level of serotonin in the brain. Increased levels can benefits those with major depression, obsessive-compulsive disorder, panic disorder, post-traumatic stress disorder, mood swings, premenstrual tension, alcoholism, and certain kinds of headaches. While Zoloft is not any more or less effective than the other SSRIs, fewer medication interactions have been reported with it than with other SSRIs.

Precautions and Side Effects

Those taking Zoloft should be monitored closely for insomnia, anxiety, mania, significant weight loss, and seizures. Its use should also be monitored in children and adults up to age 24 because they are at an increased risk of developing suicidal thoughts. Caution should also be exercised when prescribing Zoloft to those with impaired liver or kidney function, those over age 60, children, individuals with known bipolar disorder or a history of seizures, and those with diabetes. The risks and benefits of Zoloft should be considered by women who are or might become pregnant, and those who are

breast-feeding. Those with diabetes should monitor their blood or urine sugar carefully, since Zoloft can affect blood sugar. Alcohol should not be used while taking Zoloft. Care must be taken in driving, operating machinery, or participating in hazardous activities when taking this medication. Zoloft use should not be stopped abruptly since it can cause withdrawal symptoms (serotonin discontinuation syndrome).

There are some reported side effects with the use of Zoloft. These include insomnia, dizziness, and headache, delayed ejaculation, and decreased sex drive, nausea and diarrhea, agitation, anxiety, rash, constipation, vomiting, tremors, or visual difficulty. As already noted, Zoloft interacts with fewer medications than the other SSRIs.. Those considering taking this medication should review the other medications they are taking with their physician for possible interactions. Also, those who are taking Prozac should inform all their health providers including dentists.

As already above, Zoloft has fewer medication interactions than other SDSRIs. The risk of seizures is increased in patients using Ultram (narcotic-like pain reliever) and Zoloft. Taking Zoloft with monoamine oxidase inhibitors like Nardil or Parnate may result in the serotonin syndrome. Erythromycin (antibiotic) may inhibit the breakdown of Zoloft in the liver and cause increased central nervous system effects, such as drowsiness, and decreased mental alertness. Other antidepressants should not be taken by those using Zoloft except in rare cases where prescribed by a physician. Zoloft interacts with an herbal remedy St. John's wort. Finally, Zoloft should not be taken with grapefruit juice as the combination may increase Zoloft levels in the body.

Zone of Proximal Development

The zone of proximal development is a period of time that children must take to make sense of something they've learned as they undergo a significant development change.

Description

The zone of proximal development is the brainchild of the Jewish Russian psychologist Lev Vygotsky (1896–1934). As defined by Vygotsky himself, the zone of proximal development is the distance between the actual developmental level as defined by independent problem solving and the level of potential development as determined through problem solving under adult guidance or in collaboration with more capable peers. The premise is that whenever children undergo a significant developmental change, they must go through a period of time—or zone—when they strive to make sense of what they've learned.

A key concept in Vygotsky's work is the social situation of development. In his view, the social situation in which a child finds himself or herself constitutes a predicament from which the child can only emancipate himself or herself developing. When this development takes place, the child must then move through the zone of proximal development. At the beginning of the zone of proximal development, a child can usually copy only with the help of someone more skilled than him or her. By the end, he or she can manage by himself or herself. According to Vygotsky, what goes on during that zone of proximal development is the essence of human development.

In the development of his theory of the zone of proximal development, Vygotsky, who grew up, studied, and practiced in a revolutionary Russia, draw on the insights of Marx, Goethe, and Hegel. Like Marx, he conceived of the Gestalt not just as a brain structure or scheme of perception but as a system of social relationships and activities that include the person in the social situation through which his or her needs are

met. Accordingly, the child is the child of the existing social formation. The relation between the whole social formation and the child is mediated through the family and other institutions.

The social situation of development, which precedes the zone of proximal development, is made up of the child's adult caregivers and all the material conditions surrounding them. This situation is the microcosm of the whole society. Of course, every child is in a different situation and no two are just alike. It is through this concept that a researcher or psychologist can grasp the dynamics of a child's development. By grasping the situation as a predicament rather than simply as an inventory of attributes, the therapist can gain insight into exactly how a social situation drives the child's development.

Development means transforming the mode of psychological functioning and transcending the social situation of development. Overcoming the barriers and developing the new formation allows the child to escape from a social situation of development. According to Vygotsky, the fact of development of infants into adult citizens can be made intelligible only by the fact that, beginning with the birth itself, individuals strive to emancipate themselves from barrier that bar them from achieving their own expectations. The zone of proximal development is significant to Vygotsky exclusively in terms of development. In his view, all other learning is secondary to development. Also, the intervention of the adults in the child's social situation is indispensable to create for the child a social space receptive to the transformation of his or her behavior and interactions.

Transformation of the child's mode of behavior entails the adults acting in relation to the child in a way that the child is not yet fully capable of responding to. It entails acting as if the child has already completed the passage to a new, stable phase of development.

Current Status

The British radical social developmentalists of the 1970s seized upon Vygotsky's zone of proximal development as a powerful theoretical addition to their methodology. However, according to mainstream psychology, which has embraced more enthusiastically the concept of psychoanalysis, Vygotsky's work does not address the likes of intersections, contradictions, and fragmentations wrought by gender, ethnicity, and class upon the developing child.

There is a controversy about the application of Vygotsky's ideas into modern-day psychology. Some argue that the Russian psychologist's views would have a more receptive home in a hybrid psychological-sociological field, or from a more interdisciplinary perspective. Today, Vygotsky's writings are considered more research than theory.

Zyprexa (Olanzapine)

Zyprexa is a prescription medication used for treating schizophrenia and manic episodes of bipolar disorder. Its generic name is olanzapine.

Definitions

- **Antipsychotic medications** are prescription drugs used for treating psychotic disorders. They are sometimes referred to as antipsychotics or neuroleptics.
- **Atypical antipsychotic** is a class of newer (second) generation antipsychotic medications that are useful in treating schizophrenia and other psychotic disorders.
- **Extrapyramidal symptoms** are a group of side effects associated with antipsychotic medication use that are characterized by involuntary muscle movements, including rigidity, contraction, and tremor.

- **Mania** is an elevated or irritable mood as well as mental and physical hyperactivity, and disorganized behavior. It is characteristic of the manic phase of bipolar disorder.
- **Neuroleptic malignant syndrome** is a potentially fatal condition resulting from antipsychotic use characterized by severe muscle rigidity (stiffening), fever, sweating, high blood pressure, delirium, and sometimes coma.
- **Schizophrenia** is a mental disorder in which there is difficulty distinguishing real from unreal experiences. Symptoms include hallucinations, delusions, thought and communication disturbances, and withdrawal from others.
- **Tardive dyskinesia** are involuntary movements caused by certain antipsychotic medications. They include tongue thrusting, repetitive chewing, jaw swinging and facial grimacing.

Description

Zyprexa is in the class of antipsychotic medications known as "atypical" or second-generation antipsychotics. Its primary use is to treat schizophrenia and to control manic episodes of bipolar disorder. Although it is sometimes used in Alzheimer's diseases, Zyprexa is not approved by the Food and Drug Administration for the treatment of behavior problems in older adults with dementia. Zyprexa is thought to work by binding to dopamine receptors while preventing dopamine from fully activating them. This differs from first-generation antipsychotics which completely block dopamine receptors.

Precautions and Side Effects

Zyprexa should be used with caution in those with heart disease because it may cause blood pressure to fall too low, resulting in dizziness, rapid heartbeats, or fainting. Zyprexa should be used carefully in those diagnosed with epilepsy since it can increase the likelihood of seizures. Those with liver disease should have their liver function monitored regularly while taking Zyprexa. Women who are pregnant or breast-feeding should not take Zyprexa. Infants born to mothers who took Zyprexa during pregnancy may develop extrapyramidal symptoms and withdrawal symptoms, including agitation, trouble breathing, and difficulty feeding. Zyprexa has also been associated with the risk of developing a blood disorder.

Common side effects with Zyprexa use include involuntary movements, weakness, dizziness, drowsiness, constipation, weight gain, dry mouth, low blood pressure, stomach upset, increased appetite, cold-like symptoms, and fever. Less common ones include body aches and pains, elevated liver enzymes, vision abnormalities, chest pain, rash, and rapid heartbeats. Although rare, Zyprexa can cause tardive dyskinesia and neuroleptic malignant syndrome.

Any drug that causes drowsiness may lead to decreased mental alertness and impaired motor skills when taken with Zyprexa. Some examples include alcohol, antidepressants such as Tofranil or Paxil, antipsychotics such as Mellaril, and some antihistamines. Because Zyprexa may lower blood pressure, it may reduce blood pressure to dangerously low levels if taken with drugs that are used to treat high blood pressure. Tegretol, an antiseizure medication, may decrease the effectiveness of Zyprexa.

Glossary

Abandonment is a psychological concept that defines a set of emotional reactions and behavioral responses to perceptions of rejection or loss in personal relationships.

Abuse is the intentional physical, psychological, or sexual maltreatment of an individual.

Abusive personality is a term used to describe the personality of those who criticize, dominate, undermine, and physically harm their intimate partners (spouses).

Acculturation is the process of blending a person's native culture with another culture.

Acculturative stress defines the psychological, somatic, and social challenges that members of a racial or ethnic minority group experience as they adapt to the culture of the majority group.

Achievement refers to anything done successfully, typically by effort, courage, or skill.

Activism refers to the actions and behaviors taken to promote social or political changes.

Acupressure is an ancient art of healing that uses tactile manipulation of pressure points on the body to relieve pain and promote wellness.

Acute disease is medical condition with a single cause, a specific onset, and identifiable symptoms which is often treatable with medication or surgery and is usually curable.

Acute stress is the most common form of stress, is short term, and results in minor and temporary emotional and physical upset.

Addiction is a chronic disease of the brain which involves compulsive, continued, out of control use of substances, or behaviors, despite physical harm or negative consequences.

Addiction recovery is the state of abstinence from addictive behaviors, usually achieved through self-reflection and spiritual exploration.

Addictive personality is the concept that addiction is the result of preexisting personality traits or defects.

Adjustment disorder is a mental disorder characterized by emotional or behavioral symptoms in response to an identifiable stressor that is significantly distressing or causes impairment.

Adler, Alfred (1870–1937) was the Austrian psychiatrist who parted ways with Sigmund Freud and formulated Individual Psychology, which is also known as Adlerian Psychology.

Adlerian therapy is a psychotherapy approach developed by Alfred Adler, which emphasizes the individual's lifestyle, belonging, and social interest.

Adoption is the legal process of establishing the parental rights of a child by an individual or couple who is not the child's biological parent(s) and raise the child as his or her own.

Adrenaline is a neurotransmitter involved in the fight-or-flight response that increases heart rate, pulse rate, and blood pressure.

Advance directives are instructions outlined in a legal document that provide details for care that individuals want carried out on their behalf should their health, either medical or mental, become compromised; examples include living wills and do-not-resuscitate orders.

Adverse childhood experience is a traumatic experience in an individual's life that occurs before the age of 18. For the purposes of an ongoing Centers for Disease Control study to

determine the effects of these experiences on physical health in later adult years, the three main types are abuse (e.g., sexual); neglect (e.g., emotional); and household dysfunction (e.g., divorce).

Advocacy is a process in which an individual or group aims to influence decisions in political, economic, or social policies.

Alcohol use disorder is a mental disorder involving a pattern of alcohol use which leads to significant problems for the user.

Alcohol withdrawal is the unpleasant and potentially life-threatening physiological changes that occur due to the discontinuation of alcohol after prolonged regular use.

Alcoholics are individuals addicted to alcohol.

Alcoholics Anonymous (AA) is a self-help fellowship that was founded by Bill Wilson and Dr. Bob Smith in 1935 to help people struggling with alcoholism.

Alcoholism is a general term for the compulsive and uncontrolled consumption of alcohol to the detriment of the drinker's health, relationships, and social standing.

Alzheimer's disease is a medical and mental disorder that causes dementia particularly late in life. It is also referred to as Neurocognitive Disorder Due to Alzheimer's disease.

American Academy of Child and Adolescent Psychiatry is a nonprofit group of psychiatrists and other related medical professionals created in 1953. It is a national organization with 7,500 members dedicated to helping children who have been diagnosed with psychiatric disorders.

American Society of Addiction Medicine (ASAM) is an organization of physicians whose purpose is to improve the care and treatment of individuals with the disease of addiction and to advance the practice of Addiction Medicine.

Americans with Disabilities Act (ADA) is a civil rights law intended to protect against discrimination based on disability. It was originally signed in 1990 and amended in 2008.

Amnesia is the inability to recall past events or retain new information. It usually occurs as a result of physical or psychological trauma.

Amygdala is an almond-shaped mass of gray matter inside each cerebral hemisphere of the brain that is involved with the experiencing of emotions.

Androgyny is the combination of personality traits that are both feminine and masculine. Androgynous individuals are sometimes hard to identify as either distinctly male or female—whether it is in their appearance, in how they dress, or how they behave.

Anger management is a method of increasing temper control and the skill of remaining calm.

Anima is the female image that is part of the male psyche.

Animus is the male image that is part of the female psyche.

Anisogamy is what differentiates between the two sexes, male or female, referring specifically to size and form differences between sex cells, or gametes.

Anomalies are something that is different from what is considered normal or expected.

Anorexia nervosa is a mental disorder characterized by refusal to maintain minimal normal body weight along with a fear of weight gain and a distorted body image.

Antecedent is something that occurs before a behavior and includes places, people, and things involved in the environment.

Antianxiety medications are prescribed drugs that relieve anxiety symptoms. They are also called anxiolytics or tranquilizers.

Anticipatory grief is the type of grief associated with situations where the loss of a loved one is impending as with a terminal illness.

Antidepressant medications are prescription drugs that are primarily used to treat depression and depressive disorders. They are known as antidepressants.

Antimanic medications are prescription drugs that are primarily used to treat bipolar disorder (manic depression). They are also called antimanics and mood stabilizers.

Antipsychotic medications are prescription drugs used to treat psychotic disorders. They are sometimes referred to as antipsychotics or neuroleptics.

Antiretroviral therapy is regarded as the main type of treatment for HIV or AIDS consisting of drug combinations taken on a daily basis to counteract and prolong the spread of the disease.

Antiseizure medications are prescription drugs used to treat epilepsy (seizures) as well as burning, stabbing, and shooting pain. These are also called anticonvulsant medications.

Antisocial personality disorder is a mental disorder characterized by a pattern of disregarding and violating social norms (rights of others).

Anxiety is a negative emotional state characterized by feelings of nervousness, worry, and apprehension about an imagined danger.

Anxiety disorders are a group of mental disorders characterized by anxiety which tends to be intermittent instead of persistent. The group includes panic disorder, phobias, and generalized anxiety disorder.

Anxiolytics are medications that relieve anxiety symptoms. They are also called antianxiety medications or tranquilizers.

Anxious personality disorder is a personality disorder characterized by a persistent, continuous pattern of anxiety.

Apperception is the process of understanding something through associating it with a previous experience.

Applied describes something put into practical purpose or use; it also describes conclusions derived from or involved with actual phenomena.

Applied behavior analysis is a science that aims to understand and improve human behavior.

Apraxia is a disorder of the brain and nervous system in which a person is unable to perform tasks or movements when asked, even though the request or command is understood; the term is often used in regard to "apraxia of speech."

Archetype is a pattern of behavior used to organize, understand, and interpret how we experience life. Archetypes can be fluid, meaning they can change over time.

The Archetypes and the Collective Unconscious is a book written by Swiss psychiatrist Carl Gustav Jung and originally published in 1959. This book is Jung's explanation of a universal unconsciousness of mankind, which he believed was impersonal in nature and expressed as instinct. In the book, Jung states that the universal unconsciousness is not anything that has been blocked from our consciousness, but instead is a preconscious experience that has always existed.

Arousal means to stir to an action or response, especially a sexual one.

Art therapy is a mental health specialty used by specially trained therapists working with clients using a variety of art media. The process of creating art is a form of therapy that helps clients to explore their feelings, improve personal insight, resolve emotional conflicts and address a variety of challenges, including addictions, social skills, anxiety, depression, and more.

Asexual refers to the absence of a traditional sexual orientation, which may be considered a fourth category of sexual orientation.

Asperger's disorder is a mental disorder characterized by severely impaired social skills, repetitive behaviors, and narrow interests. In DSM-5, it is known as autism spectrum disorder without language or intellectual impairment.

Assertiveness is the quality of being self-assured and confident without being aggressive.

Assertiveness training is behavior change methods for increasing self-esteem and self-expression in intimidating interpersonal situations.

Assimilation refers to the gradual adaptation of a minority group member's customs, attitudes, and practices to those of the majority culture.

Ataxia is the loss of full control of bodily movements.

Atheoretical refers to untested treatments that are not based on theory.

Attachment is the emotional bond between children and caregivers that provides a secure (healthy) base from which children are able to safely explore their environment and relate to others.

Attachment style refers to the way in which an individual cognitively and emotionally interacts with others. Attachment styles are important since human relationships are central and impact all areas of a person's life.

Attention-Deficit Hyperactivity Disorder (ADHD) is a mental disorder characterized by significant problems with attention, hyperactivity, or acting impulsively that are not appropriate for an individual's age.

Autism spectrum disorders are developmental disabilities that affect a person's ability to communicate, socialize, and behave like most others.

Authoritarian parenting describes a disciplinary style that is highly structured, rule-oriented, rigid, and demanding with a low level of responsiveness.

Authoritative parenting, also known as democratic parenting, characterizes parenting that is both demanding and responsive; authoritative parents provide the proper balance of expectations, limits, and support.

Aversion is a feeling of strong dislike or repugnance toward something with a desire to avoid or turn away from it.

Aversion therapy is a treatment in which the patient is discouraged from a behavior by being subjected to a punishing stimulus when they engage in that behavior.

Avoidant personality disorder is a mental disorder characterized by a pattern of social withdrawal, feelings of inadequacy, and over-sensitivity to negative evaluation.

Banality of evil is a phrase used by political theorist Hannah Arendt to describe the mindless actions of high-ranking Nazi figures such as Adolf Eichmann, an unremarkable figure who engaged in atrocious crimes against countless numbers of Jews for senseless reasons.

Barbiturates are a class of prescribed drugs that slow the nervous system and are prescribed primarily for sedation, general anesthesia, and for treating some types of epilepsy.

Bariatric surgery is a surgical procedure on the stomach and/or intestines to help those who are extremely obese lose weight. It is also called weight loss surgery.

Beattie, Melody (1948–) rose to become a widely acclaimed self-help author, particularly among the addiction and recovery circles following the release of her international best-seller, *Codependent No More*.

Behavior is an observable action demonstrated by a human or animal caused by either internal or external occurrences.

Behavioral activation is a brief, structured treatment approach which activates those who are depressed so they can again experience pleasure and satisfaction.

Behavioral addiction is a form of addiction caused by the compulsion to repeatedly engage in a behavior that causes harmful consequences. It is also referred to as process addiction or non-substance-related addiction.

Behavioral analysis is a type of assessment which focuses on the observable and quantifiable aspects of behavior and excludes subjective phenomena such as emotions and motives.

Behavioral Health is an inclusive term referring to both mental health and substance use disorders.

Behavioral therapy is a psychotherapy approach that focuses on identifying and changing maladaptive behaviors. It is also referred to as behavior therapy.

Behaviorism is a theory of human behavior that limits the study of psychology to measurable or observable behavior rather than inner processes such as thoughts and feelings.

Benzodiazepines are a class of drugs that slow the nervous system and are prescribed to relieve nervousness and tension, to induce sleep, and to treat other symptoms. They are highly addictive.

Bereavement is the feeling of deprivation and grief following the loss of a loved one.

Biculturalism refers to the coexistence of two separate, distinct cultures.

Bilateral eye movement is to look with the eyes to the right and then to the left without moving the head.

Binge eating is a pattern of out-of-control eating consisting of episodes of uncontrolled intake of food.

Binge eating disorder is an eating disorder characterized by binge eating without subsequent purging episodes.

Biofeedback is both the process and device used to train individuals to regulate their own physiologic functions. By giving the individual constant, moment-to-moment updates on specific physiologic functions like heart rate, breathing, and so forth, this therapy allows an individual to master control over what would otherwise be unconscious bodily reactions.

Bipolar disorder is a mental disorder characterized by a history of manic episodes (bipolar I disorder), mixed, or hypomanic episodes (bipolar II disorder), usually with one or more major depressive episodes.

Bipolar and related disorders are a group of mental disorders characterized by changes in mood and in energy (e.g., being highly irritable and impulsive while not needing sleep). These disorders include bipolar I disorder, bipolar II disorder, and cyclothymic disorder.

Bisexual describes the sexual orientation of an individual who is romantically, physically, or sexually interested in both females and males.

Blended families are families in which one or both parents have children from a previous relationship and have merged to form a new family.

Body dysmorphic disorder is a mental disorder characterized by an excessive preoccupation with an imaginary or minor defect in a part of the body.

Body image is a complex psychological concept that includes a subjective picture of one's own physical appearance that comes from both self-observation and from the reactions of others.

Body work therapy is a general term that refers to all physical and physiotherapeutic treatments involving movement or touch to heal the body. These body-based therapies are often designed to unite the body and the mind or heal other injuries in the body.

Borderline personality disorder is a mental disorder characterized by a pattern of instability in interpersonal relationships, self-image, affects, self-harm, and a high degree of impulsivity.

Bowen family systems theory was developed in the 1950s by Dr. Murray Bowen (1913–1990), a psychiatrist and professor, considered a pioneer in family therapy. The foundation of his theory is the belief that a family is best understood as an interconnected emotional unit and thus any therapeutic intervention needs to address the complex interactions among various family members in context of the entire family system.

Brain is the organ at the center of the nervous system. It is responsible for a wide range of functions including learning, movement, and regulation of the body.

Brief psychotic episode is a period in which an individual experiences psychotic symptoms such as hearing voices (hallucinations), paranoid thoughts, depersonalization (feeling unreal), or disorganized speech. The episode is usually triggered by substances, medications, or extreme stress.

Brief psychotic disorder is a type of psychotic disorder characterized by a sudden onset, short duration, and the full return of functioning.

Bulimia nervosa is a mental disorder characterized by recurrent binge eating with loss of control over one's eating and compensation for eating.

Bully, the aggressor, victimizer, or perpetrator of bullying; a person who uses his or her power to intimidate, harass, or harm another person.

Bullycide refers to a suicide where the victim's death has been attributed to victim having been bullied either in person or online.

Bullying is an act of repeated aggressive behavior in order to intentionally harm another individual.

Bystander is a person who is present at, observes, or witnesses a particular event or circumstance (such as bullying), but who does not have direct involvement.

CACREP is the Council for Accreditation of Counseling and Related Educational Programs, which is the primary accrediting organization for hundreds of counseling programs at colleges and universities throughout the United States.

Cannabis use disorder is a mental disorder characterized by cannabis (marijuana) use which leads to significant problems for the user.

Career assessment is the process of using tools such as surveys, inventories, and questionnaires to gather information about a person's aptitudes, interests, and abilities to assist in determining their potential success in a certain career.

Career counseling, also referred to as career coaching or career guidance, involves working with a professional counselor or trained coach who assists clients in exploring their job interests and potential matches.

Career counselor, or vocational counselor, is a counseling professional who has received specialized coursework, training, and certification in career-related guidance in order to provide advice to persons seeking assistance in this area.

Career development defines the lifelong process of how individuals manage and navigate along their vocational paths.

Caregiver is the term applied to family members or paid helpers who regularly look after a child or a sick, elderly, or disabled person.

Case conceptualization is a method and strategy for obtaining and organizing information, understanding and explaining maladaptive patterns, focusing treatment, anticipating challenges, and preparing for termination.

Cataplexy is a medical condition characterized by loss of muscle tone resulting in slurred speech and complete weakness of most muscles. It can last for up to a few minutes.

Central sleep apnea is a type of sleep apnea in which the airway is not blocked, but the brain fails to signal the muscles to breathe.

Cerebral palsy is a condition marked by impaired muscle coordination (spastic paralysis) and/or other disabilities, typically caused by damage to the brain before or at birth.

Certification is a formal procedure by which an accredited or authorized person or agency assesses and verifies (and attests in writing by issuing a document) that a person has the knowledge and skills to perform certain activities.

Characterological anxiety is a persistent pattern or trait of anxiety which reflects an individual's general level of distress. It contrasts with state (situational) anxiety which reflects an individual's distress in a given situation.

Child abuse is the physical, sexual, or emotional maltreatment or neglect of a child or minor, usually under the age of 18, and includes any act or series of acts of commission or omission by a parent of caregiver that results in harm, potential for harm or threat of harm to a child.

A child and adolescent psychiatrist is a medical doctor with specialized training who assesses, diagnoses, and treats mental, behavioral or developmental disorders in children and adolescents, usually by prescribing medication.

Child psychoanalysis is a subfield of psychoanalysis that uses both talk and play therapy to understand psychological processes and emotional disorders in children and adolescents.

Childhood is the early stage in the existence or development of human beings before the advent of sexual maturity or pubescence, also called youth, infancy, babyhood, boyhood, girlhood, pre-pubescence.

Choice theory, first termed "Control Theory," a theory developed by William Glasser to explain human behavior which states that all humans choose to behave in ways that satisfy five basic needs, the most important being love and belonging.

Chronemics describes the study of how one communicates nonverbally using time.

Chronic disease is a disease entity which usually does not have a single cause, a specific onset, or a stable set of symptoms. While cure may be possible, it is unlikely for advanced levels of the disease process. It is also referred to as chronic medical conditions.

Chronic fatigue syndrome is a prevailing state of exhaustion that lasts longer and is more profound than normal, day-to-day weariness and can result in diminished physical, mental, and emotional capacity often requiring one to seek medical or psychological intervention.

Chronic illness is the subjective experience of a chronic disease.
Chronic stress is long-term stress that is emotionally and physically harmful to the health and well-being of the individual.
Circadian rhythms are variations in biological activities that repeat during 24-hour intervals, which influences the amount and quality of sleep. It is also called a biological or internal clock.
Circadian rhythm sleep–wake disorder is a mental disorder that is characterized by irregular patterns of sleep.
Cliques are small groups of people (typically the term refers to groups of adolescents) who have similar characteristics, common interests, and who generally socialize exclusively with one another.
Codependence is an unhealthy level of emotional or psychological dependence on a loved one whereby one or both individuals in the relationship need the other to feel fulfilled.
Cognitive describes acts or processes about learning, knowing, and perceiving.
Cognitive appraisals are what a person thinks, believes, and concludes about events, situations, and circumstances.
Cognitive behavior therapy is a type of psychotherapy that focuses on maladaptive (problematic) behaviors, emotions, and thoughts. It is also called CBT.
Cognitive behavioral modification is a psychotherapy approach that focuses on identifying dysfunctional self-talk in order to change unwanted behaviors.
Cognitive processing therapy is a form of CBT specifically designed for treating post-traumatic stress disorder (PTSD) which teaches skills for recovery from traumatic events by changings one's view of self, world, and others.
Cognitive restructuring is a psychotherapy technique for identifying maladaptive (unhealthy) thoughts and changing them to present a more accurate view of a situation.
Cognitive therapy is a type of cognitive behavior therapy that focuses on identifying and changing automatic thoughts and maladaptive beliefs.
Cognitive-behavior modification is a therapeutic technique which focuses on identifying and challenging negative self-talk patterns in order to counteract maladaptive behavior.
Cohabitation is to live together with someone in a marriage, or marriage-like, sexual relationship.
Collectivism is a psychological construct that stresses that survival and betterment of people in any given society depends upon their interrelated dependence and mutual effort.
College advising is the process of providing students with the information they need to decide upon what post-secondary options are right for them including application, admittance requirements, coursework progression, and financial aid options.
College readiness counseling is a type of counseling provided individually, in small groups, or in classroom settings to students prior to post-secondary entrance in an effort to boost preparedness and eventual completion.
Commercial sex is a sexual act in which something of value is given to or received by any of the involved parties.
Comorbid means to have more than one simultaneous medical condition.
Comorbidity is the existence of one or more mental disorders or physical illnesses that occur with a primary psychiatric illness. It is also referred to as dual diagnosis.
Compensatory behaviors include self-induced vomiting, use of laxative or diuretics, fasting, and excessive exercise.
Competence is a legal term designating that a person is capable of entering into legally binding contracts, transfer assets, and participating in legal proceedings.
Competency defines one's ability to demonstrate skill in an efficient and successful manner.
Complicated grief describes when individuals do not cope well with a loss and it begins to impact their lives in physically, emotionally, socially, psychologically unhealthy ways, or at a level that is not considered normal in that culture and/or society.

Compromise defines when opposing parties move toward one another, finding common ground in order to come to some resolution, understanding, or agreed upon solution.

Compulsions are habitual behaviors, practices, or rituals that are impulsively engaged in to defend against perceived threats, to reduce fears, or otherwise minimize distress.

Compulsory education describes the required period of schooling for every person under law; in the United States this varies by state but typically begins at age 5 till approximately age 17.

Computer-based testing is a form of automated psychological assessment that uses computer software programs to interpret, analyze, and even administer testing procedures. A broader definition of computer-based testing can also include Internet-based assessments, whereby subjects respond through an online medium.

Computer-Mediated Communication (CMC) describes the electronic means of communicating via the Internet including emailing, text messaging, social networking, and videoconferencing.

Concussion is a mild form of brain injury and is the most common type of traumatic brain injury. It involves a brief loss of brain function due to head trauma that resolves spontaneously without a lose consciousness.

Conditioning is a form of learning which involves the formation, strengthening, or weakening of an association between a stimulus and a response.

Conduct disorder is a mental disorder characterized by pervasive patterns of behavior that infringe on the rights of others or that violate social norms. These include aggressive, rule-breaking, rebellion, and other destructive behaviors.

Confidentiality is defined as keeping private the information that is disclosed by a patient, client, or other protected party within the context of a safe, trusting relationship.

Confirmation bias refers to the tendency that people have to pay attention or favor information that supports their beliefs or hypotheses.

Conflict management describes an ongoing process of mediating disputes between two parties where a resolution, though sought after, may not be reached.

Confrontational indicates tending to deal with situations in an aggressive, hostile, or argumentative way.

Congruence model is a way of characterizing organizations that thrive based on the degree of compatibility among four elements: task, people, structure, and culture.

Conjoint means consisting of, or involving two or more persons in a psychological therapy setting, for example, both partners in a marriage or relationship get therapy in the same session.

Conjoint family therapy is a form of psychotherapy which addresses the issues and problems raised by the family members as a system rather than addressing the problems being experienced by individual members of the family.

Conjoint therapy takes place when both relationship partners are present in a therapy session.

Consent is an act of voluntary willingness.

Consequence is the result or outcome that occurs after a behavior is demonstrated.

Constructivism is a philosophy that posits that meaning is continually and actively constructed based on the experiences one encounters and the value they attribute to their experiences.

Continuous Positive Airway Pressure (CPAP) is a device used for treating sleep apnea that delivers air into airways through a specially designed face or nasal mask.

Controlled Substance Act is the federal drug policy that increases research, prevention, treatment, and rehabilitation of drug abusers and strengthen existing laws and regulations against illegal drug trade in the United States.

Conversion disorder is a mental health condition characterized by conditions such as paralysis, seizures, or other neurologic symptoms that cannot be explained by medical evaluation. It is also known as functional neurological symptom disorder and hysteria.

Coping means to handle a situation or an adversity with success.

Coping strategies describe means or techniques, both positive and negative, that individuals use to help them deal with life's stressors.

Counseling means providing assistance and guidance in resolving personal, social, or psychological problems and difficulties, especially by a professional.

Counselor is a person trained to give guidance to others on personal, social, or psychological problems.

Couples refer to two people in an established married or unmarried partnership and may include, lesbian, gay, bisexual, transgender, and heterosexual couples.

Covert means something hidden, concealed, disguised, not openly acknowledged or displayed.

Craving is a strong desire for more of a substance or behavior (sex, shopping, and Internet use) in order to experience a euphoric effect, or to avoid withdrawal symptoms.

Crisis is an event, or series of events, in a person's life marked by danger, instability, and chaos that negatively impacts the person's life.

Culture refers to the knowledge and values; patterns of though, speech, and actions; and customary beliefs, social forms, and speech shared by a society.

Custody explores the rights of the parent or guardian over children. The primary purpose of a custody evaluation is to assess the best psychological interest of the child. In separation or divorce, custody evaluations review who has residential or primary care of the child or children as well as identify visitation rights and expectations. Custody evaluations are conducted to help determine which parent or caregiver best meets the child's needs and is generally conducted by a child psychologist appointed by the court or *guardian ad litem*.

Cutting is a form of self-injury whereby one makes cuts on his or her body, usually on the arms or legs, without the intent to kill oneself.

Cyberbullying refers to using technology (texting, emailing, chat rooms, social media sites, pictures, etc.) to repeatedly and intentionally degrade, threaten, or humiliate another person.

Cyclothymic disorder is a mental disorder characterized by alternating cycles of hypomanic and depressive periods with symptoms like those of some depressive disorders but of lesser severity.

Dance therapy is the psychotherapeutic use of movement to promote emotional, social, cognitive, and physical integration of the individual.

Darkness Visible: A Memoir of Madness is a book written by William Styron (1925–2006) and published in 1990. This first-person account of his near-fatal descent into depression is considered one of the most vivid and insightful even after more than 25 years since it was first published.

Dating is a stage in the human mating process when two people meet socially for companionship, beyond the level of friendship, or with the aim of each assessing the other's suitability as a partner in an intimate relationship or marriage.

Debriefing is a careful review of a situation or activity once it has been completed in order to learn how to handle it better in the future.

Defense mechanisms are unconscious, maladaptive coping strategies that individuals use to prevent unpleasant feelings and experiences.

Defiant is an adjective used to describe resistance or objection.

Deinstitutionalization is the release of a person with mental or physical disabilities from a hospital, asylum, or other medical institution, usually with the intention of providing treatment, support, or rehabilitation through outpatient community resources.

Deity means a god or a supreme being.

Deliberate self-harm, or self-inflicted injury, refers to acts of harming oneself with non-suicidal intent.

Delinquency is a general term used to describe the unlawful activity, wrongdoing, or misbehavior of young people.

Delusional disorder is a mental disorder characterized by delusions. Previously this disorder was referred to as paranoia or paranoid disorder.

Delusions are fixed, false beliefs that persist despite contrary evidence.

Delusions of reference are strongly held beliefs that events, the behaviors, or remarks of others have a particular and unusual significance to oneself, when, in fact, they do not. Unlike ideas of reference, delusions of reference must disrupt daily functioning.

Dementia is a group of symptoms including loss of memory, judgment, language, and other intellectual (mental) functions caused by the death of neurons (nerve cells) in the brain.

Denial of death is when someone refuses to accept the concept of mortality for either themselves or someone else.

Dependence, related to drug use, is the need for a drug to function normally. It can be psychological and/or physical. Psychological dependence is dependence on a psychoactive substance for the reward it provides. Physical dependence refers to the unpleasant physiological symptoms if the drug is stopped.

Dependency with drugs refers to the body's physical need for continued or increasing use of a substance in order to maintain the effect or to ward off withdrawal symptoms.

Dependent personality disorder is a mental disorder characterized by pervasive pattern of submissiveness, a lack of self-confidence, and an excessive need to be taken care of by others.

Depersonalization is a mental state of detachment or a sense of being "outside" oneself and observing one's actions or thoughts.

Depressants are a groups of drugs that are prescribed to reduce the symptoms of anxiety. These are addictive and can be abused. Benzodiazepines, like Valium, are a very common depressant.

Depression is an emotional state characterized by feelings of sadness, low self-esteem, guilt, or reduced ability to enjoy life. It is not considered a mental disorder unless it significantly disrupts one's daily functioning.

Depressive disorders are a group of mental disorders characterized by a sad or irritable mood, and cognitive and physical changes that significantly disrupt the individual's daily functioning. These include major depressive disorder and persistent depressive disorder.

Depressive personality disorder is a mental disorder characterized by a persistent and pervasive pattern of unhappiness, low self-esteem, pessimism, guilt, and an inability to relax and experience pleasure.

Depressive phase is a mental state characterized by sad mood, reduced ability to enjoy life, and decreased energy or activity seen during the course of a bipolar disorder.

Desensitization refers to diminished emotional responsiveness to a negative or aversive stimulus after repeated exposure to it.

Desensitization techniques are behavior change methods for reducing over sensitivity to fearful situations by intentionally and gradually exposing an individual to various emotionally distressing events.

Determinism is a philosophical belief that every event that exists is inevitable, predetermined, and established by preceding events.

Detoxification is the process of ridding the body of toxic substances, such as drugs and alcohol, until laboratory tests and physical examination show that the individual is free of toxins.

Developmental relates to growth and the ability to learn new things, especially in regard to the gradual learning and maturing process in children.

Diagnosis means the identification of the nature of an illness or other problem by examination of the symptoms.

Diagnostic and Statistical Manual of Mental Disorders is the handbook for mental health professionals' use to diagnose mental disorders. The current edition (fifth) is known as DSM-5.

Dialectical Behavior Therapy (DBT) is a psychotherapy approach which focuses on coping with stress, regulating emotions, and improving relationships.

Dichotomy, or dichotomous, refers to the division of two opposing or contradictory, constructs, ideas, or forces in which being high in one is to be low in the other.

***Dictionary of Occupational Titles* (DOT)** is the former print publication published during the late 1930s to 1990s by the U.S. Department of Labor that sought to match job seekers to jobs; it was replaced by an online computer system, the Occupational Information Network, or O*NET.

Diffusion of responsibility suggests that bystanders rationalize their hesitance, reluctance, or lack of intervening on a victim's behalf due to a belief that others present will take responsibility.

Disability is a physical or mental impairment that substantially limits one or more of the major life activities of an individual.

Disability evaluation is a formal determination of the degree of a physical, mental, or emotional disability.

Discrimination is the unjust treatment of others based on racist beliefs.

Disease is an objective medical condition that can be acute or chronic.

Disinhibited social engagement disorder is a mental disorder in children characterized by an overly familiar and culturally inappropriate behavior with strangers.

Disintegrative is an adjective that describes separation into parts, a break up, or deterioration, especially in regard to the self-concept or personality of a person.

Disorder is a term applied to an abnormal physical or mental condition.

Disruptive mood dysregulation disorder is a mental disorder in children characterized by a severe and frequent temper tantrums that interfere with daily functioning.

Dissociation is a psychological process in which an individual experience being disconnected from his or her sensory experience, sense of self (identity), or personal history. Daydreaming is a non-pathological form of it, while depersonalization (a sense that the self is unreal) is a pathological form of dissociation.

Dissociative amnesia is a dissociative disorder characterized by the inability to remember important personal information beyond what could be explained by normal forgetfulness. It is also known as psychogenic amnesia.

Dissociative disorders are a group of mental disorders characterized by a disturbance of self, memory, awareness, or consciousness, which cause disrupted life functioning.

Dissociative fugue is a dissociative disorder characterized by a temporary loss of personal identity, moving to a new location, and assuming a new identity.

Dissociative identity disorder is a dissociative disorder characterized by having more than one distinct identity. Previously it was referred as multiple personality disorder.

Diuretics are substances that elevate the rate of urination and water loss.

Divine refers to objects, practices, and experiences associated with God, gods, or a supreme being.

Dodo bird verdict is the claim that all psychotherapies are equally effective regardless of their components.

Domestic abuse is the abuse by one partner against the other in an intimate relationship. It can involve physical, sexual, and/or psychological abuse.

Domestic violence is a form of abuse between intimate partners (spouses). It is also called domestic abuse.

Dopamine is the chemical messenger in the brain responsible for coordinating the movement of voluntary muscle groups. It also regulates attention, pleasure, and coping with stress.

Dream interpretation is a method of deciphering and understanding the unconscious meaning of dreams.

Drug Enforcement Administration (DEA) is the federal law enforcement agency that enforces controlled substance laws and regulations.

Drugs refer to medications or other substance which have a physiological or psychological effect when ingested or introduced into the body.

DSM is the abbreviation for the *Diagnostic and Statistical Manual of Mental Disorders*, which is the handbook mental health professionals use to diagnose mental disorders. The current edition is the fifth, and is known as DSM-5.

Dyscalculia refers to difficulty in performing simple mathematical functions. It is another name for Mathematics Disorder.

Dysfunction means an abnormality or impairment in the operation of a specified or expected system or organization, physical or mental.

Dyslexia is a learning disorder that impairs a person's ability to read.

Dyspareunia is the experience of pain during sexual intercourse.

Dyspraxia is a learning disorder characterized by the inability to perform tasks or movements when asked, even though the request or command is understood. It is also called apraxia of speech.

Dysregulation is a problem with the control of physical or emotional functions.

Early recollections is a personality assessment method developed by Alfred Adler that analyzes single incident memories from childhood.

Eating disorder is a class of mental disorders that are characterized by difficulties with too much, too little, or unhealthy food intake, and may include distorted body image.

Economic and financial stress is often a response to trying unsuccessfully to balance outgoing money for bills and earning enough income, which numerous studies have found is strongly linked to an increased rate of mental health issues. Among the most significant factors in the onset of mental health issues are job loss and underemployment, both of which have been connected to depression and substance abuse.

Ego depletion is the term used to describe the temporary exhaustion of self-control. It is also known as willpower depletion.

Elder abuse is the physical, sexual, or emotional abuse of individuals, usually one who is disabled or frail.

Ellis, Albert (1913–2007) was an influential American psychologist and author. He began his career as a sexologist before pioneering the development of Rational Emotive Behavior Therapy (REBT). Designed to help people actively overcome challenges and live more fulfilled lives, REBT grew from a fringe school of thought to become a major philosophy and practice.

Emotion is the individual experience of psychological and physical activity which may be positive or negative.

Emotional abuse is a form of abuse characterized by one individual subjecting or exposing another to behavior that may result in anxiety, chronic depression, or post-traumatic stress disorder.

Emotional intelligence is the ability to accurately identify and respond to emotions in oneself and others.

Empathy is the capacity to recognize and respond to another's expression of emotion.

Empathy training is a method of increasing skills of recognizing and responding to another's expression of emotion.

Empty nest is a phrase that describes the family after all of the children have permanently left the home.

Envy and Gratitude is a now famous monograph written by the well-known psychoanalyst Melanie Klein (1882–1960). In this controversial work, Klein theorized that even infants are torn between the struggle for goodness or destructiveness, which she defined as gratitude and envy.

Envy and jealousy are generally considered negative emotions associated with a person's desire to have something or someone that someone else already has, and not having it feels like a threat to the person's sense of self. Envy can sometimes be connected to depression and low self-esteem and, when left unchecked, may escalate to destructive or even violent behavior.

Epistemology is the study of knowledge and understanding and is grounded in philosophy.

Ethnicity refers to a shared distinctive culture based on region of the world, language, religion, and lifestyle.

Evidence-based practice is a form of practice that is based upon integration of the best research evidence with clinical experience and client values.

Evolution is a theory first proposed by Charles Darwin that states all species and organisms develop and change through the natural selection of small, inherited variations that increase the ability of the species or organism to compete, survive, and reproduce.

Evolutionary time refers to an unspecified amount of time usually in the hundreds of thousands to millions of years.

Executive functions are high-level cognitive abilities such as planning, organizing, reasoning, decision-making, and problem-solving that influence more basic abilities such as attention, memory, and motor skills.

Existential psychotherapy is an experiential and relationship-oriented approach to psychotherapy that focuses on meaning and the nature of the human experience.

Exploitation involves illegal taking, misuse, or concealment of funds, property, or assets of a vulnerable elder.

Exposure therapy is a behavior therapy intervention (method) in which an individual is exposed to a feared object or situation. It is also referred to as flooding.

Expressive means effectively conveying thoughts or feelings.

Expressive arts therapy is the practice of using storytelling, imagery, dance, drama, poetry, movement, music, dream work and visual arts to help promote and encourage personal growth and healing.

Expressive language is the ability to communicate with others through words and speech; when children begin to talk, their receptive language skills are usually much more advanced than their expressive language skills.

Extended families consist of the parents and their children and other biologically related family members such as grandparents, aunts, uncles, and cousins. They may or may not live in the same household.

External locus of control is the belief that one's decisions and life is controlled by forces outside the individual's control.

Externalization is the process of separating an idea from oneself and looking at it from a different view.

Extrapyramidal symptoms are side effects of certain antipsychotic drugs. They include repetitive, involuntary muscle movements, such as lip smacking, and the urge to move constantly.

Eye Movement Desensitization and Reprocessing is a treatment method to reduce trauma-based symptoms by visualization of the traumatic event while concentrating on the rapid lateral movements of the therapist's finger. It is also known as EMDR.

Factitious disorders are a group of mental disorders in which individuals intentionally act as if they are physically or mentally ill, but who have created their own symptoms. One such disorder is Munchausen syndrome.

False memory syndrome is a condition in which a person believes they were the victims of abuse that in reality never actually occurred.

Family assessment is the evaluation of family characteristics, relationship patterns, and family dysfunction (disturbing behavior) and their influence on individual family members.

Family constellation refers to the relationship characteristics with a family unit.

Family counseling and family therapy are synonymous terms used to describe a form of therapy that focuses on at least two or more members of a couple or family unit that works to improve relationships and communication. Instead of focusing on a single individual, family counseling involves the family being treated as a whole unit using one of the various psychotherapy approaches to improve communication and family relationships.

Family of origin refers to the family an individual grew up in and is recognized by mental health experts as having a significant influence on patterns of thinking, feeling, and behaving.

Fear is an emotional response to a known danger.

Feeling Good, The New Mood Therapy is a self-help book by David D. Burns, MD, to offer practical advice, insight and hope to those struggling with depression who want an alternative to medication. It advocates the use of simple cognitive behavioral therapy techniques.

Fetal alcohol syndrome is a medical condition characterized by birth defects, learning, and behavioral problems in children resulting from the mother's alcohol use during pregnancy.

Figure drawing is a projective test used to gain insights on intelligence, trauma, emotional state, and relational interactions. Often used with young children, trauma survivors, and non-native speakers, figure drawing offers a chance to access what may not be able to be expressed in words.

Filial Therapy is a form of therapy geared toward helping children aged 3 to 13 in their mental and emotional development by strengthening the bonds between the child and his or her parent or caregiver.

Flirting is acting as if one is sexually attracted to another person, usually in a playful manner.

Fluency is the ability to speak or do anything correctly and seemingly easily.

Foster care is the temporary placement of a child or infant with surrogate caregivers. It was designed as a proactive attempt by society to address the needs of children in at-risk situations.

Fragile X syndrome is an inherited condition characterized by an X chromosome that is abnormally susceptible to damage, especially by folic acid deficiency. Affected individuals tend to be mentally handicapped.

Frankl, Viktor (1905–1997) was the Austrian psychiatrist who developed logotherapy and was the author of the popular book, *Man's Search for Meaning,* which details his experience as a Holocaust survivor.

Freud, Anna (1895–1982) was a psychiatrist and daughter of Sigmund Freud who is best known for founding the field of child psychoanalysis.

Freud, Sigmund (1856–1939) was the Austrian neurologist who founded psychoanalysis and considered one of the most influential thinkers of the 20th century.

Fundamentalism refers to strict, narrow, and demanding beliefs and practices, usually in reference to religion.

Gambling is the term for playing games of chance for money or betting.

Ganser's syndrome is a mental disorder in which individuals give silly or absurd answers to simple questions.

General intelligence is traditionally understood to be a measurable single capacity that every human being possesses.

Generalized anxiety disorder is a disorder characterized by chronic anxiety and multiple exaggerated worries even when there is little or nothing to provoke it.

Genito-pelvic pain/penetration disorder is a mental disorder in women characterized by persistent fear, pain, or difficulty with vaginal intercourse. Previously this disorder was referred to as dyspareunia and vaginismus.

Genocide is the large-scale murder of people belonging to a particular racial, political, or social group.

Genogram is a detailed graphic that represents an individual's family tree. It is used by family therapists to succinctly portray information about the individual's relationships, family, medical, social, and even developmental history.

Gerontological counseling is a psychological method for working with older clients who face the emotional and mental health challenges associated with aging.

Gestalt psychotherapy is an existential, experiential, and insight-oriented form of psychotherapy and counseling.

Gifted is an adjective that indicates the persons described have talent or natural ability greater than the expected norm or average.

Glasser, William (1925–2013) was the American psychiatrist who developed Reality Therapy.

Going postal is a slang term referring to the sudden and uncontrollable expression of anger to the point of violence. The term originated from a series of shootings involving U.S. postal employees.

Group counseling is two or more people gathering for a face-to-face meeting for the purpose of working toward mutually agreed upon goals.

Group home is a residence for persons requiring care or supervision, such as troubled youth, the developmentally disabled, the elderly or those suffering from addiction. Group homes were a response to the closing of institutions, asylums, and orphanages in the 1960s and 1970s.

Group therapy involves one or more therapists meeting with several clients at one time and it is widely used for a variety of psychiatric problems. Group therapy can be an important part of a client's treatment, depending on his or her diagnosis. Some patients may require a combination of group and individual therapy to improve.

A Guide to Rational Living is a book written by psychologists Albert Ellis and Robert A. Harper. It describes how irrational beliefs lead to suffering and shows how to change them to rational beliefs that result in rational living and increased well-being. First published in 1961, it continues to be near the top of the self-help bestseller lists.

Habit reversal is a behavior therapy intervention for treating repetitive behavior disorders such as tics. It works by increasing tic awareness and developing a competing response to the tic.

Haley, Jay (1923–2007) was a pioneer who changed the approach to family therapy. He believed that therapists were problem solvers who should guide their clients toward a solution. He was one of the developers of strategic therapy which promotes the belief that therapists should acknowledge their ability to influence the behavior of their clients.

Hallucinations are false or distorted sensory perceptions that appear to be real perceptions that are generated by the mind rather than by an external stimuli.

Harlow, Harry (1905–1981) is the psychologist best known for his discoveries of the infant–mother relationship which he uncovered through experimental studies with rhesus monkeys.

Hate crimes are hostile criminal acts such as assault or vandalism motivated by racial, sexual, or other group prejudices.

Heritage refers to the practices, traditions, or characteristics that are passed down from one generation to the next.

Histrionic refers to behavior that is very dramatic or excessive.

Histrionic personality disorder is a personality disorder in which individuals first appear to be charming, likable, energetic, and seductive. But as time passes, others find them to be emotionally unstable, immature, and egocentric.

Hoarding disorder is a mental disorder characterized by persistent difficulty discarding or letting go of possessions regardless of their actual value.

Homeless individuals are those who lack permanent housing and often face mental health issues as a result of being homeless.

Horney, Karen (1885–1952) is the psychologist and psychoanalyst best known for character and character development, feminine psychology, the conception of the self, and her theories on neurosis.

Hospitalization is the act of placing a person as a patient in a formal medical facility.

Household dysfunction is a category of adverse childhood experience that includes household substance abuse, household mental illness, and parental separation or divorce.

House-Tree-Person Test is a projective drawing technique used originally as a measure of intelligence and later as a tool to investigate potential exposure to abuse. The House-Tree-

Person Test is often used to gain insight for the presence of abuse and child's perception of safety and security and has grown to include an assessment of personality dynamics and more.

Humanistic Psychology is based on the idea that people are inherently good. This theory focuses on the exploration of human potential, while emphasizing wholeness and creativity.

Hyperactivity means more active than is usual or desirable.

Hypersomnia refers to difficulty staying awake during the day. Hypersomnolence disorder is a sleep disorder characterized by a recurrent pattern of excessive daytime sleepiness.

Hypnagogic hallucinations are false perceptions that occur when individuals fall asleep.

Hypnopompic hallucinations are false perceptions that occur when individuals are awakening.

Hypnosis is a psychological technique used to induce a trance state.

Hypnotics are substances that induce or cause sleep.

Hypochondriasis is a mental disorder characterized by a preoccupation with having a serious medical condition based on a misinterpretation of bodily symptoms. In DSM-5, this disorder is replaced by illness anxiety disorder.

Hypocretin is a brain chemical that regulate wakefulness and REM sleep and is associated with some symptoms of narcolepsy.

Hypomania is a mental state similar to mania but less intense.

Hypomanic personality disorder is a mental disorder characterized by an enduring pattern of hypomania that shapes cognition, attitudes, and identity. This pattern predictably shapes an individual's behavior and relationships with others.

Hysterical personality comes from the word hysteria which referred to a medical condition caused by the uterus (in Greek: "hysteria" means uterus). The belief was that various symptoms were caused by the movement of a uterus throughout various locations within a woman's body.

Idealizing is the exaggeration of positive qualities and the minimization of negative qualities.

Ideas of reference are the beliefs that events, the behaviors, or remarks of others have a particular significance to oneself when, in fact, they do not.

Illness is the subjective experience of a disease.

Illness anxiety disorder is a mental disorder characterized by severe anxiety and a preoccupation of having a serious medical condition. Previously, this disorder was called hypochondriasis.

Illusions are a misperception or false interpretation of an actual sensory image or impression.

Immigration occurs when people move and settle in a country in which they were not born.

Incomplete grief is grief that persists and is chronic with no resolution, which may include a lack of satisfaction regarding the end of relationship with a deceased parent or other loved ones.

Inferiority complex is a behavioral manifestation of a subjective feeling of inferiority.

Inferiority feeling is the emotional reaction to a self-appraisal of deficiency that is subjective, global, and judgmental.

Infidelity is the act of having a romantic or sexual relationship with someone other than a wife, husband, or committed partner; also referred to as cheating, adultery, or having an affair.

Informed consent means to voluntarily consent in writing, by a competent person, to inpatient or outpatient treatment

Insecure attachment is a lack of trust or consistency in the relationship between a caregiver and child. The caregiver may fail to respond to the infant's needs where the child may become distressed or anxious.

Insomnia refers to difficulty falling asleep or remaining asleep during normal sleep times.

Insomnia disorder is a sleep disorder characteristic by persistent difficulty in falling asleep and staying asleep.

Intellectual refers to the ability to think and understand ideas.

Intelligence is the capacity a person has to learn and understand information and solve problems.

Intelligence quotient is a measure of intellect to determine a person's level of cognitive ability.

Intermittent explosive disorder is mental disorder characterized by impulsive, aggressive, violent behavior or angry verbal outbursts.

Intervention is the act or method of interfering with the outcome or present course of a condition or process so as to prevent harm or improve functioning.

Intrinsic refers to the inherent and essential nature of a thing.

Involuntary commitment is a legal process in which someone suffering from a severe mental disorder can be involuntarily admitted to for psychiatric hospitalization or treatment.

Involuntary hospitalization is the legal process whereby individuals are placed in inpatient mental health treatment against their will.

IQ stands for "Intelligence Quotient," which is a numerical score obtained on standardized tests of human intelligence.

James, William (1842–1910) was one of America's first psychologists. He was a major influence on the modern views of cognitive neuroscience, and wrote extensively on attention, motivation, emotion, and perception. He is also known as an influential philosopher.

Jung, Carl Gustav (1875–1961) was the Swiss psychoanalyst and psychotherapist recognized as the founder of Analytical Psychology. Based on archetypal and symbolic theory, he suggested that the unconscious, especially the collective unconscious, is the starting point and purpose of pursuing ultimate spirit or psychological reality.

Jungian therapy is a specialized form of psychotherapy in which the analyst and patient work together to increase the patient's consciousness in order to move toward psychological balance and wholeness, and to bring relief and meaning to psychological suffering. Its fundamental goal is to build a vital relationship between the conscious and unconscious parts of the mind so that psychic development can be ongoing. Jungian therapy was developed by Carl Jung (1875–1961).

Kernicterus is a brain dysfunction due to severe jaundice.

Kinesiology is the study of anatomy, physiology, and the mechanics of body movements.

Klein, Melanie (1882–1960) was an influential pioneer in the psychoanalysis of children. Many list Klein as second only to Freud in her influence on modern psychoanalysis. She took analyzing young children to a level that had never before been seen. As a result of her work, more is understood about the nonverbal communication of children and patients at all ages.

The Language and Thought of the Child was written by Jean Piaget in 1923. Piaget was the first to apply the insights of social psychology and psychoanalysis to the observation of children, uncovering ways in which children actively constructs their understanding of the world through language.

Law is the collection of rules that govern the behavior of individuals in a community, state, or country.

Laxatives are drugs, medications, or substances that stimulate the evacuation of the bowels.

Lazarus, Arnold (1932–2013) was a psychologist who was one of the pioneers in behavior therapy, particularly the version known as multimodal therapy. He is also known for emphasizing the value of technical eclecticism and stressing the dangers of theoretical integration, and developing the multimodal BASIC I.D. model.

Learning is the acquisition of knowledge or skills through experience, study, or by being taught.

LGBT is an abbreviation for lesbian, gay, bisexual, and transgender people.

Light therapy is a medical treatment in which doses of bright light are administered to normalize the body's internal clock and treat depression. It is also called phototherapy.

Linehan, Marsha M. (1943–) is the driving force behind the development of dialectical behavior therapy, which *Time* magazine noted as one of the top 100 most important discoveries. Her writings on the treatment is the most cited work in the field of mental health in the past 25 years. DBT began as a treatment primarily for suicidal and self-injurious behavior. It has expanded to include many other areas, including addictive and eating disorders, depression, and family conflict.

Logotherapy is a form of therapy that is based on the meaning-focused, existential philosophy of Viennese psychiatrist Viktor E. Frankl (1905–1997). At its essence, logotherapy involves healing and the enhancement of one's well-being through changing one's attitude and beliefs.

Magnetic resonance imaging is a medical diagnostic test which uses magnetic field to produce detailed images of the brain and internal organs. It is also referred to as nuclear magnetic resonance imaging.

Major depressive disorder is a mental disorder characterized by a depressed mood and other symptoms that interfere significantly with an individual's daily functioning. It is also referred to as clinical depression.

Male privilege is the belief in some societies that men have power which exempts them from certain responsibility which women are expected to perform because of their subordinate status.

Malingering is the practice of intentionally exaggerating or faking physical or psychological symptoms for personal gain. It is also known as fictitious illness.

The Man Who Mistook His Wife for a Hat and Other Clinical Tales is a best-selling book written by neurologist Oliver Sacks and published in 1985. The book is a collection of several of the Dr. Sacks's case studies that explores the worlds of his patients, and offers an interesting look at a series of neurological anomalies.

Mania is a mental state of expansive, elevated, or irritable mood with increased energy or activity.

Manic phase is a mental state characterized by expansive, elevated, or irritable mood with increased energy or activity seen in during the course of a bipolar disorder.

Man's Search for Meaning is a book that emphasizes the importance of meaning, faith, hope, humor, and many other adaptive constructs. Meaning-focused existential psychologist and psychiatrist, Viktor E. Frankl (1905–1997) wrote this book over a nine-day period in 1945, shortly after his concentration-camp liberation during World War II.

Marriage Counseling is another term for couples therapy or counseling.

Marriage and Family Therapist is a protected professional title that designates an individual as meeting the educational standards set forth by the Commission on Accreditation for Marriage and Family therapy Education.

Mathematics is the study of numbers, equations, functions, and geometric shapes and their relationships, as in arithmetic, algebra, geometry, and calculus.

Melatonin is a chemical messenger in the brain which regulates the sleep–wake cycle and promotes restorative sleep.

Memory recovery techniques include an array of methods including recovered memory therapy, hypnosis and age regression, guided imagery, dream interpretation, body memory, free association, past life regression, and the use of sodium amytal (the so-called truth serum). Some memory recovery techniques have been associated with false memory syndrome.

Mental disorder is a mental or behavioral pattern or anomaly that causes either distress or an impaired ability to function in daily life. It is also known as a mental illness or psychiatric disorder.

Mental imagery includes visual and bodily sensation images that take place within one's mind and imagination.

Mental retardation is a disorder that describes people with well below average level of intelligence, an IQ of 70 or below, and who have major limitations in the skills needed for daily living.

Methadone is a drug that reduces symptoms of withdrawal for people addicted to other drugs.

Mild cognitive impairment is a mental condition characterized by memory problems that do not significantly impact daily functioning. Commonly, the condition is hardly noticeable or troublesome to the individual. It is also known as MCI.

Mindfulness is the moment-by-moment awareness of one's thoughts, feelings, sensations, and environment without evaluating or judging them.

Mindfulness practices are intentional activities that foster living in the present moment and awareness that is nonjudgmental and accepting.

Mindfulness-based psychotherapies are forms of therapy whose primary intention is to increase a client's capacity for an awareness or attention that is nonjudgmental, accepting, and engaged in experiencing the present moment.

Minnesota Multiphasic Personality Inventory is a psychological test used to assess personality and psychopathology. It is also known as MMPI.

Minuchin, Salvador (1921–) is an Argentinian psychiatrist best known for his work in creating Structural Family Therapy.

Mobbing is harassment of a coworker by a group of others in a workplace to force the targeted individual out of the workplace.

Modeling is a form of teaching where individuals learn how to act or perform by observing other individuals.

Morality is the perception of correct and proper behavior, often based on culture or religion.

Motivational Interviewing is a counseling strategy for helping individuals to discover and resolve their ambivalence to change. It is also referred to as MI.

Movement describes an individual's style of interactions with others, which may be toward, against, or away.

Multicultural counseling refers to the integration of multicultural and culture-specific awareness, knowledge, and skills into counselor interactions, training, and practices.

Multimodal Therapy is a form of psychotherapy which attends to seven modalities of human functioning: behavior, affect, sensation, imagery, cognition, interpersonal relationships, and drugs or biological processes.

Munchausen Syndrome is a mental disorder characterized by fabricated and convincing physical symptoms and a false medical history. It was named after Baron von Munchausen who is known for telling exaggerated stories. It is also known as factitious disorder.

Munchausen syndrome by proxy is a mental disorder in which caregivers fabricate or cause symptoms, falsify medical history, or tamper with laboratory tests in order to make a child appear sick.

Muscle dysmorphia is the obsessive belief that one is not muscular enough.

Muscular dystrophy is a hereditary condition marked by progressive weakening and wasting of the muscles.

Mutual Aid Fellowship is a community in which individuals struggling with the same problem (e.g., alcoholism) help one another.

Narcissistic rage is a reaction to narcissistic injury and can range from aloofness, to mild irritation or annoyance, to serious outbursts, including violent attacks.

Narcissistic injury is the perceived threat to a narcissist's self-esteem or self-worth. It occurs after experiencing a defeat or criticism and results in feelings of emptiness, degradation, or humiliation.

Narcissistic personality disorder is a mental disorder characterized by a pattern of grandiosity, lack of empathy, and a need to be admired by others.

Narcolepsy is a sleep disorder involving daytime sleepiness and uncontrollable episodes of falling asleep during the day.

Narcotics Anonymous is a self-help and support group for those addicted to drugs to help them learn how to live without the use of mind- and mood-altering chemicals. It is a Twelve-Step Program.

Narrative Therapy is an approach that connects identity as shaped by the individual's story and perception of those stories.

National Institute of Mental Health (NIMH) is one of 27 components of the National Institutes of Health based in Bethesda, Maryland. The goal of the NIMH is a world in which mental illnesses are prevented and cured. Its mission is to transform the understanding and treatment of mental illness through basic and clinical research and in so doing aims to pave the way for the prevention, recovery, and cure of the mental illness. The NIMH is a governmental agency. As such, it holds a great deal of authority and credibility on mental health issues.

Natural selection is a process by which an organism or species best adapted to an environment is able to survive longer and reproduce in greater numbers with the adaptive traits being passed down to the next generation. As the number of adapted offspring increases, there is an ever-decreasing chance for the less-adapted organism to reproduce eventually resulting in the extinction of the less-adaptive traits.

Neglect involves refusal or failure by those responsible to provide food, shelter, health care, or protection for a vulnerable child or elder.

Neurocognitive disorders are a group of disorders in DSM-5 that are characterized by a decline from a previous level of neurocognitive (mental) function.

Neurodegenerative disease is a medical condition in which the nervous system progressively and irreversibly deteriorates.

Neurodevelopmental disorders are neurological disorders characterized by impairments of the growth and development of the brain or central nervous system.

Neuroscience is the scientific study of the nervous system and the brain.

Neurosis is an outdated but still used term for various mental disorders characterized by considerable anxiety, irrational fears, depression, or obsessive thoughts. It is also called psychoneurosis.

Nightmare is a dream that results in feelings of terror, fear, or extreme anxiety.

Nightmare disorder is a sleep disorder that is characterized by recurrent troubling dreams.

Noncompliance is the failure, in whole or part, to follow a prescribed treatment regimen.

Nondirective refers to a clinical approach to treatment where the therapist allows the client to set the pace and content of therapeutic counseling sessions.

Non-REM sleep is one of the two basic states of sleep consisting of stages 1, 2 (light sleep) and 3, 4 (deep sleep). It is also known as non-rapid eye movement and NREM sleep.

Nuclear families are traditional families that comprise a cohabiting and committed couple and their biological children.

Obesity is an excessive accumulation of body fat, usually 20% or more over an individual's ideal body weight.

Object Relations Theory is a form of psychoanalytic psychology which explains the essential need for close relationship. The attempted fulfillment of this need through mental representations of self and others is believed to determine one's motivations and behaviors.

Obsessions are persistent, intrusive, inappropriate, and unwanted thoughts, impulses, or images that result in anxiety or distress.

Obsessive-compulsive disorder is a mental disorder that is distressful to the individual and is characterized by unreasonable obsessions or compulsions that are inappropriately time-consuming or cause marked distress or impairment. It is commonly referred to as OCD.

Obsessive-compulsive personality disorder is a mental disorder characterized by a pattern of preoccupation with perfectionism, orderliness, and control.

Obstructive sleep apnea is a type of sleep apnea in which a blockage of the upper airway causes the body to snore and struggle for air.

Oedipus complex is the desire for sexual involvement with the parent of the opposite sex with a concurrent sense of rivalry with the parent of the same sex. Freud considered the complex a critical stage in normal development.

One Flew over the Cuckoo's Nest was a bestselling novel by Ken Kesey (1935–2001) that portrayed life in a mental hospital. It was published in 1962 and later made into a movie in 1975, winning five Academy Awards, including for best picture.

Opioids are a group of drugs that reduce pain. They are highly addictive and include both prescription drugs like Percocet and illegal drugs like heroin.

Oppositional is the act of displaying anger or hostility toward a person or group of people.

Oppression is the unjust exercise of authority or power.

Panic is an intense sense of fear.

Panic attack is an episode of a sudden, intense, and debilitating sense of fear that is short lived.

Panic disorder is a mental disorder characterized by severe panic attacks that occurs frequently and produces significant distress and/or impaired functioning.

Paranoia is an unfounded or exaggerated distrust or suspiciousness of others.

Paranoid personality disorder is a mental disorder characterized by a pattern of a high level of distrust and suspiciousness of the motives of others.

Paraphilia is a sexual disorder in which an individual can only become aroused by inappropriate objects, actions, or fantasies.

Paraphilic disorders are a group of sexual disorders in which an individual can only become sexually aroused by inappropriate objects, actions, or fantasies.

Parasomnias are a group of sleep disorders characterized by abnormal events that occur during sleep such as sleepwalking, talking, or limb movement.

Parkinson's Disease is a disease of the nervous system that causes tremor, rigidity, slowness of movement, and unstable posture. When cognitive impairment is also present, this disease can is known as neurocognitive disorder due to Parkinson's disease in DSM-5.

Passive-aggressive behavior is the indirect expression of hostility characterized by procrastination, stubbornness, forgetfulness, sarcasm, inconsistency, stubbornness, resentment, and repeated failure to accomplish requested tasks for which an individual is responsible.

Passive-aggressive personality disorder is a mental disorder characterized by an enduring pattern of negative attitudes and passive aggressive behaviors. It is also known as the negativistic personality disorders.

Pathology is the study of the essential nature of diseases and especially of their cause, development, structure, and consequences.

PDM stands for the *Psychodynamic Diagnostic Manual*, a diagnostic framework and handbook that characterize individuals in terms of their psychodynamics.

Pedophile is the term given to those who engage in pedophilia, sexual activity with children.

Pedophilic disorder is a sexual disorder in which sexual arousal is achieved with fantasies, urges, or behaviors that involve sexual activity with prepubescent children (13 years of age or younger). It is also referred to as pedophilia.

Perfectionism is the belief that striving for perfection is important because one's self-worth is measured by one's productivity and accomplishments.

Periodic limb movement in sleep is a medical condition characterized by involuntary, jerking movements of the legs or arms.

Persistent depressive disorder is a depressive disorder characterized by a chronic, depressed mood lasting for more than two years. It was previously called dysthymic disorder.

Personality is the enduring pattern of perceiving, feeling, relating, and thinking about one's environment and oneself.

Personality disorder is a long-standing pattern of maladaptive (problematic) behavior, thoughts, and emotions that deviates from the accepted norms of an individual's culture.

Personality type refers to a collection of personality traits and preferences that produce a consistent and predictable pattern of thinking, feeling, and behaving.

Pervasive means present or noticeable in every part of something or in every stage of life.

Phantom limbs is the sensation of feeling that a part of the body that is physically missing or has been removed is still present. The feelings are generally painful.

Phobias are extreme or irrational fears of objects or situations.

Phonological pertains to the distribution and patterning of speech sounds in a language and/or the tacit rules governing pronunciation.

Physical abuse involves inflicting, or threatening to inflict, physical pain or injury on individuals, or depriving them of a basic need.

Pica is the persistent craving and compulsive eating of nonfood substances, like dirt, paint chips, or ice. It is considered an eating disorder in DSM-5.

Play therapy is a therapeutic modality used by a trained play therapist who provides carefully selected play materials in a safe setting for the child to express his or her feelings, emotions, fears, and beliefs. There are many different theoretical approaches to play therapy, including filial therapy, client-centered play therapy, Adlerian play therapy and nondirective play therapy to name a few.

Polysomnography is a medical test that records aspects of sleep (circadian rhythms, REM, NREM, and number of arousals) as well as breathing patterns, heart rhythms, and limb movements.

Positive Psychology is the science about the best things in life with a focus on positive emotions, traits, and institutions.

Post-concussion syndrome is a collection of symptoms that some develop as a complication of concussion such as headache, disorientation, amnesia (inability to remember the injury), and memory and concentration problems which usually clear within three months after the head injury.

Post-traumatic stress disorder is a mental disorder characterized by nightmares, irritability, anxiety, emotional numbing, and recurrent flashbacks of a traumatic event that an individual experienced or witnessed. It is also referred to as PTSD.

Practice is a method or process used to accomplish a goal or objective.

Prejudice is a preconceived opinion about a group or class of people, based on limited, inaccurate, or assumed information.

Premenstrual dysphoric disorder is a mental disorder characterized by a severe form of premenstrual syndrome in which depression, mood swings, irritability, and anxiety disrupt daily functioning.

Premenstrual syndrome is a medical condition in which cramps, breast tenderness, bloating, irritability, and depression occurs prior to a woman's menstrual period and subsides after it.

Primary Care is health care that is provided by nonspecialist physicians like family doctors and pediatricians.

Process is a series of actions or steps taken in order to achieve a particular end result.

Process addiction is a compulsive behavior pattern, not involving substances or chemicals, which interferes with daily living.

Proprioception is the sense of how our bodies are positioned in relation to our environment.

Psychedelic is a term applied to drugs (especially lysergic acid diethylamide, mescaline, or psilocybin) that produce hallucinations and apparent changes in consciousness.

Psychoactive refers to a drug or substance that has a significant effect on mental processes. There are five groups of psychoactive drugs: opioids, stimulants, depressants, hallucinogens, and cannabis.

Psychoanalysis is a theory of human behavior and a form of therapy based on psychoanalytic theory. It focuses on conflicts and compromises between the unconscious (internal) and the conscious mind. Clients are encouraged to talk freely about personal experiences, particularly their early childhood and dreams. It was initially developed by Sigmund Freud.

Psychoanalytic theory is a psychological theory that explains behaviors and perceptions as the result of unconscious, sexual, and biological instincts. It was originally developed by Sigmund Freud.

Psychoanalytic Therapy is a form of psychotherapy that emphasizes unconscious (outside awareness) conflicts and focuses on an individual's early childhood and dreams.

Psychodrama is a form of psychotherapy in which patients act out events from their past.

***Psychodynamic Diagnostic Manual* (PDM)** is a diagnostic system based on psychoanalytic theory that is used by professionals to identify mental disorders with specific diagnostic criteria.

Psychoeducation is a psychological treatment method that provides individuals with knowledge about the condition as well as advice and skills for reducing their symptoms and improving their functioning.

Psychological abuse involves inflicting mental pain, anguish, or distress on individuals through verbal or nonverbal acts. It is also called emotional abuse.

Psychological factors affecting medical conditions is a mental disorder characterized by emotional factors that worsen a medical condition.

Psychopathic personality is a mental disorder characterized as amoral behavior, inability to love and understand another's feelings (empathy), extreme self-centeredness, and failure to learn from experience. It is also known as psychopathy and psychopath.

Psychopharmacology is the study of drugs that affect thinking, feeling, and behavior. It includes antipsychotic, antianxiety, antidepressant, and antimanic medications.

Psychosis is a severe mental condition in which an individual loses touch with reality.

Psychotherapists offer a form of treatment known as talk therapy with individuals, couples, and families, in order to help clients overcome a wide range of psychological and emotional challenges. Employing a variety of theoretical approaches, psychotherapists work to build rapport and trust with clients in an effort to help them address maladaptive thought processes, feelings, and behavior.

Psychotherapy is a psychological method for achieving desired changes in thinking, feeling, and behavior. It is also called therapy and therapeutic counseling.

Psychotherapy integration is a psychotherapeutic process that involves a combination of psychotherapy techniques. It is based on the belief that there are common factors in nearly every treatment approach. The combining and integration of such techniques can create a synergistic effect that leads to more effective treatment.

Psychotic disorder is a severe mental disorder in which an individual loses touch with reality. Symptoms can include hallucinations (hearing or seeing things that are not there), delusions (fixed false beliefs that persist despite contrary evidence), and disordered thinking.

Psychotic features are characteristics of psychotic disorders: delusions, hallucinations, disorganized thinking and speech, grossly disorganized or abnormal motor behavior, and negative symptoms, for example, lack of initiative and diminished emotional expression.

Psychotropic medications are prescribed drugs that affect thinking, feeling, and behavior. These include antipsychotic, antianxiety, antidepressant, and antimanic medications.

Purging, in eating disorders, is a means of clearing the stomach and/or the intestines of material by the use of laxatives, diuretics, or self-induced vomiting.

Race refers to a socially constructed system of classifying individuals according to observable characteristics such as physical attributes (skin tone, height, eye shape, etc.) or language.

Racism is a socially shared belief that all members of a particular race possess characteristics that are inferior to another race, resulting in oppression.

Rational Emotive Behavioral Therapy (REBT), developed by Albert Ellis, is a form of psychotherapy based on the idea that problems are caused by irrational thoughts, beliefs, and expectations.

Reactive attachment disorder is a mental disorder characterized by disturbed and developmentally inappropriate social relatedness.

Receptive means able or willing to receive something, especially (new) signals or stimuli.

Recidivism, within criminal justice terms, refers to the behavior of individuals who relapse back into criminal behavior after having served jail time or some other form of criminal penalty.

Recovered memories are the apparent recollection of childhood abuse of which the person had no previous knowledge of prior to therapy.

Reduction is the action or fact of making something smaller or less in amount, degree, or size.

Reflex indicates an action that is performed as a response to a stimulus and without conscious thought.

Reggae is a musical style built on an irregular, offbeat rhythm accompanied by spoken-song lyrics. It is built on jazz and Rhythm & Blues traditions, breaking through to worldwide popularity in the late 1960s. Early reggae stars came primarily from Jamaica, but reggae is now performed worldwide. Songs often focus on social issues with a view toward illuminating injustices and inspiring marginalized peoples (particularly of African heritage) to take action and make changes.

Rehabilitation is the process of restoring to good health or improved quality of life through therapy or education.

Rehabilitation counseling is a type of counseling that focuses on helping individuals who have disabilities in order to achieve their career, personal, and independent living goals.

Rehabilitation counselors are certified counseling professionals who help people with emotional and physical disabilities live independently.

Reinforcement is a result of a behavior that will strengthen the likelihood of the behavior happening again in the future.

Relapse is the recurrence of symptoms after a period of improvement or recovery.

Relapse prevention is the effort to maintain health and prevent the recurrence of relapse.

Relaxation is the state of being free from tension and anxiety or the restoration of equilibrium following emotional disturbance.

Religion refers to the beliefs, doctrines, and practices associated with membership in a specific group or system that believes in a god or gods.

REM sleep is a stage in the normal sleep cycle characterized by rapid eye movement, dreaming, loss of reflexes, and increased brain activity. It is also known as rapid eye movement and REM sleep.

Repression is a Freudian defense mechanism in which memories of traumatic experiences are hidden from or "repressed" out of conscious awareness.

Reprocessing means to rethink, reorganize, and reconsider the meaning and significance of painful events.

Restless leg syndrome is a sleep disorder characterized by an irresistible urge to move one's legs while attempting to rest.

Retardation means the act, process, or condition of being delayed or impaired from an expected course of development.

Retirement, psychological factors, are the mental and emotional factors that impact individuals who are considering retirement or have retired from their occupation. They include well-being, self-worth, social supports and networking, goals and financial stability. An individual's perception of retirement can largely impact his or her ability to participate or enjoy in separating from the work environment.

Rituals are a series or sequence of actions and behaviors performed in a specific order.

Role-playing is a therapeutic technique which is designed to reduce the fear or discomfort that people experience in various social situations.

Sacred refers to those things that are holy, "set apart," and include objects, rites, and rituals.

Sand tray therapy is a nonverbal form of communicating thoughts, feelings, emotions, and worldviews through the use of specific materials, such as sand; a sand tray; and collection of miniatures, symbols, and figurines all guided by a trained therapist.

Satir, Virginia (1916–1988) was a pioneer in the family therapy movement. She was one of the first therapists to work with the entire family, instead of just individuals, and many

of her methods are still in use today. She is also remembered for her theories on family systems and how they affect individuals.

Schizoid personality disorder is a mental disorder characterized by a pattern of detachment from social relationships and a limited range of emotional expression.

Schizophrenia is a chronic mental disorder that affects behavior, thinking, and emotion and which makes distinguishing between real and unreal experiences difficult. Symptoms include hallucinations, delusions, thought and communication disturbances, and withdrawal from others.

Schizophrenia spectrum and other psychotic disorders are a group of mental disorders characterized by psychotic features. These disorders include schizophrenia, schizophreniform disorder, schizoaffective disorder, and schizotypal personality disorder, and delusional disorder.

Schizophreniform disorder is a psychotic disorder with the signs and symptoms of schizophrenia but with a total duration of less than six months.

Schizotypal personality disorder is a mental disorder characterized by a pattern of acute discomfort in close relationships, eccentric behaviors, and distorted thinking and feeling. It is also referred to as schizotypal and schizotypal personality.

Scope of practice includes the procedures, processes, and acts which professionals can legally use in their jobs.

Seasonal affective disorder is a mental disorder in which depression comes on during the late fall and winter and begin to lift during spring and summer. It is also called SAD, winter depression, and winter blues.

Secure attachment is an emotional bond between children and caregivers. Children with secure attachments trust their caregivers to meet their needs.

Sedatives are substances that have a soothing, calming, or tranquilizing effect.

Selective mutism is a mental disorder in which children or adolescents fail to speak in some social situations although they have the ability to talk normally at other times. Previously it was called elective mutism.

Selective serotonin norepinephrine reuptake inhibitors (SNRI) are medications that act on and increase the levels of serotonin and norepinephrine in the brain that influences mood. These differ from selective serotonin reuptake inhibitors which only act on serotonin.

Selective serotonin reuptake inhibitors (SSRI) They are a class of antidepressant medications that work by blocking the reabsorption of serotonin in nerve cells and raising its level in the brain resulting in symptom reduction.

Self-actualization is the highest level need at the top of Maslow's pyramid of needs and is based on the human desire for self-fulfillment once other, more basic needs have been met.

Self-control is the capacity for self-discipline. Some use this term interchangeably with willpower.

Self-help groups are a group of individuals, sometimes led by a therapist, who provide each other emotional support, information, and advice on problems relating to some shared concern such as an addiction. Alcoholics Anonymous is such a group.

Self-instruction, a strategy used in cognitive behavior modification, teaches an individual to actively engage in verbal self-prompting and then follow up with a related behavior or action.

Self-transcendence is the sense of going or being beyond oneself, of overcoming the limits of the physical self.

Separation anxiety disorder is an anxiety disorder characterized by excessive anxiety resulting from separation from those to whom a child is attached.

Serotonin is a chemical messenger in the brain that regulates learning, sleep, mood, and appetite. It is involved in disorders such as depression and anxiety.

Serotonin discontinuation syndrome results from the abrupt discontinuation of a SSRI medication. It is characterized by withdrawal symptoms such as anxiety, agitation, in-

somnia, nausea, vomiting, diarrhea, fatigue, vivid or bizarre dream, dizziness, and other sensory disturbances.

Sexual abuse involves non-consensual sexual contact of any kind, coercing an elder to witness sexual behaviors.

Sexual dysfunction disorders are a group of mental disorders characterized by significant difficulty in the ability to respond sexually or to experience sexual pleasure. Disorders include delayed ejaculation, female orgasmic disorder, and genito-pelvic pain/penetration disorder.

Shyness is a type of social withdrawal that results from fear and anxiety. It is described as wariness when confronted with novel social situations and/or self-conscious behavior in a social setting. Many view shyness as a subclinical condition or normal personality trait that is not pathological.

Sick role is the protective role given an individual with a medical or mental condition which accords them special treatment and excuses them from specific expectations or responsibilities.

Sleep is the body's rest cycle which is triggered by a group of hormones that respond to cues from the body itself and from the environment.

Sleep apnea is a temporary disruption or stoppage of breathing during sleep which can result in daytime sleepiness.

Sleep deprivation is a condition characterized by insufficient sleep, which if it is chronic, can cause fatigue, daytime sleepiness, and loss of concentration and productivity.

Sleep disorders are a group of mental disorders characterized by disturbance in the amount and quality of sleep and that cause significant emotional distress or interfere with daily functioning.

Sleep hygiene refers to the habits, practices, and nonmedical treatments for insomnia and which improve the quality of sleep.

Sleep paralysis is a condition in which individuals are aware of the surroundings but are unable to move when they awaken from sleep.

Sleep stages refers to five stages of sleep: 1, 2, 3, 4, and REM.

Sleep terror disorder is a sleep disorder characterized by repeated temporary arousal from sleep, during which the individual appears extremely frightened. This disorder is also known as night terrors and is often confused with nightmares and nightmare disorder.

Sleep–wake disorders are a group of mental disorders that are characterized by various sleeping disturbances including circadian rhythm sleep-wake disorder.

Sleepwalking is a condition in which individuals get up and walk around while still sleeping. In DSM-5 it is a diagnosable sleep disorder called a non-rapid eye movement (non-REM) sleep arousal disorder. Sleepwalking is also known as somnambulism.

Sober, in relation to alcohol and drug addiction, means not consuming alcohol, drugs, or engaging in other related addictive activities.

Sobriety refers to the state of being sober and of not having any mood altering substances such as drugs or alcohol in one's system.

Social means related to human society or its ways of being organized.

Social anxiety disorder is an anxiety disorder characterized by excessive and unreasonable fear in social situations of being judged or evaluated by others. It was previously referred to as social phobia.

Social inequality refers to the existence of unequal opportunities or distribution of resources because of social position or status with a social group.

Social Interest is one of Alfred Adler's key concepts that describes a feeling of community, when a person acts in the best interests of others as opposed to being consumed by their own personal needs and concerns.

Social skills training is treatment method that assists individuals to learn specific skills that are missing or those that will compensate for the missing ones.

Sociopathic personality is a mental disorder characterized by amoral and criminal behavior and a diminished sense of moral responsibility. It is also known as sociopathy and sociopath.

Somatic sensitivity refers to the high level of sensitivity and attentiveness to bodily sensations in some individuals leading them to overly focus on physical symptoms.

Somatic symptom and related disorders are a group of DSM-5 mental disorders characterized by prominent somatic symptoms and significant distress and impairment. They include somatic symptom disorder and factitious disorder. Previously they were known as somatoform disorders.

Somatic symptom disorder is a mental disorder characterized by bodily symptoms that are very distressing or result in disrupted functioning,

Somatization disorder is a mental disorder characterized by multiple bodily symptoms that cannot be explained by medical condition. This term is no longer used and has been replaced with somatic symptom disorder in DSM-5.

Somatoform disorders are a group of mental disorders characterized by physical symptoms that cannot be explained by a medical condition. DSM-5 calls them somatic symptom and related disorders.

Specific phobia is a mental disorder characterized by a marked and enduring fear of specific situations or objects. Previously this disorder was referred to as simple phobia.

Spectrum is the entire range over which some measurable property or observed phenomenon can vary.

Speech-language refers to verbal means of communicating.

Spirituality is the sum total of an individual's unique world- and self-view, religious beliefs, attitudes, and behaviors.

Splitting is the inability to synthesize (put together) contradictory qualities, such that the individual views others as either all good or all bad.

Spousal battering is a type of domestic violence which involves a systematic pattern of intimidation, control, terror and physical violence for the purpose of gaining total control over the partner.

SSRI stands for selective serotonin reuptake inhibitors. They are a class of antidepressant medications that work by blocking the reabsorption of serotonin in nerve cells and raising its level in the brain resulting in symptom reduction.

Standardized means something has been brought into conformity with a norm or standard.

Stereotype means to categorize, characterized, or group people into oversimplified and inaccurate classifications.

Stereotyping is an activity where people or events are classified according to conventional, formulaic, and oversimplified conceptions, opinions, or images.

Stigma is an identifying mark or characteristic especially of shame or discredit; often applied to the symptoms of psychological or mental health issues.

Stimulant use disorder is a mental disorder that is characterized by the use of stimulants that leads to significant problems for the user. It includes stimulants such as amphetamine and cocaine, but not caffeine or nicotine.

Stimulants are a class of drugs which increases brain activity and produces a sense of alertness, euphoria, endurance, and productivity, or suppress appetite. Examples are: cocaine, amphetamines, and Ritalin.

Strategic Family Therapy is a form of therapy that involves the whole family unit in a brief therapeutic intervention designed to bring about rapid change. The therapist plays the leading role, with the family members completing various tasks to shift their systems of interaction toward the contracted outcome.

Stress is the psychological, emotional, and physical state of strain resulting from negative appraisals of events, situations, and circumstances.

Stress management is a set of psychological techniques for increasing the capacity to better cope with psychological stress. It usually includes relaxation methods.

Structural Family therapy looks at the organization of a family.

Stuttering is talking with continued involuntary repetition of sounds, especially initial consonants.

Subconscious is that part of the conscious mind which consists of information that is not in awareness unless attention is directed to it. It is also called the preconscious.

Substance abuse involves the use of substances (drugs or alcohol) in amounts or with methods that are harmful.

Substance-induced psychotic disorder is a mental disorder characterized by hallucinations or delusions caused by the use of or withdrawal from substance like alcohol or cocaine. It is referred to as substance/medication-induced psychotic disorder in DSM-5.

Substance-related and addictive disorders are a group of DSM-5 mental disorders that include substance disorders characterized by physiological dependence, drug-seeking behavior, tolerance, and social withdrawal. It also includes the non-substance disorder of gambling.

Substance use disorders are a category of conditions associated with the continued use of substances, such as alcohol or drugs, despite causing significant cognitive, social, behavioral, and psychological consequences.

Support means to help bear the weight of something, psychologically especially applied to bearing the burden of diseases or losses.

Symptoms are physical or mental features that are regarded as indicating a condition of disease, or of an undesirable situation.

Syndrome is a group of symptoms that consistently occur together or a condition characterized by a set of associated symptoms.

Systematic desensitization is form of cognitive behavior therapy that gradually exposes individuals to their phobia (fear) while remaining calm and relaxed.

Systemic abuse refers to the existence and maintenance of social inequalities due to a larger system such as the laws, policies, and practices of the land.

Target is the individual who is the recipient or victim of bullying or mobbing.

Temper tantrums are disruptive behaviors or emotional outbursts displayed in response to unmet needs or desires.

Theology refers to the study of and concepts about the nature of God.

Theoretical integration is the assimilation of two or more theories of psychotherapy.

Theory refers to a body of knowledge, or set of principles, that explains the phenomenon in question.

Therapeutic is of or relating to the healing of disease

Therapy means treatment intended to relieve or heal mental or psychological disorders.

The Three Faces of Eve was both a bestselling book and a major motion picture. The movie, starring Joanne Woodward, first appeared in theaters in 1957 but remains a classic to this day. Woodward won a Best Actress Oscar and Golden Globe award for her role as Eve, a young, unassuming Georgia housewife suffering from "multiple personalities," a term currently known in the DSM-5 as dissociative identity disorder.

Tics are involuntary, compulsive, repetitive and stereotyped movements or vocalizations. While they are experienced as irresistible, they can be temporarily suppressed.

Tolerance refers to the need for higher doses of a substance or more frequent engagement in an behavior to achieve the same effect.

Tourette's Syndrome is a neurological disorder characterized by recurrent involuntary movements and vocal tics such as grunts, barks, or words, including obscenities.

Trance is an altered mental state of consciousness in which a person experiences heightened concentration with a greater ability to block out distractions.

Transcendence refers to the perception that there are extraordinary dimension to life that go beyond the limits of our physical reality.

Transcendent means going beyond the physical realm and exceeding conventional limits of ordinary consciousness and personal identity.

Trauma is a singular or recurrent event that is both extraordinary and severely distressing. It is also called traumatic event. This can include abuse, domestic violence, medical trauma, accidents, acts of terror, war experiences, natural and man-made disasters.

Trauma symptoms are any symptoms (anxiety, angry outburst, depression, etc.) that occurs as a result of a severely distressing event.

Trauma and stressor-related disorders are a group of mental disorders characterized by exposure to a traumatic or stressful event. These include post-traumatic stress disorder, reactive attachment disorder, and disinhibited social engagement disorder.

Traumatic brain injury is an insult or injury to the brain from an external force. In DSM-5, this disorder is known as neurocognitive disorder due to traumatic brain injury.

Treatment noncompliance is the phrase used when individuals fail to follow treatment instructions, regimens, or advice. It is also known as non-adherence.

Triggers are situations that activate memories and emotional states associated with a past traumatic event.

Twelve-Step Program is a self-help group whose members attempt recovery from various addictions based on a plan called the 12 Steps.

Twelve Steps refers to the 12 guiding principles on which Alcoholics Anonymous is based.

Twelve Traditions are the rules that govern how Twelve-Step Program groups operate.

Unconscious is the part of the conscious mind which consists of the primitive, instinctual wishes and information that operates without awareness and over which one does not have active control.

Vaginismus is the inability to allow vaginal penetration because of anxiety and fear of pain.

Values are principles that govern virtuous behavior. When values are lived or put in action they are known as virtues.

Vocation is a person's employment, trade, or main occupation.

Vocational counseling is therapy for people looking to obtain or maintain work.

Vygotsky, Lev (1896–1934) is considered one of the most significant and influential educational psychologists of the late 20th and early 21st centuries. He has been credited as the key figure in developing a social constructivist understanding of psychological development.

Well-being is the state of being happy, healthy, or successful.

Wellness is the state or condition of being in good physical and mental health and steps to promote it.

Willpower is the ability to resist a short-term temptation in order to achieve a long-term goal. It also involves the ability to delay gratification.

Withdrawal is the unpleasant and potentially life-threatening physiological changes reaction (e.g., cravings, depression, pain, trembling, and hallucinations) that occur due to the discontinuation of certain drugs after prolonged regular use.

Wundt, Wilhelm (1832–1920) is often referred to as the father of experimental psychology. His most notable achievement was to demonstrate that psychology can be a valid experimental science as described in his influential book, *Principles of Physiological Psychology*.

Yoga is a spiritual and ascetic discipline founded in India, a part of which, including breath control, simple meditation, and the adoption of specific bodily postures, is widely practiced for health and relaxation.

Zimbardo, Philip (1933–) is the psychologist best known for the controversial Stanford Prison Experiment which involved testing the reactions of male volunteers recruited for the roles of either guard or prisoner in a simulated prison environment. With the flip of a coin, the young men were divided into two groups—prisoners and guards. This study has offered an incisive explanation for dehumanizing conditions of the penal system.

Zone of proximal development is the brainchild of the Jewish Russian psychologist Lev Vygotsky (1896–1934). The premise is that whenever children undergo a significant developmental change, they must go through a period of time—or zone—when they strive to make sense of what they've learned.

About the Editors and Contributors

Editor-in-Chief

Len Sperry, MD, PhD, is currently professor of mental health counseling and director of clinical training at Florida Atlantic University and clinical professor of psychiatry and behavioral medicine at the Medical College of Wisconsin. He is board certified in psychiatry, in general preventive medicine, and in clinical psychology, and is a Fellow of the American Psychiatric Association, the American College of Preventive Medicine, and the American Psychological Association. He is the editor-in-chief of the *American Journal of Family Therapy* and co-editor of *Spirituality in Clinical Practice*. His more-than-1,000 professional publications include refereed journal articles, book chapters, and 76 professional books.

Associate Editors

Alexandra Cunningham, PhD, is assistant professor of psychology at Lynn University in Boca Raton, FL. She is a licensed mental health counselor and clinical consultant for the Center for Autism and Related Disabilities. Her experience, research, and specialization is in working with parents and individuals affected by autism to enhance their social relationships, including friendships and romantic relationships.

Melissa A. Mariani, PhD, is an assistant professor in the Department of Counselor Education at Florida Atlantic University in Boca Raton, Florida. She has more than 10 years of experience as a professional school counselor and guidance coordinator at the elementary and middle school levels. She writes and presents use of data-driven decision making to positively impact student outcomes.

Mindy Parsons, PhD, is a therapist in private practice in Delray Beach, Florida, where she specializes in working with families and children. Dr. Parsons earned her master's degree and PhD in counseling at Florida Atlantic University. She also teaches graduate counseling courses at both Florida Atlantic University and Lynn University in Boca Raton, Florida.

Steven R. Vensel, PhD, is an assistant professor at Palm Beach Atlantic University in West Palm Beach, Florida. He received his PhD in counseling from Florida Atlantic

University. His research interests include abusive religious organizations, workplace mobbing and bullying, forced terminations, and its impact on targets and their families. He has maintained a clinical practice for the past 25 years.

Contributors

Jeremy Connelly, MEd, is a graduate student and researcher at Florida Atlantic University. His academic interests include personality dynamics and nonverbal behavior as factors in therapeutic outcomes. He is also a provisional private practitioner in South Florida.

William M. Cunningham, MA, received his master's degree from the Aquinas Institute in St. Louis and was an ethics professor at several universities, a hospital chaplain, and a master teacher of quality improvement initiatives in both health care and manufacturing.

Elizabeth Smith Kelsey, PhD, is the managing editor of *The American Journal of Family Therapy*. She completed her PhD in counseling from Florida Atlantic University. Her academic interests include addiction, case conceptualization, and individual and family therapy.

Christina Ladd, PhD, is a licensed mental health counselor in private practice in South Florida. She completed her PhD in counseling at Florida Atlantic University. Her academic interests are in case conceptualization and teaching competency-based psychotherapy skills.

Ashley J. Luedke, PhD, is an assistant professor of counseling and educational psychology at the University of Nevada, Reno. She completed her PhD in counseling at Florida Atlantic University. She is actively involved in clinical research and is a licensed mental health counselor.

Layven Reguero, MEd, completed his master's degree in clinical mental health counseling at Florida Atlantic University and is doctoral student in clinical psychology at Palo Alto University in California.

Jon Sperry, PhD, is an assistant professor of psychology at Lynn University and also a staff therapist at the Counseling and Psychological Services at Florida Atlantic University in Boca Raton, Florida. He is licensed psychotherapist and a certified addictions professional.

George Stoupas, MS, is an associate professor of psychology at Palm Beach State College in Florida, and a licensed mental health counselor and certified addiction professional. He is a doctoral student in Counseling at Florida Atlantic University.
