Luciano Gattinoni
Mervyn Singer

OXFORD

Oxford Textbook of

Critical Care

Free personal online access for 12 months

Individual purchasers of this book are also entitled to free personal access to the online edition for 12 months on *Oxford Medicine Online* (www.oxfordmedicine.com). Please refer to the access token card for instructions on token redemption and access.

Online ancillary materials, where available, are noted at the end of the respective chapters in this book. Additionally, *Oxford Medicine Online* allows you to print, save, cite, email, and share content; download high-resolution figures as Microsoft PowerPoint slides; save often-used books, chapters, or searches; annotate; and quickly jump to other chapters or related material on a mobile-optimized platform.

We encourage you to take advantage of these features. If you are interested in ongoing access after the 12-month gift period, please consider an individual subscription or consult with your librarian.

Oxford Textbook of

Critical Care

SECOND EDITION

Edited by

Professor Andrew Webb, MD, FRCP, MFMLM

Clinical Professor, Division of Critical Care, Faculty of Medicine,
The University of British Columbia, Canada

Professor Derek C. Angus, MD, MPH, FRCP

Distinguished Professor and Mitchell P. Fink Endowed Chair

Department of Critical Care Medicine

University of Pittsburgh and UPMC Health System

Professor Simon Finfer, MBBS, FAHMS, FRCP, FRCA, FCICM, DrMed

Professor of Critical Care, The George Institute for Global Health, University of Sydney

Senior Staff Specialist in Intensive Care, Royal North Shore Hospital, Sydney

Professor Luciano Gattinoni, MD FRCP

Chief of the Department of Anaesthesia, Resuscitation and Emergency Medicine,
Fondazione IRCCS Ca' Granda—Ospedale Maggiore Policlinico

Full Professor in Anesthesiology and Intensive Care Medicine, Department
of Pathophysiology and Transplantation, University of Milan

Professor Mervyn Singer, MD FRCP, FRCP, FFICM

Professor of Intensive Care Medicine, University College London

Asia Pacific Offset Ltd

Foreword

One may ask in today's internet-based world whether there is still a need for textbooks when there is so much opinion and advice already available online. Although possibly not able to capture and include the very latest research results, textbooks provide a solid basis and background of the subject in question giving an essential framework of understanding on which to build. This *Oxford Textbook of Critical Care* is a true example of quality. All the authors are well-known experts in their field, the chapters have all been carefully reviewed and the contents are, therefore, relevant and reliable. What is more, as with many recent publications, this textbook is also available as an online version for easy reference.

This completely revised and comprehensive version of the 1999 edition covers all possible aspects of intensive care medicine making it an impressive tome. The chapters are short, concise and to the point, and thus easy to read and understand. The book is well-illustrated and the layout is fresh and attractive. The key points, highlighted at the start of each chapter, provide a useful summary of each topic and the book in general is clinically-orientated, making it of value for the practicing clinician, as well as physicians in training. The book benefits from an impressive list of true experts from around the globe, giving it international appeal and insight—it is a real credit to the editors that so many leading authorities have contributed!

I believe textbooks still have an important role in providing a trustworthy source of knowledge. As different textbooks will have a slightly different focus, include different authors, and use various presentation formats they can complement each other. This book will occupy an important place in this field and is a highly recommended reference for all involved in the care of critically-ill patients.

Jean-Louis Vincent, MD PhD
Professor of Intensive Care Medicine, Université Libre de Bruxelles

Preface

Since the first edition of the *Oxford Textbook of Critical Care* was published there have been many advances in our understanding and management of critical illness. We prefaced the first edition with a note on the exacting nature of critical care; the holistic complexity of the patient with multisystem dysfunction, the out-of-hours commitment, the often stressful and highly charged situations requiring considerable agility of brain and hand, and the continuing evolution (and occasional revolution) in perceived 'best practice'. However, these challenging demands are precisely what attract the critical care practitioner to the specialty. The importance of strong support mechanisms—from colleagues, from national and international societies, and from robust educational and research outputs—is paramount to not only sustain but also enhance the quality of care given.

Recognizing the increasing use of electronic media for reference, we have continued the format used in the first edition. The traditional chapter layout of a textbook gave way to system-orientated sections. Each section has been subdivided into short topics grouped within the section according to clinical problems. We believe the reader will often come to this book, in paper or electronic format, wishing to update on a specific clinical problem that matches an issue experienced at the bedside. Furthermore, this layout facilitates manageable and relevant searches in electronic media.

The *Oxford Textbook of Critical Care* is a single-volume major reference book aiming to cover the breadth of clinical and organizational aspects of adult critical care medicine in readable chunks. We clearly acknowledge that every single topic cannot possibly be covered in detail, but hope its comprehensive nature will be found useful by all health care providers who look after critically-ill patients.

We recognize there are often local, national, and international differences in philosophy and management strategy. Some of these differences are seemingly contradictory and it is often difficult for physicians in one country to assimilate information produced for another. We intended from the outset to offer the *Oxford Textbook of Critical Care* as an international text. We have attempted to give a balanced view where international differences exist and, in many cases, have sat squarely on the fence. We make no apology for this since we believe the book should inform rather than dictate.

Producing this edition has been a mammoth task, co-ordinating the efforts of over 600 authors from all corners of the world. We thank all those who have contributed to this project and to members of the staff of Oxford University Press for persuading us to take on this second edition, and whose skill and support have been essential to the editorial and production process. Finally, the editors are saddened to hear of the passing of Dr Mitchell Fink, Prof Albert Jaeger and Dr Jan Kornder since the submission of their contributions to the book.

Contents

SECTION 4
The respiratory system

PART 4.1
Physiology

PART 4.2
Respiratory monitoring

PART 4.3
Upper airway obstruction

PART 4.4
Airway access

PART 4.5
Acute respiratory failure

PART 4.6
Ventilatory support

SECTION 12
The skin and connective tissue

PART 12.1
Skin and connective tissue disorders

PART 12.2
Wound and pressure sore management

SECTION 13
Infection

PART 13.1
Diagnosis and surveillance

PART 13.2
Nosocomial infection

PART 13.3
Infection in the immunocompromised

PART 13.4
Tropical diseases

Abbreviations

18F-FDG	fluorine-18 fluorodeoxyglucose
5-HIAA	5-hydroxyindoleacetic acid
5HT	5-hydroxytryptamine
A–a PO2	alveolar–arterial oxygen gradient
AA	amino acids
AAA	abdominal aortic aneurysm
AACN	American Association of Critical Care Nurses
AAD	anti-arrhythmic drugs
AAG	alpha 1-acid glycoprotein
AAN	American Academy of Neurology
AAOS	American Academy of Orthopedic Surgeons
AASLD	American Association for the Study of Liver Disease
AST	aspartate aminotransferase
ABA	American Burn Association
ABC	Airway, Breathing Circulation
ABCD	airway, breathing, circulation, and disability
ABCDE	airway breathing circulation disability exposure
ABG	arterial blood gas
ABLE	age of blood evaluation
ABM	acute bacterial meningitis
ABO	red cell antigen
AC	assist control
ACA	American College of Cardiology
ACCM	American College of Critical Care Medicine
ACD	active compression-decompression
ACE	angiotensin-converting enzyme
ACH	air changes per hour
AChR	acetylcholine receptors
AChS	acute chest syndrome
ACLF	acute on chronic liver failure
ACLS	advanced cardiac life support
ACOS	Adult Respiratory Distress Cognitive Outcomes
AcPC	activated protein C
ACR	acute cellular rejection
ACS	acute coronary syndrome
ACT	activated clotting time
ACTH	adrenocorticotropic hormone
AD	autonomic dysreflexia
ADC	apparent diffusion coefficient
ADE	antibody dependent enhancement
ADH	antidiuretic hormone
ADHD	attention-deficit hyperactivity
ADL	activity of daily living
ADMA	asymmetric dimethylarginine
ADP	adenosine diphosphate
ADQI	Acute Dialysis Quality Initiative
AED	automatic external defibrillator
AEP	auditory-evoked potentials
AF	atrial fibrillation
AFE	amniotic fluid embolism
AFLP	acute fatty liver of pregnancy
AG	anion gap
AG_c	anion gap corrected
AGE	advanced glycosylation end-products
AGEP	acute generalized exanthematouspustulosis
AHA	American Heart Association
AHF	acute heart failure
AHL	acyl-homoserine-lactones
AHR	adjusted hazard ratio
AIDP	acute inflammatory demyelinating polyradiculoneuropathy
AIDS	acquired immune deficiency syndrome
AIH	autoimmune hepatitis
AIHA	auto-immune haemolytic anaemia
AIIR	airborne infection isolation room
AIVR	accelerated idioventricular rhythm
AJ	adherens junction
AKI	acute kidney injury
AKIN	Acute Kidney Injury Network
ALDH	alcohol dehydrogenase
ALF	acute liver failure
ALI	acute lung injury
ALL	acute lymphoblastic leukaemia
ALS	advanced life support
ALT	alanine transaminase
AMAN	acute motor axonal neuropathy
AML	acute myeloid leukaemia
AmLS	amyotrophic lateral sclerosis
AMOFS	acute multi-organ failure syndrome
AMPA	α-amino-3-hydroxy-5-methyl-4-is axazole-proprionic acid
AMS	acute mountain sickness
AMSAN	acute motor and sensory axonal neuropathy
ANA	antinuclear antibody
ANCA	anti-neutrophil cytoplasmic antibodies

ANP	atrial natriuretic peptide
ANT	adenine nucleotide translocase
AP	action potential
APACHE	Acute Physiology and Chronic Health Evaluation
APC	argon plasma coagulation
APE	acute pulmonary embolism
APF	alveolopleural fistula
APL	acute promyelocytic leukaemia
APP	abdominal perfusion pressure
aPPT	activated partial thromboplastin time
APR	acute phase reaction
APRV	airway pressure release ventilation
APS	Acute Physiology Score
APSAC	acylated plasminogen-streptokinase activator complex
APTT	activated partial thromboplastin time
AR	aortic regurgitation
ARB	angiotensin II receptor blockers
ARDS	acute respiratory distress syndrome
ARF	acute respiratory failure
ARS	acute radiation syndrome
ART	assisted reproductive technology
AS	mitral stenosis
aSAH	aneurysmal subarachnoid haemorrhage
ASA-PS	American Society of Anesthesiologists Physical Status
ASC	active surveillance cultures
ASIA	American Spinal Injury Association
ASPEN	American Society for Parenteral and Enteral Nutrition
AST	aspartate transaminase
AT	antithrombin
ATC	acute traumatic coagulopathy
ATCH	adrenocorticotrophic hormone
ATh	anaerobic threshold
ATICE	Adaptation to the Intensive Care Environment
ATLS	advanced trauma life support
ATN	acute tubular necrosis
ATP	adenosine triphosphate
ATS	American Thoracic Society
ATSe	antitetanus serum
AUC	area under the curve
AUIC	area under the inhibitory curve
AUROC	area under the receiver operating characteristic curve
AV	atrioventricular
AVM	arteriovenous malformations
AVNRT	atrioventricular nodal re-entry tachycardia
AVP	arginine-vasopressin
AVR	aortic valve replacement
AWS	acute withdrawal syndrome
BABT	behind armour blunt trauma
BabyBIG-IV	baby botulinum immune globulin
BAL	broncho-alveolar lavage
BARTS	battlefield advanced resuscitation techniques and skills
BATLS	battlefield advanced trauma life support
BB	β blocker
BBB	blood–brain barrier
BBP	blood-borne pathogens
BCG	Bacillus Calmette–Guérin
BCNE	blood culture-negative endocarditis
BD	base deficit
bd	twice daily
BDE	base deficit/excess
BDG	base deficit gap
BDI-II	Beck Depression Inventory-II
BDNF	brain-derived neurotrophic factor
BDZ	Benzodiazepine
BE	base excess
BEE	basal energy expenditure
BiLE	bilirubin, lactate, and aetiology score
BIPAP	bi-phasic positive pressure
BIS	bispectral index
BiV	biventricular
BiVAD	biventricular assist device
BKCa	large conductance calcium-activated potassium
BLS	basic life support
BMI	body mass index
BMPR	bone morphogenetic protein receptor
BMR	basic metabolic rate
BMT	bone marrow transplants
BNP	B-type natriuretic peptide
BOS	bronchiolitis obliterans syndrome
BP	blood pressure
BPS	behavioural pain scale
BPW	biphasic waveform
BRAIN-ICU	Bringing to Light the Risk Factors and Incidence of Neuropsychological Dysfunction in ICU
BSA	body surface area
BSI-30	Brief Symptom Inventory-30
BSS	balanced salt solutions
BTE	biphasic truncated exponential
BTF	Brain Trauma Foundation
BUN	blood urea nitrogen
BVM	bag valve mask
BW	body weight
C	compliance
CA	carbonic anhydrase
CA-AKI	contrast-associated acute kidney injury
CAB	circulation, airway and breathing
CABG	coronary artery bypass grafting
CAD	coronary artery disease
CaMK	calcium/calmodulin-dependent protein kinases
cAMP	cyclic adenosine monophosphate
CA-MRSA	community-acquired methicillin-resistant Staphylococcus aureus
CAP	community-acquired pneumonia
CARS	compensatory anti-inflammatory syndrome
cART	combination antiretroviral therapy
CAUTI	catheter-associated urinary tract infections
CBF	cerebral blood flow
CBG	corticosteroid-binding globulin
CBV	cerebral blood volume
CC	closing capacity
CCB	calcium channel blocker (163)
CCHR	Canadian CT Head Rule
CCI	chronic critical illness

CCK	cholecystokinin
CCM	critical care medicine
CCTV	closed circuit televisions
CD	collecting duct
CDC	Centers for Disease Control
CDI	cranial diabetes insipidus
CDS	clinical decision support
CDSS	computerized decision support systems
cEEG	continuous EEG monitoring
CEPD	chronic equilibrated peritoneal dialysis
CES-D	Center for Epidemiological Studies Depression Scale
CEUS	contrast-enhanced ultrasonography
CFPD	continuous flow peritoneal dialysis
CFTR	cystic fibrosis transmembrane conductance regulator
CG	Cockcroft-Gault
cGM	continuous glucose monitors
CgMD	congenital muscular dystrophies
cGMP	cyclic guanosine monophosphate
CGRP	calcitonin gene-related peptide
CHEST	Crystalloid versus Hydroxyethyl Starch Trial
CHF	congenital heart failure
CHR	reticulocyte haemoglobin concentration
CHS	cerebral hyperperfusion syndrome
CI	confidence interval
CICal	circulatory indirect calorimetry
CIDP	chronic inflammatory demyelinating polyneuropathy
CIM	critical illness myopathy
CINM	critical illness neuromyopathy
CINV	chemotherapy-induced nausea and vomiting
CIP	critical illness polyneuropathy
CIPN	chemotherapy-induced peripheral neuropathy
CIRCI	critical illness-related corticosteroid insufficiency
CK	creatine kinase
CKD	chronic kidney disease
CKD-EPI	CKD Epidemiology Collaboration
CKMB	creatinine kinase MB isozyme
CLABSI	central line-associated bloodstream infections
CLD	chronic lung disease
CLP	caecal ligature and puncture
CLR	C-type lectin receptors
CLS	combat lifesaver
Cmax	maximum concentration
CMD	cerebral microdialysis
CML	chronic myelogenous leukaemia
CMRO2	cerebral metabolic rate for oxygen
CMV	cytomegalovirus
CN	cyanide
CNS	central nervous system
CO	cardiac output
CoA	coenzyme A
COHb	carboxyhaemoglobin
COMPACCS	Committee on Manpower of Pulmonary and Critical Care Societies.,
CoNS	Coagulase-negative staphylococci
COPD	chronic obstructive pulmonary disease
COPE	Critical Care Outcome Prediction Equation
COX	cyclo-oxygenase
CP	cancer procoagulant
CPA	cardiopulmonary arrest
CPAP	continuous positive airway pressure
CPAx	Chelsea Critical Care Physical Assessment Tool
CPB	cardiopulmonary bypass
CPE	cardiogenic pulmonary oedema
CPET	cardiopulmonary exercise testing
CPIS	Clinical Pulmonary Infection Score
CPK	creatinine phosphokinase
CPOE	computerized physician order entry
CPP	cerebral perfusion pressure
CPR	cardiopulmonary resuscitation
CR	complement receptors
CR-BSI	catheter-related blood stream infections
CrCl	creatinine clearance
CRE	carbapenem-resistant enterobacteriaceae
CRF	corticotropin-releasing factor
CRH	corticotropin-releasing hormone
CRM	crew resource management
$CRMP_2$	collapsin response mediator protein 2
CRP	C-reactive protein
CRRT	continuous renal replacement therapy
CS	cardiogenic shock
CSA	compressed spectral array
CSCI	cervical spinal cord injury
CSF	cerebral spinal fluid/cerebrospinal fluid
CSS	Churg–Strauss syndrome
CSV	continuous spontaneous ventilation
CSW	cerebral salt wasting
CSWS	cerebral salt wasting syndrome
CT	computed tomography
CTA	computed tomography angiography
CTEPH	chronic thromboembolic pulmonary hypertension
CTP	Child–Turcotte–Pugh
CT-PA	computed tomographic pulmonary angiography
CTSI	CT severity index
CUS	compression ultrasonography
CUSP	Comprehensive Unit-based Safety Programme
CV	closing volume
CVA	cerebrovascular accident
CVC	central venous catheter
CVD	cerebrovascular disease
CVP	central venous pressure
CVS	cardiovascular system
CVVH	continuous veno-venous haemofiltration
CXR	chest X-ray
CyC	cystatin C
CYP	cytochrome-P450 superfamily
DA&O	Disclosure, Apology and Offer
DAF	decay-accelerating factors
DAI	diffuse axonal injury
DALY	disability-adjusted life years
DAPT	dual antiplatelet therapy
DAT	direct antiglobulin test
DBD	donation after brain death
dBP	diastolic blood pressure
DC	dendritic cells
DCCV	direct current cardioversion

DCR	damage control resuscitation
DCS	decompression sickness
DCT	distal convoluted tubule
DDAVP	desamino-D-arginine vasopressin
DECT	dual-energy CT
deoxyHb	deoxyhaemoglobin
DGA	diglycolic acid
DSA	digital subtraction angiography
DH	dorsal horn
DHA	docosahexaenoic acid
DHP	dihydropyridine
DI	diabetes insipidus
DIC	disseminated intravascular coagulation
DILI	drug-induced liver injury
DIS	daily interruption of continuously infused sedative
DKA	diabetic ketoacidosis
DL	decompressive laparotomy
DLBCL	diffuse large B cell lymphoma
DMARD	disease-modifying anti-rheumatic drug
DMD	Duchenne muscular dystrophy
DMV	difficult mask ventilation
DNAR	Do Not Attempt Resuscitation
DND	delayed neurological deficits
DNR	Do Not Resuscitate
DO_2	oxygen delivery
DPA	diagnostic peritoneal aspirate
DPG	diphosphoglycerate
DPL	diagnostic peritoneal lavage
DSS	dengue shock syndrome
DSV	Dengue Strain Virulence
DTI	diffusion tensor imaging
DTPA	diethylenetriaminepentaacetate
DVT	deep vein thrombosis
DWI	diffusion-weighted imaging
EA	endotracheal aspirates
EACA	Epsilon amino-caproic acid
EBL	Endoscopic band ligation
EBM	evidence-based medicine
EBP	evidence-based practice
EBV	Epstein–Barr virus
EC	extracellular
$ECCO_2R$	extracorporeal carbon dioxide removal
ECDC	European Centre for Disease Control
ECF	extracellular fluid
ECG	electrocardiogram
ECLA	extracorporeal lung assist
ECLS	extra-corporeal life support
ECMO	extracorporeal membrane oxygenation
ECPR	extracorporeal cardiopulmonary resuscitation
ECT	electroconvulsive therapy
ED	emergency department
EDD	extended daily dialysis
EDP	end-diastolic pressure
EDTA	ethylenediaminetetraacetic acid
EDV	end-diastolic volume
EE	energy expenditure
EEG	electroencephalogram
ETT	endotracheal tube
eFAST	extended focused assessment with sonography for trauma
EFIC	exception from informed consent
EGA	extraglottic airway devices
EGDT	early goal-directed therapy
EGF	epidermal growth factor
EGL	endothelial glycocalyx layer
EGNB	enteric gram-negative bacteria
EGPA	eosinophilic granulomatosis with polyangiitis
EHEC	enterohaemorrhagic E. coli
EHF	Ebola Haemorrhagic Fever
EI	emotional intelligence
EIA	enzyme immunoassays
eICU	electronic intensive care unit
ELAD	extracorporeal liver assist device
ELNEC	The End-of-Life Nursing Education Consortium
EMG	electromyography
EMR	electronic medical record
EMS	emergency medical services
EN	enteral nutrition
EOL	end-of-life
EPA	eicosapentaenoic acid
EPAP	expiratory positive airway pressure
EPCR	endothelial protein C receptors
EPIC	European Prevalence of Infection in Intensive Care
EPIC II	Extended Prevalence of Infection in Intensive Care
EPP	exposure prone procedures
EQ	emotional quotient
EQ-I	Emotional Quotient Inventory
ER	endoplasmic reticulum
ERC	European Resuscitation Council
ERCP	endoscopic retrograde cholangiopancreatography
ERP	enhanced recovery programmes
ERV	expiratory reserve volume
ESA	erythropoiesis stimulating agent
ESBL	extended spectrum beta lactamase
ESKD	end stage kidney disease
ESL	endothelial surface layer
ESLD	end-stage liver disease
ESPEN	European Society for Clinical Nutrition and Metabolism
ESPVR	end-systolic pressure volume relationship
ESRD	end-stage renal disease
ET	endotracheal
ET-1	endothelin-1
ETA	endothelin-1 receptor antagonists
ETC	oesophageal tracheal combitube
$ETCO_2$	end-tidal CO_2
ETT	endotracheal tube
EUS	endoscopic ultrasound
EVD	external ventricular drain
EVL	endoscopic variceal ligation
EVLW	extravascular lung water
EVLWI	extravascular lung water index
FABP	fatty acid binding protein
FACTT	Fluid and Catheter Treatment Trial
$FADH_2$	flavin adenine dinucleotide
FAST	focused assessment with sonography for trauma
FCCS	Fundamental Critical Care Support

FCD	functional capillary density
FDP	fibrin degradation products
FEAST	fluid expansion as supportive therapy
FES	fat embolism syndrome
FET	forced expiratory technique
FFA	free fatty acid
FFM	fat-free mass
FFP	fresh frozen plasma
FFS	five factor score
FGR	fetal growth restriction
FHVP	free hepatic venous pressure
FIM	Functional Independence Measure
F_IO_2	fraction of inspired oxygen concentration
FLAIR	fluid attenuated inversion recovery
fMRI	functional magnetic resonance imaging
FMV	facemask ventilation
FNHTR	febrile non-haemolytic transfusion reactions
FO	fluid overload
FO_2Hb	fractional saturation of haemoglobin
FPR	false positive rate
FRC	functional residual capacity
FSH	follicle-stimulating hormone
FST	forward surgical teams
FT3	free triiodothyronine
FT4	free thyroxine
FTc	corrected flow time
FV	flow velocity
FVC	forced vital capacity
GABA	γ-aminobutyric acid
GAD	generalized anxiety disorder
GAG	glycosaminoglycan
GALT	gut-associated lymphoid tissue
GAVE	gastric antral vascular ectasia
GBS	Glasgow Blatchford score
GBStr	group B Streptococci
GC	glucocorticoids
GCS	Glasgow Coma Scale
G-CSF	granulocyte colony-stimulating factor
GDFT	goal-directed fluid therapy
GDS	Geriatric Depression Scale
GDT	goal-directed therapy
GEDV	global end-diastolic volume
GEDVI	global end-diastolic volume index
GFAP	glial fibrillary acidic protein
GFR	glomerular filtration rate
γGT	gamma-glutamyltransferase
GH	growth hormone
GHB	gammahydroxybutyrate
GHRH	growth hormone releasing hormone
GI	gastrointestinal
GIP	glucose-dependent insulinotropic peptide
GLA	γ-linolenic acid
GLC	gas liquid chromatography
GLP-1	glucagon-like peptide-1
GLP-2	glucagon-like peptide-2
GLUT	glucose transporter
GM-CSF	granulocyte-macrophage colony-stimulating factor
GNB	Gram-negative bacilli
GnRH	gonadotropin-releasing hormone
GOS	Glasgow outcome scores
GPA	granulomatosis with polyangiitis
GR	glucocorticoid receptors
GRADE	Grading of Recommendations, Assessment, Development, and Evaluation
GRE	glucocorticoid response element
GRV	gastric residual volumes
GSH	glutathione
GST	pi-glutathione-S-transferase
GS-VL	GlideScope® videolaryngoscope
GTN	glyceryltrinitrate
GuBS	Guillain–Barré syndrome
GVHD	graft-versus-host disease
GVO	gastric varicealobturation
GWA	genome-wide association
GWAS	genome-wide association studies
H2RA	histamine-2-receptor antagonist
HA	hepatic artery
HAAF	hypoglycaemia-associated autonomic failure
HABR	hepatic arterial buffer response
HACO	high altitude cerebral oedema
HADS	Hospital Anxiety and Depression Scale
HAI	health care-associated infection
HAP	hospital-acquired pneumonia
HAPO	high altitude pulmonary oedema
HAT	haemorrhage after thrombolysis
HAV	hepatitis A
Hb	haemoglobin concentration
HBcAg	hepatitis B core antigen
HBeAg	hepatitis B envelope antigen
HBO	hyperbaric oxygen therapy
HbO_2	haemoglobin-bound O2
HBsAg	hepatitis B surface antigen
HCC	Hepatocellular carcinoma
HCN	hydrogen cyanide
Hct	haematocrit
HCV	hepatitis C virus
HCW	health care worker
HDL	high-density lipoprotein
HDU	high-dependency unit
HDV	hepatitis D
HE	hepatic encephalopathy
HEAA	hydroxyethoxyacetic acid
HELICS	Hospital Infection Link for Infection Control through Surveillance
HELLP	haemolysis, elevated liver enzymes, low platelets
HEPA	high efficiency particulate air
HES	hydroxyethyl starch
HEV	hepatitis E
HF	haemofiltration
HFE	human factors engineering
HFMD	hand, foot, and mouth disease
HFOV	high-frequency oscillatory ventilation
HFPV	high-frequency percussive ventilation
HFRS	Haemorrhagic Fever with Renal Syndrome
HFV	high-frequency ventilation
HGF	hepatocyte growth factor
HH	heated humidifier
HHS	hyperglycaemic hyperosmolar state

HHV	human herpes virus
HICP	intracranial hypertension
HIE	health information exchange
HIET	high-dose insulin euglycaemia therapy
HIF	hypoxia-inducible factor
HIG	human antitetanus immunoglobulin
HIR	Host Innate Responses
HIT	heparin-induced thrombocytopenia
HIV	human immunodeficiency virus
HL	Hodgkins lymphoma
HLA	human lymphocyte antigen
HME	heat and moisture exchanger
HMGB	high mobility group box
hMPV	human metapneumovirus
HPA	hypothalamic-pituitary-adrenal
HPLC	high-performance liquid chromatography
HPS	hyperperfusion syndrome
HPV	hypoxic pulmonary vasoconstriction
HR	heart rate
HRCT	high resolution computed tomography
HRE	hypoxia-responsive element
HRIG	human rabies immunoglobulin
HRQL	health-related quality of life
HRS	hepatorenal syndrome
HRSD	Hamilton Rating Scale for Depression
HSC	haematological stem cells
HSCT	haematopoietic stem cell transplantation
Hs-cTn	high sensitivity cardiac troponins
HSD	hydroxysteroid dehydrogenase
HSV	herpes simplex virus
HTLV-1	Human T-lymphotropic virus 1
HTR	haemolytic transfusion reactions
HU	Hounsfield units
HUS	haemolytic uraemic syndrome
HUSEC	haemolytic uraemic syndrome–associated enterohaemorrhagic *E. coli*
HVPD	High volume PD
HVPG	hepatic venous pressure gradient
I/E	inspiratory/expiratory
I/R	ischaemia/reperfusion
IABP	intra-aortic balloon pump
IAH	intra-abdominal hypertension
IAP	intra-abdominal pressure
IASP	International Association for the Study of Pain
IAV	intra-abdominal volume
IBD	inflammatory bowel disease
IBW	ideal body weight
IC	intracellular
ICal	indirect calorimetry
ICAM-1	intercellular adhesion molecule-1
ICBT	intercostobronchial
ICD	implantable cardioverter defibrillator
ICG	indocyanine green
ICH	intracranial hypertension
ICmax	maximal insufflation capacity
ICNARC	Intensive Care National Audit and Research Centre
ICP	intracranial pressure
ICRP	International Commission of Radiological Protection
ICU	intensive care unit
ICUAW	ICU-acquired weakness
ID	internal diameter
IDF	incident darkfield
IDMS	isotope dilution mass spectrometry
IE	infective endocarditis
IED	improvised explosive device
Ig	immunoglobulin
IGF	insulin-like growth factor
IGFBP	insulin-like growth factor-binding protein
IgG	immunoglobulin G
IgM	immunoglobulin M
IGRA	Interferon Gamma release Assay
IGV	isolated gastric varices
IHCA	in-hospital cardiac arrest
IHD	intermittent haemodialysis
IHI	Institute for Healthcare Improvement
IJV	internal jugular vein
IL	interleukin
iLA	interventional lung assist
ILE	intralipid emulsion
ILMA	intubating laryngeal mask airway
im	intramuscular
IMV	intermittent mandatory ventilation
iNO	inhaled nitric oxide gas
iNOS	inducible nitric oxide synthase
INR	international normalized ratio
INvR	interventional neuroradiology
IPAP	inspiratory positive airway pressures
IPC	infection prevention and control
iPC	inhaled PCs
IPPB	intermittent positive pressure breathing
IPPV	intermittant positive pressure ventilation
IPPW	intermittent pyloric pressure waves
IPSS	transjugular intrahepatic portosystemic shunt
iPV	inhaled pulmonary vasodilator
IQ	intelligence quotient
IR	infrared light
IRB	institutional review board
IRIS	immune reconstitution inflammatory syndrome
IRV	inverse ratio ventilation
IS	incentive spirometry
ISF	interstitial fluid
IT	information technology
ITBVI	intrathoracic blood volume index
ITP	intrathoracic pressures
ITT	insulin tolerance test
ITU	intensive treatment unit
iv	intravenous
IVC	inferior vena cava
IVIg	intravenous immunoglobulin
IVPC	intravenous prostacyclin
JAM	junctional adhesion molecules
KDIGO	Kidney Disease Improving Global Outcomes
KE	kinetic energy
KIM-1	kidney-injury molecule-1
KIU	Kallikrein inhibitory units
LACI	lacunar infarcts
LAH	lactic acid
LAP	left atrial pressure

LBBB	left bundle branch block
LBW	lean body weight
LDF	laser Doppler flowmetry
LDH	lactate dehydrogenase
LDL	low-density lipoprotein
LED	light emitting diode
LEMS	Lambert–Eaton myasthenic syndrome
L-FABP	liver fatty acid-binding protein
LGIB	lower gastrointestinal bleeding
LGM	limb girdle myopathies
LH	luteinizing hormone
LIP	lower inflection point
LIS	locked-in syndrome
LMA	laryngeal mask airway
LMWH	low molecular weight heparins
LOC	lower-oesophageal contractility
LODS	Logistic Organ Dysfunction System
LOH	the loop of Henle
LOS	length of stay
LP	lumbar puncture
LPS	lipopolysaccharide
LSD	Lysergic acid diethylamide
LSF	least square fitting
LT	liver transplantation
LTA	light transmission aggregometry
LTACH	long-term acute care hospital
LTACH	long-term acute care hospital
LTP	long-term potentiation'
LUS	lung ultrasound
LV	left ventricle
LVAD	left ventricular assist device
LVEDD	left ventricle end-diastolic diameter
LVEDP	left ventricular end-diastolic pressure
LVEF	left ventricular ejection fraction
LVESD	left ventricle end-systolic diameter
LVF	left ventricular overload or failure
LVH	left ventricular hypertrophy
MA	metabolic acidosis
mAb	monoclonal antibody
MAC	minimum alveolar concentration
MALDI-TOF	matrix-assisted laser desorption ionization–time of flight
MAMC	mid-arm muscle circumference
MAMP	microbial-associated molecular patterns
MAOI	monoamine oxidase inhibitor
mBP	mean blood pressure
MAPK	mitogen-activated protein kinases
MARS	molecular adsorbent recirculating system
MAT	multifocal atrial tachycardia
MBA	Masters of Business Administration
MBI	Maslach Burnout Inventory
MBP	myelin basic protein
MBTI	Myers Briggs Type Inventory
MCA	middle cerebral artery
MCE	mass casualty event
MCI	multiple-casualty incident
MCP	membrane cofactor proteins
MCP-1	monocyte chemotactic protein-1
McR	mineralocorticoid receptor
MCS	minimally cognitive state
MDCT	multidetector computed tomography
MDI	metered dose inhaler
MDMA	3,4-methylenedioxy-N-methylamphetamine (ecstasy)
MDR	multidrug resistance
MDRD	modification of diet in renal disease
MDR-GNR	multidrug resistant gram negative rods
MDS	monophasic damped sinusoidal
MEE	measured energy expenditure
MEGX	monoethylglycinexylidide
MELD	model for end-stage liver disease
MEP	maximal expiratory pressures
MERS-CoV	Middle East respiratory syndrome coronavirus
MET	medical emergency teams
MetHb	methaemoglobin
MEWS	modified early warning system
MG	myasthenia gravis
MgIF	migrating inhibitory factor
MH	malignant hyperthermia
mHLA-DR	monocytic expression of antigen leukocyte-DR
MHRA	Medicine and Healthcare Products Regulatory Agency
MI	myocardial infarction
MIBG	metaiodobenzylguanidine
MIC	minimum inhibitory concentration
MICA	MHC Class I chain A
mid-AC	mid-arm circumference
MIF	micro-immunofluorescence
MILS	manual in-line stabilization
MIP	maximal inspiratory pressures
MMC	migrating motor complex
MMF	Mycophenolate mofetil
MMP	matrix metalloproteinases
MMT	manual muscle testing
MNC	mononuclear cells
MNTX	methylnaltrexone
MODS	multiple organ dysfunction syndrome
MOF	multi-organ failure
MPA	microscopic polyangiitis
mPAP	mean pulmonary arterial pressure
MPM	Mortality Probability Model
MPN	myelo-proliferative neoplasias
MPTP	mitochondrial permeability transition pore
MPV	mean platelet volume
MRCC	manual rib-cage compression
MRCP	magnetic resonance cholangiopancreatography
MRI	magnetic resonance imaging
MRP	multidrug resistance associated proteins
MRS	maximum recruitment strategy
MRSA	methicillin-resistant Staphylococcus aureus
MS	mitral stenosis
MSC	mesenchymal stem cells
MSc	multiple sclerosis
MSFP	mean systemic filling pressure
mTOR	mammalian target of rapamycin
MUSK	muscle specific protein kinase
MUST	Malnutrition Universal Screening Tool
MV	mechanical ventilation
MVA	motor vehicle accident
MVT	multi-visceral transplant

MyD	myeloid differentiation factor
NAAT	nucleic acid amplification tests
NAC	N-acetylcysteine
NADH	nicotine adenine dinucleotide
NADPH	nicotinamide adenine dinucleotide phosphate
NAFLD	non-alcoholic fatty liver disease
NAPQI	N-acetyl-p-benzoquinonimine
NAT	nucleic acid detection test
NAVA	neurally-adjusted ventilatory assist
NCCT	non-contrast computed tomography
NCEPOD	National Confidential Enquiry into Patient Outcome and Death
NCS	nerve conduction studies
NCSE	non-convulsive seizures or status epilepticus
NDMR	non-depolarizing muscle relaxants
NF-κβ	nuclear factor-κβ
NG	nasogastric
NGAL	neutrophil gelatinase-associated lipocalin
NGT	nasogastric tube
NHL	non-Hodgkin lymphomas
NHP	nonhuman primates
NHSN	National Healthcare Safety Network
NICE	National Institute for Health and Clinical Excellence
NIHSS	National Institutes of Health Stroke Scale
NIPPV	non-invasive positive pressure ventilation
NIRS	near-infrared spectroscopy
NIV	non-invasive ventilation
NJ	nasojejunal
NK	natural killer (cells)
NLOI	neurological level of injury
NLR	Nod-like receptors
NMBA	neuromuscular blocking agents
NMDA	N-methyl-D-aspartate
NMES	neuromuscular electrical stimulation
NMJ	neuromuscular junction
NMR	nuclear magnetic resonance
NMS	neuroleptic malignant syndrome
NNRTI	non-nucleoside reverse transcriptase inhibitor
NNT	number need to treat
NO	nitric oxide
NOAC	new oral anticoagulants
NOC	New Orleans Criteria
NP	nurse practitioner
NPE	neurogenic pulmonary oedema
NPPV	non-invasive positive pressure ventilation
NPT	negative pressure therapy
NRI	Nutritional Risk Index
NRS-2002	Nutritional Risk Screening tool 2002
NRTIs	nucleoside reverse transcriptase inhibitors
NS	nociceptor-specific
NSAID	non-steroidal anti-inflammatory drug
NSBB	non-selective beta-blockers
NSE	neuron-specific enolase
NSTE-ACS	non-ST segment elevation-acute coronary syndromes
NSTEMI	non- ST segment elevation myocardial infarction
NT-BNP	N-terminal pro-B type natriuretic peptide
NTS	nucleus tractus solitaries
ntSAH	non-traumatic subarachnoid haemorrhage
NTSCI	non-traumatic spinal cord injury
NVE	native valve endocarditis
O_2ER	O_2 extraction ratio
OA	open abdomen
OAS	original antigenic sin
OCD	obsessive-compulsive disorder
OCSP	Oxfordshire Community Stroke Project
OD	outer diameter
od	once daily
ODM	oesophageal Doppler monitor
OFS	organ failure scores
OG	osmolal gap
OGD	oesophagogastroduodenoscopy
OH	orthostatic hypotension
OHCA	out-of-hospital cardiac arrest
OHS	obesity-hypoventilation syndrome
OHSS	ovarian hyperstimulation syndrome
OLT	orthotopic liver
OP	organophosphorus
OPS	orthogonal polarized spectral
OR	odds ratio
ORT	oral rehydration therapy
OSA	obstructive sleep apnoea
oxyHb	oxyhaemoglobin
PA	pulmonary artery
PAC	pulmonary artery catheter
PACE	probing, alerting, challenging, emergency language
PACI	partial anterior circulation infarcts
$PACO_2$	alveolar partial pressure of carbon dioxide
$PaCO_2$	partial pressure of carbon dioxide in arterial blood
PAcR	protease-activated receptor
PACS	picture archiving, and communication systems
PACU	post-anaesthesia care unit
PAD	peripheral arterial disease
PAF	platelet-activating factor
PAH	pulmonary arterial hypertension
PAI	plasminogen activator inhibitor
PAMOR	peripheral μ-opioid receptor
PAMP	pathogen-associated molecular pattern
PAO_2	alveolar partial pressure of oxygen
PaO_2	partial pressure of oxygen in arterial blood
PAOP	pulmonary artery occlusion pressure
PAP	pulmonary artery pressure
PAR	pressure-adjusted heart rate
PARP	poly(ADP-ribose)polymerase
PAV	percent alpha trend
P_{AW}	airway pressure
PAWP	pulmonary artery wedge pressure
P_B	Barometric pressure
PBN	phenyl-t-butylnitrone
PbO_2	brain tissue oxygen tension
$PbtO_2$	brain tissue oxygenation
PBW	predicted body weight
PC	prostacyclins
PCA	patient-controlled analgesia
P-ACV	pressure-assist control ventilation
PC-APRV	pressure-controlled airway pressure release ventilation

PCC	prothrombin-complex concentrate
PC-CMV	pressure controlled continuous mandatory ventilation
PC-CSV	pressure controlled continuous spontaneous ventilation
PCD	percutaneous catheter drainage
PCI	percutaneous coronary intervention
PC-IMV	pressure controlled intermittent mandatory ventilation
PC-IRV	pressure-controlled inverse-ratio ventilation
PCP	phencyclidine
PCR	polymerase chain reaction
PCS	physical component score
PCT	pro-calcitonin
PCV	pressure-controlled ventilation
PD	programmed cell death
PDE	phosphodiesterase
PDEI	phosphodiesterase inhibitor
PDGF	platelet-derived growth factor
Pdh	pyruvate dehydrogenase
Pdk1	pyruvate dehydrogenase kinase, isoenzyme 1
PE	pulmonary embolism
PEA	pulseless electrical activity
$PECO_2$	partial pressure of expired carbon dioxide
PEEP	positive end-expiratory pressure
PEF	pericardial effusion
PEG	polyethylene glycol
PEM	protein energy malnutrition
Pes	oesophageal pressure
PET	positron emission tomography
$P_{ET}CO_2$	end tidal partial pressure of carbon dioxide
PET-CT	positron emission tomography-computed tomography
PFIT	Physical Function ICU Test
PFO	patent foramen ovale
PGD	primary graft dysfunction
PGEI	prostaglandin E-1
PGI2	prostaglandin I-2
PH	pulmonary hypertension
PH_2O	partial pressure of fully saturated water vapour
PHG	portal hypertensive gastropathy
PI	protease inhibitor
PICC	peripherally/percutaneously-inserted central venous catheter
PICU	paediatric intensive care unit
PINI	Prognostic Inflammatory Nutritional Index
PIP	positive inspiratory pressure
PJP	Pneumocystis jirovecii pneumonia
PKA	protein kinase A
PLED	periodic lateralized epileptiform discharge
PLGF	placental growth factor
P_{liq}	pleural liquid pressure
PLR	passive leg raise
PLT	platelets
PM	predictive modelling
pMDI	pressurized metered-dose inhalers
PML	progressive multifocal leukoencephalopathy
PMN	polymorphonuclear neutrophils
PMP	polymethlypentane
PN	parenteral nutrition
PNF	primary non-function
PNI	Prognostic Nutritional Index
PNMT	phenylethanolamine-N-methyltransferase
po	oral, by mouth
POC	point-of-care
POCI	posterior circulation infarcts
POCT	point-of-care testing
PONV	post-operative nausea and vomiting
PORC	post-operative residual curarization
POSSUM	Physiologic and Operative Severity Score for the enUmeration of Mortality and Morbidity
PP	pancreatic polypeptide
Ppulse	pulse pressure
PPH	primary pulmonary hypertension
PPHTN	porto-pulmonary hypertension
PPI	proton pump inhibitor
PPID	positive patient identification
Ppl	pleural pressure
PPT	partial prothrombin time
PPV	pulse pressure variation
PQOL	perceived quality of life
pr	per rectum
PRA	panel-reactive antibodies
pRBC	packed red blood cells
PRES	posterior reversible encephalopathy syndrome
PRIS	propofol-related infusion syndrome
PRM	prolonged recruitment manoeuvre
prn	as needed
PROWESS	Protein C Worldwide Evaluation in Severe Sepsis
PRR	pattern recognition receptor
PRx	pressure reactivity index
PS	pituitary surgery
PSB	protected sheath brush
PSI	pneumonia severity index
PSV	pressure support ventilation
PT	prothrombin time
PTH	parathyroid hormone
$PtiO_2$	brain-tissue oxygenation probes
P_{TP}	post-transfusion purpura
PTP	transpulmonary pressure
PTS	post-traumatic seizures
PTSD	post-traumatic stress disorder
PTV	pulmonary thermal volume
PUD	peptic ulcer disease
PUFA	polyunsaturated fatty acid
PVD	pulmonary vasodilators
PVA	polyvinyl alcohol
PVC	premature ventricular contractions
PVE	prosthetic valve endocarditis
PVL-SA	Panton–Valentine leukocidin-producing Staphylococcus aureus
PVN	paraventricular
PVR	pulmonary vascular resistance
PVT	pulseless ventricular tachycardia
PxCT	proximal convoluted tubule
PYY	peptide YY
QALY	quality-adjusted life years
Qb	blood flow

Qd	dialysis flow
qEEG	quantitative EEG
Qf	of flow
QI	quality improvement
QTc	QT corrected for heart rate
QWB	quality of health and well-being
RA	right atrium
RAAS	renin-angiotensin-aldosterone system
RAG	recombinase gene
RAGE	receptor for advanced glycation end-products
RAI	relative adrenal insufficiency
RAP	right atrial pressure
RAR	rapidly-adapting stretch receptor
RASS	Richmond Agitation-Sedation Scale
RAST	radioallergosorbent test
RBB	right bundle branch block
RBBB	right-bundle branch block
RBC	red blood cells
RBF	renal blood flow
RCT	randomized controlled trial
REE	resting energy expenditure
REM	rapid eye movement
RES	reticuloendothelial system
RFID	radio frequency identification
rFVIIa	recombinant activated factor VIIa
RhA	rheumatoid arthritis
RI	reduced intensity
RIC	reduced intensity conditioning
RIJ	right internal jugular
RLB	rectilinear biphasic
RLG	riboleukograms
RLN	recurrent laryngeal nerve
RM	recruitment manoeuvres
RMI	Rivermead Mobility Index
RMI	Rivermead Mobility Index
RMR	resting metabolic rate
RN	registered nurse
RNA	ribonucleic acid
ROC	receiver operator characteristic
ROS	reactive oxygen species
ROSC	return of spontaneous circulation
RoTEG	rotational TEG
ROTEM	rotational thrombelastography
RPC	reactive protein C
RPTCs	renal proximal tubular epithelial cells
RPTCs	renal proximal tubular epithelial cells
RQ	respiratory quotient
RR	relative risk
RRRs	relative risk reduction
RRS	rapid response system
RRT	renal replacement therapy
rSO_2	NIRS oxygen saturation
RSS	Ramsay Sedation Scale
RSV	respiratory syncytial virus
RT	reptilase time
RTLS	real time locating systems
rtPA	recombinant tissue plasminogen activator
rt-PCR	real-time polymerase chain reaction
RT-PCR	reverse transcriptase polymerase chain reaction
RV	right ventricle
RVAD	right ventricular assist device
RVEDP	right ventricular end-diastolic
RVEF	right ventricle ejection fraction
RVF	Rift Valley Fever
RVF	right ventricular overload or failure
RVSP	right ventricular systolic pressure
RWMA	regional wall motion abnormalities
Rx	treatment
SA	sinoatrial
SAD	supraglottic airway devices
SAH	subarachnoid haemorrhage
SaO_2	arterial blood oxygen saturation
sBP	systolic blood pressure
SAPS	Simplified Acute Physiology Score
SAR	slow-adapting stretch receptor
SARS	severe acute respiratory syndrome
SAS	Sedation Agitation Scale
SB	spontaneous breathing
SBAR	situation, background, assessment, recommendation
SBE	standard base excess
SBP	spontaneous bacterial peritonitis
SBT	spontaneous breathing trial
sc	subcutaneous
SCAP	severe community-acquired pneumonia
SCCM	Society of Critical Care Medicine
SCD	sickle cell disease
SCDC	subacute combined degeneration of the cord
SCID	Structured Clinical Interview for DSM-IV
SCN	suprachiasmatic nucleus
SCr	serum creatinine
$ScvO_2$	central venous oxygen saturation
SD	sudden death
SDD	selective decontamination of the digestive tract
SDF	sidestream dark field
SE	standard error
SEMs	self-expandable metal stents
sEng	soluble form of endoglin
SENIC	Study on the Efficacy of Nosocomial Infection Control
SET	signal extraction technology
SGA	subjective global assessment
SGLT1	sodium-dependent glucose co-transporter
SGRQ	St. Georges Respiratory Questionnaire
SI	sustained inflation
SIADH	syndrome of inappropriate antidiuretic hormone
sICH	symptomatic intracerebral haemorrhage
SID	strong ion difference
SIDa	apparent SID
SIDe	effective SID
SIG	strong ion gap
SIGN	Scottish Intercollegiate Guidelines Network
SIGRR	single-immunoglobulin-interleukin-1 receptor-related
SIMV	synchronized intermittent mandatory ventilation
SIP	Sickness Impact Profile
SIRS	systemic inflammatory response syndrome
SJS	Stevens–Johnson syndrome

$SjvO_2$	jugular venous oxygen saturation
SLAF	subcutaneous linea alba fasciotomy
SLE	systemic lupus erythematosis
SLED	slow low-efficiency dialysis
SMA	spinal muscular atrophy
SMC	smooth muscle cell
SMR	Standardized Mortality Ratio
SNP	single nucleotide polymorphism
SNRI	serotonin norepinephrine reuptake inhibitor
SNS	sympathetic nervous system
SOAP	Sepsis Occurrence in Acutely Ill Patients
SOCS	suppressor-of-cytokine signalling
SOD	superoxide dismutatase
SOFA	Sequential Organ Failure Assessment
SON	supra-optic nuclei
SOpD	selective oropharyngeal decontamination
SPAD	single pass albumin dialysis
sPAP	pulmonary artery systolic pressure
SPECT	single photon emission computed tomography
SPV	systolic pressure variation
SRUS	Solitary rectal ulcer syndrome
SS	serotonin syndrome
SSC	Surviving Sepsis Campaign
SSEP	somatosensory-evoked potentials
SSG	surviving sepsis guidelines
SSRI	selective serotonin reuptake inhibitor
SST	short tetracosactride test
StE	status epilepticus
STEMI	ST segment elevation myocardial infarction
sTFR	soluble transferrin receptor
STICH	Surgical Treatment of Intracerebral Haemorrhage
StO_2	tissue oxygen saturation
SUP	stress ulcer prophylaxis
SV	stroke volume
Vsys	systolic volume
SvAP	severe acute pancreatitis
SVC	superior vena cava
SvO_2	venous oxygen saturation
SVR	systemic vascular resistance
SVT	supraventricular tachyarrhythmias
SVV	stroke volume variation
sBP	systolic blood pressure
T3	triiodothyronine
T4	thyroxine
TA	tranexamic acid
TAAA	thoracoabdominal aortic aneurysm
TAAR	trace amino-associated receptors
TAC	temporary abdominal closure
TACI	total anterior circulation infarcts
TACO	transfusion-associated circulatory overload
TAFI	thrombin activatable fibrinolysis inhibitor
TAPSE	tricuspid annular plane systolic excursion
TAR	titrable acid/alkali reserve
TAVR	transcatheter aortic valve replacement
TBI	traumatic brain injury
TBSA	total body surface area
TBV	total blood volume
TBW	total body water
TCA	tricyclic antidepressants
TCCC	tactical combat casualty care
TCD	transcranial Doppler
TCR	T-cell receptor
TDP	torsade de pointes
tds	three times a day
TEB	thoracic electrical bioimpedance
TED	thromboembolic disease
TOE	transoesophageal echocardiography
TEG	thromboelastography
TEMS	Tactical Emergency Medicine Services
TEN	toxic epidermal necrolysis
TEnE	total energy expenditure
TEVAR	thoracic endovascular aneurysm repair
TF	tissue factor
TFPI	tissue factor pathway inhibitor
TGF	transforming growth factor
TH	therapeutic hypothermia
T-H	trauma-haemorrhage
THAM	tris-hydroxymethylaminomethane
THC	T helper cells
TIA	transient ischaemic attack
TIC	trauma-induced coagulopathy
TIMP	tissue inhibitor of metaloprotinases
TIPSS	transjugular intrahepatic portosystemic shunt
TISS	Therapeutic Intervention Scoring System
TJ	tight junction
TKI	Thomas–Kilmann Conflict Mode Instrument
TLC	total lung capacity
TLR	toll-like receptors
TLS	tumour lysis syndrome
TM	thombomodulin
TNA	total nitrogen appearance
TNF	tumour necrosis factor
TNM	Tumor Nodes Metastases
TOF	train of four
TOLLIP	toll-interacting protein
t-PA	tissue plasminogen activator
TPE	Therapeutic plasma exchange
TPN	total parenteral nutrition
TR	tricuspid regurgitant
TRALI	transfusion-associated acute lung injury
TREM	triggering receptor expressed on myeloid cells
TRH	thyrotropin-releasing hormone
TRIP	translating research into practice
TRP	transient receptor potential
TSCI	traumatic spinal cord injury
TSH	thyroid-stimulating hormone
TST	Tuberculin skin testing
TT	thrombin time
TTE	transthoracic echocardiography
TTI	transthoracic impedance
TTM	targeted temperature management
TTP	thrombotic thrombocytopenic purpura
TTr	transthyretin
TXA	tranexamic acid
TxA_2	thromboxane A2
UAI	upper airways infection
UAO	upper airway obstruction
UCH-L1	ubiquitin C-terminal hydrolase-1

UDS	urine drug screening
UDS	urine drug screening
UF	ultrafiltration
UFH	unfractionated heparin
UGIH	upper gastrointestinal haemorrhage
UIP	upper inflection point
UMA	unmeasured anion
uN2	urinary nitrogen component
UO	urine output
u-PA	urokinase-type plasminogen activator
US	ultrasound
V/Q	ventilation–perfusion
VA	veno-arterial
VAD	ventricular assist device
VA-ECMO	veno-arterial extracorporeal membrane oxygenation
VAED	Victorian Department of Health Administrative Episode Dataset
VALI	ventilation-associated lung injury
VAP	ventilator-associated pneumonia
VASST	Vasopressin in Septic Shock Trial
VAT	ventilator-associated tracheobronchitis
VATS	video-assisted thoracoscopic surgery
VC	vital capacity
VCAM-1	vascular cell adhesion molecule 1
VC-CMV	volume controlled continuous mandatory ventilation
VC-CSV	volume controlled continuous spontaneous ventilation
VCD	vocal cord dysfunction
VCE	video capsule endoscopy
VC-IMV	volume controlled intermittent mandatory ventilation
VC-IRV	flow-controlled, inverse ratio ventilation
VCO_2	amount of CO_2 produced
VCV	volume-controlled ventilation
VD	dead space ventilation
VDAC	voltage-dependent anion channel
VEGF	vascular endothelial growth factor
VF	ventricular fibrillation
VFB	ventilator-free breathing
VGCC	voltage-gated calcium channels
VGSC	voltage-gated sodium channels
VHF	viral haemorrhagic fever
VIDD	ventilator-induced diaphragmatic dysfunction
VILI	ventilator-induced lung injury
VIP	vasoactive intestinal peptide
VL	videolaryngoscopy
VLPO	ventrolateral pre-optic area
VMA	vanillylmandelic acid
VO2	amount of O_2 consumed
VOC	vaso-occlusive crises
VOD	veno-occlusive disease
VR	ventilator rate
VRE	vancomycin-resistant enterococci
VS	vegetative state
VSD	ventricular septal defect
VSMC	vascular smooth muscle cell
Vt	tidal volume
VT	ventricular tachycardia
VTE	venous thromboembolism
VTI	velocity-time integral
VV	veno-venous
VVO	vesiculo-vacuolar organelle
vWF	von Willebrand Factor
VZV	varicella zoster virus
WBC	white blood cell
WDR	wide dynamic range
WFNS	World Federation of Neurosurgeons Scale
WHO	World Health Organization
WHVP	wedged hepatic venous pressure
WLST	withdrawal of life-sustaining treatment
WOB	work of breathing
WPGS	whole pathogen genome sequencing
WPW	Wolff–Parkinson–White
XD	xanthine dehydrogenase
YAG	yttrium-aluminum-garnet
YF	yellow fever
βB	β-blockers

Stuart McKechnie Consultant in Intensive Care Medicine & Anaesthetics, Oxford University Hospital NHS Trust, Oxford, UK

Anthony S. McLean Director, Intensive Care Medicine, Sydney Medical School, Sydney, Australia

David D. McManus Associate Professor, Departments of Medicine and Quantitative Health Sciences, University of Massachusetts Medical Center, Worcester, USA

Alexandre Mebazaa Chairman of Department, Département Anesthésie-Réanimation, Hôpital Lariboisière, Paris, France

Ravindra L. Mehta Clinical Research Department of Medicine, UCSD Medical Centre, San Diego, USA

Philippe Mercier Paediatric Neurosurgery Fellow, Le Bonheur Children's Hospital, Memphis, USA

Dieter Mesotten Catholic University Leuven (KU Leuven), Department Intensive Care Medicine, University Hospitals Leuven, Leuven, Belgium

Emersom C. Mesquita Laboratório de MedicinaIntensiva, Instituto de PesquisaClinicaEvandro Chagas (IPEC), Rio de Janeiro, Brazil

Cristina Mietto Dipartimento di Fisiopatologia Medico-Chirurgica e dei Trapianti, Fondazione IRCCS Ca' Granda – Ospedale Maggiore Policlinico, Universita' degli Studi di Milano, Milan, Italy

Frederick Mihm Professor of Medicine, Codirector, Intensive Care Units, Department of Anesthesiology, Pain and Perioperative Medicine, Stanford University Medical Center, Stanford, CA, USA

Jean-Paul Mira Head of the Medical Intensive Care Unit, Groupe Hospitalier Cochin- Broca-Hotel dieu, Paris, France

Eduardo Mireles-Cabodevila Director, Critical Care Medicine Fellowship and Assistant Professor of Medicine, Clinic Lerner College of Medicine of Case Western Reserve University, Respiratory Institute, Cleveland Clinic, Cleveland, OH, USA

Giovanni Mistraletti Medical Director and University Researcher, Dipartimento di Fisiopatologia medico-chirurgica e dei trapianti, Università degli Studi di Milano, Milan, Italy

Jerome H. Modell Professor Emeritus, Department of Anesthesiology, University of Florida College of Medicine, Gainesville, USA

Francesco Mojoli Anesthesia and Intensive Care Division, Emergency Department, Fondazione IRCCS Policlinico San Matteo, and Anesthesia, Intensive Care and Pain Therapy, University of Pavia, Pavia, Italy

Sean F. Monaghan Assistant Professor of Surgery, Division of Surgical Research, Department of Surgery, Rhode Island Hospital/Alpert Medical School of Brown University, Providence, RI, USA

Hugh Montgomery Professor of Intensive Care Medicine, University College London, London, UK

S. Ramani Moonesinghe Consultant and Honorary Senior Lecturer, Anaesthesia and Critical Care Medicine, Surgical Outcomes Research Centre, Department of Anaesthesia, University College London Hospitals NHS Foundation Trust, London, UK

Ernest E. Moore Professor and Vice Chairman of Surgery, University of Colorado, Denver, co, USA

Rui Moreno Professor da Nova Medical School, Unidade de Cuidados Intensivos Neurocríticos, Hospital de São José, Centro Hospitalar de Lisboa Central, E.P.E., Lisboa, Portugal

Peter Thomas Morley Director of Medical Education, Senior Specialist in Intensive Care, University of Melbourne Clinical School, Royal Melbourne Hospital, Melbourne, Australia

Emma C. Morris Reader in Immunology and Immunotherapy, Consultant Haematologist (BMT), UCL Institute of Immunity and Transplantation, Department of Haematology, University College London Hospitals NHS Foundation Trust, and Department of Immunology, Royal Free London NHS Foundation Trust, London, UK

Linda-Jayne Mottram Critical Care Consultant, Belfast HSC Trust, Belfast, UK

Thomas Muders Senior Attending, Division of Intensive Care Medicine, Department of Anaesthesiology and Intensive Care Medicine, University Hospital Bonn, Bonn, Germany

Myrna Y. Munar College of Pharmacy, Oregon State University, Corvallis, OR, USA

Claus-Martin Muth Professor of Anesthesiology, Sektion Notfallmedizin, Klinik für Anaesthesiologie, Universitaetsklinikum Ulm, Ulm, Germany

Katie M. Muzevich Division of Pulmonary and Critical Care Medicine, Virginia Commonwealth University Health System, Richmond, USA

John Myburgh Professor of Critical Care, University of New South Wales, Director of the Division of Critical Care and Trauma, The George Institute for International Health, Senior Intensive Care Physician, St George Hospital, Sydney, Australia

Jae Myeong Lee Assistant Professor of Surgery and Critical Care Medicine, Department of Surgery, Ajou University School of Medicine, Chief of the Surgical Intensive Care Unit, Ajou University Hospital, Suwon, Republic of Korea

Monty Mythen Smiths Medical Professor of Anaesthesia and Critical Care, University College London, London, UK

Simon Nadel Adjunct Professor of Paediatric Intensive Care, St Mary's Hospital and Imperial College London, London, UK

Raquel Nahra Assistant Professor of Medicine, Infectious Diseases and Critical Care, Cooper Medical School of Rowan University, Camden, USA

Joseph L. Nates Professor, Deputy Chair, Medical Director Intensive Care Units, Division of Anesthesiology and Critical Care, University of Texas MD Anderson Cancer Center, Houston, USA

Paolo Navalesi Department of Translational Medicine, Università del Piemonte Orientale (UPO), Novara, Anesthesia and Intensive Care, Sant'Andrea Hospital, Vercelli, Moncrivello (VC), Italy

Jeffrey S. Neiger Cardiac Electrophysiologist, University of Illinois, Chicago, IL, USA

Patrick J. Neligan Consultant in Anaesthesia and Intensive Care, Medical Director, Critical Care Services, University College Hospitals, Galway, Honorary Senior Lecturer in Anaesthesia & Intensive Care, National University of Ireland, Galway, Ireland

Catherine Nelson-Piercy Consultant Obstetric Physician and Professor of Obstetric Medicine, Guy's and St Thomas' NHS Foundation Trust, Imperial College Healthcare NHS Trust, and King's College London, London, UK

Judith E. Nelson Associate Chief, Palliative Medicine Service, Attending Physician, Critical Care Service, Memorial Sloan Kettering Cancer Center, New York, NY, USA

Imran Khalid Niazi Consultant Radiologist, Shaukat Khanum Memorial Cancer Hospital & Research, Lahore, Pakistan

Niklas Nielsen Helsingborg Hospital and Lund University, Helsingborg, Sweden

Sara Nikravan Assistant Professor of Anesthesiology and Critical Care Medicine, Director of Critical Care Ultrasound, Stanford University Hospital and Clinics, Palo Alto, USA

Graham Nimmo Consultant Physician in Intensive Care Medicine and Clinical Education, Intensive Care Unit, Western General Hospital, Edinburgh, UK

Jerry P. Nolan Consultant in Anaesthesia and Intensive Care Medicine, Royal United Hospital, Bath, UK

Muna Noori Consultant Obstetrician and Sub-specialist in Maternal and Fetal Medicine, Queen Charlotte's and Chelsea Hospital, Imperial College Healthcare NHS Trust, London, UK

Ayodeji Nubi Attending, General Surgery, Trauma & Critical Care Medicine, Lancaster General Hospital, Lancaster, USA

Alastair O'Brien Reader in Experimental Hepatology and Consultant Hepatologist, University College London, and The Royal Free Hospitals NHS Trust, London, UK

Michael O'Dwyer Senior Lecturer and Honorary Consultant in Intensive Care Medicine, Barts and The London School of Medicine and Dentistry, London, UK

Ronan O'Leary Consultant in Neurosciences and Trauma Intensive Care Medicine, Addenbrooke's Hospital, Cambridge, UK

Göran Olivecrona Department of Cardiology, Lund University, Skane University Hospital-Lund, Lund, Sweden

Charles M. Oliver Anaesthetic Registrar and Health Services Research Fellow, The National Institute of Academic Anaesthesia Health Services Research Centre, London, UK

Evelien Oostdijk Departments of Medical Microbiology and Intensive Care Medicine, University Medical Center Utrecht, Utrecht, The Netherlands

Steven M. Opal Professor of Medicine, Infectious Disease Division, Alpert Medical School of Brown University, Memorial Hospital of RI, Pawtucket, RI, USA

Efrat Orenbuch-Harroch Physician, Medical Intensive Care Unit, Medical Intensive Care Unit, Hadassah Hebrew University Medical Center, Jerusalem, Israel

David Orlikowski Hôpital Raymond-Poincaré, Garches, France

Marlies Ostermann Consultant in Critical Care, Nephrology and Transplantation, Guy's and St Thomas' Foundation Hospital, London, UK

Ali J. Olyaei Nephrology and Hypertension, Oregon State University/ Oregon Health & Sciences University, Portland, USA

Anand D. Padmakumar Specialist Trainee Registrar ST7 in Anaesthesia and Critical Care Medicine, St James's University Hospital, Leeds Teaching Hospitals NHS Trust, Leeds, UK

Colin Page Clinical Toxicologist & Emergency Physician, Princess Alexandra Hospital, Brisbane, Australia

Pratik P. Pandharipande Professor of Anesthesiology and Surgery, Department of Anesthesiology, Division of Critical Care, Vanderbilt University School of Medicine, Nashville, TN, USA

Preet Panesar Lead Pharmacist in Microbiology, University College London Hospitals NHS Foundation Trust, London, UK

Marianna Parlato Unit of Cytokines and Inflammation, Institut Pasteur, Paris, France

John A. M. Paro Stanford University School of Medicine, Palo Alto, Stanford, USA

Bela Patel Associate Professor, Division Director of Critical Care Medicine, Assistant Dean of Healthcare Quality, University of Texas, Houston, USA

Bhakti K. Patel Section of Pulmonary Clinical Care, University of Chicago Medical Centre, Chicago, USA

Brijesh V. Patel Clinical Lecturer, Section of Anaesthetics, Pain Medicine and Intensive Care, Department of Surgery and Cancer, Faculty of Medicine, Imperial College London, London, UK

Mayur B. Patel Assistant Professor of Surgery and Neurosurgery, Section of Surgical Sciences, Department Of Surgery and Neurosurgery, Division of Trauma & Surgical Critical Care, Vanderbilt University School of Medicine, Nashville, TN, USA

Sameer Patel Consultant in Intensive Care, Liver Intensive Care & ECMO, King's College Hospital, London, UK

Gilbert Park North Middlesex Hospital, UK

Michael J. A. Parr Director of Intensive Care, Liverpool Hospital and Macquarie University Hospital, University of New South Wales, Macquarie University, and University of Western Sydney, Sydney, Australia

Joseph E. Parrillo Chairman, and Professor of Medicine, Heart and Vascular Hospital, Hackensack University Medical Centre, and Rutgers New Jersey Medical School, Hackensack, USA

David L. Paterson Professor of Medicine and Infectious Diseases Physician, University of Queensland Centre for Clinical Research and Royal Brisbane and Women's Hospital, Brisbane, Australia

Caroline Patterson Clinical Research Fellow, Imperial College, London, UK

Richard Paul NIHR Research Fellow, Royal Brompton Hospital, London, UK

Paul M. Palevsky Chief of Renal Section, and Professor of Medicine and Clinical and Translational Science, United States Department of Veteran Affairs and University of Pittsburgh School of Medicine, Pittsburgh, USA

Didier Payen Professor in Medicine, General ICU at Raymond Poincaré hospital (AP-HP), Laboratory of Cell Death, Inflammation and Infection UM1173, University of Versailles and INSERM, Versailles, France

Sandra L. Peake Senior Staff Specialist, Department of Intensive Care, The Queen Elizabeth Hospital, Associate Professor, School of Medicine, University of Adelaide, Adelaide, Australia, Adjunct Associate Professor, School of Epidemiology and Preventive Medicine, Monash University, Melbourne, Australia

Rupert Pearse Professor and Consultant in Intensive Care Medicine, Queen Mary's University of London, Royal London Hospital, London, UK

Giles Peek Chief of Pediatric Cardiacthoracic Surgery, Children's Hospital at Montefiore, New York, NY, USA

Stephen P. Pereira UCL Institute for Liver and Digestive Health, Royal Free Hospital Campus, London, UK

Paolo Pelosi Professor in Anaesthesiology, Department of Surgical Sciences and Integrated Diagnostics, IRCCS San Martino IST, University of Genoa, Genoa, Italy

Frédéric Pène Medical Intensive Care Unit, Cochin Hospital, Assistance Publique-Hôpitaux de Paris and Paris Descartes University, Sorbonne Paris Cité, Paris, France

Paul E. Pepe Professor of Emergency Medicine, Internal Medicine, Surgery, Pediatrics, Public Health and the Riggs Family Chair in Emergency Medicine, Director of Regional Out-of-Hospital Care Systems and Event/Disaster Preparedness Office of Health System Affairs, University of Texas Southwestern Medical Centre, Dallas, USA

A. G. Peppelenbosch Department of Surgery, Maastricht University Medical Center, Maastricht, The Netherlands

Gavin D. Perkins Professor of Clinical Care Medicine, Warwick Medical School and Heart of England NHS Foundation Trust, Coventry, UK

J. Perren Cobb Massachusetts General Hospital, Boston, MA, USA

Jerrold L. Perrott Clinical Pharmacy Specialist – Critical Care (ICU), Royal Columbian Hospital, New Westminster, Canada

Antonio Pesenti Università degli Studi Milano Bicocca, Dipartimento di Scienze della Salute, A.O. San Gerardo, Dipartimento di Emergenza e Urgenza, Via Pergolesi 33, Monza (MB), Italy

David Pilcher Intensive Care Specialist, The Alfred Hospital, Melbourne, Australia

Michael R. Pinsky Professor of Critical Care Medicine, Bioengineering, Cardiovascular Disease and Anesthesiology, Department of Critical Care Medicine, University of Pittsburgh, Pittsburgh, USA

Tasneem Pirani Advanced ICM and Gastroenterology Registrar, Kings College Hospital, London, UK

Didier Pittet Director, Infection Control Programme and WHO Collaborating Centre on Patient Safety, University of Geneva Hospitals and Faculty of Medicine, Geneva, Switzerland

Esteban Poch Senior Consultant, Nephrology Department, Hospital Clinic, Barcelona, Spain

Martijn Poeze Department of Surgery, Maastricht University Medical Center, Maastricht, The Netherlands

Tom van der Poll Professor of Infectious Diseases, Department of Medicine, Division of Infectious Diseases, Center for Experimental Molecular Medicine (CEMM), Academic Medical Center, University of Amsterdam, Amsterdam, The Netherlands

Sebastian Pollandt Neurologist, Rush University Medical Center, Chicago, IL, USA

Brian J. Pollard Professor of Anaesthesia, Manchester Medical School, Manchester, UK

Thaddeus M. Pope Director and Associate Professor, Health Law Institute and Hamline University School of Law, Saint Paul, USA

Udaya B. S. Prakash Consultant, Division of Pulmonary and Critical Care Medicine, Mayo Clinic, Professor of Medicine, Mayo Clinic College of Medicine, Rochester, MN, USA

Laura Price Consultant Physician, Pulmonary Hypertension Service, Royal Brompton Hospital, London, UK

Susanna Price Consultant Cardiologist & Intensivist, Royal Brompton Hospital, London, UK

Peter J. Pronovost Professor of Anaesthesiology and Critical Care Medicine, Armstrong Institute for Patient Safety and Quality, Johns Hopkins University School of Medicine, Baltimore, MD, USA

John R. Prowle Clinical Senior Lecturer in Intensive Care Medicine, William Harvey Research Institute, Barts and the London School of Medicine and Dentistry, Queen Mary University of London, Honorary Consultant in Intensive Care & Renal Medicine, Royal London Hospital, Barts Health NHS Trust, London, UK

Christian Putensen Professor of Intensive Care Medicine and Head Division of Intensive Care Medicine, Department of Anaesthesiology and Intensive Care Medicine University Hospital Bonn, Bonn, Germany

Lirong Qu Co-Director, Centralized Transfusion Service, Institute for Transfusion Therapy, Pittsburgh, USA

Alberto Quaglia Consultant Histopathologist, Institute of Liver Studies, Kings College Hospital, London, UK

Michael Quintel Head of Department, Department of Anesthesiology, Center for Anesthesiology, Emergency and Intensive Care Medicine, University Hospital Göttingen, Göttingen, Germany

Peter Radermacher Professor of Anesthesiology, Institut für Anaesthesiologische Pathophysiologie und Verfahrensentwicklung, Universitaetsklinikum, Ulm, Germany

Mohamed Y. Rady Consultant and Professor, Department of Critical Care Medicine and Mayo Clinic College of Medicine, Mayo Clinic Hospital, Phoenix, AZ, USA

Karthik Raghunathan Assistant Professor, Anesthesiology Service Durham VA Medical Center, Duke University Medical Centre, Durham, USA

Tony Rahman Director of Gastroenterology & Hepatology, The Prince Charles Hospital & College of Medicine & Dentistry, James Cook University, Queensland, Australia

Keshava Rajagopal Assistant Professor of Cardiac Surgery and Cardiac Surgeon, Center for Advanced Heart Failure, University of Texas-Houston, Houston, USA

Ram E. Rajagopalan Consultant and Head, Department of Critical Care Medicine, Sundaram Medical Foundation, Chennai, India,

Rajkumar Rajendram Consultant in Anaesthesia, Intensive Care, and Peri-operative Medicine, Royal Free London Hospitals, Barnet General Hospital, Barnet, UK

Raghavan Raju Professor, Departments of Laboratory Sciences and Surgery, Georgia Regents University, Augusta, GA, USA

Navin Ramachandran Consultant Radiologist, University College London Hospitals NHS Foundation Trust, London, UK

Jared Randall Curtis Professor, Pulmonary and Critical Care Medicine, University of Washington, Seattle , USA

V. Marco Ranieri Professor of Anesthesia and Critical Care, Università di Roma 'La Sapienza', Policlinico Umberto I Rome, Roma, Italy

Didier Raoult Director, Unité de Recherche des Maladies Infectieuses et Emergentes (URMITE), Faculté de Médecine, Unité des Rickettsies, France

Raymond Raper Intensive Care Unit, Royal North Shore Hospital, St Leonards, Australia

Michael C. Reade Lieutenant Colonel, Joint Health Command, Australian Defence Force, Canberra, Professor of Military Medicine and Surgery, University of Queensland, Brisbane, Consultant Intensivist, Royal Brisbane and Women's Hospital, Brisbane, Australia

Ugan Reddy Consultant in Neuromedical Intensive Care, The National Hospital for Neurology & Neurosurgery, London, UK

Konrad Reinhart Clinic for Anaesthesiology and Intensive Care, Jena, Germany

Annika Reintam Blaser Intensivist and Scientist, Intensive Care Unit, Lucerne Cantonal Hospital, Lucerne, Switzerland, University of Tartu, Tartu, Estonia

Jordi Rello Professor of Medicine, Vall d'Hebron Institut of Research, CIBERES, Universitat Autonoma de Barcelona, Barcelona, Spain

Andreas Wolfgang Reske Klinik und Poliklinik für Anästhesiologie und Intensivtherapie, Universitätsklinikum Leipzig AöR, Leipzig, Germany

Andrew Retter Intensive Care Consultant, Guy's and St. Thomas' NHS Foundation Trust, London, UK

Steven C. Reynolds Critical Care & Infectious Diseases, Regional Medical Director and Department Head, Critical Care–Fraser Health, Medical Administration, Royal Columbian Hospital, New Westminster Canada

Andrew Rhodes Consultant in Intensive Care and Anaesthesia, Royal Berkshire Hospital, Reading, UK

Jonathan K. J. Rhodes Consultant Intensivist and Anaesthetist, Department of Anaesthesia and Critical Care, University of Edinburgh & NHS Lothian Western General Hospital, Edinburgh, UK

Zaccaria Ricci Department of Paediatric Cardiac Surgery, Bambino Gesù Children's Hospital, Rome, Italy

Saxon Ridley Anaesthetics Department, Glan Clwyd Hospital, Rhyl, Denbighshire, North Wales, UK

Michael A. Rie University of Kentucky, Lexington, USA

Darren M. Roberts Staff specialist, nephrology and clinical pharmacology/ toxicology, The Canberra Hospital, Woden, ACT, Australia, Associate Professor, Medical School, Australian National University, Canberra, Australia

Claudia S. Robertson Professor, Department of Neurosurgery, Baylor College of Medicine, Houston, USA

Stefano Romagnoli Department of Anesthesia and Intensive Care, Azienda Ospedaliero-Universitaria Careggi, Florence, Italy

Claudio Ronco International Renal Research Institute (IRRIV), Vincenca, Italy

Matthew R. Rosengart Associate Professor, Departments of Surgery and Critical Care Medicine, University of Pennsylvania Medical Centre, Pittsburgh, USA

Ori D. Rotstein Professor of Surgery, University of Toronto, Toronto, Canada

Charis Roussos Academician and Professor of Medicine, University of Athens and McGill University, Athens, Greece

Sebastian G. Russo Consultant Anaesthesiologist, Department of Anesthesiology, Center for Anesthesiology, Emergency and Intensive Care Medicine, University Hospital Göttingen, Göttingen, Germany

Omar Sabri Consultant Trauma & Orthopaedic Surgeon, Newcastle Upon Tyne University Hospitals and Nuffield Hospital Newcastle, Newcastle, UK

Jonathan B. Salmon Consultant in General Medicine and Intensive Care, Adult Intensive Care Units, Oxford University Hospitals NHS Trust, Oxford, UK

Brett G. Sampson ICCU, Flinders Medial Centre, Adelaide, Australia

Damon C. Scales Associate Professor, Interdepartmental Division of Critical Care, University of Toronto, and Sunnybrook Health Sciences Centre, Toronto, Canada

John R. Schairer Senior Staff, Division of Cardiovascular Medicine, Henry Ford Hospital, Detroit, USA

Leslie P. Scheunemann Fellow of Pulmonary and Critical Care, University of Pittsburgh, Pittsburgh, USA

Gregory A. Schmidt Professor, Division of Pulmonary Diseases, Critical Care, and Occupational Medicine, Associate Chief Medical Officer, Critical Care, University of Iowa, Iowa City, USA

Marcus J. Schultz Department of Intensive Care Medicine & Laboratory of Experimental Intensive Care and Anesthesiology, Academic Medical Center at the University of Amsterdam, Amsterdam, The Netherlands

Michael J. Scott Consultant in Anaesthesia and Intensive Care Medicine, Royal Surrey County Hospital NHS Foundation Trust, Guildford, UK

Marie Scully Consultant Haematologist, Department of Haematology, University College London Hospital, London, UK

David B. Seder Director of Neurocritical Care and Assistant Professor of Medicine, Maine Medical Center and Tufts University School of Medicine, Portland, OR, USA

Ayan Sen Consultant and Assistant Professor, Critical Care and Emergency Medicine, Mayo Clinic, Phoenix, AZ, USA

Curtis N. Sessler Division of Pulmonary and Critical Care Medicine, Virginia Commonwealth University Health System, Richmond, USA

Jon Sevransky Division of Pulmonary, Critical Care, Allergy, and Sleep, Emory Center for Critical Care, Atlanta, GA, USA,

Shahriar Shahrokhi Assistant Professor, Department of Surgery, Division of Plastic Surgery, University of Toronto, Toronto, Canada, Staff Surgeon Ross Tilley Burn Centre, Sunnybrook Health Sciences Centre

Nathan I. Shapiro Harvard University, Boston, USA

Micha Shamir Anesthesiology and Critical Care, Hadassah Medical Center, Jerusalem, Israel

Tarek Sharshar Professor, Department of Intensive Care Medicine, Raymond Poincaré Teaching Hospital, University of Versailles Saint-Quentin en Yvelines, Garches, France

Andrew Shaw Professor and Chief, Division of Cardiothoracic Anesthesiology, VUMC Department of Anesthesiology, Nashville, TN, USA

Ben Shippey Director of Clinical Skills and Honorary Consultant Anaesthetist, University of Dundee College of Medicine, Dentistry and Nursing and NHS Tayside, Dundee, UK

Andrew F. Shorr Section Director (Interim), Pulmonary and Critical Care Medicine, Director, MICU, Medstar Washington Hospital Center, Washington, USA

Lori Shutter Professor, Critical Care Medicine, Neurology &Neurosurgery, Vice Chair of Education, Critical Care Medicine Director, Multidisciplinary Critical Care Fellowship Program Medical Director, Neurovascular & Neurotrauma ICUs, University of Pittsburgh School of Medicine, Pittsburgh, USA

Henry J. Silverman Professor of Medicine, University of Maryland, School of Medicine, Baltimore, MD, USA

Mervyn Singer Professor of Intensive Care Medicine, University College London, London, UK

Pierre Singer Director, Department and Institute for Nutrition Research, Rabin Medical Center, Beilinson Hospital, Tel Aviv University PetahTikvahIsrael

Jeffrey C. Sirota Division of Renal Diseases & Hypertension, University of Colorado, Denver CO, USA

James R. A. Skipworth Department of Surgery and Interventional Science, University College London, London, UK

Michel Slama Chair of Critical Care Medicine, Head of Medical Intensive Care Unit, Vice President of University of Amiens, Réanimation Médicale CHU Sud and INSERM 1088, Amiens, France

Leigh Ann Slater Johns Hopkins University School of Medicine, Baltimore, MD, USA

Martin Smith Consultant and Honorary Professor in Neurocritical Care, The National Hospital for Neurology and Neurosurgery, University College London Hospitals, London, UK

Jasmeet Soar Consultant in Anaesthesia and Intensive Care Medicine, Southmead Hospital, Bristol, UK

Neil Soni Consultant, Chelsea and Westminster Hospital, Honorary Senior Lecturer, Imperial College Medical School, London, UK

Antoinette Spevetz Professor of Medicine, Cooper Medical School of Rowan University, Cooper University Hospital, Camden, USA

Giulia Spoletini Clinical Fellow in Pulmonary and Respiratory Medicine and Clinical Research Fellow in Pulmonary Medicine, Department of Pathophysiology and Transplantation, Università degli Studi di Milano, IRCCS Fondazione Ospedale Maggiore Policlinico Ca' Granda, and Division of Pulmonary, Critical Care and Sleep Medicine, Tufts Medical Center, Milan and Boston, Italy and USA

Charles L. Sprung Director, General Intensive Care Unit, Department of Anaesthesiology and Critical Care Medicine, Hassadah Hebrew University Medical Centre, Jerusalem, Israel

Nattachai Srisawat Assistant Professor, Division of Nephrology, Department of Medicine, Faculty of Medicine, Chulalongkorn University, and King Chulalongkorn Memorial Hospital, Bangkok, Thailand, And Center for Critical Care Nephrology, The CRISMA Center, Department of Critical are Medicine, University of Pittsburgh School of Medicine, Pittsburgh, USA

Bashar S. Staitieh Senior Fellow, Division of Pulmonary, Allergy, Critical Care and Sleep Medicine, Emory University School of Medicine, Atlanta, GA, USA

Simon Stanworth Consultant Haematologist, Department of Haematology, NHS Blood and Transplant/Oxford University Hospitals NHS Trust, Oxford, UK

Michael Sterling Department of Surgery, Emory University Hospital, Atlanta, GA, USA

Theodore A. Stern Chief, Avery D. Weisman Psychiatric Consultation Service, Director, Office for Clinical Careers, Ned H. Cassem Professor of Psychiatry in the field of Psychosomatic Medicine/Consultation, Massachusetts General Hospital and Harvard Medical School, Boston, MA, USA

Marion Sternbach Associate Professor of Medicine, Faculty of Medicine, Division of Haematology, McMaster University, Hamilton, Canada

Philip Stevens Consultant Surgeon, Glasgow Royal Infirmary, Glasgow, UK

Robert D. Stevens Associate Professor of Anesthesiology Critical Care Medicine, Neurology, Neurosurgery, and Radiology, Johns Hopkins Institute for Cell Engineering, Johns Hopkins University School of Medicine, Baltimore, MD, USA

Nino Stocchetti Professor, Department of Physiopathology and Transplant, Milan University and Neuro ICU, Fondazione IRCCS Cà Granda Ospedale Maggiore Policlinico, Milan, Italy

Karen K. Stout Professor of Medicine and Director, Adult Congenital Heart Disease Service, University of Washington Medical Centre, Seattle, WA, USA

Jose Ignacio Suarez Department of Neurology, Divisions Vascular Neurology and Neurocritical Care, Baylor College of Medicine, Houston, TX, USA

Kamalakkannan Subhas Clinical Fellow in Neuroanaesthesia, The National Hospital for Neurology and Neurosurgery, University College London Hospitals, London, UK

Anthony F. Suffredini Senior Investigator, Critical Care Department, Critical Centre, National Institutes of Health, Bethesda, MD, USA

Charlotte Summers University Lecturer in Critical Care Medicine, Cambridge University, Cambridge, UK

Ajay Suri Specialist Trainee in Cardiology, Barts Health Centre, St Bartholomew's Hospital, London, UK

Erik R. Swenson Professor of Medicine and Physiology, Attending Physician, University of Washington and Pulmonary and Critical Care Medicine, VA Puget Sound Health Care System, Seattle, WA, USA

Paolo Taccone Department of Anesthesiology, Policlinico Hospital of Milan, Milan, Italy

Sharla K. Tajchman Critical Care/Nutrition Support Clinical Pharmacy Specialist, Division of Pharmacy, University of Texas MD Anderson Cancer Center, Houston, TX, USA

Jukka Takala Professor of Intensive Care Medicine and Director, Department of Intensive Care Medicine, Bern University Hospital and University of Bern, Bern, Switzerland

Sébastien Tanaka AP-HP, Service d'Anesthésie-Réanimation, Hôpitaux Universitaires Paris-Sud, and Hôpital de Bicêtre, Le Kremlin-Bicêtre, Paris, France

Paolo Tarsia Department of Pathophysiology and Transplantation, University of Milan, IRCCS Fondazione Ospedale Maggiore, Policlinico Cà Granda Milano, Milan, Italy

Eva Tejerina Intensive Care Unit, Hospital Universitario de Getafe, and Ciber Enfermedades Respiratorias, Instituto Carlos III, Madrid, Spain

Eric J. Thomas Professor of Medicine, Associate Dean for Healthcare Quality, and Director, Memorial Hermann Center for Healthcare Quality and Safety, University of Texas at Houston, Houston, TX, USA

Peter D. Thomas Colonel, 3rd Health Support Battalion, Australian Defence Force, Adelaide, Australia, Director, Intensive Care Unit, Lyell McEwin Hospital, Adelaide, Australia

Kevin Thornton Associate Professor, Department of Anesthesia and Perioperative Care, University of California San Francisco, San Francisco, CA, USA

Franck Thuny Unit of Heart Failure and Valvular Heart Diseases, Department of Cardiology, University Hospital Nord, Marseilles, France

Isaac Teitelbaum Professor of Medicine, Director, Home Dialysis Program, University of Colorado Hospital, Aurora, CO, USA

Marius Terblanche Honorary Senior Lecturer (Research), Division of Health & Social Care Research, Faculty of Life Sciences & Medicine, King's College London and Department of Critical Care Medicine, Guy's & St. Thomas' NHS Foundation Trust, London, UK

Martin J. Tobin Division of Pulmonary & Critical Care Medicine, Loyola University Medical Centre, Maywood, USA

Ariella Tomasini Department of Anaesthesia and Intensive Care Medicine, University of Trieste, Trieste, Italy

Antoni Torres Department of Pneumology, Hospital Clinic, Barcelona, Spain

William M. Townsend Lymphoma Research Fellow, University College London Hospitals NHS Foundation Trust, London, UK

Darrell J. Triulzi Medical Director, Institute for Transfusion Medicine, Pittsburgh, USA

Richard G. Trohman The Grace DeForest and William Louis Veeck Professor of Cardiovascular Research and Director Electrophysiology, Arrhythmia and Pacemaker Services, Rush University Medical Center, Chicago, IL, USA

David V. Tuxen Senior Intensivist, Department of Intensive Care, The Alfred Hospital, Melbourne, Australia

Hans Ulrich Rothen Professor, Departments of Anaesthesiology and Intensive Care Medicine, Bern University Hospital (Inselspital) and University of Bern, Bern, Switzerland

Franco Valenza Department of Anesthesiology, Policlinico Hospital, University of Milan, Milan, Italy

Benoit Vallet Professor, Lille University Teaching Hospital, Lille School of Medicine, Lille North of France University, Lille, France

Paul Van Buynder Professor Griffith University, Staff Specialist Gold Coast Health, Gold Coast Health Service, Southport, Queensland, Australia

Sophie Van Cromphaut Catholic University Leuven (KU Leuven), Department Intensive Care Medicine, University Hospitals Leuven, Leuven, Belgium

Marc Van Nuffelen Department of Emergency Medicine, Erasme University Hospital, Brussels, Belgium

Eduard E. Vasilevskis Assistant Professor of Medicine, Vanderbilt University and VA Tennessee Valley: Geriatric Research, Education and Clinical Center (GRECC), Nashville, TN, USA

Theodoros Vassilakopoulos University of Athens Medical School, 'Evangelismos' Hospital, Department of Critical Care and Pulmonary Services, Athens, Greece

Fabienne Venet Assistant Professor, Immunology Laboratory, Hôpital E Herriot, Hospices Civils de Lyon, Lyon, France

Chethan P. Venkatasubba Rao Department of Neurology, Baylor College of Medicine, Houston, TX, USA, Princess Alexandra and Wesley Hospitals, University of Queensland, Brisbane, Australia

Bala Venkatesh Pre-eminent specialist, Intensive Care Unit, Princess Alexandra & Wesley Hospitals, University of Brisbane, Brisbane, Australia

Paul M. Vespa Professor of Neurosurgery and Neurology, Director of Neurocritical Care, David Geffen School of Medicine at UCLA, Los Angeles, USA

Antoine Vieillard-Baron Professor of Intensive Care Medicine, Head of the Medical and Surgical ICU, University Hospital Ambroise Paré, Assistance Publique des Hôpitaux de Paris, Université Versailles Saint Quentin en Yvelines, Boulogne, France

Laura Vincent ST5 Joint CCT Intensive Care Medicine and Anaesthetics, Oxford University Hospitals, Oxford, UK

Hans-Dieter Volk Chairman, Institute for Medical Immunology and Berlin-Brandenburg Center for Regenerative Therapies, University Medicine Berlin, Berlin, Germany

Peter D. Wagner Distinguished Professor of Medicine & Bioengineering, University of California, San Diego, La Jolla, USA

Carl Waldmann Consultant in Anaesthesia and Intensive Care, Royal Berkshire Hospital, Reading, UK

Allan J. Walkey Assistant Professor of Medicine, University of Boston, Boston, USA

David J. Wallace Core Faculty, Clinical Research, Investigation, and Systems Modeling of Acute Illness (CRISMA) Center, Assistant Professor of Critical Care and Emergency Medicine, University of Pittsburgh School of Medicine, Pittsburgh, USA

Timothy Walsh Professor of Critical Care, Edinburgh University and Edinburgh Royal Infirmary, Edinburgh, UK,

Ruth Y. Y. Wan Expert Pharmacist in Critical Care, Guy's and St Thomas' Foundation Hospital, London, UK

Lorraine B. Ware Professor of Medicine, Professor of Pathology, Microbiology and Immunology, Vanderbilt University School of Medicine, Nashville, TN, USA

David Watson Honorary Professor of Intensive Care Education, Homerton University Hospital NHS Foundation Trust, Barts and The London School of Medicine and Dentistry, London, UK

Andrew Webb Clinical Professor, Faculty of Medicine, University of British Columbia, Vancouver, Canada

Yoram Weiss Director, Hadassah Ein Kerem Medical Center, Hadassah Medical Organization, Jerusalem, Israel

Julia Wendon Clinical Director for Intensive Care and Liver Intensive Care, Institute of Liver Studies, King's College Hospital, London, UK

Jan Wernerman Professor of Anaesthesiology and Intensive Care Medicine, Karolinska Institutet, Karolinska University Hospital Huddinge, Stockholm, Sweden

Michael Weston Consultant Radiologist and Lead Clinician Radiology, Ultrasound Department, St James's University Hospital, Leeds, UK

Claire Westrope University Hospitals of Leicester NHS Trust, Leicester, UK

Douglas B. White UPMC Endowed Chair for Ethics in Critical Care Medicine, Associate Professor of Critical Care Medicine, and Director, Program on Ethics and Decision Making in Critical Illness, University of Pittsburgh Medical Centre, Pittsburgh, USA

Simon Whiteley Consultant Intensive Care, Leeds Teaching Hospitals NHS Trust, Leeds, UK

Christopher J. M. Whitty Consultant Physician and Professor, The Hospital for Tropical Diseases, London, UK

A. P. R. Wilson Consultant Microbiologist, Clinical Microbiology & Virology, University College London Hospitals NHS Foundation Trust, London, UK

Bradford D. Winters Associate Professor of Anaesthesiology and Critical Care Medicine, Armstrong Institute for Patient Safety and Quality, Johns Hopkins University School of Medicine, Baltimore, MD, USA

S. John Wort Lead Consultant Physician, Pulmonary Hypertension Service and Consultant Intensive Care Physician, Adult Intensive Care, Royal Brompton Hospital, London, UK

Hannah Wunsch Associate Professor of Anaesthesiology, University of Toronto, Toronto, Canada

Sully Xiomara Fuentes Patarroyo The George Institute for Global Health and Neurology Department, Royal Prince Alfred Hospital, University of Sydney, Sydney, Australia

G. Bryan Young Emeritus Professor, Department of Clinical Neurological Sciences, Western University, London, Canada

Samuel J. Youssef Cardiac Surgeon, Swedish Heart & Vascular Institute, Seattle, WA, USA

Giovanni Zagli Department of Anesthesia and Intensive Care, Azienda Ospedaliero-Universitaria Careggi, Florence, Italy

Walter Zingg Senior Consultant in Infection Control and Infectious Diseases, Infection Control Programme, University of Geneva Hospitals, Geneva, Switzerland

SECTION 1

ICU organization and management

PART 1.1

The intensive care unit

CHAPTER 1

Design of the ICU

Neil A. Halpern

Key points

- The intensive care unit (ICU) design process is complex and time consuming, and needs to balance innovation with practicality, space availability, physical limitations, and cost.
- The ICU patient room is at the core of the ICU patient, family member, and staff experiences.
- All ICU rooms should be similarly designed and equipped, and provide an environment that promotes healing, and infection prevention and control, in concert with supportive spaces.
- An ICU is an autonomous mini-hospital, whose design and functionality must be synchronized with the rest of the hospital.
- Advanced ICU informatics systems seek to electronically integrate the ICU patient with all aspects of care, utilize the data, and monitor the ICU environment.

Introduction

Intensivists are periodically asked to participate in the construction of new intensive care units (ICU) or the renovation of older ones. This chapter explores ICU design through three prisms: concept to occupancy, the patient room and supportive services, and advanced informatics. This chapter is meant to supplement existing ICU and hospital facility guidelines and recommendations [1–5].

Concept to occupancy

Working with the hospital and ICU design team

The ICU design process begins with a shared critical care medicine (CCM) and hospital vision for a new ICU that reflects the desired appearance and feel of the new ICU, and addresses the goals for patient care, workflow, technology, and the environment [3,5]. Two core principles should be appreciated. First, an ICU is an autonomous mini-hospital, whose design and functionality must be synchronized with the hospital. Secondly, the ICU design process is complex, and must balance innovation with practicality, space limitations, healing, and cost restraints.

The core membership of the ICU design team should reflect its broad responsibilities. The CCM clinical chief should chair the project with the hospital's ICU project manager. Only experienced ICU architects should be engaged. Rapid exposure to excellent ICU designs can be gained through the study of ICU design award videos [6] (see Award Winning ICU Designs at http://www.sccm.org) and visits to selected ICUs. Openness to new ideas should be encouraged [3,7].

Several questions must be addressed. Is the ICU project a renovation or a new build? How will the ICU be physically related to other hospital areas? Is the ICU to be a multipurpose or specialty unit? How many ICU beds are planned? How much space is available and how will space be allocated (patient versus supportive areas)? Will the ICU have centralized or decentralized care and support services, or both? Will smart technology be incorporated?

Design timeline

From the start of design to occupancy may take 3–5 years. The ICU design team should meet regularly and utilize continuously updated schematics, computerized design renderings, and full-scale mock-ups.

New construction or renovation

New construction offers greater opportunity than renovation for innovation and the proper location of ICU patient rooms within the rest of the ICU. Once an ICU is completed, it is unlikely that further major changes will be implemented. As most upgrades will be informatic or technological in nature, networking and power capabilities should be expansive to meet future needs.

Technology standardization and purchase

A list of equipment must be developed, finalized, and purchased early in the design process so that the equipment will be available for installation as construction nears completion. Early purchase of technology, however, may lead to the installation of out-of-date devices; therefore, purchases should be protected through 'non-obsolescence' insurance agreements.

Standardizing technologies allows staff to move easily from room to room, minimizes training, simplifies maintenance, limits repair contracts, and permits quantity discounts. Modern devices are really informatics platforms, so the purchase must address software licenses and updates, connectivity, and interoperability. New technologies should also be tested in a simulation laboratory prior to purchase.

Ramifications of the new ICU

The consequences of the new design must be assessed. For example, if additional ICU beds are being added, then more staffing may be required. Similarly, if point-of-care testing is being newly incorporated, the ICU staff will need to be trained and qualified.

Team roles during construction

ICU design team members should monitor the ICU construction and look for problems that may not have been previously anticipated. Changes may be necessary, but they are expensive and time

consuming. The project should be photographed stage by stage to provide a basis for repair or retrofit.

Occupancy, post-occupancy, do-overs, and expectations

A transition team and simulated move will help the changeover to the new ICU, and will minimize moving-in problems and anxieties. A post-occupancy group should address unforeseen surprises. Hopefully, the new ICU will provide a modern workplace, but will not necessarily improve outcomes or correct challenging staff dynamics.

The patient room and supportive services

The ICU patient room

The ICU patient room [1,3,4,6,8] is at the core of the ICU patient, visitor, and staff experience. Each room should function semi-autonomously, be designed similarly, accommodate one patient only to maintain infection control and privacy, and provide a healing environment. ICU rooms have zones (patient, caregiver, and visitor) that are differentiated by room layout; however, the zones must be operationally flexible. The patient's bed should be the room's focal point.

Medical devices, utilities, communications, and room controls are commonly mounted on stationary headboards or columns, or on mobile articulating columns (booms). Booms, although expensive and requiring much maintenance, offer greater flexibility and patient access than stationary units because of their mobility [9]. Core equipment includes an ICU bed, physiological monitor, mechanical ventilator, infusion pump, feeding pump, pneumatic compression devices, webcam, and specimen label printer. Point-of-care testing (POCT) and ultrasonography devices may also be considered to be core technologies, as they speed diagnosis and therapies, and are decreasing in their sizes and costs.

Room environment

The emotional welfare of ICU patients, staff, and visitors is greatly impacted upon by the room's environment [10]. Thus, a healing milieu that controls sound, light, temperature, time, artwork and entertainment, and provides visiting areas and privacy should be developed [3].

Physical noise barriers should be supplemented by control of device alarms and ICU communications. Windows with shades (manual or electric) and multiple lighting configurations help maintain diurnal rhythms. Each room should have artwork (displayed on the walls, curtains, and ceiling tiles, or electronically), televisions or integrated television-computers, thermostat, and clock. Comfortable chairs, Wi-Fi, and electrical and USB outlets should also be available [2,10]. The patient room should include a long-term visiting area if space permits.

Privacy is provided with curtains, double-paned glass with blinds, or electronic glass. Curtains may be more economical than glass solutions, although curtains can become contaminated and must be changed between patients, while glass barriers are easily cleaned.

Room supplies and waste management

Supplies should be stored in secured and non-secured drawers, cabinets, and/or mobile carts or nurse servers (cabinets with bi-directional access—from both outside and inside the room). Resupplying nurse servers from outside the room supports privacy and aids infection control. ICU rooms should have their own bathrooms with automated bedpan macerators or closed bedpan cleaners [8].

Room entry

The ICU room may open directly to or be set back from the hallway. ICU doors may be controlled manually or electronically. The area outside the patient room should include a decentralized staff workstation, computer, sink, storage space, hangers, and a manual or electronic identification or message board.

Supportive services

Centralized work areas

Centralized work areas provide important functions, including greeting desks, and quiet work and conferencing areas. Limited central bed visibility is supplemented with bed-based webcams.

Corridors and central-based storage for medical devices and carts

ICU corridors establish physical and emotional ICU cohesiveness through their lighting, artwork, sound control, and finishings. Local device and cart alcoves near the patient rooms minimize retrieval times. Hallway closets provide access to non-bedside ICU equipment and supplies. Preferably, ICU patients and supplies should enter the ICU via hallways that bypass the waiting room and visitor entranceways.

Floorings and furnishing

Floors should be comfortable to walk on, non-slip, easy to clean, durable, and impermeable [7]. Walls should be impact-resistant and hallway walls should have fixed protective barriers.

The waiting room

A waiting room with soft-lighting, warm colours, artworks, Wi-Fi, power and USB outlets, televisions, vending machines, bathrooms, lockers and coat hangers, and long-term sleeping arrangements, if possible, should be located adjacent to the ICU. Seating arrangements should be configured as small groups of chairs separated by privacy dividers. Consultation rooms and a social worker's office should support family meetings.

Staff lounge

The staff lounge should have a pleasant ambiance with comfortable seating, artwork, ICU communications, televisions, computers, and a food area and refrigerator. There should also be private changing areas, scrub dispensers, lockers, bathrooms, nap alcoves, and storage areas (for coats and footwear).

Staff communications

Telephones, overhead speakers, nurse-call (intercom) systems, and bi-directional transmitters should be integrated into the ICU. Nurse-call systems are capable of point-to-point and global communications, and can be integrated into real time locating systems (RTLS). Similarly, staff assigned bi-directional transmitters can handle point-to-point and global ICU and hospital communications, and convey voice, telephone, pagers, alarms, and e-mail using wireless and cellular networks.

Pharmacy

A fully equipped satellite ICU pharmacy is necessary if the hospital has a decentralized medication system. In contrast, less

support is required if the hospital pharmacy system is centralized. Stand-alone secure medication storage compartments should be strategically positioned in the ICU and linked to the hospital network. Medications may also be stored in secured cabinets at the ICU bedside.

POCT

POCT devices may be positioned in a free-standing laboratory within the ICU, in defined centralized areas, on mobile carts, or at each ICU bedside. POCT models depend on the ICU workflow, testing needs, space available, and resources. All POCT devices should be networked with hospital systems.

ICU logistics

Bulk supplies are usually stored in supply rooms in stationary or track-based shelving, closed supply cabinets, or rolling exchange carts. Optimally, these storage units are fitted with electronic inventory management scanners. The challenge is to 'right-size' the centralized and decentralized supply areas. This process is dependent on accurate projections of ICU occupancy, supply usage, and re-supply patterns.

Infection control

Infection prevention requires good design and a 'culture' of infection prevention. As hand-washing and surface disinfection are the corner stones of infection control, ICUs should have multiple sinks, cleansing fluid dispensers, and easy to clean surfaces [1,2,8]. However, design teams are now supplementing these with automated hand-washing surveillance, surface hygiene monitoring systems, copper or silver antibacterial surface coatings, impermeable, washable, and antimicrobially-coated keyboards and mice, and environmental decontamination (hydrogen peroxide or ultraviolet light) systems.

Conference facilities, on-call suites, and offices

On-call suites, conference facilities, CCM, and respiratory therapy offices should be located within or near the ICU to facilitate staff availability for patient and family matters and meetings. Conference rooms should include advanced informatics, large electronic displays, and video systems, electronic scanners to track attendance, and electronic conference displays to provide notifications of room utilization.

Signage

Signs identify destinations, and provide directions and information. The signage process is facilitated by virtual ICU walk-throughs to simulate patient, staff, and visitor traffic patterns, and maximize hallway efficiencies.

Security

ICU security must be balanced with warmth. Electronic locks with card access should be used to protect and monitor entry to all sensitive ICU areas. Additionally, the ICU should be monitored with a mix of hospital-based video cameras, locally-based webcams, and closed circuit televisions (CCTV).

Advanced informatics

Advanced ICU informatics systems seek to electronically integrate the ICU patient with all aspects of care (devices, data, supplies, caregivers, medical and administrative applications), and the electronic medical record (EMR). These systems should also help utilize the data, and monitor the ICU environment [11].

Connectivity envelope

The creation of a smart ICU requires the construction of a connectivity envelope around the patient. This multistep process starts with the installation of a wired and wireless infrastructure that is integrated with the hospital's network in each patient room. The second step is the attachment of auto-identification (Auto-ID) tags (i.e. bar codes, infra-red, radio frequency identification (RFID), ultrasonic, and/or hybrid tags) on all data sources, and adaptors and/or computers to the data output ports of the medical devices. The Auto-ID tags facilitate the tracking of all tagged sources; the adaptors and/or computers connect the devices to the envelope if the devices do not have their own internal communications. The computers additionally provide 'interoperability' by translating proprietary device data into a standardized language, so that the data can be read and understood by the ICU middleware, and ultimately placed into the EMR [12]. The third step is the installation of data receivers (i.e. access points, readers, scanners, multimode integrators, and multiport concentrators) in each room to track the Auto-ID tagged data sources and capture data from the medical devices. The last step is the placement of ICU middleware on the hospital network to utilize the data originating from the ICU patient room. This middleware stores and transmits data, records and transforms alarms and data to actionable information, develops virtual device communities, promotes RTLS, and prepares data for smart displays.

Advanced ICU informatics design

Three elements are critical to the success of the connectivity envelope. The first is 'association' of all data sources with the ICU patient. This can be achieved through either patient-centric (linked to a unique identifier) or location-centric (linked to the patient's location) approaches [13]. The patient-centric solution is preferable because the data is 'permanently' attached to the patient, regardless of the patient's physical location. The second core element is time synchronization across all bedside devices and systems; this is necessary for maintaining the time integrity of the electronic flow sheet and all data tracking. The third is interoperability or data recognition between data sources, middleware, and the EMR. This process requires data conversion and alignment protocols to synchronize proprietary data output languages of medical devices with industry standards (see http://www.ihe.net/) and the middleware [12].

Alarm and data transformation

ICU device data and alarms will tire the staff mentally [14]. Although alarms can be partially managed at the device level, a systematic approach requires the deployment of network-based alarm applications. Alarm systems capture alarms and convert them into actionable information [15] using 'message delivery' software, which filters and transmits alarms to dedicated receivers or through the use of an 'intelligent' alarm system that combines alarms and patterns, and analyses raw device data and creates its own alarms [16]. Alarm systems can be supplemented by decision support, sniffers that monitor the EMR, and profiling patients at risk of clinical deterioration by fusing alarms, and other preselected data and trends [17].

Virtual device communities

Enterprise-wide views of all devices of a specific genre can be created by ICU middleware that 'looks' at each device and builds

a virtual device community. This application allows global device monitoring (local telemedicine), data uploads and downloads, alarm transmission, and report generation. Device middleware also allows vendors to remotely troubleshoot and update their software.

RTLS

RTLS represents a wide variety of solutions to improve the management and workflow of all types of tagged assets. RTLS may be used in real time or historically [18] to track and locate assets, monitor device utilization, harmonize device distribution, control consumable product inventories, identify products near their expiration dates or subject to recall, and create reports for future purchases and par-level determinations [19]. RTLS can also be integrated with existing systems to improve infection control, personnel location, and patient room management.

Smart displays

ICU middleware supports a variety of smart displays (monitoring, greaseboard, smartboard, and dashboard) that can be used individually or in combination. Smart monitoring enables clinicians to rapidly identify changes in a patient's condition by merging data from bedside devices and the EMR, and processing this data through artificial intelligence algorithms [20]. Electronic greaseboards track ICU bed utilization using hospital bed management middleware or by local ICU data entry. Smartboards provide basic bed information, plus RTLS data to track ICU staff and patient movements. Dashboards sit above EMR and non-EMR applications, and simultaneously display recent patient data from preselected systems.

Telemedicine

ICU design should address the installation of telemedicine solutions if this monitoring process is being considered. The telemedicine technologies include interfaces for the physiological monitoring system, the EMR, the electronic ICU flowsheet, and the computerized physician order entry system. Additionally, high-definition, bi-directional cameras and communication systems should be installed in each ICU room. Bi-directional teleconferencing should also be installed in the ICU waiting room.

CHAPTER 2

Staffing models in the ICU

Tim Buchman and Michael Sterling

Key points

- Due to several factors, including an ageing population, retirement, and changing priorities of the newer generations of physicians, there is now and will continue to be a shortage of board-certified intensivists.
- This shortage will require alternative models of critical care delivery in order to meet the demands for critical care in the future.
- Although there are controversies surrounding the training and experience necessary for hospitalists to function as intensivists, hospitalists do currently provide critical care services in some settings where intensivists are not available or where it is impractical to recruit an intensivist.
- Affiliate providers (nurse practitioners (NPs) and physician assistants (PAs)) have proven to be effective in delivering high quality critical care under the direction of a board certified intensivist.
- Tele-intensive care units (ICU) or electronic intensive care unit (eICUs) can be effective in reducing mortality particularly in low acuity patients by helping to prevent their conversion to higher acuity patients, augmenting best practice, and improving financial performance of ICUs.

Alternative provider staffing models in critical care

The team of professionals caring for patients in critical care units can be divided into three large groups:

- Nurses, whose numbers include bedside nurses, administrative and educator nurses, and practical nurses.
- Providers including physicians and advanced care practitioners.
- Allied health personnel, including respiratory therapists, nutrition support specialists, pharmacists, physiotherapists, and social workers.

This chapter examines the evolution of provider staffing.

Three decades ago, provider surplus was forecasted. Projections changed at the turn of the century when the Committee on Manpower of Pulmonary and Critical Care Societies (COMPACCS) report was issued [1]. Demographers, statisticians, and clinicians used population, patient, hospital, and provider data to forecast that supply for critical care physicians would not keep pace with demand, and the shortfall would be around 22% short of demand by 2020, climbing to 35% by 2030. The prediction was subsequently validated by the US federal government. In 2006, the Health Resources and Services Administration (HRSA) similarly forecasted a significant shortage of intensivists by 2020 [2].

The gap between supply and demand can be attributed to at least three factors. The first factor is demographic and predictable—the USA baby boomers have aged to the point that they require critical care services. Over the next two decades, approximately 10,000 Americans each day will reach 65 years of age, an inflection point in the demand for critical care services. The HRSA report estimates that 65–74-year-olds require three times more intensivist care than 45–64-year-olds. Needs increase with each passing decade, amplifying the demand as patients survive previously fatal illnesses.

The second factor is an evolving expectation of increased provider presence. Until recently, provider presence was considered optional during nights, weekends, and holidays. Numerous studies suggest that expanded provider presence reduces mortality and care complications. Such expanded provider presence became an objective advocated by the Leapfrog Group, a consortium of American business leaders created in response to the Institute of Medicine report highlighting medical errors. While, there is ongoing debate over the extent of increase—some studies suggest that daytime presence and immediate off-hour availability might be adequate in some settings—there seems to be a strong general trend towards increasing provider presence as a safety and quality strategy [3].

The third factor is the imbalance between intensivist production and attrition. Although the number of medical schools and their graduates has expanded, neither residency slots nor fellowships appear likely to grow in proportion. The production rate of qualified intensivists is fairly flat, and those qualified have employment options in alternative practice settings that do not require night, weekend, and holiday duty. Given the heightened emphasis placed on work–life balance by many recent medical graduates who are part of the 'millennial generation' and 'Generation Y', it is understandable and not surprising that many choose disciplines with less demanding lifestyles. Alternatively, many who were scheduled to retire during the 2008 global economic collapse postponed their retirement for as long as their retirement accounts took to recover. They continue to work only because of the 2008 economic collapse. Economic recovery is thus something of a double-edged sword, and the projected reduction in physician compensation may well accelerate decisions to retire.

All signs suggest that the COMPACCS prediction is correct—a count of the 'help wanted' advertisements in the professional literature reveals the shortage of intensivist physicians is here and

growing. Three novel strategies by which intensivist expertise can be leveraged to provide care for a larger group of critically ill patients are discussed here. The three strategies include:

- The use of hospitalists.
- Engagement of affiliate providers (nurse practitioners and physician assistants with advanced critical care competencies).
- Investment in tele-intensive care units (tele-ICU) services.

These strategies are complementary and, therefore, can be combined to provide models tailored to local needs and resources.

Hospitalists

The specialty of hospital medicine emerged in response to the changing economic pressures during the managed care era [4]. Generalist practice, and its ideals of comprehensiveness and continuity confronted a need to create efficiency in care delivery, leading to a new division of internist labour. Primary care providers focused on ambulatory practice, while 'hospitalists' have multiplied to provide in-patient care. There are now more than 30,000 hospitalists nationwide and, in a recent survey, more than 75% of them report caring for patients in intensive care units [5].

Hospitalists integrate into the ICU workforce in a collaborative model utilizing a supervising intensivist- or a hospitalist-only model generally used in lower acuity ICUs where intensivists cannot be recruited. All models require knowledge, skills, and attitudes appropriate for the local cohort of critically-ill patients. While hospitalists must be able to recognize and treat acute physiological derangements, and perform basic procedures, such as central/arterial line placement, their comfort surrounding intubation, management of mechanical ventilation, and other advanced life supports varies widely.

Recently, a controversial position paper issued by the Society of Critical Care Medicine (SCCM) and the Society of Hospital Medicine jointly endorsed a conceptual model in which practicing hospitalists with at least 3 years' experience of clinical practice would be eligible for a 1-year critical care fellowship programme, which would lead to competency, as well as to eligibility for specialist certification in critical care medicine [6]. Immediate objections to the proposal surrounded the adequacy of training time and experience to acquire the necessary competencies. For comparison, 6 years of training are required to attain critical care expertise in Australia and New Zealand.

Despite this controversy, there is wide agreement that the standardization of care for common and acute critical situations is mandatory. Such standardization can be enhanced through the use of standard courses, such as Fundamental Critical Care Support (FCCS). The FCCS course was developed by the SCCM, and uses both didactic lectures and skill stations in a 2-day format to provide a framework for assessing and managing critically-ill patients outside tertiary referral centres. The FCCS course can broaden the knowledge base and skill set of hospitalists in both community and rural hospitals. FCCS is emphatically not a substitute for in-depth training, but can serve as a strong foundation for critical care training.

Hospitalists will increase their presence and responsibilities as critical care providers as a consequence of the unmet demand for critical care services. It will be important to ensure that patient needs are matched with verified provider competencies, while avoiding divisive distinctions based solely on board certification.

Affiliate providers

At the Emory Center for Critical Care, we coined the term affiliate provider (AP) to describe our 63 nurse practitioners and physician assistants, who have received special training and demonstrated additional competencies in intensive care. We believe this term provides a more accurate description of the ICU nurse practitioner (NP) and physician assistant (PA) roles and responsibilities, when compared with the more traditional names that include 'mid-level' or 'physician extender'. We further believe that this collective term emphasizes the idea that both NPs and PAs can be trained to be effective, efficient, compassionate providers of critical care.

Certification for NPs in acute and ICU care began in 1995 [7]. The American Association of Critical-Care Nurses recognizes acute care NPs as having the appropriate training and education to manage acute and critically-ill patients. Importantly, recent changes to the scope of practice recommendations and legislation will soon exclude other categories of NPs from practicing in the ICU [8]. We expect that a modest number of well-trained and committed acute care NPs will form a cornerstone of ICUs provider workforce. These workers are especially important because they often bring years of bedside critical care experience (as nurses) to their new provider roles.

The shortage of primary care physicians almost 50 years ago was probably the stimulus for the growth in the number of PA programmes in the USA. However, PAs practicing in the ICU and acute care setting have also grown substantially over the years. According the 2010 American Academy of Physician Assistants census, about 2% of all registered PAs are dedicated full time to an ICU/critical care setting, while 21% spend at least some of their time in an ICU/critical care setting. While critical care is an attractive clinical setting for many new graduates, their relative paucity of clinical ICU experience creates special challenges in transitional training to ensure that they acquire and use the competencies needed to provide safe and effective critical care. We expect that recruitment and focused transitional training of PAs will emerge as a common strategy across the USA.

When appropriately trained, verified, and qualified, the NP and PA affiliates extend the existing provider cohort by participating in multidisciplinary rounds, performing procedures such as central/arterial line placements and endotracheal intubations. With progressive training, APs can master even the most complex procedural skills, such as insertion of ventriculostomy catheters.

APs also take on key administrative roles, participating, and even leading development and refinement of care protocols that lead to the removal of unnecessary variance in practice. Outside the clinical arena, affiliate providers participate in quality projects, assisting in the education of nursing staff, residents, medical students, and other health care professionals who are part of the multidisciplinary ICU team. Additionally, affiliate providers engage in or develop research projects related to their areas of expertise and interest [9]. Affiliate providers have been shown to have a positive impact on quality by improving communication and adhering to best practice guidelines [10,11].

With a shrinking federal health care budget, and with ICU costs estimated to be 0.7% of the US gross national product, simultaneous

emphasis on both quality and value in health care is necessary. Measuring productivity of intensivist physicians and their affiliate providers locally has become a key business strategy. Creating a mandatory time-accounting policy and providing all providers with an electronic tool to log and follow their time allocations has been a useful approach to understanding and refining clinical staffing models and assignments [12].

When building a business model for APs, it is worth noting that APs are reimbursed at 85% of the rate of physicians by federal agencies and often 100% by commercial agencies (usually defined contractually). To further improve utilization, APs can also be asked to respond to codes and with rapid response teams. They can provide another pair of hands, perform procedures, and facilitate transfer of the patients to the appropriate ICU postcode or assist in a rapid response evaluation. In our experience, the time-accounting tool is key to understand and improve utilization of their professional services.

Tele-ICU

Tele-ICU, which is branded and trademarked eICU by a major vendor (Philips Healthcare), continues to grow with the technological advancements needed to build infrastructure, as well as with the need to extend the reach of intensive care providers into under-served or rural areas, where hospitals have limited resources. First described in 1982 by Grundy and colleagues [13], tele-ICU was conceived as a way of networking critical care consultants with hospitals lacking critical care expertise. More recently, affordable high resolution two-way audio and video links, coupled with decision support software has allowed a new generation of tele-ICUs to link critical care providers to critically-ill patients in remote locations. At the time of writing, approximately 14% of the ICU beds in the USA are monitored by a tele-ICU system.

Although there are currently several tele-ICU vendors in the USA, their operating principles are similar. Generally a tele-ICU is staffed 24/7 with ICU registered nurses (RNs) or Aps, but this can vary significantly depending on need. The hours of presence of an intensivist in the central (advising) centre varies, but is dependent on the needs of the health care system. Typically, tertiary and quaternary ICUs that have a structured intensivist programme and use tele-ICU will 'sign out' to the tele-intensivist at night. In contrast, smaller ICUs in rural and under-served locations that depend on part-time physician coverage elect around-the-clock tele-intensivist presence to assure a continuous oversight. One tele-intensivist may be associated with up to 125 patients, but 70 patients are more typical. One tele-ICU RN can manage up to 40 patients [14].

High resolution audio and video allows direct interaction between the tele-ICU team and members of the bedside team, including the nurse, clinical pharmacist, respiratory therapist, AP, or physician. Addressing concerns about the patient, facilitating weaning from mechanical ventilation, and writing orders remotely are just some of the tasks that can be accomplished by the tele-ICU team, in collaboration with the bedside team.

The logistics of setting up a tele-ICU system are complex. Start-up costs include finding and leasing space for the command centre, hiring staff, and purchasing licenses and equipment for the number of beds in the system. However, the benefits of a tele-ICU can have a significant positive impact on patient care, improve best practice compliance, and improve the financial bottom line by emphasizing efficiency and decreasing waste. For-profit companies have emerged that offer turn-key tele-ICU services to hospitals. Should a hospital choose to establish its own tele-ICU command centre, some of the costs can be offset by marketing tele-ICU services to small community or rural hospitals on a per occupied bed basis 'at cost', with the benefit of load-balancing critical care across a larger network and channelling appropriate patients to the larger coordinating hospital. Smaller referring hospitals often cannot afford hospitalists or intensivists to oversee their ICUs, but can utilize the expertise of the tele-ICU team to improve patient care.

There are current data supporting the positive impact on mortality of tele-ICUs (up to 29% in one large acuity-adjusted analysis), best practice, and financial performance [15–20]. The benefits seem to accrue significantly in low-risk patients. Effective management can mitigate their conversion to long-stay patients, and prevent complications through close observation and early intervention.

Unfortunately tele-ICU services are not universally billable through either Centers for Medicare and Medicaid Services (CMS) or private payers. However, this seems likely to change in the future, based on proposed CMS payment guidelines and a drive to increase efficiencies of care.

Alternative models of critical care provider staffing internationally

The need for alternative models of provider staffing in critical care is dependent on many factors including, but not limited to the number of critical care beds that need to be staffed, the availability of critical care trained providers, the presence or absence of training programmes, physician staffing ratios, and nurse staffing ratios. In the USA, these factors have combined to drive a robust need for alternative critical care provider staffing models. However, there is evidence that interest has grown in these models internationally. A query placed on the Critical Care Medicine International Internet Group (CCM-L; ccm-l@pitt.edu)) regarding the utilization of physician extenders in critical care, their prevalence, and their responsibilities, yielded a response from members in 14 countries. Of the respondents, two (Australia and the UK) utilized physician extenders in critical care.

Canada, India, Netherlands, Malaysia, Liberia, Haiti, Lesotho, and South Africa all use physician extenders in their health care systems, but little is currently known specifically regarding their use in critical care medicine.

Conclusion

The decline in supply of board-certified intensivists versus the expanding demand appears inexorable. We have described three core mitigation strategies:

- The use of on-site physicians (hospitalists) who will require additional training in critical care.
- Deployment of critical care trained non-physician providers.
- The use of tele-ICU to expand the benefit of experienced intensivist physicians and seasoned critical care nurses as a second layer of caregivers, who can be spread over large distances.

These three strategies are not exclusive, but are rather complementary, and combinations will probably provide unique solutions to local needs.

CHAPTER 3

Rapid response teams for the critically ill

Ken Hillman and Jack Chen

Key points

- Like intensive care units (ICUs), rapid response systems (RRSs) are interventions aimed at managing serious illness.
- The implementation of a new system has different challenges to the implementation of a new drug or procedure, both operationally and in its evaluation.
- The implementation of a RRS across an organization requires five elements: standardized triggering criteria; a standard response; organization wide education; support by senior management and clinicians, and involvement of the whole organization; and an agreed way to monitor the system.
- RRS improve over time as the organization adapts, and improves its effectiveness. Currently, the most accurate way of evaluating effectiveness is to monitor the number of calls/1000 admissions that correlates strongly with the reduction of death, and cardiac arrest rates.
- As yet, there is little data to support what are the most appropriate calling criteria or make-up of the response team. The response team must have the skills, knowledge, and experience necessary to match the level of illness of patients that they will be attending.

Introduction

Rapid response systems (RRSs) are based on the simple premise that early intervention in patients with a serious illness is better than neglect. They have in common the early identification of at-risk patients, followed by a rapid response by staff who have the appropriate knowledge, skills, and experience to care for those patients. While the calling criteria used to identify at-risk patients vary, they are all based on severely abnormal vital signs and observations. The systems operate mainly across the general wards in acute hospitals, where the level of care is less appropriate for caring for deteriorating patients compared with patients in environments such as intensive care units (ICUs). Their role has become more important as the population of hospital patients has become older, with an increasing number of co-morbidities and having more complex interventions. In fact, the population of patients subject to RRS interventions is similar to those already being managed in ICUs. Implementing a RRS has different challenges to implementing a new drug or procedure. Successfully implementing a hospital-wide system requires a comprehensive educational programme, support by every level in the organization, and the integration of outcome indicators into the implementation process. For example, the reduction of deaths and cardiac arrests in a hospital is directly related to the number of calls/1000 admissions. RRSs have now been implemented in one form or another in the majority of Australasian, North American, and UK hospitals. Hospitals with a RRS have a significant reduction in cardiac arrest and death rates.

Patients in areas such as operating theatres or ICUs rarely deteriorate without early detection, and can then receive appropriate management. On the other hand, it is the seriously ill or deteriorating patients on general wards who are likely to suffer potentially preventable deaths or cardiac arrests [1]. There are many reasons for this, including low staff–patient ratios, poor monitoring, outdated ways of manually recording vital signs, bedside staff who are not trained in how to recognize and manage serious illness, and rigid silo-based systems that do not encourage a rapid response to at-risk patients. As a result, there are many potentially preventable deaths that occur in acute hospitals [2]. There is a similar slow deterioration in patients who have cardiac arrests [3], and in patients before admission to the ICU from general wards [4]. The situation has been summarized as the wrong people with the wrong skills arriving too late to manage at-risk patients [5].

RRSs were developed in response to a problem. They are aimed at detecting, and responding to the seriously ill, as well as patients who are at-risk of becoming seriously ill. The system is usually implemented across the whole hospital, and has two major features—standardized triggering criteria and an agreed response to patients who conform to those criteria. The objective of RRSs is to identify, and manage serious illness early in order to improve patient outcome, and reduce complications.

Calling criteria

There are many different variations in how we define the threshold level of illness when urgent intervention is required—the triggering or calling criteria [6]. The criteria are usually a combination of abnormal vital signs, such as respiratory and pulse rate, blood pressure, and oxygen saturation, combined with abnormal observations, such as airway obstruction, seizures, and sudden decrease in the level of consciousness. Many criteria also include 'worried' or 'concerned'. This empowers clinical staff to use their clinical judgement, as well as numbers. The rate of 'worried' calls is usually low

when the system is first introduced and then often becomes the single most common trigger as the system matures. This is as a result of nursing staff, gradually feeling empowered to exercise their clinical judgement, confident that they will not be derided for doing so.

The trigger sometimes involves a response when only one of the vital signs or observations fits the calling criteria [7]. Other triggers involve scores that elicit different levels of response, such as the modified early warning system (MEWS) [8]. Potential disadvantages of scoring systems are that they are complex, subject to error, overlook some life-threatening observations, and exclude clinicians from summoning help based on clinical judgement. There may be increasing interest in using RRS-type criteria to predict mortality and prognosis, as well as to investigate even earlier markers of serious illness, such as abnormal biochemistry and the patient's underlying condition. Predictive scores, such as APACHE and SAPS, measure risk and have much in common with calling criteria.

There is little agreement around the balance of sensitivity and specificity needed to identify serious illness without over-burdening the system. As yet, only systems based on single calling criteria have been subject to large patient-outcome studies. It may be that the details of the various triggering criteria are not as important as the effect of simply using a system to identify and respond to serious illness. This, in turn, changes the culture of an organization, increasing the awareness that there are at-risk patients in hospitals and that support to help manage those patients is always available. Supporting this is the observation that the acceptance of the system improves over time [9].

The response

As with calling criteria, there are many different ways to respond to at-risk patients. The overarching principle in determining the nature of the response personnel required is relatively straightforward. First, the type of patient and level of illness of those patients needs to be determined. From that information, the level of skills, knowledge, and experience necessary to match the needs of the patients can be determined [10]. For example, in the largest study on the levels of response, it was found that of the 2376 calls to patients responded to, only five did not require critical care interventions such as central line insertion, inotrope administration, airway control, and ventilation [11]. On the other hand, other hospitals will have a different population of patients with different needs. For example, the usual or admitting team could respond to lower levels of illness, with the back-up of appropriately trained staff, who would also respond to patients with more severe calling criteria [12]. There is no obvious reason why other clinicians, such as nurses, could not be trained to an appropriate level of skills and knowledge. There is also no reason why the usual team could not be trained in all aspects of advanced resuscitation, including critical care skills and knowledge. However, this would probably be extremely expensive and resource consuming. For example, the cost of training staff for relatively simple cardiopulmonary resuscitation intervention is estimated to cost over $600,000/survivor [13]. Another approach would be to organize widespread education to increase awareness of seriously-ill and at-risk patients, so that appropriate triggering occurs and then to respond with a small team of staff, appropriately trained in critical care skills, who operate 24 hours/day [12].

Implementation

Unlike a new drug or procedure, the challenges of implementing a new system are more complex, and require skills, and experience not necessarily familiar to physicians. Acute hospitals operate in professional and geographical silos which is the major reason why so many patients fall through the gaps between the silos, suffering potentially preventable deaths, and serious adverse events [1]. Rapid response systems are unique in being constructed around specific patient needs, and being organization wide, involving all physicians and nurses, as well as being supported by administrative and other hospital staff. There are five main elements necessary to effectively implement a RRS [12]. The calling criteria and the appropriate response have been discussed. However, for optimal implementation, the system also needs clinical and administrative leadership. Usually, several respected senior staff in the hospital are key to successful implementation. An education strategy is also needed. First, all staff in a hospital need to be aware that the system exists and urgent help can be summoned in an easily accessible way. Secondly, the response team needs to have the appropriate skills to manage any emergency. Thirdly, all direct patient care deliverers need to be able to recognize serious illness, and to initiate urgent management before the response team arrives.

Finally, the system needs to be monitored, and the outcome data made available in an easily understood and aggregated fashion to both those monitoring the hospital's performance, but also targeted to hospital departments, and key personnel [14].

One of the more important determinants of the effectiveness of the system's performance is the rate of calls/1000 hospital admissions. This is directly related to the reduction of deaths, and cardiac arrests [15]. Usually, when a system is first implemented, rates can be as low as 3 calls/1000 admissions. More mature and effective systems usually achieve rates of more than 40 calls/1000 admissions. Other outcome data include crude mortality and cardiac arrest rates [12]. A RRS is not aimed at resuscitating patients who are made do-not-attempt-resuscitation (DNAR). The more accurate indicator is probably unexpected deaths and cardiac arrests, i.e. those without an explicit DNAR order. A further refinement is to examine all unexpected deaths and cardiac arrest rates to determine if there were calling criteria in the 24 hours before the event that were not responded to, i.e. 'potentially preventable' [15]. Thus 'unexpected, potentially preventable' become powerful descriptors for monitoring patient safety in a hospital. Measuring and appropriately targeting outcome indicators ensures ownership for those responsible for operating the system, as well as giving information about trends for those monitoring the effectiveness of the system.

Rapid response systems and end-of-life care

An increasing problem in the practice of intensive care is inappropriate admission for end-of-life (EOL) care. There are many possible reasons for this, including the reluctance of doctors to discuss the issue and the increasing specialization of medicine resulting in incremental management. In the process, perhaps we are losing the ability to diagnose dying. Often that task is left to the intensivist in terms of making the decision that further escalation of treatment would be futile. As a result of the failure to diagnose dying, up to one-third of all RRS calls may involve making EOL decisions [16].

This can be frustrating, time-consuming, and resource intensive for intensive care staff. There are early initiatives to define dying and respond more appropriately in systems similar to a RRS, but designed around better EOL care.

Other implications of rapid response systems

Research around RRSs have highlighted major deficiencies in the care of the seriously ill, especially the recording and use of vital signs in general wards. They are often inaccurately and inconsistently measured, especially in the measurement of respiratory rate [17]. This represents a major weak point in any system designed to respond to serious illness. Even when vital signs and observations meet calling criteria, in up to half of all cases, nurses are reluctant to call the response team [18]. Patients in acute hospitals are increasingly older, with co-morbidities, and having more complex drugs and interventions that can result in serious complications. As such, the need for delivering critical care to patients in ICUs can be the same as for patients in general wards. The lack of agreed definitions for defining the need to be admitted to an ICU is blurred by factors such as the nature of the hospital population, the admission and discharge criteria for the ICU, and the number of beds in the ICU. A patient in a general ward in one hospital could easily be a patient in an ICU in another hospital. The level of illness and risk of mortality in patients responded to by a RRS is becoming similar to those in an ICU.

The effectiveness of rapid response systems

Proof that interventions designed to care for the seriously ill in hospitals, such as ICUs, and RRSs is equivocal. Before and after studies of RRSs have shown impressive improvements in serious adverse events [19].

One of the problems in attempting to demonstrate the effectiveness of RRSs and ICUs is that they both need committed staff to make them effective, and thus there would be a large and, indeed, welcome Hawthorne effect necessary in any research attempting to demonstrate effectiveness. The largest study of RRSs was inconclusive for some end-points [17], but did demonstrate a significant reduction in mortality rate in adult hospitals with a RRS [15]. Similarly, the largest meta-analysis on RRSs has demonstrated a one-third reduction of cardiac arrests and deaths in paediatric hospitals, and a one-third reduction of cardiac arrests in adult hospitals [20]. It is hard to imagine many other interventions that are used in the seriously ill that have had a similar impact on mortality and cardiac arrest rates.

CHAPTER 4

In-hospital transfer of the critically ill

Lorna Eyre and Simon Whiteley

Key points

- Critically-ill patients require in-hospital transfer for a variety of reasons.
- Transportation outside of the normal critical care environment can be associated with deterioration and adverse events.
- Wherever possible, patients should be resuscitated and stabilized before transportation.
- Portable monitoring and equipment should be used that are appropriate to the patient's condition.
- Patients should be accompanied by appropriately-trained staff who are able to respond to any changes in the patient's condition and/or critical incidents that may arise.

Introduction

The intensive care unit (ICU) provides a safe environment for the critically-ill patient where optimal standards of critical care can be delivered. However, patients typically develop critical illness outside the ICU, necessitating transport from their point of presentation to the ICU, while those in the ICU frequently need to be transferred out, in order to undergo diagnostic or therapeutic interventions.

The risks and hazards associated with such transfers are often underestimated. This may be because much of the published literature concentrates on inter-hospital transfer, where distance, transport-modality, logistics, and health care economics provide a focus for such attention. Numerically, however, far more in-hospital transfers occur [1]. While these are logistically simpler than inter-hospital transfers, there is evidence that they are associated with a high level of critical incidents, adverse events, and increased morbidity and mortality [2].

The UK Royal College of Anaesthetists National Audit Project 4, for example, reported three serious untoward events relating to airway complications during in-hospital transfer [3]. In another study of incidents occurring over a 6-year period during in-hospital transfer, serious adverse outcomes occurred in 31% of incidents reported, with 2% resulting in death [4]. Of the incidents recorded, 39% related to equipment problems, such as battery failure, while 61% related to poor staff communication, inadequate monitoring, and inadequate positioning of patients.

Many of the adverse cardiovascular and respiratory complications that arise can be related to movement of the non-optimized patient, dislocation of essential life sustaining devices (endotracheal tubes, venous access devices), and equipment failure [5]. One key issue in preventing critical incidents during in-hospital transfer is the training and competence of the accompanying staff. Critically-ill patients should be accompanied by personnel with the appropriate knowledge skills and experience to carry out the transfer safely and to deal with any complications or incidents that arise.

The in-hospital transport of critically-ill patients therefore, deserves the same focus as inter-hospital transfer.

Indications for in-hospital transfer

Indications for the in-hospital transfer of critically-ill patients are shown in Table 4.1.

The in-hospital transfer of the deteriorating patient requiring escalation to a higher level of care can be particularly challenging. Focus on pre-transfer resuscitation and stabilization prior to transfer is mandatory.

Transfer of a patient out of the ICU environment for diagnostic or therapeutic intervention can often be for prolonged periods and to discreet locations some distance away from the ICU. The decision to transfer should be based on the balance between probable benefit of the proposed intervention and potential risk. Observational studies do suggest, however, that the yield from diagnostic intervention in this group is high. Wadyhas et al. [5] noted angiography and abdominal computed tomography (CT) resulted in therapeutic consequences in more than 50% of patients. However, alternative strategies, including the use of bedside investigations such as ultrasound, should be considered.

There is evidence that discharge of patients from intensive care during the night shift hours is associated with increased morbidity and mortality [6,7]. Therefore, unplanned, out-of-hours transfers/discharges should be avoided wherever possible.

Accompanying personnel and training

Critically-ill patients should be accompanied by at least two appropriately trained attendants during transfer. Although not all transfers require a physician; responsible personnel must be able to respond to the individual needs of the patient.

While much of the published data relates to inter-hospital transfers, there is evidence that poor training and performance of staff contribute to the risk during transfer. Beckman et al. [4], for example, examined human factors contributing to critical incidents

Table 4.1 Indications for in-hospital transfer

Indication	Example
Escalation of care	E.g. from ward, operating room, emergency department, following development/recognition of critical illness or deterioration of the patient
Investigation	E.g. for CT or MRI or angiography
Therapeutic	E.g. for definitive surgery, interventional radiology, cardiac catheterization
Planned/emergency evacuation of ICU	E.g. planned transfer from unit to allow essential building/maintenance work or unplanned evacuation, for example, resulting from power failure or fire
De-escalation of care	E.g. step down from ICU (level 3) care to high dependency unit (HDU; level 2)

during transfer, and identified poor knowledge, errors of judgement, delay in problem recognition, failure to follow protocol, and inadequate preparation of equipment as significant factors. All staff involved in the transfer of critically-ill patients should therefore receive appropriate training, and be able to demonstrate the range of skills and competencies required that are appropriate to their role. Detailed competency frameworks have been published by national training organizations and specialist societies [8].

There is growing interest in the use of specialist teams to transfer critically-ill patients. One study has looked at in-hospital transfers and concluded that a specially trained nursing transport team had a reduced rate of complications [9].

Communication

A vital component of all transfers is clear and concise communication between the team responsible for transfer and personnel at the destination. The 'SBAR' (situation, background, assessment, recommendation) structured format for handover is a useful method of conveying relevant information [10]. This should include relevant medical history, indication or reason for transfer and requirements on arrival. The infection status of the patient (e.g. methicillin-resistant *Staphylococcus aureus* (MRSA) status, diarrhoea, etc.) should be provided to enable source isolation if necessary.

Preparation

Except in situations where the transfer is for immediate life-saving intervention (e.g. to the operating theatre or angiography suite to control bleeding), patients should be optimally resuscitated and stabilized prior to transfer. The key elements of this are included in Table 4.2.

Monitoring

The minimum standards of monitoring required during in-hospital transfer are the same as those required for inter-hospital transfer. These are:

- Electrocardiogram (ECG).
- Non-invasive blood pressure.

Table 4.2 Key elements of stabilization prior to transfer

System	Description
Airway	*Either* ◆ Patent and maintained. *or* ◆ Secured by endotracheal intubation. ◆ Indications for intubation include Glasgow Coma Scale. (GCS) <9, actual or impending airway compromise, and facilitation of positive pressure ventilation.
Breathing	*Either* ◆ Spontaneously breathing and maintaining adequate gas exchange, with or without supplemental oxygen, continuous positive airway pressure (CPAP) or bi-phasic positive pressure (BIPAP). *or* ◆ Intubated and ventilated. ◆ Some CPAP and BIPAP systems are portable and where appropriate patients can be transferred on these modalities. If this is not available or appropriate then intubation and positive pressure ventilation should be instituted. ◆ Patients should be stabilized on the transport ventilator prior to transfer and adequacy of gas exchange confirmed by arterial blood gas analysis. ◆ Continuous oxygen saturation and capnography ($ETCO_2$) monitoring is mandatory [3]. ◆ Sedation and paralysis may be required to ensure patient comfort and effective ventilation.
Circulation	◆ Haemodynamically stable. ◆ Hypovolaemia corrected and inotropes/vasopressors used, guided by appropriate haemodynamic monitoring, to optimize cardiac output/perfusion pressure. ◆ Secure venous access is mandatory. ◆ Continuous arterial pressure monitoring should be considered.
Disability	◆ The specific needs of individual patients should be addressed. ◆ For those patients that are not intubated and ventilated (GCS >9) this should include assessment of the individual patient's ability to tolerate the proposed transfer and/or planned procedure (e.g. can the patient lie flat/still for the required length of time).
Exposure	◆ Warm, appropriately wrapped. ◆ Exposure kept to a minimum. ◆ Consider active warming devices if necessary.

- Oxygen saturation.
- Capnography (end tidal CO_2 ($ETCO_2$)) in ventilated patients.
- Temperature.

Invasive blood pressure monitoring has advantages over non-invasive, since it is continuous, less subject to motion artefact, and is less of a drain on the battery life of the monitor. The need for any additional monitoring (e.g. central venous pressure, intracranial pressure, pulmonary artery pressure) will be guided by the patient's condition and ongoing therapy.

Equipment

Equipment required for in-hospital transfer can be divided into four categories. All equipment should meet the relevant national standards, and staff should be familiar with its function and operation.

Basic care

While inter-hospital transfers require the use of a specialized transfer trolley, in-hospital transfers can often be carried out utilizing the patient's own bed. The staff involved must therefore be familiar with the operation of the bed and particularly how to lay the patient flat in an emergency. It is common to place essential equipment on the bed (in proximity to the patient), but this creates a risk of injury to the patient and prevents unhindered access in an emergency. All essential equipment therefore should be carried on portable racking/shelves either attached to the end of the bed or mounted over the bed. A number of systems are commercially available. Some of these also provide housing for portable oxygen cylinders (see Figure 4.1).

Life support

Portable ventilators should be robust, battery powered, and economical with oxygen. As a minimum they require disconnection and high pressure alarms, the ability to supply positive end expiratory pressure (PEEP) variable inspiratory/expiratory (I/E) ratio, and variable inspired oxygen concentration (FIO_2). The provision of pressure controlled ventilation, pressure support, and continuous positive airway pressure (CPAP) is also desirable [7]. A self-inflating bag and mask with oxygen reservoir and tubing should be available in case of ventilator failure.

Sufficient oxygen supply must be available to complete the transfer. Requirements will depend on the patient's minute volume, fractional inspired oxygen and the additional volume required to drive the ventilator (see manufacturers' information sheets). In the UK, oxygen cylinders containing 680 L oxygen (British Oxygen Corporation, size E) are most commonly used and are adequate for most in-hospital transfers. Similar size cylinders are available elsewhere in Europe and North America, although exact size/content may vary with manufacturer. Portable oxygen supplies should be conserved when possible by transfer to a hospital (piped) supply when available.

Syringe drivers/infusion pumps are required to deliver drug and fluid infusions. The concentrations of drug infusions should be optimized to minimize the need to change syringes during transfer.

Monitoring

Portable monitoring equipment should be designed for the purpose with an illuminated screen, the ability to display the minimum monitoring requirements, together with two invasive pressures, and have both audible and visual alarms. Monitor battery failure was common in the Australian ICU Incident Monitoring Study [4] and occurred in 14% of 125 in-hospital patient transfers. Battery life should be conserved by connection to a mains power supply when available.

Dedicated monitoring systems are usually available in magnetic resonance imaging (MRI) suites. If not, staff must be aware of the limitations of standard monitoring systems.

Treatment

Equipment required to both deliver ongoing ICU management (e.g. additional syringe drivers/infusion pumps, underwater seal drains, etc.) and to respond to a potential emergency caused by physiological deterioration or equipment failure.

Where present, underwater seal drains add complexity to the transfer process due to the risk of dislodgment or compromise of drain integrity (e.g. allowing water/air to entrain back into the chest.) Drains should not, however, be clamped during the transfer process, due to the greater risk of re-accumulation of the collection (particularly tension pneumothorax). Drains should be kept below the level of the chest at all times. Disposable one-way 'flutter valves'

Fig. 4.1 Typical end of bed 'stack system' to facilitate the transport of equipment during in-hospital patient transfer, with mountings for portable ventilator, infusion pumps syringe drivers, and monitoring and secure housing for oxygen cylinders.

Table 4.3 Emergency equipment and drugs for use during in-hospital transfer

System	Items
Airway	Oral and nasopharyngeal airways
	Suction device, and suction catheters
	Laryngeal masks
	Endotracheal and tracheostomy tubes
	Laryngoscopes
	Endotracheal tube introducers (stylet and bougie)
	Magill's forceps
	Tape for securing tracheal tube
	Stethoscope
Ventilation	Fixed performance oxygen masks and tubing
	Self-inflating bag and mask with oxygen reservoir and tubing
	Airway filters/heat moisture exchange (HME) filters
	Nasogastric tubes (assorted sizes) and drainage bag
Circulation	Needles/syringes assorted sizes
	Alcohol and chlorhexidine skin preparation
	Intravenous/arterial/central venous catheters
	Aseptic line insertion packs (including gown and gloves)
	Suture/fixation devices and dressings
	Intravenous fluids and administration sets
	3-way taps/access devises

(e.g. Heimlich valves) may be used as an alternative, but are prone to blockage and malfunction.

A list of emergency equipment and drugs for use during in-hospital transfer is included in Tables 4.3 and 4.4. All equipment should be checked and tested prior to use.

Care, documentation, and audit

The standard of care during transfer should be the same as that delivered within the critical care environment, accepting that some treatment modalities may be suspended for the duration of the transfer (e.g. renal replacement therapy).

The indications for transfer, and communications with other health care professionals and/or family members should be documented. Physiological variables and changes in the patient's treatment or condition should be recorded. Any critical incidents should be reported via the standard local reporting mechanisms. In addition, there should be continuous prospective audit of in-hospital transfers to promote quality improvement, ensuring the highest possibly standards of care.

Common pitfalls

Studies of both in- and inter-hospital transfer consistently report critical incidents resulting from communication failures, poor knowledge and training of staff, (particularly in relation to familiarity with equipment), and equipment failure. Common pitfalls include:

- Dislodgement or obstruction of endotracheal tube.
- Accumulation of airway secretions.

Table 4.4 Drugs potentially required during in-hospital transfer

Type of drug	Drugs
Sedatives/analgesics	Midazolam
	Diazepam
	Propofol
	Thiopental
	Remifentanil
	Fentanyl
	Alfentanil
	Morphine
Neuromuscular blocking agents	Succinylcholine (suxamethonium)
	Rocuronium
	Atracurium
	Vecuronium
Cardiovascular	Dopamine
	Dobutamine
	Norepinephrine
	Epinephrine
	Amiodarone
	Labetalol
	Glyceryl trinitrate (GTN)
	Furosemide
Bronchodilators	Salbutamol
	Aminophylline

List provided is indicative of the range of drugs that may be required and is in addition to drugs required for emergency cardiopulmonary resuscitation. Choice of agent(s) will be dictated by clinical circumstances, and local policies and practice.

- Incorrect setting of ventilation parameters.
- Oxygen supply failure.
- Inadequate correction of hypovolaemia (prior to transfer).
- Kinking of infusion lines.
- Depletion of infusion drugs.
- Failure of syringe pumps.
- Failure of other portable equipment (e.g. monitors).
- Logistic issues, including beds not fitting into lifts or doorways, or being difficult to manoeuvre.

Planned and unplanned evacuation of ICU

The planned decant or evacuation of patients from ICU (e.g. to allow building works or maintenance) is not uncommon. Unplanned emergency evacuation (e.g. as a result of power failure or fire within the vicinity) is a much rarer event, but can occur. All intensive care units should therefore have planned emergency evacuation procedures in place. All staff should be aware of evacuation routes and decant areas. Depending on the circumstances, progressive horizontal transfer within the building may be required to reach a location capable of managing ICU patients. Portable oxygen supplies and basic life support equipment (e.g. self-inflating bag and mask) should be readily available at each bed space to facilitate emergency unplanned in-hospital transfer of this sort.

Conclusion

Safe and effective in-hospital transfer of critically-ill patients can be achieved by adequate staff training, and a systematic approach to the stabilization and transfer process.

CHAPTER 5

Pre- and inter-hospital transport of the critically ill and injured

Kelly R. Klein and Paul E. Pepe

Key points

- Critical care delivered in the out-of-hospital setting is an integral part of modern health care that can be life-saving when used appropriately.
- Critical care transport systems have special challenges, including logistics, weather conditions, traffic, geography, and strict governmental regulations.
- Many professional societies and governments have developed specific guidelines and regulations regarding critical care transport, with which all personnel involved with transport must be familiar.
- Protocols and policies need to be in place to ensure optimal care and safety for both patients and transport crews with contingencies for weather and altitude challenges.
- Protocols and policies should address issues such as when transport is not safe or not indicated, as well as appropriate crew configurations, specific training, competencies, and equipment.

Introduction

Many elements of intensive care medicine have been brought to the out-of-hospital setting, utilizing specialized pre-hospital care providers (physicians, nurses, paramedics) who can deliver intensive care at the scene, as well as during transport [1–3]. Over the years, facilities were also designated as appropriate transportation destinations for certain critical emergencies, particularly patients with severe injuries, acute coronary syndromes, and stroke [4,5]. Furthermore, to bring such patients to specialized facilities such as trauma centres, cardiac catheterization centres, or other types of tertiary care institutions, both air and ground services have been developed for inter-facility transfer, as well as direct transport from emergency scenes [6–8].

Most emergency medical services (EMS) public safety ambulance responses, including those to motor vehicle crashes and acute illness, do not require critical care. Many of those prehospital care providers are not skilled enough to provide complex critical care support [3,9,10]. On the other hand, specialized critical care transportation vehicles (air and ground) and specialized advanced life support teams still frequently provide critical care transport in the out-of-hospital setting, particularly in terms of inter-facility transfers and specialized support for on-scene providers in distant venues [4,6–8,10–12].

Methods for transporting the critically ill and injured have evolved from the horse-drawn carts and hot air balloons in the 17th and 18th century to station wagon ambulances, fixed wing planes and helicopters in the 20th century [6]. Staffing has shifted from surgeons with amputation saws and hearse drivers with stretchers to cardiologists with portable defibrillators and, eventually, to paramedics, nurses, and accident and emergency physicians with specialized training in out-of-hospital critical care for the very sick and injured [13,14].

Today, critical care transport is considered a necessity in the world of modern health care and has evolved from the original 'scoop and run' mentality to mobile intensive care units capable of supporting care for the most fragile neonate receiving mechanical ventilation, multiple intravenous medications, and intensive monitoring devices [6,7,10, 13,14].

Depending on the distance travelled, weather, geography, environmental challenges, and patient considerations, there are multiple methods of patient transport (Table 5.1), each with relative advantages and disadvantages. Transportation medicine involves the specialized logistics of the mode of travel, and the training and provision of the appropriate health care provider to deliver the high level of care outside of the hospital setting over a period of hours and, in some circumstances, days [7,10,11,13,14].

Patient transfer issues

In many nations, patient transport, particularly those involving inter-facility transfer, are highly regulated. For example, in the United States (USA), the Emergency Medical Treatment and Labor Act (EMTALA) guides such practices [15]. To be compliant with these regulations, the sending (transferring) physician is responsible for the patient's well-being until the patient arrives at the receiving hospital. In terms of determining the mode of transportation, the sending health care provider must take into consideration risks to the patient and crew (Table 5.1).

Independent of the physician, the choice of air medical transport may be excluded for safety reasons by the aircraft pilot who makes the final determination if the flight is safe to take.

Air medical transportation can also involve physiological considerations due to change in altitude. For the most part, the effects of altitude are minimal, particularly for fixed-wing transport with highly-pressurized cabins and helicopter transport involving

Table 5.1 Advantages and disadvantages of various transportation modes

Mode	Advantage	Disadvantage	Range in miles*
Ground	◆ Large interior ◆ Quieter than an aircraft ◆ Can carry larger patients ◆ Can carry more equipment	◆ Limited travel distance ◆ Slower	200–250
Rotor (helicopter)	◆ Speed ◆ Navigates remote terrain	◆ Limited by weather conditions ◆ Expensive ◆ Weight limitations ◆ Close government scrutiny† ◆ Work hour restrictions such as ◆ FAR part 91 and 135‡	150–450
Fixed wing	◆ Speed ◆ Capable of travelling great distances ◆ No weight limitation ◆ Less restricted by weather	◆ Special landing requirements ◆ Expensive ◆ Close government scrutiny and oversight† ◆ Work hours and safety restrictions, such as FAR parts 91 and 135‡	1000–2500

*Depends on the type of vehicle and weather conditions.

†Such as the Federal Aviation Administration (FAA) in the United States.

‡FAR = Federal Aviation Regulations from the United States FAA.

altitudes less than 3000 feet (1000 m) above sea level. Nevertheless, crews should be aware of the potential for certain physiological changes in case cabin pressure is lost or compromised, or altitudes become significantly high due the location of the mission. Some considerations in such circumstances would concern certain patients such as those with:

- A potential or known pneumothorax without a decompression device in place.
- A clamped ventriculostomy tube.
- An endotracheal tube in place and the need to adjust the balloon cuff volume.
- Adjustments in supplemental oxygen in patients with respiratory compromise without closed respiratory support [14].

With proper training and anticipation of these issues with proper monitoring and procedure, these concerns should be minimized.

Staffing considerations for critical care transport

Studies have shown that transport by a specialist retrieval team compared with standard ground ambulance teams resulted a reduction in patient mortality during the first 12 hours of arrival at the receiving hospital (11,12,16). In 1993, the North American-based Society of Critical Care Medicine (SCCM), the American College of Critical Care Medicine (ACCM) and the American Association of Critical Care Nurses (AACN) developed guidelines for the transport of critical patients and recommended that all critical care transport should be performed by a dedicated, specially-trained transport team [17]. Similar guidelines have been promulgated on other continents and are consistent in terms of recommendations (13,18).

Based upon the recommendations, the general consensus is that there should be at least two personnel with critical care training attending the patient at all times during the transfer, regardless of the mode of transportation. Although a three-member team configuration may be used, it is often not necessary and may even be detrimental if space is very limited. The team composition should include a critical care nurse with multiple years of critical care experience, and either a paramedic or respiratory therapist with advanced life support training and experience [6,13,14,16,17,19]. Occasionally, a physician (fully-qualified or in-training) may be used as part of the transport team.

Tables 5.2 and 5.3 annotate crew composition and critical care training requirements for air medical transport adapted from various sources, including the AACN, American Academy of Orthopedic Surgeons (AAOS), Intensive Care Society, National Association of EMS Physicians and SCCM [6,13,14,16,17].

Table 5.2 Crew composition*

Crew	Advantage	Disadvantage
Paramedic	On-scene emergency experience	Limited ICU† experience
Nurse	ICU†/critical care experience	Limited on-scene experience
Respiratory Therapist	◆ Ventilator equipment expert ◆ Airway expertise	◆ Limited on-scene experience ◆ Not able to secure intravenous access or give medications
Physician	Critical care/emergency medicine experience and diagnostic skills	◆ Limited on-scene experience ◆ Expensive

*Or equivalency depending on country, regulatory issues, and national standard of care.

†ICU, intensive care unit.

Table 5.3 Recommended training requirements for the critical care team*

Crew	Required minimums	Additional certifications (recommended)
Paramedic	◆ Over 5 years critical care experience ◆ Advanced cardiac life support (ACLS) ◆ Paediatric advanced life support (PALS) ◆ Neonatal advanced life support (NALS) ◆ Prehospital trauma life support (PHTS) *or* ◆ International trauma life support (ITLS)	◆ Advanced trauma life support (ATLS) (audit) ◆ CCEMT-P certification† ◆ Certified flight paramedic ◆ (PF-C) ◆ Incident command ◆ Disaster life support ◆ Decontamination ◆ Life support
Nurse	◆ Over 5 years critical care experience ◆ Critical care registered nurse (CCRN) ◆ ACLS ◆ PALS ◆ NALS	◆ ATLS (audit) ◆ Paramedic certification ◆ Certified flight registered nurse (CFRN) ◆ Incident command system (ICS) training ◆ Disaster life support ◆ Decontamination ◆ Life support
Respiratory therapist	◆ Over 3 years critical care experience ◆ Critical care respiratory therapist (CCRT) ◆ ACLS ◆ PALS ◆ NALS	Emergency medical technician (EMT)
Physician	◆ Over 1 year post-medical school training ◆ ACLS ◆ PALS ◆ NALS	◆ EMT ◆ Incident command ◆ Disaster life support ◆ Decontamination ◆ Life support

*Or equivalency depending on country, regulatory issues, and national standard of care.

†Critical care emergency medical technician—paramedic certification.

Equipment considerations

Equipment and medication inventories may vary depending on the type of transport vehicle and patient condition (e.g. neonatal versus adult cardiac problem). However, at a minimum, the transport team should have the relevant competencies, appropriate monitoring devices, and capabilities in terms of administering and providing numerous interventions, including the spectrum of advanced cardiac life support medications, vasoactive medication infusions, narcotics, paralytic medications, anti-emetics, and blood products. In addition to ventilators and intravenous pumps for medication drips, the use of point-of-care (POC) testing has proved to be of great assistance for transportation crews. At a minimum, it is generally recommended that POC testing should be available for basic electrolytes, blood gas analysis, complete blood count, lactate, and glucose [20].

Procedural competencies

Recommendations for transportation teams also emphasize that the crews be cross-trained in on-scene/EMS competencies, intensive care unit procedures, advanced trauma care, and a myriad of paediatric/neonatal interventions/monitoring including, but limited to, all applicable levels of:

- Tracheal intubation.
- Surgical airway establishment.
- Needle/pigtail decompression.
- Intracranial pressure (ICP) monitoring.
- Left ventricular assist device (LVAD) monitoring.
- Intra-osseous access.
- Central venous access placement and care.
- Suturing.
- Chest tube placement and care.
- Arterial catheter placement and monitoring.
- Post-mortem caesarean section for trauma patients.
- Escharotomy for severe burns patients.
- Decontamination of contaminated patients.
- Balloon pump operations.

- Isolette operation.
- Splinting and spinal immobilization.
- Transport ventilator operation.
- The ability to appropriately use and analyse an array of monitoring devices ranging from pulse oximetry, end-tidal carbon dioxide and blood gas devices to POC testing tools.
- Experience in landing zone procedures.

Appropriate candidates for transport by critical care teams

Critical care transport teams must be configured in a manner that reliably provides the expertise necessary for the stabilization and care of critically-ill paediatric and adult patients in extraordinary environments and circumstances. It is also important that the referral hospital and the transport service have established a set of guidelines that can help the referring providers make appropriate transfer decisions. These guidelines can best facilitate the transfer, help to save invaluable time, and ensure that the mode of transportation is the appropriate one. Box 5.1 provides an annotated example of guidelines regarding certain non-trauma patients for whom critical care transport is not generally indicated, particularly by air.

Special considerations for protecting the transport team

Guidelines should also be in place for the protection of the transport team as well. Table 5.4 annotates some of these considerations and the handling of special populations for transport.

Conclusion

In summary, numerous guidelines have been established for critical care transport and these include issues such as patient transfer regulatory requirements, staffing competencies, equipment restraints, procedural skills, medical guidelines for non-transport decisions and guidelines for the safety for the crew. Air medical transport also has special considerations in terms of the physiology of altitude and limitations in space and landing zone safety conditions [14]. In all circumstances, appropriate training, guidelines, procedures, and equipment should also be balanced by appropriate continuous quality improvement and expert medical oversight to ensure optimal safety, patient care, and fiscal responsibility [1,10,16,18].

Box 5.1 Sample guidelines regarding non-trauma patients for whom critical care transport generally would not be indicated

- Terminally-ill patients without acute correctable medical problems.
- Patients with do not attempt resuscitation (DNAR) status.
- Patients in a state of cardiopulmonary arrest at the referring institution who cannot be stabilized with restored circulation prior to transport.
- Patients with mental competency not wishing transfer.
- Patients with communicable diseases without necessary precautions established.
- Patient would be transferred to a facility that offers no medical care advantage over the referring institution.

Table 5.4 Safety policies for transport

Type of issues	Things to think about
Agitated patients	Rapid sequence induction and intubation prior to flight with continued sedation as required (if safe for the patient's condition)
Family members	Depending on mode of transport, limit accompanying family members to one or two, and only if there is room, and they are judged to be capable of following safety directions
Hazardous materials incidents with affected patients	Decontamination of the patient so as not as to be a danger for the transport team, particularly considering the necessity to be in an enclosed space during a lengthy transport
Search and rescue missions	Flight operations must make a decision whether or not this will be part of the overall mission statement, and safety considerations for the crew in the environment involved
Transport of patient involving a law enforcement officer with weapons	Having firearms in a pressurized cabin is very dangerous and this consideration must be appraised

CHAPTER 6

Regional critical care delivery systems

Theodore J. Iwashyna and Colin R. Cooke

Key points

- Scarce resources result in uneven availability of care resources. Regionalization is an effort to manage that scarcity so as to ensure good patient outcomes.
- Regionalized systems concentrate patients in centres of excellence. This can be done using formal (including legal) mechanisms or informal referral patterns.
- Existing models of regionalization often lack effective incentives for moving patients and so often fail to reach many patients who might benefit.
- There is no 'right' number of intensive care unit (ICU) beds; rather bed construction compliments optimized throughput and limiting ICU admission to patients who will benefit most.
- Improving the focus on patient outcomes of regional systems requires hard trade-offs, but there is relevant evidence that should be considered.

Introduction: designing regional systems of care

There is no single 'best' way to design a regional system of care. Any design will require ongoing optimization to local need, and evolving medical technology and practice. Nonetheless, there are both more and less effective ways to reach a given set of systemic goals. This chapter seeks to layout key design decisions in regional systems of care. It focuses on evolving better systems, rather than *de novo* creation in the hope that explicit discussion of decision-makers' key challenges may give rise to more effective patient care.

Problems that require regional thinking

Regional systems of care are a response to fundamental challenges of scarce resources. If there were no scarcity, there would be no need for regionalization; one would simply provide everything everywhere [1]. Instead, even in the USA, there is substantial scarcity of operational finances, capital for big-ticket technology, or perhaps most difficult, of provider labour and expertise. Given such scarcity, hospitals become differentiated, developing different levels of competence to deal with problems.

Differentiation is common. Most prominently, many critical illnesses in the USA exhibit the so-called volume/outcomes relationship [2]. When such a relationship is present, hospitals that see more patients have better clinical outcomes. This is believed to result from learning-by-doing, usually at the systems, rather than practitioner level. High volume systems may respond by hiring dedicated faculty, developing effective protocols, adopting innovations more rapidly, or otherwise investing in human and physical capital. Such a relationship can only persist if there is some reason that new developments do not diffuse to smaller hospitals and are taken up by them. Volume/outcomes relationships have been prominently noted for mechanical ventilation and other high-acuity critical care procedures.

Interestingly, the volume/outcome relationship is not ubiquitous. It has been argued that, as procedures become routine (e.g. percutaneous coronary interventions), the volume/outcomes relationship may become less prominent. While the relationship is quite clear in the US private sector, for patients with non-post-operative mechanical ventilation [3], there is evidence against such a relationship in the integrated health system of the US Department of Veterans Affairs [4]. Similarly, there was little evidence of volume/outcomes relationships in Australia and New Zealand for mechanical ventilation or in the United Kingdom for severe sepsis [5,6]. The absence of such a relationship may be a sign that these integrated systems effectively diffuse new techniques of care throughout their systems.

The volume/outcomes relationship is merely one aspect of the general problem of variability in critical care outcomes. There is wide variation in which patients are admitted into intensive care units (ICUs), the processes of care used once they are there, and the risk-adjusted outcomes obtained. Sometimes that variation is partially explained by a volume/outcomes relationship. However, even when the volume/outcomes relationship is present, it sometimes does little to explain the variability [7].

Nguyen and colleagues have proposed three general approaches to fixing differentiation-induced variability—tiered regionalization, telemedicine, and community outreach [8]. Framed another way, one can move patients to the expertise (interhospital transfer to specialized centres), move the specific clinical expertise to the patients (telemedicine), or build the expertise and systems everywhere (quality improvement). These approaches are not mutually exclusive [1]. This chapter focuses on moving patients to the expertise.

Box 6.1 Key design decisions for regional systems of care

- What criteria are used to designate regional centres?
- Are 'Regional Centre' designations formal or informal, and static or dynamic?
- Can regional centres sustain their performance under increased load?
- What incentives are there to move patients?
- Can the system safely accomplish the physical transport needed?
- What are the consequences for patients at other hospitals?
- How many beds are needed?

Design decisions

We define a regional system of critical care as one in which it is acknowledged that hospitals vary in their care of critically-ill patients, and procedures exist to systematically refer patients to a subset of those hospitals. At least seven challenges shape the design decisions, and these challenges are summarized in Box 6.1.

What criteria are used to designate regional centres?

There are numerous patient-centred options:

- US trauma centres are largely self-designated on the basis of generalized guidelines, which describe the capacity to provide a given level of care defined in terms of key staffing and technologies. Such a system has the virtues of transparency and openness, but may lead to quite uneven availability [9].
- The volume/outcomes literature fostered the hope that volume might serve as a good indicator of high-quality care. Regional centres would then be the highest volume centres.
- One might designate as regional centres those hospitals that actually obtained the best risk-adjusted outcomes [10].
- A planner might choose to define regional centres based not on current performance or population need, but on the anticipated needs some time in the future.

Even in some unplanned systems, patients are systematically (albeit incompletely) referred to centres that provide higher quality of care [11]. Our recommendation is that patients be referred to hospitals that have recently provided the highest quality risk-adjusted outcomes for similar patients. This guided referral system should provide significant disease-specific details on outcomes to guide patient transfers. However, implementing a high-quality profiling system requires substantial investments in a modern information and statistical infrastructure to monitor and publish risk-adjusted outcome. Defraying those costs, such an infrastructure may facilitate ongoing quality-improvement efforts and real-time decision support [12].

Are 'regional centre' designations formal or informal, and static or dynamic?

Most discussions of regionalization focus on formal regionalization—a process by which regional centres are officially designated and patients are directed towards them. In the USA, trauma, comprehensive cancer, and stroke centres operate in this way. However, the absence of a formal system of regionalization does not mean that no regionalization occurs. Informal regionalization has been defined as 'the concentration of select patient populations at specific local centres as a result of selective, historic, or *de facto* referral patterns to those centres by providers and emergency medical services (EMS) systems. Such regionalization is informal primarily because selective referral is based on decentralized decisions by individual providers, and is not mandated by law or other formal administrative organizations [13].

Formal regionalization offers the advantages of transparency. On the other hand, formally regionalized systems may have a tendency towards stasis, ossifying referral patterns based on the criteria of past decades, rather than on current performance. Informal regionalization can incorporate the diverse data sources available to practitioners, and offers the possibility of dynamic reorganization in response to personnel or organizational changes. However, informal regionalization is only likely to succeed in improving care if providers have good information on hospital quality, and are both motivated and able to use it to drive decisions.

Can regional centres sustain their performance under increased load?

Many emergency departments (EDs) show worse patient outcomes when the ED is operating under the stress of acutely high patient occupancy—high volume measured by the hour or day, rather than over years [14]. Existing ED infrastructure appears unable to maintain consistent operations across the range of variability in patient load routinely experienced. In contrast, some, not all, multicentre studies in the USA of ICUs found robust performance across a wide-range of occupancies [15,16].

Thus, an important question is whether the putative regional centres will be able to maintain their excellence under any proposed system of regionalization. This assuredly varies from locale to locale. Kahn and colleagues simulated the regionalization of all patients with non-post-operative mechanical ventilation to high-volume centres. They reported that this would require only a 5.0% (interquartile range 0.9%, 12.7%) increase in total ICU census at the regional centres, suggesting feasibility for many ICUs [17].

Quantitative analysis of the past performance of individual hospitals during periods of acute stress might offer guidance about whether proposed centres could tolerate the stress of a specific regionalization plan. It is worth noting that the US study that found robust patient outcomes across periods of stress examined only ICUs that had invested in the information infrastructure of the APACHE data systems. It has been hypothesized that such data systems support high reliability organization of ICU systems.

What incentives are there to move patients?

The evaluation of a mature trauma system in California demonstrated substantial rates of under-triage, i.e. patients with high Injury Severity Scores who should have been directly transported to trauma centres were instead receiving their care at less capable hospitals. Analyses of USA acute myocardial infarction patients admitted to non-revascularization hospitals showed perverse patterns among non-emergent transports. For example, 27.2% of transferred patients went to a revascularization hospital that was

both further away and had a mortality rate more than 1 percentage point worse than a nearby alternative [11].

Both Italian and USA data suggest that current transfer destinations are selected as a result of organizational priorities and routines other than patient outcomes. This argues that regionalization plans must provide incentives (not necessarily financial) to ensure actual implementation.

Can the system safely accomplish the needed physical transports?

There is embarrassingly little information about the crucial infrastructure of the emergency transport of patients between hospitals necessary for effective regionalization. This leads to wide variation, where some systems have a physician accompany many or most transports, while other systems have only paramedics available to staff any transport. In some well-integrated systems that self-selected to publish their own data, interhospital transfer is remarkably safe [18]. However, the generalizability of such data is unclear. Interviews in community hospitals revealed widespread complaints about the availability and competence of transport, and the ways such problems prevented needed interhospital transfers [20].

The realizable benefits of regionalization depend critically on the balance between the mortality benefit of additional transport to a better facility and the mortality risk of that transportation. In economic terms, transport risk is a 'transaction cost' that prevents patients from being moved fluidly to the places they might best be served. The availability of interhospital transport needs to be examined in each locality. A regionalization plan should evaluate the transport infrastructure's adequacy, and what steps can be taken to insure uniform availability. Rigorous generalizable evidence on what constitutes a cost-effective level of training, staffing, and equipment for safe transport is, as of writing, unavailable, but urgently needed.

What are the consequences for patients at other hospitals?

Regionalization of patients may have external consequences that influence the remaining patients at the hospital from which they are transferred. Interviews with community hospitals suggest that the transfer of high acuity patients is appreciated, as it frees staff resources to focus on their more typical patients [19]. In this sense, regionalization may limit the distraction and overload effects, such as have been noted when trauma patients arrive at EDs [14]. On the other hand, regionalization should lead to reduced volumes of high acuity cases at the community hospitals. This could lead to de-skilling and loss of institutional infrastructure, resulting in significantly worse care for patients who are inadvertently not transferred to the regional centre. There are very little data by which to evaluate the magnitude of these possible effects and so system-specific implementations of regionalization need to evaluate them on an ongoing basis.

How many beds are needed?

The optimal number of beds needed to meet the changing demand for critical care services is a matter of considerable debate. One might naively multiply the number of ICU beds at a referral centre by the expected percentage increase in referred patients. Such a calculation falsely assumes that existing ICU beds cannot be used more efficiently. Optimizing efficiency in use of existing ICU beds requires facilitating the discharge of patients currently in the ICU, improving throughput to relieve 'intensive care unit outflow obstruction'.

Further optimizing ICU use will reserve admission to the ICU for individuals who will benefit most. Such patients are those with **both** an appreciable risk of death or major morbidity **and** an available effective therapy. Perhaps more than one-third of all US ICU patients do not meet these criteria [20]. The beds made available by foregoing admission to the ICU for these low-benefit patients may adequately meet the increased demand at a regional centre. Realizing such efficiency gains in practice may be challenging, given the difficulties of early identification and the potentially disruptive impact of high acuity, but low ICU-benefit patients on non-ICU ward functioning.

Most importantly, we do not yet understand the impact of withholding ICU services for low-benefit patients. In the UK it appears that there is a significant lack of ICU beds. Elsewhere, the optimal bed number seems too contingent on other aspects of the system for a clear recommendation, but it should not be simply assumed that more beds are essential for effective regionalization. Rational bed planning must happen in the context of throughput optimization and frank discussion of what an ICU is to be used for.

Conclusion

Regionalized systems of care are an inevitable result of scarce health care resources. Such systems vary widely in the extent to which this regionalization is formalized, intentionally designed, or focused on patient outcomes. Incremental changes to most systems may significantly improve patient outcomes. For example, transferring non-emergent acute myocardial infarction patients to revascularization hospitals suggested that improved regionalization might reduce 30-day mortality by an absolute 2.7 percentage points, or a 16.5% relative reduction in the USA [11]. While such efforts will not be easy, they offer the hope of dramatic improvements for patients by more effectively using the resources already in place.

CHAPTER 7

Integration of information technology in the ICU

Daniel Martich and Jody Cervenak

Key points

- People, processes, and technology are all essential elements to successfully transforming the critical care environment to meet future demands.
- Five major areas of technology evolution include: workflow automation, information exchange, clinical decision support, predictive modelling, remote monitoring, and data analytics.
- If designed properly, technology can result in doing things differently (better) and doing different things.
- Information exchange is required for quality and efficient critical care information delivery.
- Data analytics will use information for comparative effectiveness, registry reporting, population management, and research study recruiting.

Introduction

International standards mandate that airline pilots run through hundreds of checkpoints every time they sit down in the cockpit. Captains' decisions affect the lives of many individuals. Stock market traders confront a cacophony of noises, while attempting to make split-second decisions, which may result in profit or loss for their organization. Special military forces, often in sleep-deprived states, need to make clear-headed decisions that will determine the success or failure of their mission. What do these three disparate professions have in common with critical care? Similar decision-making complexities and complications are faced in a 'typical' day in the ICU by the busy critical care professional.

Critical care physicians and nurses analyse hundreds of data points to arrive at life-saving decisions. The choices of medications, procedures, and other therapies made by the intensivist, often under emergent conditions, affect not only patients' chances of survival, but also have a great effect on some of the most expensive care provided in medicine. Despite or, perhaps, because of 24/7 ICU coverage, intensivists' sleep–wake cycle can be disrupted enough to potentially cause negative patient outcomes.

The similarities among those professionals and critical care specialists dissolve quickly, however, when considering technology solutions. Pilots have automated workflow and checklists, in addition to a cohort of engineers, to ensure a correctly operating airplane, not to mention auto-pilot to help fly their plane through most of the journey. Busy stock traders have at their command electronic transaction systems, and real-time data input on smart phones and other mobile platforms, as well as remote connection to experts. Navy Seals and Green Berets in the US military use the latest night vision glasses, colleague recognition software, and global positioning equipment to run successful missions.

With an ever-growing number of critical patient volumes, increasing acuity levels, and numerous combinations of complex conditions, our profession requires a quick response to critical situations, whereupon we must be capable of considerable data analysis and rapid decision making. Critical care professionals are faced with the challenge of performing better, faster, and cheaper.

A transformation is needed to manage all of these demands, and it will require improved technology, processes, and skill sets. Yet the health care industry lacks many of the technological advances utilized by the airline, financial, and military industries. This chapter will explore several of the key areas of technology advancement and the critical factors to lead to successful outcomes.

Technology + Process + People = Success

In most instances of information technology (IT) implementation, the focus is on the technology factor of the equation. Technology is important, but should never be the sole factor. Industry examples underscore this point.

For example, at the Children's Hospital of Pittsburgh (CHP), an unexpected increase in mortality was observed when a computerized physician order entry (CPOE) was implemented [1]. Much blame was placed on the technology, but less than 1 year later, the Children's Hospital at the University of Washington implemented the same technology and noted a reduction in mortality. Their conclusions were that careful process design and coordinated team-building mitigated the associated risks even in the ICU [2]. Interestingly, the faculty from the University of Washington was on hand in Pittsburgh during the CPOE deployment at CHP, and privately noted the overlooked people and process elements. The relationship between technology, process, and people is illustrated in Fig. 7.1.

Process is the engine of critical care. It is essential that during an IT implementation, processes be redesigned to identify opportunities to not only do things differently, but also to do different things.

Undertaking the difficult task of mapping out current processes and redesigning future ones requires specific process engineering

Fig. 7.1 Successful technology requires careful process design and good teamwork.

and analytic skills. This leads to the third and most important factor in the success equation—people.

Unless there is engagement and adoption from the people who must follow the processes and utilize the technology, it does little good.

Changes in management and changing culture are two of the more complicated aspects of any transformation project. In the critical care setting, clinicians are called upon to use discretion and judgment in a very intense, time-sensitive environment. Without proper engagement, education, and training, the team is unable to achieve functional and operational success.

To specifically address the people factor, it is important to define the individuals with the right base level skill to be a part of the IT-enabled transformation project team. These skills include organization, analysis, and strong communication abilities. Perhaps the most important attribute to have is an optimistic demeanour. These individuals become the team that informs and drives the rest of the department.

The clinical team should include multiple roles and levels of hierarchy, not simply the least tenured intensivist or youngest respiratory therapist. It is essential that every individual in the critical care environment is well aware of and prepared for the changes involved, and is proficient in the new technology and processes.

Transforming critical care with technology

There are five major areas of technology evolution that will enable an efficient and effective critical care environment.

Workflow automation

Critical care IT solutions can empower a more efficient workflow if designed and implemented properly [3]. A thoughtful and detailed assessment of the current workflow state is a first step for redesigning processes for the future. Start by identifying the current workflow. Then define the opportunities for improvement, identify any gaps in communication or components of the workflow that require reworking or multiple touch points, and observe the way in which the clinical team spends their time.

Many areas will need to be redesigned to fully leverage the technology capabilities. The following are some of the high priority areas:

- **Patient care versus technology care**: minimize the time required to interact with the system and be sure to design the system flow to support efficient care processes.
- **Equipment and computer placement:** ensure clinicians are near the patient as opposed to having to work around the equipment.
- **Mobility**: plan for mobile solutions to improve efficiency in physician's access to information duringconsults, patient visits, and remote patient care.
- **User access**: improve user access through single sign-on, biometrics, and/or proximity-detection technology.
- **Efficient display of information**: consider the intensity and display of critical care data by creating relevant views for clinicians to be able to easily see the information and change parameters on trending the information (e.g. by day, by week).
- **Order sets**: design easy-to-use order sets with minimal clicks.
- **Documentation**: make sure the documentation process models the most efficient and effective data capture at the bedside.
- **Infection control**: incorporate solutions, such as special wall-mounted larger screens with motion sensing input to avoid spread of infection.
- **Ensuring the five rights**: improve patient safety and decrease medication errors by implementing a positive patient identification system (PPID), which ensures the right medication is delivered to the right patient, at the right time in the right dose, and by the right route every time.

Information exchange

Information exchange is required for quality and efficient delivery of information within the critical care setting. There are many levels of information exchange that are important to the care delivery process:

- **Biomedical device integration (BMDI):** sending data directly from biomedical devices into the patient's electronic medical record (EMR) can reduce delays in recording, errors in interpretation and transcription, and delayed or incorrect treatments [4]. Create a rigorous project plan that includes a thorough workflow assessment, engagement of key stakeholders, and tight coordination with the EMR implementation. Ultimately, clinicians need to trust the system, and trust that the data flowing into their record is timely and accurate.
- **Hospital integration:** the next level of information exchange is across the downstream and upstream processes, such as emergency department, operation room, step down, medical/surgical units, etc. This is important for medication reconciliation, transition of care documentation, and ensuring that key elements of the patient medical history and current condition is shared. With an integrated EMR system, the care team shares the same medical record, order sets, documentation tools, and messaging system. Information sharing cannot easily be replicated when the critical care approach is best-of-breed with different vendors' products.
- **Enterprise integration:** many organizations have elected to implement an enterprise EMR system extending the same vendor system beyond the hospital to the ambulatory, home care, rehabilitation, long-term care, and other service lines. This allows for the continuity of patient care across the board. In addition, many health care groups have designed these systems to enable EMS and other community partners' access to the information.
- **Regional/national health information exchange:** many communities have implemented a health information exchange

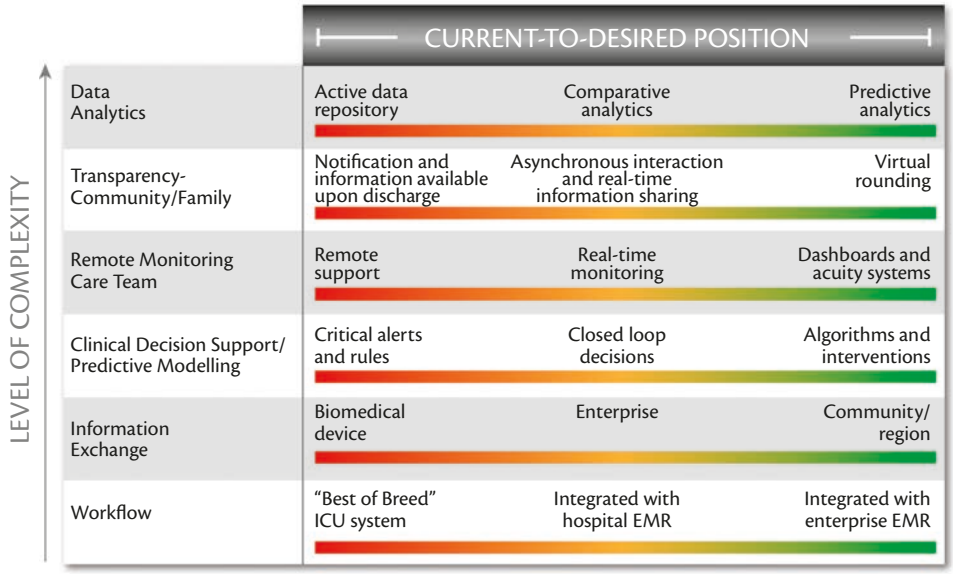

Fig. 7.2 Road map for developing technology, people, and processes in critical care IT.

(HIE) to enable information sharing across regions in order to provide information back to the patient's community physician, hospital, diagnostic centres, home care, rehabilitation, etc. While these exchanges are in a very early stage of data sharing, they provide access to key information as the patient moves across different points of care.

Clinical decision support and predictive modelling

The inherent goal of clinical decision support (CDS) is to anticipate the best care and assist the busy critical care clinician in 'doing the right thing'. CDS is most effective if the rules, which run in the background, stay in the background unless an interruption in workflow with a 'pop-up' alert is essential to avoid harm to a patient. CDS in the ICU falls into one of three broad categories:

- **Alerts:** these generate warnings in response to clinical data. For example, clinicians may want a computerized CDS to alert them (i.e. page, text message, telephone call, etc.) if a patient's heart rate has changed by some preordained percentage. For example, if the cohort of critical care clinicians decide that a 50% change in a patient's heart rate is 'pageable event', then many times the CDS will simply be notifying the intensivist of going from one end of the normal range to another (e.g. 50% increase from baseline of 60/min is only 90/min). For this reason, interruptible CDS needs to be well designed and exceedingly rare. The signal-to-noise ratio of interruptible CDS needs to be as high as possible or else alert fatigue will set in, and no CDS alert is taken seriously. The goal is to minimize the false positive alerts and maximize the clinical appropriateness.
- **Decision modification:** decision modification CDS, or non-closed loop CDS, makes the right thing to do the easy thing to do for the clinician. As an example, the busy intensivist may order Gastrointestinal (GI) prophylaxis for her patient at a standard dose of 150 mg of ranitidine bd. CDS can detect poor renal function and suggest adjusting to an alternative dosing schedule, based on the serum creatinine. These decision modification rules can be written for nearly any laboratory or other standards-based entry (i.e. ICD-10 specific diagnosis, radiological finding, problem, allergy, etc.)
- **Interventions:** CDS tools can also incorporate branched-logic, based on orders or closed-loop CDS. If a combination of sepsis thresholds is achieved for a patient during a given time frame, a set of orders, alerts, and interventions begin. For example, once an ICU patient with fever, leucocytosis, tachycardia, and a mean arterial pressure of less than 65 mmHg experiences that combination in a certain window, then cultures will be obtained, boluses of *in vitro* fertilization (IVF) will be administered, samples for laboratory analysis will be drawn, consultations will be called, the intensivist will be paged, and potentially a clinical trials researcher contacted, all by the CDS system.
- **Predictive modelling:** for the purposes of this chapter, we have combined CDS with the relatively new science of predictive modelling (PM), which leverages the vast amounts of data in an EMR with sophisticated computational data models. PM uses a wide range of clinical variables to quantitatively determine the acuity of a hospitalized patient's condition and make the best possible prediction of whether a patient is at risk of worsening. Modelling is currently based on vital signs and laboratory data, but will soon incorporate structured and unstructured information from nursing assessments and physician documentation.

A growing number of commercial products (i.e. Rothman Index, Predictive Modelling, Oxford Biosigns) tout their ability to trend every at-risk patient and notify clinicians before a life-threatening event occurs. Proving what did not happen is difficult, but increased use of PM software is anticipated because of expected critical care provider shortages and because it will provide the ability to monitor large numbers of patients with fewer bedside clinicians.

Remote monitoring/transparency

Currently, clinicians can remotely monitor critical care, and provide support and consultation to the care team. The future is promising for the provision of portals for referring clinicians, as well as authorized families and friends. This higher level of engagement

with the extended care team and patient guardians will lead to a more informed and transparent environment.

In fact, in discussions with the University of Pittsburgh Department of Critical Care Medicine faculty, early data analysis shows that remote monitoring by critical care physicians can lead to reduced length of hospital stay.

Data analytics

As hospitals, especially ICUs, collect and digitize more data, it will lead to the ability to study diseases and combinations of problems in a manner heretofore impossible. The insights gained from analytics to define operational efficiencies, quality, and performance management are tremendous. However, the real power for the bedside clinicians may reside in their ability to effectively personalize care using historical cases from the EMR in a *de facto* evidence-based medicine (EBM) approach to care.

The critical care IT environment of the future will have the opportunity to utilize information for comparative effectiveness, recruitment for research studies, registry reporting, population management, and multicentre studies. As an example, in the absence of EBM related to anticoagulation, decisions for a critically-ill 13-year-old girl with lupus, renal failure, and pancreatitis, clinicians at the Lucile Packard Children's Hospital at Stanford analysed the data from their EMR repository. Within a short period of time, they found a cohort with matching profiles treated previously, which informed their treatment decisions. As a result, the patient did not have bleeding nor thrombotic problems during her hospital course [5].

Advancing critical care IT

Critical care environments vary widely in terms of adoption and utilization across the IT continuum. As the technology, people, and processes mature, the future of critical care will achieve higher levels of quality, operational efficiencies, and cost effectiveness. The framework outlined in Fig. 7.2 can be used as a roadmap for leading the maturation.

CHAPTER 8

Multiple casualties and disaster response in critical care

Yoram Weiss and Micha Shamir

Key points

- **Definitions:**
  - *Multiple-casualty incident (MCI):* natural or man-made incident at which the number of patients arriving the hospital temporarily strain, but do not overwhelm, hospital resources. *Disaster/mass casualty event (MCE):* natural or man-made scenario at which community resources are overwhelmed mandating allocation of resources from other communities.
- Intensive care unit (ICU) physician should, upon announcement of a MCI or MCE, review the patients in the ICU and determine those that can be transferred.
- Of core importance is proper process control, which is ideally managed by a senior clinician who can assess, prioritize, and ease the transfer of patients.
- Due to the large number of severely injured, the risk of missed injuries is high. A thorough re-evaluation (tertiary survey) is recommended.
- Hospital preparedness for an MCE includes focus areas, such as supplies, communications, security, staff, and utilities to support surge capacity for appropriate clinical activity.

Introduction

Inherent ability to treat multiple casualties is related, among others, to the hospital's certification, number of trauma bays/intensive care unit (ICU) beds, time of day or day of the week. Once the number of casualties arriving at a hospital exceeds the hospital's routine capability, it becomes a **multiple-casualty incident** (MCI) scenario, mandating the allocation of personnel and resources from their routine tasks in order to provide best possible care to the patients. MCIs temporarily strain, but do not overwhelm hospital resources. Larger scenarios can be depicted as an escalating continuum, which may lead to an inability of the hospital and its community to cope. In these later scenarios, there is a need to allocate resources from city to city, from county to county, and from state to state. The smaller events on this continuum are termed '**mass casualty events'** (MCE), while the more devastating incidents are termed '**disasters**'.

There are several definitions of disaster that are related to magnitude. The US Joint Commission on Accreditation of Health Care Organizations (JCAHO) places the term disaster in a spectrum of incrementally worsening emergency events [1]:

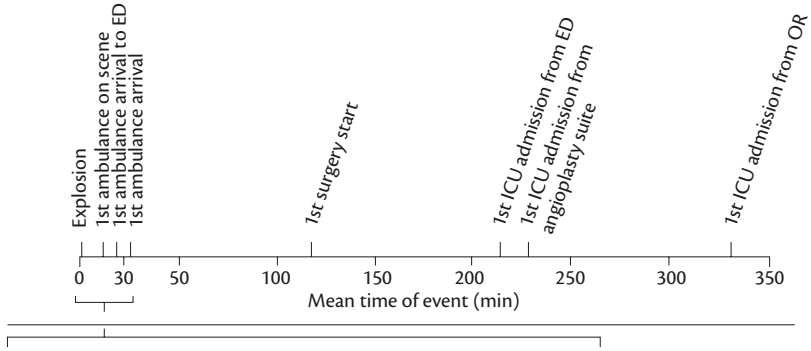
- Level one events are termed emergencies and involve major incidents, such as a suicide bomber explosion on a bus. These constitute short-lived situations (lasting up to 24 hours) that do not disrupt the operations of a hospital.
- Disasters that are defined as a community-wide event, which disrupts the health care system and the infrastructure of the community. The 2005 Katrina hurricane is one recent example of such an event.
- The most severe level constitutes catastrophes, which describe a series of disasters that affect the same community in a short period of time. An example of such a catastrophe was the 2011 earthquake in Japan followed by the huge tsunami wave that caused the leakage of radioactive material from an electric nuclear plant.

All together the continuum consists of MCI, MCE, disaster, and catastrophe. Hence, the reader must understand that concepts described in this chapter should be applied interchangeably on this continuum.

Multiple-casualty incidents

Aschkenasy-Steuer et al. described the sequence of events resulting from 20 terror-related MCIs encompassing an average of four ICU admissions per incident (Fig. 8.1) [2]. In an urban area, it takes at least 20 minutes for the first ambulance to arrive at the hospital and more time is needed for initial resuscitation. The ICU team, supervised by a senior clinician, should use this time to assess the severity of the event, prepare for admissions, determine which patients can be transferred out of the ICU, and call for back-up.

Once survivors begin arriving at the emergency department (ED), a senior intensivist should remain in the ED seeking information. Knowledge of the injuries will provide an estimate of the number of ICU beds required, will help in planning for the best placement of each patient thus enabling efficacious nursing assignments, and allow time to organize special equipment. While screening for potential admissions, knowledge of the treatment plan is important as it provides an estimation of time for admission [3]. In Jerusalem, the mean time for ICU admission was 5.5 hours. Patients arriving from the ED, computed tomography (CT) or angiography suite generally arrive to the ICU earlier, while those arriving from the



Time (min) after explosion	Event	Actions to be taken
0	Explosion	
0–10	Assess incident size and severity	Obtain information from emergency services and media sources Continue life-saving operations Hold elective operations Clear emergency department Send patients from OR waiting area back to departments Consider taking out patients from OR if operation not yet started Notify all anesthesiologists present in the hospital about the event Prepare to call in additional personnel
0–20	Backup and preparation of sites	Recruit additional staff: Head of ICU department, on-call senior physicians, ICU head nurses. Other physicians and nurses as needed Triage patients to be discharged from the ICU and recovery room Send on-call most experienced physicians to the trauma bay and emergency department Prepare trauma bay, two operating rooms and ICU beds (including PACU) for admission

Fig. 8.1 Timeline of events after an incident and actions to be taken.

ED, emergency department; ICU, intensive care unit; OR, operating room; PACU, post-anaesthesia care unit.

Reproduced from Aschkenasy-Steuer G et al., 'Clinical review: The Israeli experience: conventional terrorism and critical care', *Critical Care*, 2005, **9**, pp. 490–9, with permission from BioMed Central.

operating theatre arrive later. Some patients, however, might arrive in the ICU soon after the event because they need extensive stabilization before surgery. These, patients can be temporarily treated in the post-anaesthesia unit (PACU), which provides surge capacity for ICU beds. Additional nurses might be needed and may be recruited from other ICUs or departments, providing that an orientation was completed as part of the hospital's preparedness plan.

In these situations, due to the large number of severely-injured patients, the risk of missed injuries is high. A thorough re-evaluation (tertiary survey) together with the trauma surgeons is therefore recommended. Similar characteristics have been reported for Madrid and New York [4,5]. Activities surrounding a MCI have repercussions for the ICU that can last up to 48 hours or longer. It is recommended to add nurses and physicians to the subsequent shifts to cope with the additional work load. Table 8.1 summarizes ICU statistics following MCI.

Mass-casualty events and disasters

Disasters and MCEs are large-scale destructive events that disrupt the infrastructure and normal functioning of a community. Although semantically these terms can be interchangeable, disasters are commonly attributed to natural causes (earthquakes, tornadoes, hurricanes, floods), while MCEs are attributed to man-made events (industrial spills and explosions, structural collapse, terrorist attacks, etc.). In a large-scale destructive event, the greatest challenge to the medical community is the large number of casualties, out of proportion to the existing health system resources. In these circumstances, it is mandatory to refuse treatment to those unlikely to recover in order to save the maximum number of lives [6]. As true MCEs are rare and there is little opportunity for real-time training and experience, the key for coping with such events is proper preparedness [2,7–9].

Treatment of an enormous number of survivors can be further complicated by damage to the hospital and its infrastructure. In their review, Roccaforte and Cushman counted numerous disturbances that should be anticipated in such situations [10]. For example, the initial information obtained will probably be unreliable, communications may be impaired, transportation may be difficult, the nearest hospital will receive the most patients, but transport from the scene may not be to the designated hospital, up to 72 hours may pass before outside help arrives, volunteers will be numerous, and emergency credentialing may therefore be an issue. Accordingly, JCAHO has listed six focus areas for hospitals aimed

Table 8.1 ICU statistics following multiple casualty incident

	Madrid	Jerusalem
Mean ICU length of stay	10 ± 4	9
ICU mortality	11.1%	8.5%
ICU admissions*	32%	52%
Blast injury	63%	52%
Need for ventilation in ICU patients	80%	86%
Ventilation > 7 days	37%	NR
Injury severity score	34	24
Injury		
Spinal injury	18%	7%
Burns	59%	NR
Head injury	52%	44%
Abdominal injuries	37%	32%
Extremity injuries	62%	85%
Combined injuries	100%	86%
Chest Injuries	82%	NR

*Percentage of hospital admissions admitted to the ICU.

ICU, intensive care unit; NR, not reported.

at developing proper contingency plans and response mechanisms for a disaster (Box 8.1). Also, the ICU must have its plan as a part of the hospital and community plan.

Communications

Communications must be addressed during the preparatory phase (including multiple methods), as this is essential for in-house and home personnel recruitment, and for the provision of material and organizational resources. Ordinary land lines and cell phone reception may become dysfunctional, and flooding may cause electrical failures of systems, including the internet. As walkie-talkies are expensive, messengers appear to be a reliable method for intra-hospital use [11].

Box 8.1 JCAHO focus areas for proper planning and responding to a disaster

- Communications: both internal and external to community care partners and state/federal agencies.
- Supplies: adequate levels and appropriateness to hazard vulnerabilities.
- Security: enabling normal hospital operations, and protection of staff and property.
- Staff: roles and responsibilities within a standard hospital incident command structure.
- Utilities: enabling self-sufficiency for as long as possible with a goal of 96 hours.
- Clinical activity: maintaining care, supporting vulnerable populations, and alternate standards of care.

In the ICU, automatic communication systems sending text messages or Internet-based messages can be used to deliver messages to cell phone users who are included in the MCE response group, thereby replacing traditional emergency phone lists. Cell phones have proven themselves to be more reliable in restoring proper communication faster than cable networks, as illustrated by the 2011 9.1 earthquake in Japan. Hence, a balance must be struck between these two systems [11].

Supplies

'Just-in-time' is an organizational philosophy aimed at reducing inventory to reduce costs [12]. As demonstrated in the wake of Hurricane Katrina and the 2011 earthquake in Japan, hospitals must be prepared for a disruption in their supply chains following a catastrophe and therefore of limited use in disaster medicine. In Israel, hospitals are expected to maintain an in-house inventory that allows for 2–4 weeks of uninterrupted operations. As local suppliers may fail to respond following a catastrophe, a list of vendors outside the region should be created, including contact information. The collection and exchange of information with different suppliers is critical in the responses to changing scenarios. Many hospitals rely on a cooperation plan, whereby neighbouring institutions aim to share supplies and resources. However, in times of catastrophe, these hospitals are likely to fail as well. In the USA, hospitals are expected to be self-sufficient for as long as possible, with a goal of 96 hours, as this has been predicted as the time needed for help from outside the affected area to arrive [13].

Increasing surge capacity

Surge capacity is the ability of a health care facility to expand its operations to safely treat an abnormally large influx of patients in response to an incident [1]:

- **Triage:** if a disaster can be anticipated (an imminent nuclear plant accident, major hurricane, etc.), the ED/trauma bay should be evacuated. Elective activity should be stopped and stable patients should be discharged home. ICU patients should be discharged to step-down units and wards, or transferred to other hospitals. All of the above are part of the process of allocating and prioritizing resources in order to increase **existing** surge capacity [9].
- **Adding facilities:** surge capacity should be **increased** by adding ED, operating room (OR), and ICU spaces together with personnel to operate them [14]. The hospital's disaster plan must identify, prepare, and staff areas in advance for the management of many patients who require augmented care, but do not necessarily meet the criteria for ICU admission [2,8,9]. Preferentially, the augmented care area should be controlled or co-directed by ICU specialists and placed, if possible, in close proximity to the ICU. One possible option is utilizing the PACU, as the nursing staff is trained for the care of unstable and critically-ill patients. Furthermore, it is important to identify in advance personnel who have ED or ICU skills, especially nurses and respiratory therapists who do not practice, but can be routinely updated, so that they may staff critical areas, including the ED, OR, and ICU, in a time of crisis.

Patient flow

During the time of arrival of injured patients to the trauma bay or ED, patient flow is recommended to be uni-directional. Patients

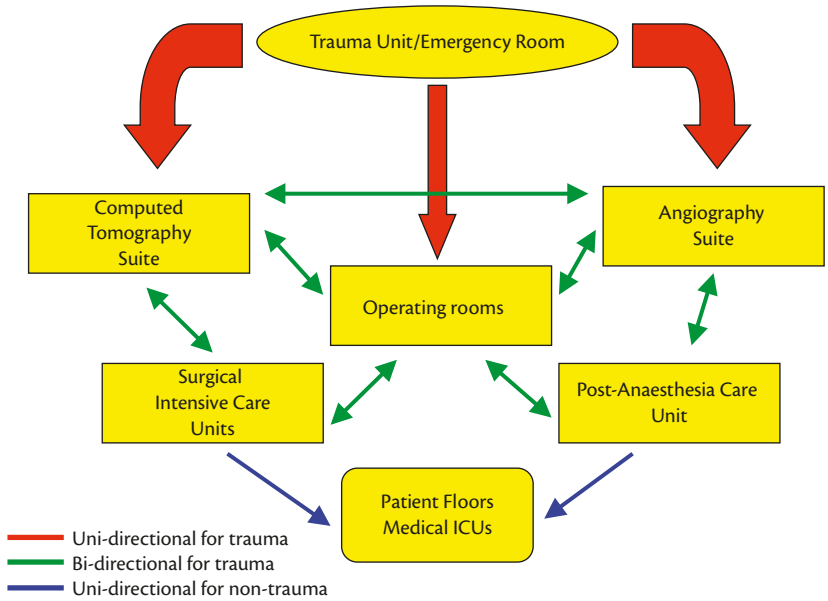

Fig. 8.2 Patient flow during the chaotic phase of an MCE.
Reproduced from Shamir M et al., 'Multiple Casualty Terror Events: The Anesthesiologist's Perspective', *Anesthesia and Analgesia*, **98**(6), pp. 1746–52, copyright 2004, with permission from International Anesthesia Research Society.

move from the ED or trauma bay to imaging (CT/angiography), and then from there to the OR, ICU, or ward (Fig. 8.2). As a rule, injured patients never return to the ED or trauma bay. This policy is of increasing importance as more survivors are expected to arrive from the scene together with secondary transfers from other hospitals.

Medical information gathering

It is nearly impossible to efficiently record all medical information during the initial phases, as both physicians and nurses are overwhelmed. This difficulty is compounded by the multiple surgical subspecialties that may be involved in the preliminary, primary, and secondary surveys in the trauma bay. To remedy this problem, some recommend the assignment of a resident to each severely-injured patient upon admission to the trauma bay. These physicians will follow the patient throughout their entire evaluation and primary care process until their admission to the ICU. Upon arrival, these physicians should record all relevant data in the admission report.

Information technology perspective

Information technologies play an increasingly central role in the provision of medical and logistic services in a modern hospital. Administrators must prioritize the mission-critical information technology systems that must be maintained operational during a catastrophic MCE, together with an expected time frame for their restoration in case of a system crash. The criteria for defining a system as mission critical must include an analysis of the impact of its loss during a MCE on staffing, medical management, etc.

Drills and protocol

It is mandatory to transfer the key elements of disaster response into a hospital protocol that identifies specific action points. Furthermore, dry (desk) and wet (simulation) drills have a central role in maintaining preparedness for a MCE.

Impact analysis

Some advocate that impact analysis is an integral part of preparation for a MCE [15]. After recording the effect of a preparedness drill on manpower and inventories, an impact analysis can be used to determine resources needed by departments and services, and the relationships between them. Impact analyses should be performed at the institutional level and should use hospital-wide input. This analysis, among others, sets the criteria for the closure and/or return of critical service areas to meet patient care needs.

The impact analysis should, among other topics, evaluate the effect of a MCE on increases in staff working hours, changes in routine therapy procedures, or the cancellation of some procedures altogether. The impact analysis should also define an endpoint for the MCE and a timeline for returning to normal operating activities [15]. The definition of 'normal' may be different for each affected department, so some departments may be able to return to normal activity faster than others.

Debriefing

Recording problems in flow and process cannot be performed during a MCE, as the focus is to provide medical care to the injured in a situation when the system is overwhelmed [15]. However, we must not overlook valuable lessons and analyse mistakes. Hence, it is of key importance to perform interdepartmental and hospital-wide reviews soon after the event for all medical and support staff who participated in the MCE. The United States Department of Homeland Security has provided a website with information about lessons learned, best practices, and after-action reports (US Department of Homeland Security. Lessons learned: information sharing. https://www.fema.gov/lessons-learned-information-sharing-program) [16].

Conclusion

Hospital preparedness for a MCE begins long before the event itself occurs, and includes:

- Defining the modus operandi during a MCE by creating hospital, department, and unit protocols.
- The creation of in-hospital working rules.
- Establishing communication alternatives.
- Preparation and storage of emergency equipment, medical supplies, and medications in accessible places (an in-house inventory that would provide for more than 2 days).
- A list of vendors outside of the region should be created and scenarios relevant to the hospital should be routinely practiced.

When an MCE occurs, the first step is to assess its size and severity, and accordingly activate a surge capacity plan and implement the proper process control procedures supervised by a senior intensivist, who can assess and prioritize patient care. The preparation and utilization of an auxiliary area for patients who need additional care outside of the ICU also assists in the treatment of survivors.

CHAPTER 9

Management of pandemic critical illness

Robert Fowler and Abhijit Duggal

Key points

- Pandemic preparedness hinges on the development of appropriately trained staff with well-defined roles.
- A goal of pandemic planning should be to have the ability to manage surge in the number of patients with optimal use of available resources throughout the duration of the disease outbreak.
- A rigorous infection control programme for pandemics should be built upon the existing infection prevention and control practices of the hospital, and based upon modes of transmission for known or suspected agents.
- Triage protocols should be based on equitable distribution of resources and on ethical principles of justice, beneficence, and non-maleficence.
- Research preparedness, with approved protocols, electronic case report forms, and harmonized clinical trials databases afford the best chance at early accurate pandemic descriptive and interventional studies.

Defining pandemics

The World Health Organization (WHO) defines a disease outbreak as 'the occurrence of new cases of a disease process in excess of what is expected in a defined community, geographical area or season' [1]. An outbreak becomes a pandemic if it extends over several countries over a defined period of time, which may be limited to days, weeks, or even years [1]. Unfortunately, pandemic preparedness is based on assumptions, and these cannot account for the uncertainty associated with the nature, magnitude, or timing of these disease outbreaks.

Adequate and appropriate provision of critical care services during pandemics may dramatically alter vital outcomes of patients who develop acute respiratory distress syndrome (ARDS) and critical illness. As a consequence of the 1918–1920 global H1N1 influenza pandemic, it is estimated that approximately 50 million people—3% of the world's population—died [2]. Today, these patients would be admitted to intensive care units (ICUs) and it is likely that the majority would survive. Indeed, the provision of critical care during the severe acute respiratory syndrome (SARS) outbreak and 2009 H1N1 pandemic had a substantial impact on the survival of the sickest patients [3–5].

However, SARS and the 2009 H1N1 pandemic also highlighted the limited capacity for increased provision of critical care, even in well-resourced settings, and the potential for dramatic differences in mortality in under-resourced settings [3]. Thus, pandemic preparedness planning must focus on the most effective utilization of available resources in times of increased need. During the SARS outbreak in particular, we were taught difficult lessons about how inadequate preparation exacerbates shortages in technical capacity and personnel, and can lead to increased risk of illness transmission, the provision of ineffective and potentially harmful therapies, and a research response that is too slow to inform patient care [5,6]. This chapter will focus upon pandemic preparedness, as well as rapid clinical, education, and research responses.

Pandemic preparedness and mitigation

Intensivists frequently are among the first to recognize the most severe presentation of severe respiratory outbreaks. Accordingly, intensivists not only help develop treatment options, but are also intimately involved with developing the case definitions, determining early case fatality rates, transmission prevention, and the challenging task of informing potential triage decisions if demand exceeds capacity.

Pandemic preparedness hinges on the development of appropriately trained staff with well-defined roles in the event of a pandemic [7]. The lack of an organizational structure, and the absence of command and communication have been recognized as key factors in failure to provide appropriate medical services in previous mass casualty events and disease outbreaks [8]. Therefore, newer models focus on defining clearer roles for the individuals involved in pandemic response with a clear line of communication between health systems, and the local and federal authorities [7,8]. The response and preparedness model for disease outbreaks borrows heavily from the incident management system concept [8]. Government authorities in conjunction with health care personnel have developed standard operating procedures for responders during an outbreak using this model [8]. Emphasis is also placed on staff education and regular training to ensure readiness in the event of an outbreak [7].

Systems surge capacity

Pandemics often present with a sudden increase in patients requiring critical care services. [7,8]. The need for resources is

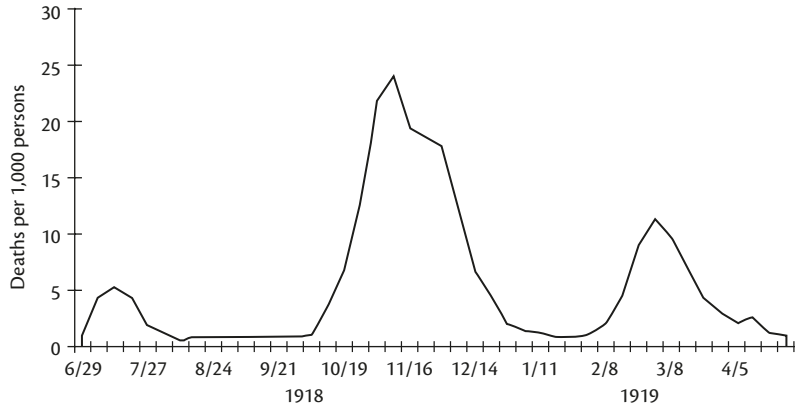

Fig. 9.1 Three waves: combined influenza and pneumonia mortality associated with the three waves of the 1918–1919 influenza pandemic in the United Kingdom.
Reproduced from Taubenberger JK, Morens DM, 1918 'Influenza: the mother of all pandemics', *Emerging Infectious Diseases*, **12**(1), pp. 15–22, 2006, with permission from Centers for Disease Control and Prevention. Data from Jordan E. *Epidemic influenza: a survey*. Chicago: American Medical Association, 1927.

variable, and is dependent on geographical and temporal factors. Pandemic surges typically come in multiple waves, lasting weeks or months at a time, separated by months, and potentially lasting for years [7,9] (see Fig. 9.1) Facilities should be equipped to provide emergency mass critical care (EMCC) services with an ability for a phased expansion to at least double the capacity for critical care beds during a pandemic (Fig. 9.2a, b). However, the scalar is critically dependent upon baseline capacity and the nature of the pandemic, and it is, therefore, impossible to prescribe for a given ICU [7,8]. Increasing ICU needs should also be balanced with other hospitals services—there is a potential for decreasing benefit with a unilateral increase in ICU capacity because of the excess demands on the available resources and health care providers [8].

Critical care staffing

Providing health care during a disaster is stressful and caregivers are at a significant risk of developing compassion fatigue, post-traumatic stress, and anxiety disorders. This results in decreased productivity and team functioning [8,10]. In most cases, there will be a need for expanded roles of non-critical care staff in specific areas in the ICU [10,11]. Members of the health care team from certain acute care areas (for example, post-anaesthetic care units, etc.) might play an important role in helping to care for critically ill patients. A mix of skilled critical care practitioners supervising less experienced health care workers in specified geographical areas may also be effective in pandemic situations [10,11]. Another strategy is to introduce a phased staffing plan where the working

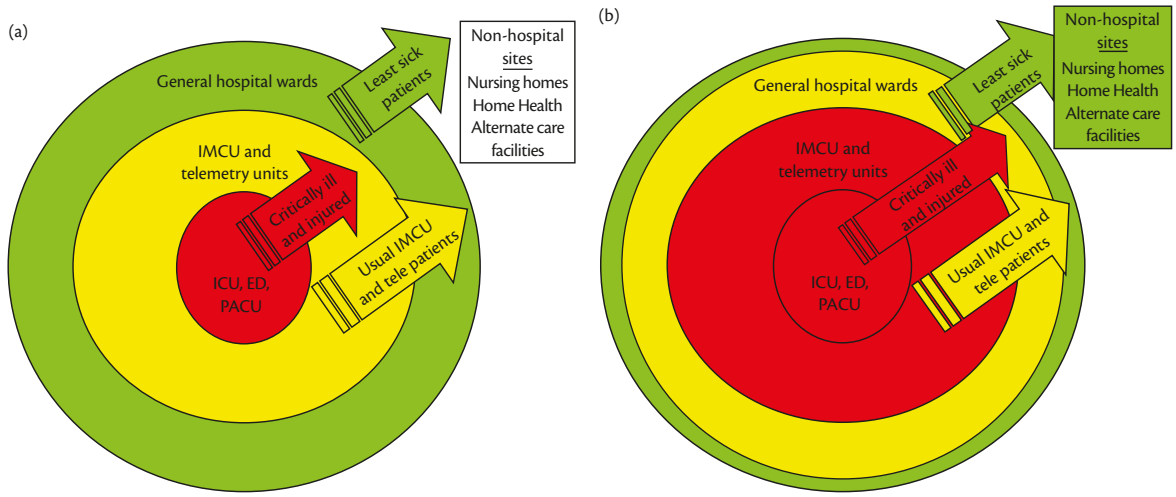

Fig. 9.2 (a) Initial expansion of critical care treatment space during disasters requires expansion into intermediate care units and telemetry spaces. Intermediate care and telemetry patients should be moved to general practice wards. The least sick patients should be discharged or transferred to community care facilities. (b) Expansion of critical care services in sustained catastrophes involves the transfer of all remaining intermediate care and telemetry patients to general hospital wards. Most, if not all, lower-acuity patients on the wards will need to be moved out of the hospital. Critical care patients will now occupy most of the hospital, including some of the general hospital wards.

SARS, severe acute respiratory syndrome; HEPA, high-efficiency particulate air.

Data from various sources (see references).

hours of care teams are staggered, to overlap individuals from different care teams. This approach is associated with lower rates of fatigue and helps the overall morale of the care team [10].

Infection control

Health care workers and patients are extremely vulnerable to nosocomial transmission of infectious agents during pandemics [10]. A rigorous infection control programme for pandemics should be built upon the existing infection prevention and control practices of the hospital, and based upon modes of transmission for known or suspected agents [12,13]. Infected and exposed patients should generally be physically separated from other hospitalized patients who are susceptible to infection. It is prudent to initiate contact, droplet, and airborne precautions in uncertain pandemic situations and de-escalate accordingly when a fuller understanding of the illness becomes available [12]. Airborne precautions should be instituted for specific pathogens or during certain aerosol generating procedures (see Table 9.1) [12–14].

Health care personnel should receive training in infection control procedures including the need for hand washing, and the implementation of isolation procedures, etc. [12–14]. These personnel should also be trained in the pre-outbreak or inter-pandemic in the use of personal protective equipment, and training such as fit testing for masks, and the use of gloves and gowns in pandemic situations updated and documented regularly [12–14]. Aerosol generating procedures, such as high frequency oscillatory ventilation, non-invasive ventilation, and bronchoscopy, may increase the risk of virus transmission, but there is limited data to implicate particular modes of ventilation, and application of any of these modes may be reasonable, with appropriate health care worker precautions [13,14]. Negative pressure airborne isolation rooms, and high efficiency particulate air (HEPA) filter machines could be considered during procedures such as non-invasive ventilation, high frequency oscillation, etc., but their effectiveness in decreasing transmission rates is still unclear [13,14].

Resource allocation

Pandemic care needs to address the potential for a necessary increase in essential equipment (see Table 9.2) for both the patients admitted as a result of the pandemic, and patients admitted due to other medical problems [7,8,11] A model of a single pool of resources to be accessed by all in a designated health facility is likely to be more effective than numerous stockpiles in various departments [7,11]. Hospitals should establish a pandemic management committee, with representation by personnel from clinical, laboratory, and ancillary health care and administrative departments. Such a group should meet face-to-face on a daily-to-weekly basis to establish effective means of information gathering and dissemination within their area. Ideally, there should be similar local state and national acute care, and public health and governmental communication and coordination of resource allocation. During SARS and H1N1, we learnt that it is common for hospitals, cities, and countries to be differentially affected, and for certain regions to be stretched beyond capacity, while others had yet to experience substantially increased caseloads. A pre-established state and national mechanism to share resources (personnel, ventilators, medication, infection prevention, and control equipment) from small regional stockpiles or from a pre-existing inventory is essential.

Critical care triage

Triage protocols for pandemic situations should only be activated if surge capacity has been maximized across a broad geographic area, calls for aid (personnel, equipment, etc.) have gone out through local, national, and international channels, and there is still

Table 9.2 Equipment and devices to consider during viral respiratory illness pandemics

Essential medical equipment		
◆ Respiratory support equipment including mechanical ventilators ◆ Peripheral, central venous, and arterial catheters for haemodynamic support ◆ Monitoring equipment		
Pharmacologic therapies		
◆ **Antivirals**: neuraminidase inhibitors specifically for influenza outbreaks ◆ **Antibiotics**: for community-acquired pneumonia, secondary bacterial infection after viral pneumonia and hospital-acquired pneumonia ◆ Resuscitation fluids ◆ Vasopressors and inotropes ◆ Sedatives and analgesics ◆ Neuromuscular blocking agents ◆ Enteral nutrition		
Infection control and prevention equipment		
Contact isolation	***Droplet isolation***	***Airborne isolation***
◆ Gloves—sterile and non-sterile	◆ Face shields ◆ Goggles ◆ Face masks ◆ N-95 respirators	◆ Powered air purifying respirators ◆ HEPA Filters
Specific equipment for supportive care in patients with oxygenation failure		
◆ High frequency oscillation ventilators ◆ ECMO ◆ Equipment to support prone patient positioning		

a substantial demand-capacity mismatch that will result in some patients being unable to receive usual care [8]. Timing of critical care triage is very important—too early results in 'over-triage' and waiting too long results in a precipitous decline in the available resources [15]. Equitable distribution based on ethical principles of justice, beneficence, and non-maleficence should drive a triage protocol. Our usual principals of admission to ICU emphasize a 'first come, first served' approach. However, triage systems based upon severity of illness scoring systems have been proposed [8]. Such systems underperform when the pandemic population differs substantially from the derivation group, by younger age, or single organ failure in the H1N1 experience for example [15]. Criteria for triaging should be objective, transparent, easy to apply, and ideally flexible enough to allow a scaled ramping up and down as capacity changes.

Education

Simulation training plays a key role in preparation for pandemics, but cannot anticipate or address the nuances of all possible scenarios, cannot reach all staff, and will not replace targeted and specific intra-pandemic training. Training should begin as soon as possible with demonstrations followed by supervised practice. Subjects to be taught will inevitably include pandemic specific medical management, deployment of personal protection techniques, environmental decontamination, handling of laboratory specimens, alert lists, potential triage systems, visitor restrictions, and stress recognition and management, among others [7,8,10,11,14].

Management

Ventilation and oxygenation

Respiratory symptoms associated with severe hypoxaemia are likely to be common during viral respiratory pandemics and will require supportive care with supplemental oxygen and mechanical ventilation. While a review of effective therapy for ARDS is beyond the scope of this chapter, lung-protective ventilation, with judicious application of positive end expiratory pressure and intravenous fluid management should form the mainstay of lung supportive care. Severe ARDS, as seen during SARS and the 2009 influenza H1N1 pandemic will lead to increased frequency of 'rescue therapies', such as extracorporeal membrane oxygenation (ECMO), prone positioning, high frequency oscillatory ventilation, and inhaled nitric oxide [3,4,16]. While the role of ECMO, high frequency oscillation (HFO), prone positioning and nitric oxide is still unclear, pandemic-specific characteristics, such as young age and single organ failure may increase the likelihood of clinical benefit among therapies proven, thus far, only to improve oxygenation [3,4,16].

Pharmacotherapy

The SARS outbreak was as a result of a coronavirus that led to rapid development of ARDS and may have had an overall mortality of almost 10% [5,6]. Clinicians used ribavirin, steroids, and interferon alpha during the outbreak [5,17]. Subsequent analysis of all these interventions failed to show survival benefit among patients with SARS [6]. So no clear recommendations can be made in regard to the pharmacological treatment options for SARS [6,17]. The 2009 influenza H1N1 pandemic was unique as a severe disease requiring critical care services, which disproportionately affected young, immunologically naïve patients [3,4,15]. In critically-ill patients, the use of neuroaminidase inhibitors (oseltamivir, zamanavir) may have been associated with a lower incidence of death, although true effectiveness is impossible to define outside a properly performed clinical trial [3]. Optimal duration and dose of these therapies is uncertain [3,4,18,19].

There is an extensive prior literature and ongoing debate about the effects of corticosteroids on severe ARDS, and pandemic-associated ARDS. We saw extensive use of corticosteroids during SARS and the 2009 influenza H1N1 outbreak [18]. Although there is suggestive clinical trial data supporting steroid use for severe ARDS, observational studies during the pandemic highlighted worse outcomes among corticosteroid-treated patients. Yet this relationship probably suffers from residual confounding [18]. Currently, there is even less evidence for other agents.

Recent studies have emphasized common bacterial co-infection among patients with severe viral pneumonia [19]. Based on the available literature, early initiation of antibiotics, covering community-acquired organisms and organisms associated with viral infections (e.g. *Staphylococcus aureus*) are probably a very important aspect of therapy [19].

Establishing the means to rapidly deploy effective immunization to the at-risk population (including health care workers) is cost-effective and should be a key component of any pandemic response.

Research

The SARS epidemic highlighted the difficulties associated with developing and implementing studies during pandemic situations [6]. The H1N1 pandemic reaffirmed the need for early clinical and epidemiological data to be developed and implemented in a timely manner to help guide clinical decisions and health policy. During the early phase of the H1N1 (2009) pandemic, a number of critical care groups collaborated with government-affiliated agencies and other funders, and developed sound methodology to study the epidemiology and outcomes of critical illness in pandemic situations [20]. However, clinical trials were still delayed as protocols had not been prepared, regulatory bodies were sometimes slow to assess them, and accruement was limited. In response, the International Forum for Acute Care Trialists (InFACT) [20] evolved, with a vision of improving the quality of care for acute life-threatening illnesses throughout the world, by establishing collaborative networks of critical care societies and research trials groups to develop specific, adaptive studies and trials ahead of subsequent threats. Research preparedness, with protocols prevetted and approved, electronic case report forms and clinical trials databases preconstructed and with internationally harmonized definitions, and placebo/comparator agents well worked out before a pandemic will afford the best chance at early accurate pandemic descriptive and interventional studies [20].

Conclusion

ICUs will play an instrumental part in the care of the sickest patients during a disease outbreak. An appropriate critical care response to disease outbreaks requires preparation for an efficient response, strengthened by regular training of health care staff. The implementation of surge capacity and triage will become important when patient volumes exceed normal limits, and these decisions should always be made based on ethical, humanitarian, and legal principles. Appropriate infection control techniques are critical to saving lives by preventing secondary transmission to health care workers or other patients. Specific anti-viral therapy, antibiotics directed towards probable secondary infections, supportive ventilation and oxygenation, and adherence to multisystem critical care 'best practices' will prevent substantial mortality and morbidity, and lessen the pandemic's impact on global health.

PART 1.2

Communication

CHAPTER 10

Effective teamwork in the ICU

Peter G. Brindley

Key points

- Without effective teamwork high-quality critical care medicine is largely impossible.
- Traditionally, medicine has focused upon the individual practitioner, not the team.
- Fortunately, practical strategies can be adapted from other high-stakes professions.
- Communication skills are integral to good teamwork and can also be adapted.
- Better teamwork is a prime means to improve patient safety and medical culture.

The importance of teamwork

The modern jet 'is too much for one man to fly' [1]. Similarly, the complexity of critical care medicine means patients are too much for one clinician to manage alone. An Israeli study, publicized by the American surgeon, Atul Gawande, estimated that the average ICU patient required 178 individual actions per-day [1]. Regardless of the exact number, critical care imposes mental and physical demands that exceed even the most seasoned individual [2]. Therefore, without effective teamwork (defined as cooperative efforts to achieve a common goal) high-quality critical care is largely impossible [2].

Research from several high-stakes industries shows human factors to be the commonest reason for preventable errors [2,3] Growing evidence suggests the same during acute medical care [2–8]. Inadequate teamwork (and the intimately-related issue of **suboptimal communication**) is amongst the commonest human error [2–8]. Accordingly, following history's largest aviation disaster, investigators concluded that individuals had simply 'failed to take the time to become a team' [1]. Therefore, teamwork cannot be assumed [2]. Fortunately, it can be taught [2].

In contrast to other professions, medical curricula have rarely addressed teamwork (or communication) during crises [6]. Therefore, this chapter offers strategies from other high-stakes industries and applied to critical care. These ideas are not indigenous to medicine [4,5]. In fact, this may reflect a culture where health care workers have rarely thought in team terms [2]. Regardless, to discuss the medical teams that we want means promoting the medical culture that we need [1].

Many ideas in critical care can be illustrated using the double-headed god, Janus: representing the best and worst of what we do [9]. Teamwork and culture are no different. Western values have bolstered patient-ownership and self-reliance, but this means we highlight individual (rather than team) achievements [2]. We also promote the personal agenda over social cohesion, and equate success with individual efforts (or innate abilities), not the advantages of the community [2,7]. Accordingly, quality care has been linked to how the solo-practitioner performs and remedies centred on individual expertise (longer training, more scholarship) or high-technology assistance for that individual (computers, information technology) [2–6]. In short, it is time that less 'me' and more 'we' became a goal for critical care medicine [2].

There are 'fewer planes crash when the co-pilot is flying' [7]. If we continue to believe that crisis management is an individual endeavour then this is nonsensical, after all, senior pilots have more experience. However, planes are probably safer with co-pilots at the controls because the senior pilot is not afraid to speak up and the subordinate is fully engaged [7]. In short, this way more than one person flies, and a team is created that brings forth collective skills, experience, and wisdom. However, in addition to accepting the importance of teamwork, we must also perfect that team. After all, a team of experts is not the same as an expert team [2].

Good teams and bad

Not all teamwork is good. Milgram's experiments demonstrate our propensity to blind-obedience [10]. Asch's experiments show that people conform to the group, even when not compelled, and even when they know the group is wrong [10]. Moreover, once a majority of team members form an opinion, they usually stick with it, in spite of contradictory information [2]. They will subconsciously alter existing beliefs or add new ones, to reduce 'cognitive dissonance' [10]. Comfort in numbers or 'group think' (if all members agree, then we cannot be wrong) means that teams may follow the majority opinion not the rational argument [2,10]. Therefore, the search for solutions is prematurely abandoned. Groups also amplify individual behaviour for good and bad; tending towards greater risk if an individual's predisposition was to be risky, and towards more caution if individuals were risk averse [2,10]. Overall, the commonest team-failings are the inability to assign roles, to hold members to account, to advocate a position or corrective action, to use check backs, to communicate clearly, to seek usable information (not just data), and to prioritize tasks [2].

There are substantial differences between aviation and critical care. However, a useful principle from aviation is to focus not on **who is right**, but **what is right** [3,4,8] Aviation research also suggests that, in a crisis, 10% of people will lead, 10% will freeze, and 80% will neither lead nor freeze . . . but can be led [11]. To do so, a good leader must establish a 'shared mental model' (a common

understanding, with everyone 'on the same page') [2,3,8]. This allows teams to prioritize, manage information, establish roles, stabilize emotions, and build confidence [2]. If time allows, the leader can invite members to suggest a mental model ('What do you think? What would you do?'). Under time-pressure, the leader has to rapidly establish a model that members will support and amplify ('I believe its septic shock, please do the following . . .') [2,3].

As complexity increases, so does the possibility for harm. Fortunately, a clear team hierarchy can combat confusion and complexity [2,10]. However, hierarchy represents another double-headed Janus. What should be a strength (after all hierachy can provide much-needed order) can be a weakness (after all team members can feel too scared to contribute freely). Aviation crashes are commonly associated with subordinates not speaking up, even with their own lives at stake! [1,7]. On the other hand, without leadership, diffusion of responsibility can occur [2]. Typically, the easiest tasks will be addressed by several people, although one would suffice, while harder tasks remain undone [2]. Inexperienced teams can function well, but typically need more direction and centralized-control [2,10]. Fortunately, physicians are authorized a priori to lead [2]. However, the best teams are dexterous enough to modify structure, hierarchy, and communication norms in response to an individual problem [1,2,7,11].

As teams mature, their members learn to volunteer relevant information, voice concerns, verbalize contingencies, and apportion responsibility (so called 'explicit coordination') [2]. 'Cross-monitoring', or 'mutual-monitoring' also increases the team's cognitive capacity [2]. As teams mature they also anticipate and act with minimal talking ('implicit coordination') [2]. In short, typically, the more unfamiliar the task, and the more unfamiliar the team members, the more that explicit coordination is required. The more routine the task, and the more experienced the members, the less explicit coordination is required [2].

Simulation is another technique adapted from aviation. While useful for teaching individual skills, simulation's real strength is as a 'team laboratory'. Team skills, or **crew resource management** (CRM) skills, have been adapted to medicine as **crisis resource management**, and honed using simulation [4,5]. Of all CRM skills, the most important appears to be communication [3,8]. After all, if communication means to 'share, join, unite, or make understanding common' [2,3], then much of what makes a good team or good leader equates with communication [3]. Accordingly, improving communication may be the single wisest investment in patient safety and 'verbal dexterity' our greatest skill or liability.

Team communication

Team communication is more than just talking: it aids task-execution, information-exchange and relationship-building [2]. It is also more than just what is said—it matters how it is said and how it is understood [2,3,8]. Moreover, non-verbal communication (gesture, posture, eye contact) and para-verbal communication (tone, loudness, pacing, emphasis) are at least as important as verbal communication (potentially more so if there is incongruence) [2,8]. This means that we are unable to **not** communicate . . . even if we do not speak [2]. Following those caveats, we will now focus on verbal communication and will again apply strategies from other high-stakes industries.

Communication during medical crises or aviation disasters is a major source of preventable death [7,8]. Aviation has mandated 'horizontal authority' and 'horizontal communication' to flatten the authority gradient [7,12]. Aviation also demands 'transmitter orientated' communication (i.e. it is the speaker's responsibility to be understood), rather than 'receiver orientated' communication (where listeners are forced to work out what was meant) [7]. This requires a culture that empowers subordinates to speak up and to do so clearly [1,7,8]. It also requires 'active-listening' where others confirm understanding or demand clarification, regardless of seniority or embarrassment. [2–5,8]. In short, all members take responsibility for how messages are delivered, received, understood, and completed [2,3].

'Say what you mean; mean what you say'

Even experienced professionals can be prone to silence during crises [2,3]. In aviation, this means black-box silence for the few minutes before a crash [2]. Similarly, during resuscitation, health care workers may not speak due to stress or uncertainty. Instead, leaders should be taught useful phrases to break the silence ('Still no pulse . . . what am I missing?') [3]. Similarly, the military's situation, background, assessment, recommendation (SBAR) communication strategy offers a communication tool that, while being overly formal for some teams, offers structure for junior staff and unfamiliar situations [8,13]. A simple example would be: Situation: 'I'm Dr X, I need your help with . . .'; Background: '… a 35-year old trauma from today'; Assessment: '… still hypotensive despite blood'. Recommendation: 'You should review him, now' [3,13].

Pilots learn to grade their assertiveness [2–4,7,8,11,14–17]. This includes Besco's archetypal four-step PACE model (probing, alerting, challenging, emergency language) [14]. Others teach up to six steps, but all progress from least to most direct. This includes the 'hint' ('Should things look like this?'), 'preference' ('I would suggest . . .'), 'query' ('What do you think?'), 'shared suggestion' ('You and I could . . .'), 'statement' ('we need to . . .') and 'command' ('Do this now!') [6]. Without instruction, junior members may only hint, and, if ignored, fail to escalate their assertiveness [7]. Senior members may rely too much upon 'commands' as they are not concerned about being blunt [7]. Aviation also teaches a five-step model of advocacy and confirmation [17]. The following has aviation examples with medical corollaries: 'Attention getter' ('Excuse me, captain/doctor'); 'State your concern' ('We're low on fuel/the patient is hypotensive'); 'State the problem as you see it' ('I don't think we can land/I think we need vasopressors now'); 'State a solution' ('Let's re-route to another airport/I'll arrange ICU transfer'); and 'Obtain agreement' (e.g. 'Okay, captain/doctor?' [17].

Ambiguous or non-committal speech (aka 'mitigating speech') is common prior to airline crashes and during medical crises [7]. This is why we must replace comments like 'Perhaps we need a surgeon' or 'We should think about intubating', with 'Get me a surgeon' and 'Intubate the patient, now'. Junior members may mitigate to show deference, when embarrassed or if unsure. If time permits 'mitigating language' can be harmless, and may even aid team building ('If you get a moment could you help me with this patient?'). However, in a crisis, using the wrong communication tool is at least as dangerous as selecting the wrong surgical tool [2]. Regardless, over-cautious language is inappropriate during a crisis, just as overly brusque language is inappropriate during team building.

Crisis communication should still be polite, but also unequivocal and task-focused [3,8].

An aviation adage states that 'You never let a plane take you where your brain hasn't already been' [18]. Therefore, pilots are taught to communicate proactively [8] (i.e. to 'fly ahead of their planes') [18]. The principle could be adapted by both medical team-leaders ('I will be intubating soon, get the difficult airway cart') and subordinates ('The bolus is almost in, how about another?'). Communication must also be addressed to a specific person to avoid diffusion of responsibility [2,4,5]. This is why comments like 'could someone' and 'does anybody' are inappropriate [2]. Closed-loop (or challenge-response) communication means reinforcing instructions by demanding feedback ('John, intubate the patient, and tell me when it's done') [3–5,8,17]. 'Call outs' [17] alert the team to important changes ('He's going back into ventricular fibrillation') [18] and the 'Step back method' [17] means verbally forcing a 'time out' ('Stop compressions and reassess the cardiac rhythm'). The 'Repeat back method' [17] provides a safety check by repeating to confirm mutual understanding ('So that's one milligram of epinephrine?'). Similarly, the 'Read back method' [17] requires confirming an order before processing it.

Team members must speak up [7]. However, contributions must be task-focused and appropriately timed, otherwise it can further exacerbate chaos [2]. Accordingly, aviation's 'Sterile cockpit rule' applies to critical phases, such as take-off and landing [8,19,20]. The team ensures **no** unnecessary talk, and those silenced know not to take offence [19,20]. Similarly, medical practitioners should focus comments during resuscitation. In less-critical situations, we should confirm if others are free to talk. Once the crisis has abated, time should also be provided for more free-flowing communication. This is essential for debriefing, conflict management, stress relief, and to maintain the team for the next crisis [2].

CHAPTER 11

Communication with patients and families in the ICU

Leslie P. Scheunemann and Robert M. Arnold

Key points

- Structured meetings should occur regularly with families of all intensive care unit (ICU) patients.
- Premeetings help to ensure all the appropriate people have been included and that the clinical team has a coherent understanding of the patient's prognosis and treatment options.
- Family meetings should typically follow the format introductions, goal setting, family illness narratives, clinical updates, responses to family emotions and questions, understanding the patient, transitions to decision-making, making treatment decisions, and wrapping up.
- Debriefing allows the team to review how the patient's treatment plan has changed, to reinforce effective communication behaviours, and to troubleshoot places where communication faltered.
- Listening and responding to families' emotions are essential clinical communication skills.

Introduction

Over the past decade, holding regular, structured meetings between clinicians and the families of patients in the intensive care unit (ICU) has been increasingly advocated by leaders in quality improvement, critical care, and bioethics. Their most commonly cited benefits are reduced family emotional distress and reduced time in the ICU for dying patients [1]. Their structure and content has been informed by theoretical models of ethical decision-making for incapacitated patients [2,3].

Although informal meetings should occur continually, formal meetings are indicated:

- Within the first 72 hours of ICU admission [4].
- When conflict occurs among family members, or between the family and the clinical team [5].
- When the clinical team feels that the current goals of care should probably be revised [6].
- When the family or clinical team requests a meeting.
- When the patient's clinical status changes.

Additionally, the clinical team should meet every 5–7 days with families of patients who have longer than average stays. Because accurate prognostication for ICU patients is notoriously difficult, even families of ICU survivors are at increased risk of psychological symptoms compared with the general population, and families of survivors are less satisfied with communication with the ICU team than families of those who die, regular meetings should occur with families of all ICU patients [7].

The purpose of this article is to review the procedures teams can follow and skills they can develop to improve outcomes of care.

Mechanics of the family meeting

Formal family meetings should include short, focused premeetings and debriefing sessions (see Box 11.1) [8].

Premeeting

Before the family meeting, the clinical team should meet to ensure all the relevant people have been invited, ensure an appropriate space is available, and plan a communication strategy.

Inviting attendees

If a previously competent patient has requested that certain people should not be involved in decision-making, the request should be honoured [9]. Otherwise, any family members wishing to attend should generally be allowed to do so, particularly key family support figures and legal decision-makers. The minimal clinical representation is one member of the primary service responsible for the patient's care. Nurses, social workers, primary care providers, and consultants can contribute a spectrum of knowledge about the patient as a person, the patient's medical condition, possible treatments, and the practical aspects of future transitions (e.g. to hospice or a nursing facility, or for a family to make funeral arrangements), and thus should be included [6,7].

Setting

Most families feel uncomfortable discussing potentially sensitive issues about patient care at the bedside, and patient rooms are poorly structured for such discussions. If possible, ICUs should designate a quiet, private, comfortable room for family meetings [10]. Enough chairs should be available for everyone to sit, and clinicians and family members should ideally be interspersed among each other. Clinicians should minimize possible interruptions, put their pagers and phones on vibrate, and bring tissues.

Communication plan

Finally, clinical teams should take time before the family meeting to review the relevant clinical information, and establish their overall

Box 11.1 Generalized structure of the ICU family conference

Premeeting

Attendees

Representatives of all clinical services planning to attend the meeting proper.

Overarching goals

- Ensure relevant individuals have been invited to meeting proper.
- Ensure an appropriate space has been secured.
- Plan the communication:
  - Establish a facilitator for the meeting proper.
- Achieve consensus among the team about prognosis, appropriate possible treatments, where current decisions fall on the spectrum of shared decision-making.
- Plan a communication strategy.

Key suggestions

- Aim for efficiency—should rarely exceed 10 minutes.

Meeting proper

Attendees

- All family who want to attend, especially designated surrogates.
- Physician and nurse representative(s) of primary ICU service.
- Meaningfully involved consultants and primary care providers.
- Social workers.
- Chaplains.
- Interpreters.

Overarching goals

- Variably focus on updates, family support, or decision-making.
- Ensure flexibility in response to family needs.

Key behaviours

- Introductions:
  - Introduce team members and explain their roles.
  - Ask families to introduce themselves.
- Goal setting:
  - Explain the team's goals.
  - Ask the family to suggest other goals.
- Family illness narratives: ask the family what they understand.
- Clinical updates: provide big-picture, jargon-free clinical updates.
- Answer questions and respond to emotions.
- Understanding the patient:
  - Ask about the patient as a person.
  - Ask about previously expressed health care preferences.
  - Reflect on values evidenced by the descriptions of the patient.
- Transitioning to decision-making:
  - Summarize discussion of the patient's values.
  - Ask permission to talk about treatment plans.
  - Explain the principle of substituted judgment.
- Making decisions.
- Wrapping up.

Debriefing

Attendees

- Representatives of all clinical services who attended the meeting proper.

Overarching goals

- Delegate responsibility for items in the treatment plan and for where family support will be needed.
- Review what went well.
- Troubleshoot places where communication faltered.

Key Suggestions

- Keep it brief.
- Keep it action-orientated.

goals and expectations for the meeting [9]. Families are sensitive as to whether the team appears to have internal consensus [11]. Therefore, the team should internally resolve any apparent conflict about the patient's prognosis or potentially appropriate treatments ahead of time.

The meeting proper

Introductions

Families like to know who the people on the clinical team are and what their role is [10]. Introductions also explain who the family members are, and often give insights into their relationships, including hierarchies or conflicts [9].

Goal setting

It can be helpful to ascertain what the family's expectations and goals are for the meeting, and to clarify the goals of the clinical team. For example, 'We wanted to meet today to update you on how your mother is doing, to give you an idea of some things to expect in the short term, and to understand more about who she is, so we can provide her the best care possible. Do you have anything else that you would like to discuss?'

Family illness narratives

Asking the family what other health care providers have told them about the clinical situation targets several goals. First, their descriptions show their understanding of and reactions to the illness. Secondly, clinicians can avoid unintentionally contradicting or seeming to contradict other members of the team who may have talked to the family. Finally, having the family narrate the clinical course can avoid unintentionally and abruptly providing information for which they are unprepared. If the narrative indicates low expectation of bad news, clinicians can give a warning shot, such as, 'We all hope that being more awake than before is a good sign for him . . . Unfortunately, despite being more awake, he has developed new and serious problems this week.'

Clinical updates

Using this foundation, clinicians should explain the diagnosis and prognosis in clear, jargon-free language. Doing this well reduces families' uncertainty, removes barriers to patient-centred surrogate decision-making, and strengthens the relationship between families and providers [12]. It is often helpful to prognosticate in terms of 'hoping for the best, and preparing for the worst', and give specific details about when uncertain prognoses will be clearer [13]. Clinicians should not provide more than three pieces of information without pausing to assess family understanding.

Answering questions and attending to emotions

Families need the opportunity to react to the clinical update. Clinicians should stop and elicit questions and emotional responses by asking something like, 'This must be difficult to hear. What questions do you have?' Clinicians should answer briefly and focus on the big picture—they should continue eliciting questions until all of them have been asked.

Transitioning to decision-making

Decision-making is a common priority in family meetings. Clinicians can signal this transition by summarizing the important information about the patient, then saying, 'Given how her illness is going, and all these important things about her we've discussed, I'd like to talk about the future. Is that okay?' As long as the family accedes, clinicians should explain the goals of decision-making with statements like, 'We want the treatments we provide to honour and respect her. If your mom was sitting here and could hear what we have been talking about, what would she say?'[3].

Understanding the patient

If this question yields little information, it is important to stay focused on the patient as a way of being a good surrogate. Most of the time, ICU clinicians have not met the patient prior to the incapacitating critical illness. Asking, 'In order to make sure our treatments honour and respect her, it is helpful to know more about what she was like. Could you tell me about her?' opens up another avenue to understanding the patient. It allows ICU clinicians to connect to the patient in a more personal way, demonstrates caring to families, and generates a gestalt about the patient's core values that may be relevant for decision-making [14].

Making decisions

The initial approach to making decisions should be to ask whether the patient has any written or oral directives regarding care as above. Absent applicable directives, providers should discuss possible treatment pathways and their expected outcomes in the context of the understanding of the patient they have achieved. They should assess family understanding of and reactions to this information, and be ready to provide a patient-centred recommendation that links the values discussed previously to a treatment pathway [15]. Regardless of the chosen pathway, they should reassure the family that they will not be abandoned and that the patient's symptoms will be minimized [7].

Wrapping up

Before concluding, the next meeting should be scheduled, a family contact person designated, and the family informed about how to reach the team if needed before the next meeting.

Debriefing

Debriefing is an important way to summarize the information exchanged during the meeting, process reactions to it, and identify strategies for improving communication with individual families or in general.

Key skills and behaviours for clinicians

The most effective family communication focuses primarily on listening and responding to emotions (Box 11.2). Especially when complex transitions or conflict are anticipated, palliative care and ethics consultation can provide further specialized skills and support [1].

Listening

Clinicians tend to dominate family meetings, but families are more satisfied if they have greater opportunity to talk [16]. Therefore, clinicians should adopt practices that counteract this tendency. Among the most effective is 'ask-tell-ask,' in which they bookend their own insights with inquiries about the family's perspective or understanding [17].

Allowing silence

Especially after delivering bad news, clinicians should allow families time to digest and react to it. This may involve pauses of more than 15 seconds [14].

Responding to emotions

Families of critically-ill patients experience sadness, anger, guilt, fear, grief, and anxiety, most commonly expressed according to a 'fight or flight or freeze' paradigm. Clinicians should meet expressions of emotion with empathy [18]. Two mnemonics have been developed to organize clinicians' thinking about skills for managing family emotions—NURSE and VALUE (see Box 11.2) [19,20].

Conclusion

Communication with families in the ICU requires essential and unique clinical skills. A systematic approach to communication improves family satisfaction and emotional outcomes, and facilitates patient-centred decision-making. Clinicians should strive to communicate in a timely way that emphasizes emotional support for families, to explain the diagnosis, prognosis, and treatment options in a concise, jargon-free manner, and to help families connect patient values to the most appropriate treatment pathway. When more specialized communication skills are needed, they should collaborate with palliative care or ethics consultants.

Box 11.2 Key behaviours and skills for communicating with families

Listening

Ask-tell-ask

Tell me what you expect will happen? Why? . . .

I hope that he will get better, too. Unfortunately, the most likely thing is that, even if he gets out of the hospital, he will have to live in a nursing home and be dependent for most of his care . . .

How would he feel about that?

Allow silence.

Responding to emotions

NURSE mnemonic

N → Naming the emotion:

'I can see this is upsetting'.

'It sounds like you're frustrated'.

'Your clearly love your brother very much'.

U → Understanding the emotion:

'This must be so overwhelming'.

'I cannot imagine all you're going through'.

R → Respecting the family:

'You are doing an amazing job representing your mother'.

S → Supporting the family:

'Can we help at all?'

'It is so hard to have someone you love in the ICU'.

'Would it be helpful if I made a recommendation based on what we've talked about?'

E → Exploring the feeling:

'Tell me more about why you feel that way'.

'You seem upset'.

'What are you hoping for right now?'

VALUE mnemonic

V → Value family statements:

Reflect the statement back ('I heard you say . . . is that right?').

Try to understand what motivated the statement (e.g. emotions, need to express hope/caring).

A → Acknowledge families' emotions:

'This really has been worrying you, huh?'

'It seems like you feel strongly about this'.

L → Listen to the family:

'Tell me more'.

'Why do you think that?'

U → Understand the patient as a person:

'Tell me about him/her'.

'What did he most like to do?'

'Were there things she was really afraid of, as she got sicker?'

E → Elicit family questions:

'What questions do you have?'

'Does it make sense that we make decisions for people based on what they thought was important?'

VALUE mnemonic: Reprinted from *Journal of Critical Care*, **17**, 3, Curtis JR et al., 'Studying communication about end-of-life care during the ICU family conference: Development of a framework', pp. 147–160, copyright 2002, with permission from Elsevier and World Federation of Societies of Intensive and Critical Care Medicine (WFSICCM) and Society for Complex Acute Illness (SCAI).

CHAPTER 12

Telemedicine in critical care

Bela Patel and Eric J. Thomas

Key points

- The majority of critically-ill patients are admitted to hospitals that do not have physician intensivist coverage, despite the strong evidence that clinical outcomes are improved with intensivist staffing.
- Telemedicine can leverage clinical resources by providing critical care expertise to patients in intensive care units (ICU) by off-site clinicians using video, audio, and electronic links. Telemedicine in critical care has seen tremendous growth in the number of ICU patients being supported by this care model across the USA.
- The impact of ICU telemedicine coverage on ICU outcomes has been studied rigorously in only a few studies over the last 15 years, and the outcomes have been mixed and inconsistent.
- Telemedicine studies show improved adherence to best practices for the prevention of deep venous thrombosis, stress ulcers, cardiovascular protection, prevention of ventilator-associated pneumonia, and catheter-related bloodstream infections.
- Further research in ICU telemedicine is required to understand the variability of outcomes among the telemedicine programmes studied, and to effectively implement the technology to consistently improve outcomes and reduce costs in the critical care environment.

Background and definition of ICU telemedicine

In the United States alone, more than 5 million patients are admitted to the intensive care units (ICUs) every year. A great majority of these patients are admitted to hospitals that do not have physician intensivist coverage, despite strong evidence that clinical outcomes are improved with intensivist staffing [1]. Shortage of skilled critical care professionals combined with increasing health care demands from the ageing population may pose a serious threat to the health care delivery in the intensive care units [2]. Technology-enabled care models have been developed to expand the availability of critical care expertise, regardless of the location of the patient over the last few decades. Telemedicine is the use of medical information exchanged from one site to another via electronic communications to improve health [3]. Telemedicine in critical care is care provided to patients in ICUs by off-site clinicians using video, audio, and electronic links to leverage clinical resources. Telemedicine in critical care was first described in the late 1970s and has subsequently seen tremendous growth in the number of ICU patients being supported by the technology [4,5].

Classification: care models, structure, technology

A lexicon was recently designed and described to facilitate communication, comparison and evaluation of ICU telemedicine. Based on this lexicon, ICU telemedicine care models can be divided based on the delivery of care—continuous care, pre-emptive/scheduled care, or reactive ICU telemedicine care. As the field rapidly evolves, there may be care models that are a combination of these designs [6].

In a continuous care model, care is provided based on different staffing models (8-, 12-, 18-, or 24-hour coverage). Within an institution that initiates a continuous care model, individual attending physicians may still have the liberty to opt-in or opt-out of specific services. In the pre-emptive/scheduled care model, visits occur by the virtual care team at defined intervals, corresponding to morning and afternoon rounds in a traditional ICU model. In the reactive ICU telemedicine care model, the tele-intensivist responds to an issue and/or provides clinical expertise on an as-needed basis.

The organizational structure of ICU telemedicine can be a centralized or a de-centralized model. In the centralized model, which has also been described as a hub-and-spoke model, the centre is an established remote location staffed by intensivists, nurses, and other team members. The comprehensive centres have ICU telemedicine workstations that display clinical information, physiological and laboratory alerting systems, and allow 2-way audio and video communication with the hospitals IT services. In the decentralized model, multiple computers are connected to the site that ICU telemedicine is servicing, and these computers may be inter-connected by tele-providers at multiple locations, such as from homes, offices, etc. [6,7].

Rapid development of technology has been one of the major driving forces behind the robust growth of this field, and such technology has allowed the remote care provider to effectively provide patient care. Such technology can be broadly divided into either technology based on the ICU telemedicine end or at the ICU patient end. The ICU telemedicine end is defined as the site where the remote care provider originates the telemedicine service that may utilize fixed and/or portable technology. Fixed technology at this end relays information from the ICUs that the ICU telemedicine is servicing. Portable technology at the ICU telemedicine end could be a laptop enabled with Internet access, built-in or attached camera, microphone, software, and the required memory space. Mobile technology at the ICU telemedicine end has also seen

growth, through mobile devices that have audio-visual access together with graphic capabilities. Technology that is fixed at the ICU end are devices such as audio-video devices that are permanently attached to some site near the patient. Portable technology at the ICU are systems that are capable of arriving at the bedside, which are capable of having two-way communication. This portability of technology at the ICU end has been further subcategorized as those devices that have dependent portability, semi-autonomous independent portability, or autonomous independent portability. Dependent portability devices, for example, include cart systems dependent on personnel for all activities; these carts have audio-visual access built-in, so the remote clinicians can communicate with on-site providers regarding the ongoing care of the patient. Semi-autonomous independent portability devices are those that are under the direct control of the remote clinical care provider. These devices operate via the wireless environment. Autonomous independent portable devices are currently under development, and these will be programmed to recognize the layout of the ICU and respond to emergencies by automation [6].

Telemedicine ICU outcomes

The impact of ICU telemedicine coverage on ICU outcomes has been studied rigorously in only a few studies over the last 15 years, and the outcomes have been mixed and inconsistent. Initiation of a commercial system installation was first described in Norfolk, Virginia, where the feasibility of utilizing telemedicine as a means of achieving 24-hour intensivist coverage was first reported. This study was an observational study in a 10-bed surgical ICU in a 450-bed, academic-affiliated community hospital. They enrolled patients that presented to the ICU during a 16-week period (n = 201) where the intensivists provided support from home, 24 hours/day. This group was compared with two different baseline periods at the same facility (n = 225, n = 202). The authors reported a 45% reduction in severity-adjusted ICU mortality, and a 30% reduction in hospital mortality and length of stay. ICU costs were also shown to be decreased by 16%. This was one of the first studies that demonstrated the feasibility of continuous intensivist oversight in an ICU by means of computer-based data transmission to obtain clinical information and manage patients remotely [8]. A follow-up study evaluated the outcomes of an ICU telemedicine model in a 10-bed general medical ICU and an 8-bed surgical ICU over a 6-month period. The intervention group received tele-intensivist directed care from 12.00 to 07.00 hours every day from an off-site location. The study demonstrated ICU and hospital mortality reduction during the period by 27% (9.4 versus 12.9%). ICU length of stay was decreased by 16% (3.63 versus 4.35 days). This study also reported a hospital cost savings of 2556 dollars per case due to decreased ICU length of stay [9]. Another study of more than 4000 patients conducted to determine the impact of a telemedicine system in two community hospitals revealed no significant effect on ICU and non-ICU total mortality or hospital length of stay.[10]

An observational study from our medical centre evaluated the ICU telemedicine model in six ICUs in five hospitals, where a total of 2034 patients from the pre-intervention period were compared with 2108 patients in the post-intervention period. Local physicians delegated full authority to the ICU telemedicine for only 655 patients (31.1%) in the study. For the remaining patients, ICU telemedicine intervention required direct communication with the treating physician except for life-threatening events. The hospital mortality rates were 12.0% in the pre-intervention period and 9.9% in the post-intervention period (p = 0.03). However, after adjusting for severity of illness there were no differences between the intervention and control group. Interestingly, in this study, we found that there was a correlation between the ICU telemedicine intervention and severity of illness ($p < 0.001$) [11].

Improved mortality and ventilator use in a study that used the ICU telemedicine staffing model at night times to achieve intensivist coverage 24 hours/day, 7 days/week. This study involved a 727-bed academic community hospital, a total of 954 control patients receiving care for 16 months before the implementation of the model, and a total of 959 study patients received care for 10 months after implementation. Mortality of the control and intervention groups were 21.4 and 14.7%, respectively. The observed mortality for the intervention group was 75.8% ($p < 0.001$) of that predicted by the Acute Physiology and Chronic Health Evaluation IV hospital mortality equations, which was 29% lower than the control group. The intervention patients also had significantly less time on mechanical ventilation (p = 0.001) [2].

A well-established group at the University of Massachusetts found that the implementation of ICU telemedicine was associated with reduced adjusted odds of mortality (adjusted odds ratio (OR), 0.40 (95% CI, 0.31–0.52)). Furthermore, the study showed a higher rate of best practice clinical adherence for the prevention of deep venous thrombosis, stress ulcers, cardiovascular protection, prevention of ventilator-associated pneumonia, and catheter-related bloodstream infections. They reported a shorter hospital length of stay (9.8 versus 13.3 days, respectively) and concluded that their implementation of an ICU telemedicine intervention was associated with reduced adjusted odds of mortality, reduced hospital length of stay, together with changes in best practice adherence [12].

Given the conflicting evidence, a meta-analysis that was conducted in 2011 analysed the combined outcomes of studies in ICU telemedicine, and further focused on 13 studies that met the quality criteria for inclusion in the meta-analysis. Out of the 12 studies that reported ICU mortality, the meta-analysis reported that the ICU mortality among 40,541 patients (15,311 pre-intervention and 25,230 post-intervention), was significantly reduced (pooled OR, 0.80; 95% CI, 0.66–0.97; p = 0.02). Out of these studies, only 10 studies reported in-hospital mortality for patients admitted to an ICU, and the pooled analysis revealed that the ICU telemedicine monitoring was not associated with a statistically significant reduction in in-hospital mortality for patients admitted to an ICU (p = 0.08). Out of the seven studies that reported ICU length of stay, implementation of ICU telemedicine coverage was associated with a significant reduction in ICU length of stay (mean reduction of 1.26 days; 95% CI = 2.21 to –0.30 days; p = 0.01), but was not associated with a reduction in hospital length of stay (p = 0.16) [13].

Implementation and measurement strategies

The inconsistent findings in ICU telemedicine studies are probably due to variable implementation strategies and differences in organizational contexts. A comprehensive plan has to be devised keeping the institution goals and objectives, physician capacity, patient flow, and existing infrastructure in mind. There should be careful consideration given to the kind of care model that will be utilized in

providing care. The technical aspects have to be thoroughly evaluated both at the ICU telemedicine and the ICU end. Both portable and fixed technologies have to be meticulously tested prior to decision endpoints. There are several barriers that organizations have to overcome to implement ICU telemedicine in their hospital environment. There may be a dearth of financial resources for initiation and maintenance of the telemedicine technology and staffing together with competition from IT for other electronic medical record (EMR)-related financial expenses. The ICU telemedicine workstation will have a technical learning curve that needs to be mastered by the ICU telemedicine physicians and nurses. Global acceptance of ICU telemedicine by the bedside physician and staff will require education and development of unit-based support. Physician licensing across states and credentialing at multiple facilities could pose a barrier to initial implementation. Lack of integration of the ICU telemedicine into the hospital medical records may delay care in some instances. Assessment of the programme effectiveness should be incorporated into the overall implementation plan. There are two main methods reported to evaluate an ICU telemedicine programme. The first method is to compare acuity-adjusted hospital, ICU mortality, and/or length of stay between the pre- and post-implementation period. The second method is to compare these standardized ratios over a period of time. This ratio can be compared with a reference population.

Multidisciplinary team

Successful ICU telemedicine is based on a team approach similar to the standard ICU model. The ICU telemedicine multidisciplinary team of intensivists, pharmacists, technicians, and critical care nurses are crucial to the success of the programme. The ICU telemedicine's nurses play a key role in monitoring the patients on a continuous basis and highly-skilled nurses with a vast experience may like providing patient care in a new setting. Those that are excellent at problem solving, and have good communication and computer skills will be assets to an ICU telemedicine model. Implementation of ICU telemedicine is associated with improved teamwork climate and safety climate in ICUs among nurses [14].

Supporting ICU telemedicine

The main argument in favour of telemedicine relates to extending the reach of the short supply of intensivists and improving efficiency of critical care delivery [15]. Based on estimates of current and future requirements for adult critical care physicians in the USA, with the ageing US population, the demand for critical care physicians will grow rapidly, with a projected shortfall of specialists equal to 22% of demand by 2020 and 35% by 2030 [1]. A number of strategies have been suggested to bridge this gap, including organizational changes to incorporate ICU telemedicines, because a single intensivist can manage multiple patients at multiple ICUs that would otherwise not have an intensivist to direct critical care. Furthermore, a recent Agency for Healthcare Research & Quality (AHRQ) report suggests that increasing use of electronic ICUs may have a crucial role in improving patient access to cost-effective and quality care, especially in rural areas [15]. Providing critical care expertise in rural areas that would otherwise not be serviced by an intensivist even during the daytime is not only of benefit to adult populations, but crucial in paediatric populations [16,17].

Utilizing technology to analyse large volumes of objective real-time clinical data leverages the intensivist team in expanding coverage capabilities. Smart alarms can alert the on-call physician and enable them to provide efficient patient care in a time-sensitive manner. Providing cost-effective care by decreasing ICU length of stay will help relieve the burden on leading health care organizations. Utilizing technology to improve adherence to best practice guidelines will further enable physicians to improve overall outcomes in the critical care population with traditionally high mortality rates. The results from the meta-analysis reporting a reduction in ICU mortality and ICU length of stay are important, but more studies are needed to understand the lack of translation to overall improvement in hospital mortality or hospital length of stay [18].

Against ICU telemedicine

General arguments against ICU telemedicine have been centred on the lack of robust evidence that such models improve overall outcomes consistently. Another limitation of remote telemedicine is the lack of bedside presence of the physician in providing appropriate critical care interventions in an unstable patient and lack of the traditional patient–physician relationship. Finally, some of the beneficial studies in ICU telemedicine are industry sponsored, and more independent research should be conducted and validated prior to introducing generalizations.

Conclusion

Implementation of a comprehensive programme in ICU telemedicine can redesign health care delivery in the critical care environment to improve outcomes. Although studies have been conflicting on whether ICU telemedicine improves outcomes, a recent meta-analysis demonstrated a significant reduction in ICU mortality and ICU length of stay, but not in-hospital mortality or hospital length of stay. There are substantial variations in the organization of ICU telemedicine programmes across the USA, and perhaps the greatest value may be in rural areas with limited or no intensivist staffing. Further research into ICU telemedicine is required to understand the variability of outcomes among the programmes studied and advance health care delivery science in telemedicine to effectively improve outcomes and reduce costs in the critical care environment.

PART 1.3

Training

CHAPTER 13

Clinical skills in critical care

Graham Nimmo and Ben Shippey

Key points

- Some clinical skills are labelled 'basic', such as basic airway management. The derogatory connotations of this label devalue **fundamental** skills, which if correctly applied can be life saving.
- Decision making is likely the most frequently enacted clinical skill in intensive care, yet it is inadequately understood by clinicians and sparsely taught. This needs to be addressed.
- Knowing when **not** to perform a practical procedure is as important as knowing **how** to perform it.
- So-called soft skills involving communication, team working, and situation awareness are actually the hardest. They are harder to do, learn, teach and evaluate than are practical skills.
- No matter how much support we provide a patient, if the diagnosis is wrong and definitive treatment missing, improvement is unlikely. Ensuring the correct diagnosis is a pivotal clinical skill.

Introduction to clinical skills in intensive care

When we think of clinical skills in the context of critical care it is usual to consider practical procedures [1] such as those listed in Box 13.1. These clinical skills are highly visible in clinical practice, can be taught in an easily understood, well-defined sequence (Box 13.2), and can be readily assessed both in the clinical area and in the skills laboratory. A capable critical care practitioner should be able to perform these skills safely and effectively.

However, the performance of even the most fundamental practical skill involves thinking and decision making as detailed by Croskerry [2]. Indeed, the decision on how to perform the skill, or even not to perform the skill at all, may be the most important step in the whole process. Taking central venous access as an example, choices need to be made about the site of access, with the internal jugular the preferred route, but the subclavian or femoral being indicated in certain circumstances. For example, if the patient has a significant coagulopathy, or is to receive thrombolysis, but central venous access is mandatory, the femoral or internal jugular routes are preferable to the subclavian as the related arteries are compressible. In a resuscitation situation, the use of large bore peripheral venous access may be entirely satisfactory, with the use of central access a secondary consideration further down the line.

So a great deal of our clinical time in intensive care is spent in the cognitive domain: thinking, analysing, weighing-up options, making decisions. In addition to this, many of the clinical skills that we practice, particularly as we become more experienced, comprise an amalgamation of a number of different practical, cognitive, and behavioural elements, which need to be coordinated into the final blended skill. Box 13.3 gives some examples of these. The 'emergency intubation checklist' (Fig. 13.1) shows how the different elements can be teased out both as a practical guide for the procedure, but also as a template for teaching the skill. Individual components are learnt in the skills lab and under clinical supervision (e.g. laryngoscopy, confirmation of endotracheal intubation). These are then integrated into the whole process incorporating the non-technical skills, as delineated by Reader [3,4], of decision making, team working and coordination, planning and prioritization, task management, situation awareness, and communication. These skills have been described as 'soft', but this belies the reality. These skills are actually **harder**. They are harder to perform, harder to learn, harder to teach, and harder to assess than practical skills. As we spend most of our time in clinical practice undertaking these non-technical skills, it behoves us to concentrate much more time in understanding and researching them, providing training to, and educating, clinicians than we have previously done. Although these skills were traditionally learnt 'on-the-hoof' in clinical practice they can now also be rehearsed in the simulation situation, in the simulation laboratory or using point-of-care simulation in the ICU, but also under supervision in clinical practice, of course.

Complex clinical skills in intensive care

The blended skills listed in Box 13.3 involve the integration of cognitive, behavioural, and affective components for the successful completion of the process involved.

Thinking

Clinical decision making is a pivotal skill in intensive care. Knowledge of the dual process theory of thinking and decision making is helpful both in the teaching and practice of clinical decision making [2]. There are two main thinking processes involved. System 1 is intuitive, quick, and demands little energy, but is prone to error and emotional influence—this is 'gut' reaction. System 2 is analytical, relatively laborious, but is more reliable and considered. If we know how we have made a decision, e.g. rapid-fire, and realize it could be wrong we can actively toggle between system 1 and system 2, to calibrate and improve our decision making (see Fig. 13.2). The main elements of the dual process model are:

- **The toggle function**: awareness of the processes and how to move from one mode to the other.

Box 13.1 Practical clinical skills

General

- Hand washing.
- **Vital signs**: respiratory rate, pulse, cuff blood pressure, conscious level, temperature.
- Oxygen therapy and nebulizers.
- Basic airway management, basic life support.
- Clinical examination.
- Bedside glucose measurement, urinalysis, pulmonary function tests, occult blood testing, urinary bladder catheterization, gastric tube insertion.
- Venepuncture, blood cultures, cannulation, intravenous fluid and drug administration, injection (subcutaneous, intramuscular), arterial blood gas sampling.
- Pleural aspiration, chest drain insertion, lumbar puncture.

Advanced

- **Airway management**: intubation, ventilation.
- **Advanced life support**: defibrillation, cardiac pacing.
- **Invasive monitoring**: arterial cannulation, central venous cannulation, cardiac output monitoring.
- Intra-osseous access.

Box 13.2 Teaching practical clinical skills

Knowledge

- Indications and contraindications: decision making.
- Consent.
- Safety aspects: e.g. coagulation, allergy, sharps.
- Anatomy and physiology.
- Equipment and technique.
- Complications and treatment.
- Interpretation of results.

Skills

- Preparation.
- Aseptic technique.
- Handling equipment.
- Practice on skills trainer.
- Supervised clinical practice.
- Independent experiential learning.

Box 13.3 Blended complex skills

- Recognition, assessment, management of the critically ill.
- Emergency intubation.
- Echocardiography.
- Handover.
- Brain stem death testing.
- Withdrawal of support.

- **Metacognition**: thinking about how we are thinking can allow us to move from intuitive to analytical thinking and also, in the case of an expert, to go with the intuitive decision, as it is based on experience and repetitive learning, as long as it is remembered that the decision may still be wrong!
- Most errors occur in System 1.
- Repetitive operations of System 2 allow more accurate decision making in System 1. As clinicians gain experience they are able to utilize System 1 more effectively, and also have a greater understanding of when and why this might fail, necessitating a move to a more analytical approach.
- System 2 can override System 1 to make decision making better.
- System 1 can override System 2, particularly when emotion, fatigue, and distractions are present jeopardizing decision making.
- To reduce costs in terms of time and energy, the brain's natural default position is System 1, the so-called 'cognitive miser function'.

Behaviours

Whether you are the trainee doctor, bedside nurse, advanced practitioner, nurse in-charge or a consultant, working in intensive care constantly involves multi-tasking—prioritization of tasks, illness severity assessment and prioritization of patients, juggling multiple clinical problems, managing interruptions as proposed by Nimmo (5), planning admissions and discharges, and coordinating care. The individual non-technical skills involved have been delineated earlier, but there are added levels of complexity. Whatever the nature of the patient's problems and diagnosis are, the intensivist is in the unique position of appreciating how these apply in the context of critical illness and intensive care. In interactions with referring speciality clinicians, it is the place of the intensivist to synthesize an agreed management plan, which may involve accepting or declining specialist advice. This skill requires disciplined listening and sensitive negotiation, as well as knowledge and experience.

Affect

Intensive care can be a high tension environment and emotional elements interweave with the practical and clinical aspects. Particularly in end-of-life care, other aspects of clinical skills are required. In this situation, it may be appropriate to delay decisions, to give more time for the patient, family, and staff. Recognition of our own feelings is an important factor in optimizing these decisions.

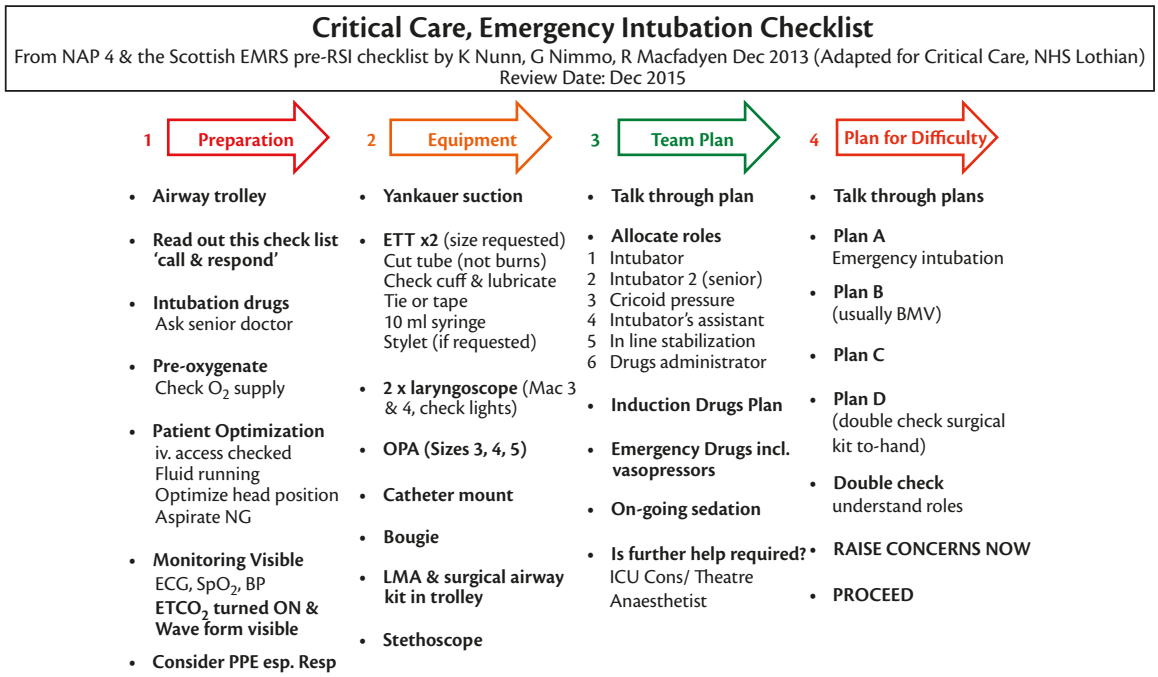

Fig. 13.1 Emergency intubation checklist.

From NAP 4 & the Scottish EMRS pre-RSI checklist by K Nunn, G Nimmo, R Macfadyen Dec 2013 (Adapted for Critical Care, NHS Lothian), review date: Dec 2015.

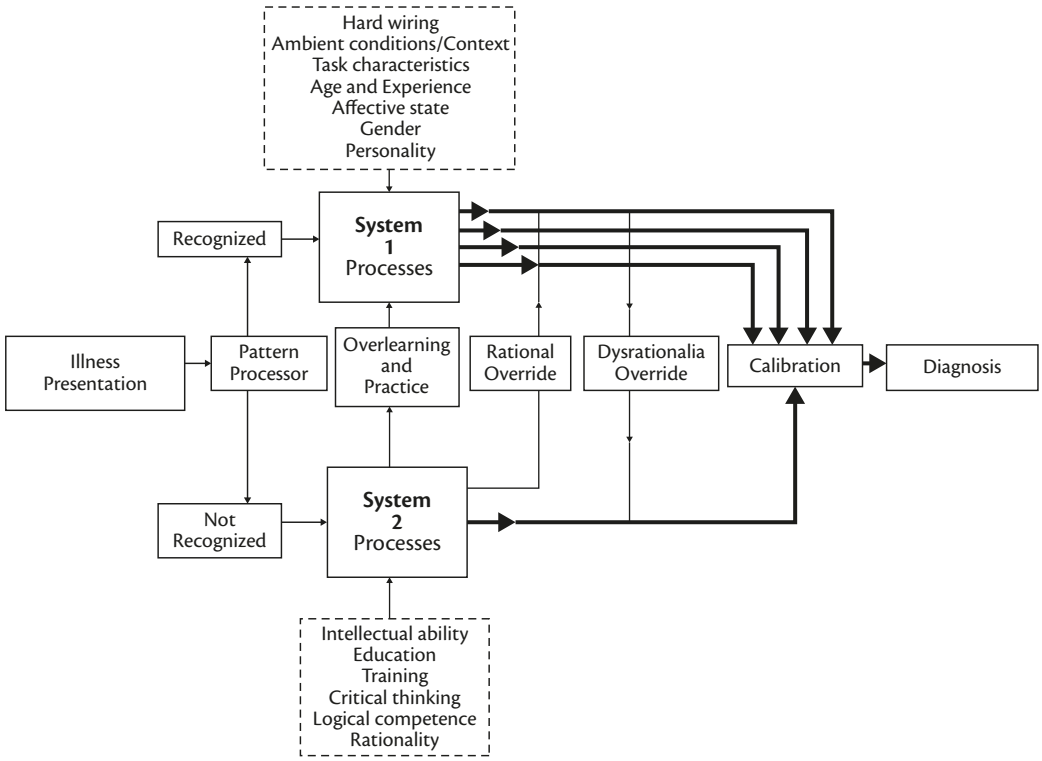

Fig. 13.2 Model for diagnostic reasoning, based on pattern recognition and dual-process theory. The model is linear, running from left to right. The initial presentation of illness is either recognized or not by the observer. If it is recognized, the parallel, fast, automatic processes of System 1 engage; if it is not recognized, the slower, analytical processes of System 2 engages instead. Determinants of Systems 1 and 2 processes are shown in the dotted-line boxes. Repetitive processing in System 2 leads to recognition and default to System 1 processing. Either system may override the other. Both system outputs pass into a calibrator in which interaction may or may not occur to produce the final diagnosis.

Handover

Handover of care is a bread-and-butter part of everyday emergency and scheduled clinical practice. **Good** handover is said to improve patient safety and reduce error. The risks of poor handover have also been identified and are emphasized by its description as **a perilous procedure**.

Handover is the medium whereby the continuity of patient care can be constructed and assured. An individual patient's clinical course, co-morbidities, diagnoses, and specific therapeutic requirements are just some of the strands which are entwined by their nurse and doctor to construct a **life thread**, which is passed to incoming staff across the potential disrupted space, which comprises a transfer of care, such as a change of shift or a move from one clinical area to another. Handover could also be viewed as a place of concatenation, of linking the chain of events in the patient's journey, and therefore a valuable check point to pick up missed aspects of care or errors.

Thus, in order to minimize risk and to deliver good quality care an acute appreciation of the pitfalls of handover allows those receiving the handover to check that certain elements are indeed accurate—name, date of birth, diagnosis, treatment given so far, relatives, and what they have been told. We are in a particularly vulnerable position, as a diagnosis has often been made prior to transfer to intensive care. The questions we must ask as part of our diagnosis checklist are these:

- Is the diagnosis correct?
- Is the diagnosis complete?
- Is there something else going on?

If we don't get the disease modifying *treatment* right, no matter how much organ system support we apply, the patient will not do well.

Conclusion

Clinical skills range from simple tasks to complex interactions of thinking and doing. Acquisition of knowledge followed by practice of these skills allows the novice to gain experience and become capable of delivering these skills capably in clinical practice. For the more complex skills, the expert will continue to learn and hone these throughout their career, particularly in the light of verbal and non-verbal feedback from patients and their families, and from colleagues.

CHAPTER 14

Simulation training for critical care

Ben Shippey and Graham Nimmo

Key points

- Simulation is an effective, but resource-intensive educational method.
- Simulated educational interventions should be directed by the learning needs of participants and planned around the resources available.
- The simulation faculty should be clear about the intended outcomes for the scenario before it is performed.
- Post-scenario debriefing is needed to promote reflection, and should be undertaken carefully by skilled facilitators.
- While simulation is useful as a formative assessment tool, the value of summative assessment using simulation is unclear.

Introduction

The obvious attraction of training using models that replicate aspects of real patients has led to the development of many different types of simulator, from the simple part-task trainer (venous cannulation, tracheal intubation), to the high-fidelity, physiologically-driven, whole-patient simulator. This chapter will restrict its focus to immersive simulation, using mid- and high-fidelity manikins to train clinicians to manage a clinical situation in its entirety. While there are undoubtedly aspects of technical performance that can be taught in the simulator, there are more efficient ways to do this. Non-technical skills (the raft of interpersonal and cognitive skills involved in effective and safe provision of critical care) are more difficult to observe in other situations, but can be observed and analysed in the simulated environment. Simulation can also be used to test systems and to reinforce emergency drills [1].

The importance of fidelity in simulation is often overstated. The purpose of a simulated environment is to allow the participants to demonstrate behaviours that can be analysed in a constructive manner, usually after the simulation. In order for this to occur, the participants need to put aside their conceptions that the 'patients' are not real, and treat them as if they are. This is often called 'suspending disbelief'. There are many aspects to the simulation experience that aid suspension of disbelief, of which manikin fidelity is only one [2]. Others are the quality of supporting materials, a coherent and appropriate 'story', or clinical course, the environment in which the simulation takes place, and the briefing and support given by the facilitator. The addition of stressors, such as an argumentative colleague or equipment failure can, if done carefully, help the participant to suspend disbelief.

Mid-fidelity simulators are often 'faculty driven'—the displayed physiology being directly controlled by a faculty member—although relatively cheap physiological model-driven mid-fidelity simulators now exist. Perhaps the greatest difference between mid- and high- fidelity manikins is with regard to the lung model, which in high-fidelity manikins is capable of reliably reproducing lung physiology that will allow the simulation of the complex lung mechanics required for many critical care scenarios, but at a cost.

Whole patient simulation is expensive. Space, equipment, and staff time should be built into the simulation budget. At the very least, a permanent simulation centre needs a 'simulator room', ideally with a separate control room, storage space for equipment, and break-out space for debriefing. This space is not required if the simulation is to be performed in clinical areas, but all equipment will need to be easily portable if this is the case. Mid-fidelity simulators cost in the region of £25,000, and that cost rises to £250,000 for a high-fidelity manikin. It is extremely useful to have the ability to record simulated activity, and modern digital recording equipment allows instantaneous replay. Staff costs are more difficult to quantify. It is useful to have a member of staff responsible for the maintenance of the simulation equipment, particularly if a large temporary faculty uses the equipment on an intermittent basis. As activity increases, consideration should be given to administration, centre management, and possibly permanent faculty members.

Planning scenarios

It is almost a *sine qua non* that the scenarios the simulation trainer uses to create the educational experience should be planned with the intended learning outcomes of the participants in mind. Those educational outcomes can be defined by the course or curriculum context in which the simulation experience takes place (adherence to a failed intubation drill in the context of a course designed for novice anaesthetists, for example), in which the scenario can be carefully scripted and programmed well in advance. Alternatively, the simulation facilitator can invite the participants to define their own educational outcomes (aligned to the general trajectory of the simulation experience) in which case the scenario skeleton can be adapted 'on the fly' to enable behaviour, which will allow those intended educational outcomes to be achieved. Other aspects to take into account are the experience and prior knowledge of the participants, and their previous experience of simulation training (which, in the context of 'whole team' training, may be mixed). Considering the environment in which the simulation scenario is to take place allows the scenario

to be tailored to the equipment and facilities that will be available in situ: there is little point in writing a scenario that requires the use of a fibre-optic laryngoscope if there one is not available [3].

It is difficult to facilitate learning around more than two educational objectives in any single simulation scenario, and this should be taken into account when planning the scenario. While it is undoubtedly tempting to create complicated and challenging clinical situations, it is unusual that a complex scenario will succeed in fulfilling educational objectives where a simpler scenario will not, and an over-complex scenario has the potential to disengage with the participants. There seems to be a 'Goldilocks' region where the scenario is neither too simple, where the participants become bored and disengaged, nor too complex, so the participants become over-stimulated and disengaged [4].

Many simulation centres use a template or storyboard to develop scenarios. This has the advantage that all the scenarios that are developed within a centre use a common language and can be delivered by different simulation facilitators—who may not necessarily have been involved in the development process. Many templates exist, but common elements should include a briefing for the participants and faculty members (particularly if one of the faculty members is to be 'planted' within the scenario), the 'set-up', baseline physiology, and subsequent stages in the scenario. The planner should consider the triggers that move the scenario on, the transitions between stages, and prompts that can be used if the participants are struggling. An example is shown in Fig. 14.1.

Running the scenario

The faculty should be clear about the intended outcomes for the scenario before it is performed, and they should have an allocated role or roles. Some roles are:

- **'Observer' (often also the debriefer)**: should watch and mark behaviour within the scenario that can be analysed during the debriefing.
- **'Driver'**: controls the physiology of the manikin, often also providing the patient's voice.
- **'Telephonist/Senior Help'**: controls communication in and out of the simulated environment.
- **'Collaborator'**: a faculty member can be placed within the simulated environment, to introduce physiology not apparent from the manikin and to prompt behaviour if required. He either needs to be very well briefed or in communication with the 'Driver' (usually via one-way radio).

The participants should be briefed immediately before each scenario. The content of this briefing varies between simulation centres, but should include the environment in which the scenario is to take place, the role that is expected of the participants (they should usually be themselves), and their relationships. For example:

> It is 1400 hours on a Saturday afternoon. You are the critical care registrar on call at a level 1 trauma centre. You have been called to the Emergency Department to assist with the management of a young man brought to hospital by paramedics after a motor vehicle collision. Your supervising consultant is not in the hospital, but is available via the hospital switchboard by dialling '0'. Other resources that you would expect in a level 1 trauma centre are available to you.

The scenario should be run according to the script, accepting that the facilitator does not have complete control over the events that occur, and that therefore adjustments (through prompts and interventions) may have to be made to keep the scenario on track, and to allow learning objectives to be achieved.

Debriefing

It is widely accepted among facilitators of simulation-based learning that a debriefing after the simulated scenario is an essential part of the learning process [5]. Certainly, an experiential educational cycle, as described by Kolb [6] or Gibbs [7], contains a stage of reflection on experience, followed by the process of definition of developmental needs, and it is these stages in the learning cycle that the debriefer should be aiming to facilitate. Many debriefing styles exist and there is little evidence for any one style over another, but there are common themes. It is not absolutely necessary for the debriefer and the participant to be different people; the participant may debrief himself, either unguided or using a structured tool to aid reflection and analysis,. More commonly a process of debriefing where a conversation occurs between the debriefer and participants, or a facilitated conversation that takes place between the participants, is used [8].

It is essential that the debriefer creates a supportive environment of mutual trust in which the learner understands that his views will be respected and valued, and the debriefer expects that the input of those learning is offered openly and honestly. This must be achieved before the simulation scenario happens and so the foundations of a good debriefing are made in the prescenario briefing [3]. It is helpful to set the 'Rules of Engagement' in the briefing, in the context of explaining how the simulation experience will be conducted, including a discussion of the aspects of the participant's performance, which will be explored as part of the debriefing process. Many of those learning are apprehensive at this stage in the simulation experience, especially if their performance is to be observed by their peers [9].

At the end of the scenario, if it has been planned and driven well, the participants will be at least engaged with the clinical material, perhaps emotionally affected by the outcome or by their perceived performance. The debriefer should disengage the participant from the situation, and 'decompress' the sometimes emotionally-charged reaction (while acknowledging it as real and valuable), in order to allow the participant to reflect and contribute effectively to the subsequent debrief.

Debriefing should take place away from the simulated environment, partly to allow disengagement, but also to enable the room to be turned round for the next event. The setting should be relatively intimate and comfortable, and be equipped for video playback if this is required. The use of audiovisual aids can be very useful in stimulating discussion leading to the intended learning outcomes, particularly if a video clip is shown that illustrates the behaviour under discussion [10].

Facilitators will have varying input into the discussion, depending on the ability of the participants to analyse their own behaviour. High-level facilitation, paradoxically, implies a low level of intervention, guiding a largely unmoderated conversation towards the intended educational outcomes. Some groups may need a more directed approach, using open questioning, reflective listening, rewording and rephrasing, and structuring analysis (low-level facilitation). Whatever the level of facilitation, there is broad agreement on the characteristics of effective and ineffective debriefing (see Table 14.1) [8].

(a)

SCSC
Scottish Clinical Simulation Centre

Briefing
Patient: Name unknown. Appears c.25 years old. Brought in by ambulance to emergency department after MVC. **Personnel:** Anaesthetist (participant), Emergency Physician (faculty), Emergency department nurse (faculty) **Orientation :** *'It is 1400h on a Saturday afternoon. You are the critical care registrar on call at a level one trauma centre. You have been called to the Emergency Department to assist with the management of a young man brought to hospital by paramedics after a motor vehicle collision. Your supervising consultant is not in the hospital but is available via the hospital switchboard by dialling "0". Other resources that you would expect in a level one trauma centre are available to you.'*

Facilitator's Notes
The patient is semi-conscious and will require tracheal intubation before CT scanning. He will prove impossible to intubate using direct laryngoscopy, and either fibre-optic intubation or tracheostomy will be required.

Environment, Equipment, Essential props
Equipment: Standard ER setting. Long board, stiff collar, sandbags and tape. Failed airway cart including fiberscope. **Drugs :** Standard ER. **Medical Notes & Charts:** Paramedic report form. Blank Emergency Room note. Blank Anaesthetic Form. Blank CT request. **Other:**

Table 14.1 Effective and ineffective debriefing

Effective debriefing	Ineffective debriefing
Open questions	Closed questions
Positive reinforcement	Ridicule or criticism
Cognitive aids	Concentrating on errors
Good audiovisual use	Overemphasis on technical debriefing
Self-debriefing	

Assessment using simulation

Simulation should **always** be used as a formative assessment tool, in so far as the performance of the participants is analysed, and the outcome used to guide future learning. Participants often compare their performance against a standard (even if the standard chosen is self-referenced), and usually in a negative way [9]. It is inevitable that the use of simulation as a summative assessment tool will continue to grow throughout the world. Simulated clinical environments (SCEs) have immediately obvious attractions as an assessment tool. They can be used to recreate rare crises. Reproducibly, they allow the observation of non-technical aspects of medical practice and they seem to test the ability of the candidate to actually practise medicine in a way that a written paper or *viva voce* examination cannot.

Yet there is little evidence of the validity or reliability of simulated clinical environments as assessment tools [11]. Content (face) validity is perhaps self-evident, simulating common presentations or specific emergencies, with clearly-defined interventions, would lend itself to an assumption of content validity. Using a metric based around key actions in emergency treatment algorithms, Murray showed construct validity (experts score more highly than novices) in a series of emergency care scenarios [12], but evidence for criteria-referenced validity (candidates who score highly in SCEs score highly in other assessment modalities) is lacking.

With regard to reliability, inter-rater reliability is probably underestimated, and can be corrected to a large degree by using explicit (checklist style) metrics, norming, and training examiners [13]. Assessment of performance in SCEs using global rating scales (implicit metrics) seems to have a greater degree of inter-rater variability, which is disappointing, as scoring non-technical aspects of behaviour is difficult using explicit metrics [14]. Inter-task reliability is low, perhaps due to the differing clinical content of successive SCEs, and it is estimated that between one and three examiners and 12–15 SCEs are required for acceptable inter-task reliability [15]. This constitutes significant resource usage, and is perhaps too high to be widely adopted.

CHAPTER 15

Leadership skills in the ICU

Carole Foot and Liz Hickson

Key points

- There is no gold standard definition or tool for measuring leadership, but there are a range of useful theories and assessments.
- The term 'management' refers to a different concept, but this is often incorrectly and interchangeably used.
- Leadership and management skills are both important, but to different degrees in different contexts.
- Poor ICU leadership is associated with adverse patient and clinician outcomes.
- Efforts to incorporate leadership training into doctor's training are progressing.

Definition of leadership and related concepts

Leadership is a concept that can be recognized more readily than described. It is much talked about, written about, studied, valued, needed, and appreciated. There is no universally agreed upon definition and great diversity exists in how it is executed.

Throughout the ages, leaders have influenced the development of individuals, communities, organizations, and humanity. In Table 15.1, key theories of leadership are summarized and examples of each are provided [1–3]. The common themes of all these models are the existence of important specific traits, behaviours, and strategies that are used to influence, facilitate future development, and inspire progress in those being lead.

The ongoing **excellence period** of theories comprises a diverse range of ideas. In addition to the groundbreaking work of McGregor Burns and the Translational–Transformational leadership dichotomy, other contemporary theories have sought to merge aspects of different preceding era concepts.

Emotional intelligence (EI) was popularized by Daniel Goleman in the 1990s, combining aspects of trait and behaviour theories, and correlating excellence in leadership with having high levels of EI, measurable as an emotional quotient (EQ). EI is described as the ability, capacity, or skill to perceive, assess and manage the emotions of one's self, others and groups [4]. His ongoing work has purported neuroscientific links between EI and leadership, and unlike intelligence quotient (IQ), there exists the capacity for individuals to improve their EQ.

The **Substitutes for Leadership theory** is another distinct model that argues that factors can exist within organizations outside the leaders control and so can have an overriding effect on how individuals function within a group. This may be in a positive or negative way [5]. For example, significant resource limitations may reduce the ability of a leader to progress an innovative vision and thwart his/her effectiveness to implement change, thereby losing credibility and influence with followers.

Servant leadership theory states that, to be effective, leaders must place their own needs below all others and by serving these individuals they will be successful in achieving their vision [5].

In contrast with leaders who are focused on the strategic direction and vision of an organization, **managers** are directed towards the co-ordination and stewardship of activities in order to effectively meet predetermined mandates.

The term 'management' is often confused with leadership, and the words associated with both are used interchangeably and incorrectly in many industries including health care.

Management is concerned with current, rather than forward thinking and more focused on order than change, or as Peter Drucker has stated 'Management is doing things right; leadership is doing the right things' [6]. In Fig. 15.1, words that are frequently associated with the term 'leadership', such as inspirational, strategic, innovative, and visionary, are illustrated. In contrast, managers are often described with seemingly more negative terms—bureaucratic, maintaining, administering, regulating, preserving the **status quo**, controlling, system focused, and risk averse [7].

Individuals in positions of responsibility may possess strengths in both leadership and/or management. Incorrectly, such individuals are often labelled as leaders by default, even though they are principally tasked with functions requiring managerial skills. Leaders and managers also share other organizational assets, such as the ability to communicate, make decisions, prioritize, consider goals, and appraise situations. **Power** is the social construct that enables both to get others to do things.

Power has been traditionally described as originating from five bases according to John French and Bertram Raven. **Reward** and **Coercive** power rely on the respective use of enticements and punishments. **Legitimate** power flows from authority inherent to a specific position. **Referent** power originates from respect for an individual's desirable features and **Expert** power from an appreciation of their specific knowledge or experience [2].

The literature suggests that both leadership and management are contextually important to different degrees for entities to flourish, that leaders may be created and grown, and that training in leadership is achievable and measurable [3].

Robert Sutton has recently placed a useful perspective on Drucker's observation stating that 'to do *the right thing*, a leader needs to understand what it takes to *do things right*, and to make sure they actually get done' [8].

Table 15.1 Key leadership theories

Ancient	Trait 1940–50s	Behavioural 1950–60s	Situational 1960–70s	Excellence 1970+
Important lessons on leadership may be gained from leaders of the past	Leaders are born with traits that enable them to lead	Leaders demonstrate behaviours that may be learnt and are of varying utility	Leaders adjust their style to different contexts	Leaders use whatever traits, behaviours, or styles are needed to achieve excellence in their context
Sun Tzu [1] Know yourself and the enemy. Avoid war when possible and when necessary conclude war quickly **Machiavelli** [1] Avoid injuring those critical to your survival; disarm the envious; it is better to be feared than loved; use deception and manipulation in politics	**Stogdill's Great Man theory** [2] Great men are born with certain traits that allow them to emerge and take power (e.g. intelligence, self-confidence, determination, integrity, sociability)	**Blake and Mouton's Managerial grid** [3] Leaders can be classified on a 4 × 4 grid into five types, based on their expressed degree of concern for people versus production issues	**Tannenbaum and Schmidt's Contingency theory** [2] Adjustments in style are needed, with greater or lesser use of authority and control versus freedom for different levels of subordinate	**McGregor Burns and Bass's Translational versus Transformational styles** [2] Translational leaders use reward and punishment compared with Transformational leaders who engage followers, set goals, identify needs, and use charisma, inspirational motivation, intellectual stimulation, and individualized consideration

Data from various sources (see references).

The importance of leadership in intensive care medicine

The need for skills in leadership and management is well established by the medical licensing authorities. There are expectations regarding professional conduct in areas ranging from leading an inter-professional team to contributions within organizations related to patient safety and resource utilization, which are well defined [9].

Studies on career derailment in many professions emphasize the inability to lead a team as a key cause of ineffectiveness and failure to meet career goals [10]. Clinicians who have participated in leadership and management training have been associated with an enhanced ability to negotiate, understand complex systems and be able to effect change [11].

In intensive care medicine, the need for practitioners to function as leaders in multiple contexts is wide (see Fig. 15.2). It should be appreciated that some of these situations, particularly those with clearly delineated expectations may, in reality, require more management than leadership skills. As an example, when considering the non-technical skills associated with improving outcomes for critical care emergencies, using the term leadership may be imprecise, as these situations demand more managerial type skills (see Fig. 15.3 and Box 15.1).

The challenge for leaders in ICU is increasingly to manage a heterogeneous workforce with varied cultural and generational expectations. It is well documented that younger workers (so called **generations X and Y**) have significant differences compared with their older (**baby boomer**) seniors when it comes to what they will respond to. An authoritarian style is generally ineffective compared with a more consensus seeking, flexible, participative approach consistent with more contemporary leadership theories [14].

Qualitative studies have associated poor intensive care unit leadership with various negative outcomes, ranging from adverse patient events related to poor team functioning, to increased clinician burnout, and a reduced ability to attract and retain staff [15].

Fig. 15.1 The essence of leadership.

ICU
- Multidisciplinary team leader
- Project lead (e.g. education, echocardiography)
- Subspecialty unit director (e.g. Cardiothoracic surgical patient lead)
- Department head

Regional/National
- Intensive Care Clinical Networks
- Intensive Care Societies
- ICM College Board and regional committee activities (e.g. training programs and examinations, credentialing of practitioners, maintenance of professional standards)
- Course director (e.g. BASICS, ALTS, APLS, ICM Exam preparation programs)
- Multidisciplinary initiatives (e.g. National resuscitation councils, Disaster preparedness, planning for major public events)
- Conference convening

Hospital
- Service head (e.g. MET team)
- Committee chair/representative (e.g. Resuscitation, Patient safety, Ethics)
- Charity/fundraising entities
- Interdisciplinary team meetings (e.g. management of high-risk elective surgical patients)

International
- Humanitarian aid work and disaster response
- Multinational clinical initiatives (e.g. CoBaTrICE, Surviving Sepsis Campaign)
- Journal and textbook editing / subediting
- Major conference organisation

Box 15.1 Crisis Resource Management Principles—Leadership or Management?

Fig. 15.3. In the mid-90s David Gaba translated important aviation lessons regarding human factors that influence team effectiveness to health care with development of Crisis Resource Management courses for Anaesthesiologists at Stanford University. These courses are based around Crisis Resource Management principles which include 'leadership' (as well as followership, knowing the environment, calling for help, anticipation and planning, using cognitive aids, using all available information, preventing and managing fixation errors, communicating, distributing the workload, and effective use of resources) [12].

Later the Harvard group introduced their own version of these concepts with their Crisis Event Management principles differing in their recognition that crisis outcomes depend more on having an 'event manager' than a 'leader' [13] and removing the term leadership as a principle. In situations where direction and compliance with recognized clinical interventions and therapies are needed, the individual in charge requires management, rather than true leadership skills if these words are used correctly.

Leadership competencies

The Human Resource Competency Movement has had a profound influence on organizations globally, and health care is no exception. This now engrained concept underpins strategies related to employee recruitment and role delineation, training and development, performance and career development. The underlying idea is attributed to foundation work done by David McClelland in the 1960s; in response to a need to reform education and improve worker competitiveness in the USA market in cold war times. His seminal work emphasized the central nature of competencies as necessary traits and enduring characteristics beyond traditional knowledge and skill frameworks for determining workers' abilities to perform at high levels [16].

Despite ongoing controversy, it seems to have become entrenched, particularly in professional arenas, including medicine, where some argue that ensuring competencies alone does not sufficiently guarantee success in a role. Job descriptions, specialty training programmes and undergraduate medical school degree curriculums all commonly revolve around specific competencies. Such competencies typically define the desirable characteristics, as well as core knowledge and technical skills of prospective doctors. Leadership competencies are being increasingly identified as important components of such lists.

John Zenger and Joseph Folkman have published extensively on the competencies that define extraordinary leaders and emphasize the synergistic effects of possessing combinations [17]. The ability to inspire other individuals appears to be of paramount importance. Other competencies include character, personal capability, a focus on results, interpersonal skills, and the ability to achieve change [18].

Strategies to measure leadership

Management consultancy refers to the process of providing advice and interventions to organizations in order to improve their functionality. Executive coaching and leadership development is an important aspect of this and has driven the market for development of tools that may be utilized by Human Resources departments, supervisors, and educationalists for this purpose. It is also increasingly common for such assessments to form part of a comprehensive selection process for individuals, particularly to executive positions. Examples of such commonly used tools are provided in Table 15.2.

There is no single gold standard tool for measuring leadership, a reflection of the fact that there is no single agreed definition or theory of leadership. Many tools have been developed in conjunction with the developers of individual theories. Other tools examine less specific constructs that can be used to predict or characterize diverse behaviours, including leadership (e.g. Myers Briggs Type Inventory (MBTI), Thomas–Kilmann Conflict Mode Instrument (TKI), BarOn Emotional Quotient Inventory (EQ-i)). Some of these methods rely on self-assessment (e.g. CPI) and others on feedback from followers (e.g. LMX-7) [18].

Measurement of the leadership ability of an individual may be gained from surveys or statistics of quasi-markers, such as employee satisfaction and commitment, staff retention, and productivity outcomes. In multisource or 360-degree appraisals, multiple sources of feedback on selected areas (e.g. from subordinates, supervisors, and clients on items, such as leadership and communication) are typically collated anonymously for the purposes of performance assessment and improvement of individuals [2].

Table 15.2 Leadership coaching tools

Multifactor Leadership Questionnaire	Measures Transactional and Translational leadership behaviours
Leadership Skills Inventory	Aims to identify individuals leadership potential
Leader Member Exchange (LMX-7)	Examines the quality of relationships between a leader and subordinates most relevant to hierarchical organizations
California Psychological Inventory (CPI™)	Generates a leadership coaching report that provides insights into an individual's self-management, organizational capabilities, team building and teamwork, problem-solving, and ability to sustain a vision
FIRO-B™	Quantifies the frequency and number of exchanges with others for the purposes of achieving inclusion, control, and affection
Myers Briggs Type Inventory (MBTI™)	Widely-used personality assessment tool that differentiates individuals based on preferences based on how people perceive and interact with the world
BarOn EQ-i™	Quantifies parameters of emotional intelligence
Thomas–Kilmann Conflict Mode Instrument (TKI)	Defines conflict handling styles and applies it to various aspects relevant to leaders, including leadership style, approach to change, and teamwork

Strategies to improve leadership

There are a myriad of educational resources to assist learning about leadership. In addition to the utilization of leadership measurement tools, a range of other materials that may be used by management consultants and educators are outlined in Table 15.3.

Over the last two decades there has been much written on the importance of leadership and management training for health care professionals, predominantly originating from North America and the United Kingdom.

It has become increasingly common for doctors to complete a Masters of Business Administration (MBA), particularly mid-career to facilitate career development [11], although dual degree programmes in medicine and business management are now increasingly available in some countries. Hard end points in terms of the associated benefits of such programmes and their ability to develop leadership remain unclear. Such programmes do teach leadership as part of organizational behaviour, and would therefore be expected to improve knowledge and highlight the importance of this topic. Shorter courses that introduce individuals to leadership and management topics may be of similar effectiveness.

Efforts to incorporate leadership education into undergraduate medical curriculums are progressing. Teaching about leadership is now generally accepted as important, but there is on-going

Table 15.3 Examples of educational resources to teach leadership*

Classic books that describe theories or perspectives	*The Art of War* by Sun Tzu. Theophania Publishing; 2012 *Leadership* by James M Burns. discussion and controversy regarding the best educational methods, as well as core content. It is well described that such education needs to start early and be career long, with a changing focus on the material and variations on how it is contextualized and reinforced [19].

There is an essential need for role modelling and opportunities for real-world, work place experience and exploration of concepts. This may be limited by a lack of educated senior personnel who have not been privy to such an education and became 'leaders by accident' [20]. The potential to rectify this situation by investing in executive coaching initiatives is realistic and being embraced in some hospitals. The material costs, plausibility, effectiveness, acceptance of and perceptions about the value of such initiatives need further evaluation.

Health care systems that do not nurture and support developing leaders may also sabotage what is being taught. The need to drive change in resource-limited, pressured systems may be the greatest obstacle to improving the leadership skills of health care professionals, including intensivists.

PART 1.4

Safety and quality

CHAPTER 16

Patient safety in the ICU

Bradford D. Winters and Peter J. Pronovost

Key points

- Preventable patient harm is probably the third leading cause of death. Despite over a decade of focus, measureable improvement in patient harm is limited to a handful of conditions, such as central line-associated bloodstream infections.
- The delivery of health care should be treated as a science with rigorous methods and metrics.
- Poor outcomes (patient harm) result from flawed health care systems. In order to improve patient safety and quality, we need to take a systems approach to solutions, rather than assuming that individual providers are to blame. Focusing on individual providers only risks further harm to patients.
- To improve safety and quality, we need a standard process to identify and learn from our mistakes. We must transition from a culture of first-order problem solving ('a solution for this patient right now') to second-order problem solving ('an enduring systems solution that protects future patients').
- We must develop a culture of safety that translates evidence into practice, uses the principles of safe design applied to both technical work and teamwork, and relies on the continuous application of the 4 E's—engage, educate, execute and evaluate.

Introduction

The focus on patient safety is often rooted to the 1999 *To Err is Human* report [1]. While a breakthrough publication, the struggle to bring this neglected area of medicine to the public and funding agencies began many years before. Efforts by clinicians and others have raised awareness about medical errors and avoidable harm over the 15 years. Yet, research funding for patient safety or quality improvement still woefully lags behind funding for basic and clinical research [2]. More worrisome, and possibly the result of inadequate funding, is that progress in reducing preventable patient harm has been slow. A recent assessment asking where we stand since the 1999 report [1] found progress in reducing central line-associated bloodstream infections (CLABSI) and intensive care unit (ICU) mortality [3–5], but found little progress overall in improving patient safety and harm [6].

A wide **quality gap** remains between the evidence-based care a patient qualifies for and the delivery of this care. We need to apply the strategies learnt through successful interventions, to areas of urgent need—areas where many people die or are harmed needlessly, including ventilator-associated pneumonia, deep venous thrombosis and pulmonary embolus, diagnostic errors, delerium, surgical site infection, deteriorating general ward patients, and harm from disrespectful and undignified care. The main principle of this chapter is that patient safety and quality improvement are the science of health care delivery, a science that must be rigorous. This chapter describes a framework for developing a culture of safety.

Developing a culture of safety

Understand the science of safety

Systems not individuals

One central tenet of the science of safety is that every system achieves results based on its design, and health care providers work within a health care system. Poor outcomes (e.g. patient harm or indirect harm, such as omitting an evidence-based therapy) result from flawed systems. Fix the systems, and you improve patient safety and quality of care. Historically, patient safety and quality of care were treated as the responsibility of the provider, and when outcomes were poor, individual providers were blamed. This approach drove medical and nursing education, practice, and the tort system for decades. This maladaptive culture encouraged clinicians to blame each other, hide, or downplay errors when they occur, and ultimately led to patient harm. While providers are often the visible connection to medical errors, other latent systems factors, including patient characteristics, task factors, teamwork issues, the work environment (physical space, workload), organizational influences, governmental/regulatory policies, and the economic climate. Learning to transition from individual blame to a systems approach is at the core of creating a culture of safety and quality.

Metrics

A second central tenet is the need to be rigorous in our methodology. Too often, patient safety and quality interventions are developed without a clear goal or valid metrics to evaluate performance. They also often lack a clear theory about how the intervention will lead to improved outcomes or processes. For example, many health care organizations believed that implementing the electronic health record would magically lead to improved quality and reduced costs. Without rigorous metrics, we present a disservice to patients by implementing interventions that we cannot confidently conclude have made care safer and waste time and resources in the process.

There are several types of metrics we can use in our pursuit of improved patient safety and quality. One is an outcome measure, such as infection rates. Outcome measures are preferred, especially by the public and regulators, because measurement on performance is straightforward, more easily understood,

and more directly answers the pressing question, 'is care safer?' Unfortunately, there are few valid outcome measures or it takes too long to collect enough data to determine if the intervention was effective. Wrong-sided surgery is a good example of such a rare, but devastating outcome. This is so uncommon that it would take many years of data collection to measure any statistically significant improvement. In combination with outcome measures, or as an alternative, is to use process measures such as a surrogate for the outcome. In this case, we assume that adherence to specific evidence-based practices (the processes) should reduce the harm and then measure how well we consistently adhere to those practices. While this is an indirect measure of harm, it is sometimes the most feasible approach. This approach taps into the theory that improving the quality of health care delivery through adherence to evidence-based best practices will close the quality gap, thereby improving outcomes. Nonetheless, it is most desirable to measure both processes and outcomes, providing evidence for the relationship between an intervention and improved outcomes.

Implement the comprehensive unit-based safety programme

The foundation for building and maintaining a safety-centric culture is the Comprehensive Unit-based Safety Programme (CUSP) [7]. This programme evolved from the understanding that culture is local, the unit is a powerful component of improvement, and frontline staff possesses the wisdom to identify and mitigate hazards. Yet staff often feel disempowered. The programme is built on five principles:

- Understanding the science of safety.
- Partnering with an executive.
- Identifying and learning from defects.
- Implementing teamwork tools.
- Technical tools to improve safety and quality.

A unit-based multidisciplinary CUSP team has been the cornerstone of some of the most successful patient safety and quality improvement programmes to date [4,8,9]. This programme reverses the traditional top-down one-size-fits-all approach to hospital quality and safety. Although hospital-level safety and quality officers have value in coordinating hospital-wide efforts, the work of improving patient safety and quality must be owned by frontline staff.

The reasoning for a bottom-up approach is the known variation in local culture and patient safety threats across units, differences only frontline staff will know and appreciate. Top-down institution-wide interventions often fail because they are imposed on providers and do not account for the local culture and wisdom. Institution-wide interventions may not realize that a patient safety problem in one clinical unit may not exist or be minimal in other units. For example, central lines are used by many units; yet, their use is greatest in the ICU, where CLABSI is a deadly threat. On the general ward, falls are probably the greater threat to patient safety than a CLABSI. Thus, the ICU may focus on CLABSI, while the general ward might instead focus on falls.

A CUSP team can identify the greatest threats to their patients and devise locally relevant interventions with few implementation barriers, making success more likely. Despite the strong local focus of CUSP, the team needs a hospital executive partner to help the team prioritize interventions and to remove institutional barriers. The executive is the liaison between hospital management and frontline staff, providing resources when necessary and demonstrating commitment. The executive should attend the regular (usually monthly) CUSP team meeting and be an active partner in the process. They also have the central role of ensuring accountability for the CUSP team to collect metrics and demonstrate improvement and to help align local and institution-wide goals.

Identify and learn from defects

In order to improve safety and quality, we need a process to identify and learn from defects. This is perhaps the most important CUSP element. Defects are anything with the potential to cause patient harm or waste. Ideally, this process does not wait for adverse events to occur, but is proactive in identifying problems before they even rise to the level of causing harm. While there are other sources of data to identify defects, such as sentinel events, these defects tend to surface after the harm has occurred. Proactive strategies, such as asking frontline providers how the next patient will be harmed and how to prevent it [7] taps into wisdom and tacit knowledge long before actual harm takes place. There are several strategies to learn from defects, including root cause analysis, failure mode effects analysis [10], sense making [11], and learning from defects (LFD) [12].

Frontline providers use LFD to identify defects in their unit and develop solutions that are suited to workplace practices. Understanding the principles of problem solving is essential to learn from defects. Problem solving is often first order, meaning the problem gets fixed with a plaster not with a permanent solution. First-order problem solving focuses on recovering from the immediate mistake, yet does not learn, thereby not reducing the risk that the same harm will happen to a future patient. These fixes are often viewed as heroic but may have unintended consequences. For example, a nurse borrows a drug from one patient's supply to provide another patient with urgent need. This fixes the immediate need, but it does not prevent the problem from recurring, and it may even endanger the patient whose supply was depleted. The challenge is to move beyond first-order problem solving to a systems-based solution that prevents the problem, thereby protecting future patients. This is second-order problem solving, and the core of LFDs and other learning strategies. A second-order solution for the medication borrowing issue would develop a restocking system to ensure that critical medications were available.

The LFD process asks four straightforward questions:

- What happened (or could have happened)?
- Why did it happen?
- What will you do to reduce the risk of this defect?
- How will you know the risk was reduced?

The question of what happened is addressed by making a timeline of the events, taking the perspective of those involved as the event was unfolding, trying to understand what they were thinking, and the reasoning behind their actions/decisions.

Answering why the event occurred requires a system perspective to understand how latent factors in the system led to the event. Damaging consequences may not become evident until a *triggering event* occurs, but the latent factors that set it up have often long been present, but not appreciated. James Reason described this

concisely, 'Rather than being the main instigators of an accident, operators tend to be the inheritors of system defects . . . Their part is that of adding the final garnish to a *lethal brew* that has been long in the cooking' [13].

Evaluate what happened and what should be done by 'walking the process'

This could be done in the unit where the event occurred or in a simulation environment, recreating the event to analyse what factors led to the event. The goal is to understand why clinicians made their decisions, not to judge those decisions. Answering why creates opportunities to answer the third question, 'What will we do to reduce the risk?'. First, prioritize the most important contributing factors to consider when developing interventions, noting any mitigating factors, as these may be leveraged to prevent harm.

Finally, select appropriate metrics to determine if the risk is reduced. Importantly, measure a baseline for comparison. Too often safety and quality improvement efforts never measure the baseline metric, resulting in an unclear understanding of whether the efforts have improved care. This undermines the science of safety.

Reduce harm by ensuring patients receive recommended therapies

The CUSP is effective at identifying and mitigating local risks, risks with limited empirical evidence, which generally cannot feasibly be measured as a rate. While these risks represent one type of harm, another type of harm occurs when patients fail to receive evidence-based therapies. Efforts to reduce the omission of therapies require different theories and methods, and given the burden of developing programmes, are often developed among multiple units.

Developing these interventions relies on the model of translating research into practice (TRIP) [14]. Start by summarizing both explicit (medical literature) and tacit evidence (e.g. frontline provider experiences) that supports likely interventions. Next, prioritize the interventions based on the strength of the evidence, probable impact, barriers to implementation, and costs. Barriers to implementation are best understood by walking the process to examine the workflow and understand how the intervention will be best implemented in the local unit.

As we develop interventions or redesign systems to reduce harm, we need to focus on the principles of safe design. These principles are to standardize what we do, create independent checks, and make it visible. An example of technical safe design is the engineering of incompatible connectors to avoid infusion of intravenous medications into epidural catheters. Applying safe design principles to technical work often involves better engineering and product design. Historically, manufacturers have performed this work, although those who do an admirable job of creating safe medical products are in the minority.

Recently, there has been a push to partner clinicians and industry to apply human factors engineering (HFE) during the conceptual phase to develop safer medical products. HFE studies the interaction of people, technology, and workflow to identify potential problems in a system and offer solutions. Without HFE, clinicians will develop workarounds if the product does not integrate well in the workflow, potentially endangering patients by bypassing manufacturer-created safety features.

Safe design is applied to teamwork through tools to standardize processes, improve communication, create redundancies, and develop a culture that supports safe practices. Teamwork tools make the work visible and behaviours unambiguous. For example, rounds in an ICU are often subject to distractions, competing patient care issues, and provider fatigue. A daily goals checklist standardizes the plan of care for patients and allows the care team to clearly understand the goals for the day [15,16]. Checklists act as a cognitive tool to close the quality gap [17], creating an independent check/redundancy to ensure nothing is forgotten.

Use the four Es

Finally, ensuring patients reliably receive the recommended practices rely on having a culture of safety and the continuous application of the four Es: engage, educate, execute, and evaluate. Each of the four Es encompasses different parts of the science of safety, learning from our mistakes and the activities of the CUSP. Engagement emphasizes and explains the importance of the problem and the interventions designed to address it. Education is sharing with the staff the evidence that supports the interventions and the results of the interventions. Execution puts the interventions into place and strives to anticipate and overcome barriers. Evaluation ensures that the metrics are collected, analysed, and disseminated, with the process circling back to engagement and starting again. In this way, developing a culture of safety and quality becomes an iterative ingrained part of health care.

Both the CUSP intervention and the TRIP model are informed by the change management literature, wherein interventions done to professionals, rather than with them, are highly resisted, are usually never implemented locally, but if implemented, are not effective. To be effective, safety efforts must engage the wisdom of clinicians.

Future directions

While efforts have focused on reducing a preventable harm, patients remain at high risk. In the Armstrong Institute for Patient Safety and Quality, transdisciplinary research teams are examining harm clusters and developing systems of care to reduce all harms, including harm from undignified care [18]. This integrates the perspectives of all relevant disciplines (patients, health services research, social science, medicine, economics, HFE, biostatistics, device manufacturers, and informatics) to develop a comprehensive approach [19], in this case to create systems to prevent all harms. As the science matures, the vision is an integrated system, wherein medical technologies are linked to clinical analytics systems to support patients, their families, and clinicians. The ICU of the future should be like an iPad®; a device-integrating hardware, software, and content.

CHAPTER 17

Policies, bundles, and protocols in critical care

Jeffrey Mazer and Mitchell M. Levy

Key points

- Checklists, protocols, bundles and guidelines decrease variability in care and enhance the translation of evidence-based medicine to bedside care.
- Patient safety and minimizing variability is central to the quality movement.
- Performance measurement using audit and feedback systems is essential to help physicians bridge the gap between perceived care and the actual care provided.
- The tools that are central to quality improvement to aid in decreasing variability, include checklist, protocols, guidelines, and bundles.
- Quality improvement projects need to be shaped and guided to meet the needs of patients, staff, units, and hospitals, where they are implemented.

Introduction

Quality and Safety have become central issues in health care as systematic errors and deficiencies in the way health care is delivered have been identified. Prior to this 'quality care' was assumed to be the norm in medical care. Mistakes were thought to be isolated errors and anomalies, rather than routine and widespread. They were the cost of the complexity of care. Errors that made it to the public attention were considered outliers. Several studies have shown that errors are not isolated events. One such intensive care unit (ICU) study found an average of 1.7 errors per day; 37% of them due to miscommunication [1]. Patient safety is now central to both individual physician's daily practice and broad-based institutional initiatives. Central to this transition to safer health care delivery systems is an increased commitment to the identification and maintenance of quality care. Quality care is the application and tracking of best practices, based on best-known evidence for the purpose of limiting practice variability, and thus providing the highest likelihood of patient safety and optimal outcomes.

Should practice variability be limited? Several large studies have demonstrated that clinical care is often quite variable and not necessarily in line with guidelines [2]. In a classic study by McGlynn et al., only 54.9% of 6712 patients in the USA received care that was compliant with recognized best practices for preventative care [3]. This variability in performance may be due to the complexity of patient care, individual patient physiology, professional values, cost, or other important processes. When deviation is due to knowledge deficits, oversight, or the faulty application of knowledge, it is unacceptable. Variability linked to poor outcomes has been demonstrated in the ICU. Adherence to IDSA guidelines for the treatment of severe community-acquired pneumonia (CAP) was only 57.8% in a cohort of 529 ICU patients [4]. Mortality was higher in the guideline non-adherent population. Other deviations are frequently linked to worse outcomes [5].

Limiting variability is central to the quality movement, but has been met with resistance. Standardization of care is seen as an attack on physician and patient autonomy, and a minimization of the importance of physician experience [6]. Some feel that the experience garnered cannot be replaced with quality metrics. Reliance on clinical experience has been called into question. In a systematic-analysis of 62 published studies, the majority of these studies suggested a steady decline in both physician competency and patient-centred clinical outcomes after completion of training [7]. Thus, dependence on accrued knowledge, i.e. 'experience', alone may not be in the best interest of patients.

Performance measurement

Essential to the quality movement is the process of measuring performance. Audit and feedback have been demonstrated to be a key aspect in any intervention targeting change in clinical practice behaviour [8]. Often there exists a gap between clinician-reported perception of practice patterns and audit of actual practice. This 'perception/practice gap' is well described, and supports the potential need for monitoring and reporting practice performance. Physicians have unrealistic expectations around their own competency and performance when compared with external assessments, but also inflated views around the adequacy of care they provide [9]. A survey of ICU directors comparing perception of care provided versus actual care delivered demonstrates this gap. Perceived adherence to low tidal volume ventilation and tight glycaemic control was 79.9 and 65%, while actual adherence was 2.6 and 6.2%, respectively [10]. Physician reporting and clinical experience can play a role in patient care, but evidence suggests that outside evaluation provides a better assessment of practice patterns, and therefore a better basis for informing high quality and reliable care.

Protocols, bundles, checklists, and guidelines

Checklists, protocols, bundles and guidelines are the tools of quality improvement. These tools decrease variability in care and

enhance the translation of evidence-based medicine to bedside care. Checklists are the least complex and have been shown to facilitate efficient, high quality care. Checklists are simple reminders to facilitate routine care patterns, like the provision of deep vein thrombosis (DVT) prophylaxis. Protocols are precise detailed plans to guide a regimen of therapy and provide a guide to clinicians to a default therapy. Protocols are of varying complexity and drive behaviour towards a common standard. Their prescriptive nature facilitates use in both routine bedside care and clinical research. Guidelines are systematic statements of policy, rules, or principles, which serve to capture the rules of clinical judgment, but provide little direct assistance in clinical decisions. Often less proscriptive, they serve as general guides for clinical management.

Bundles are a set of interventions, distilled from evidence-based guidelines, and target specific disease states. The assumption underlying the development of bundles is that 'bundling' proven interventions, together should result in better outcomes than when implementing them individually. Monitoring compliance is a key to the successful utilization of care bundles to drive change in behaviour [11,12]. It is important to emphasize that these tools serve to enhance, not replace the skills of the bedside clinician. They aid in bridging the gap between the discovery and publication of new knowledge with clinical implementation. This path of knowledge translation can help lead to a broad-based application of best practices for appropriate patients.

Two examples of multifaceted interventions in the ICU to improve care include the Michigan experience with an intervention to reduce catheter-related blood stream infections (CR-BSI) and the Surviving Sepsis Campaign's (SSC's) performance-improvement initiative for sepsis management [13,14]. These projects used local interdisciplinary teams, introduced education, and monitored performance using checklists (CR-BSI) or bundles (SSC). Local commitment allowed for large scale implementation. In Michigan, the median CR-BSI rate dropped from 2.7/1000 catheter days to 0 at 3 months and over the next 18 months. In 15,022 patients with severe sepsis and septic shock worldwide over a 2-year period, the SSC initiative demonstrated improved compliance with bundled management strategies leading to a 6.2% decline in mortality.

Conflicting results

Despite these and other quality metrics successes, not all of the results have been positive. Decreased time from knowledge acquisition to bedside care may lead to unintended consequences. The first example of this is the story of tight glucose control. In 2001, Van den Berghe reported that normalization of glucose in critically-ill cardiac patients, i.e. tight glucose control, was associated with decreased mortality. This was rapidly translated into clinical practice in medical and surgical ICU's worldwide. Over the next 9 years studies suggested these findings may be less pronounced in the medical patients, culminating in the NICE-SUGAR trial, which demonstrated harm to these patients [15].

A second example of the potential deleterious effects of widespread application of quality metrics is in treatment of CAP. The Joint Commission established a 4-hour goal for antibiotic administration in response to two large retrospective studies, demonstrating improved outcomes with earlier antibiotics administration [16]. As an unintended consequence, the accuracy of a clinical diagnosis for CAP declined, leading to excessive antimicrobial use and misuse [17]. The Joint Commission has since added a diagnostic category of 'diagnostic uncertainty' and increased the time goal to 6 hours. These stories serve to remind that ongoing evaluation is central to the quality movement. When rapid translation of evidence into clinical practice is associated with unintended consequences detection and response is essential.

Establishing a quality improvement programme

Hospitals and ICUs worldwide have embraced the field of quality improvement (QI). QI includes four essential phases: development, implementation, evaluation, and maintenance. Each phase has key features. The first step of the first phase is to establish a collaborative interdisciplinary leadership group. This group is central to the success of the QI project and so members need to be selected thoughtfully. Members from all parties affected by the potential intervention should be represented, this may include local experts. This team guides the process and needs to have shared commitment to both QI and a collaborative approach.

Understanding the target environment is important for the initiation of a QI project. Characteristics of the target ICU, size, hospital and ICU type, regional culture, and other factors, are essential in the success of a QI initiative. A mature and high functioning ICU with prior QI experience may perform differently to a QI-naive ICU. This will determine the size and scope, as well as dictate the type of data collection and/or feedback systems. Pre-existing systems can decrease the project costs and help ensure sustainability. Goals should be achievable, thus understanding baseline practices is essential. Projects should target low functioning metrics to achieve change [18].

After establishing the scope and goals, a plan for implementation is made. Understanding the target environment will aid the process, utilizing existing assets and targeting potential barriers shape implementation. Cook et al. demonstrated that barriers to implementation are not necessarily complex, but easily overlooked [19]. Poor communication between the bedside nurse and physician was one of the main reasons for inconsistent use of semi-recumbency. Through an understanding of process and barriers, solutions may be identified to improve compliance.

Multifaceted-interventions are more effective than single interventions for influencing behavioural change. Guidelines and education alone are unlikely to make substantial changes, so the addition of audit and feedback systems is important [11]. While designing an audit and feedback system, both outcome (long-term) and process (short-term) measures should be considered. There are arguments both for and against the use of either one, so that understanding the benefits of each become important. Examples of outcome measures include incidence of ventilator-associated pneumonia (VAP), CR-BSI, ICU length of stay, or mortality. Tracking and reporting outcomes data is easier as most institutions collect this data, but demonstrating change may be more difficult. Process measurement, i.e. a marker of 'what we do', such as time to antibiotics, is more difficult to track, may require new systems/people and often a financial investment, but is more likely to show change/success, over a short period of time. Outcomes measures are often better accepted, because they are more obvious measures of patient care. Linking process measures to patient outcomes may facilitate acceptance of specific performance metrics and lead to improved compliance.

The final piece of a QI programme is sustaining the effort. Depending on the complexity of the intervention and level of success, sustaining the initial process may require variable work.

Balancing cost in terms of manpower and financial resources with value, or impact is essential. Augmenting or a downscaling of the audit and feedback system will depend on success in measured outcomes. Not all achievements will decay at the same rate, so the maintenance phase has to be dynamic, and institution-specific, similar to implementation [12].

Running a successful QI project requires sustained, but incremental interdisciplinary teamwork. At the heart of its success and maintenance is leadership and perseverance—continuous pursuit of improvement and sufficient resource allocation to allow it to succeed and persist over time. A full review QI implementation is beyond the scope of this chapter, a useful resource is the 'how to' guide published by Curtis et al. [20].

Conclusion

The ICU is a complex environment, in which multiple teams and care processes operate simultaneously in an environment of intricate physiological derangements that expose patients to the risk of highly variable care. Variation in care is common, even in areas where evidence supports standardized interventions. Variation potentially exposes patients to unnecessary risk. Given the growing demands of critical care practice, physicians in the ICU are challenged to consistently deliver reliable, evidence-based care. The push for quality measures using checklists, protocols, guidelines, or bundles is an important to limit this variation and provides feedback mechanisms to clinicians about actual clinical practice and behaviour. Although a call for respecting and maintaining physician autonomy has been made, it is clear that we can and must do better. QI initiatives are one way to achieve our ultimate goal of enhancing patient safety and quality.

CHAPTER 18

Managing biohazards and environmental safety

Ferenc Kovari and Gilbert Park

Key points

- Washing hands is the key to reducing biological hazards.
- Wearing appropriate protective gear minimizes the risk of chemical hazard.
- Complying with safety rules, attending regular training help avoiding risks resulting from handling dangerous materials, electronic equipment.
- Protect your back—lift, handle, and move patients with care.
- If stressed get help early.

Introduction

The intensive care unit is a dangerous place full of potential harm, not only for the patients, but also for the team members. Excessive sound, electromagnetic fields, radiation, chemicals, moving patients, dealing with infectious materials, slips, falls, and stress are just a few. Safety is often considered to be a first step in achieving health care quality. The challenge for the ICU practitioners is to optimize benefits and minimize the occurrence of risk [1]. This chapter covers the key concepts in the hazard control process and environmental hazards.

Hazards

Identifying hazards helps to determine the consequences and the probability of occurrence, and allows the risks associated with them to be minimized. The categories most present in the critical unit are biological and chemical.

Biological hazards

Biological agents can be classified as:

- **Live agents**: including bacterial, viral, fungal, chlamydial and rickettsial.
- **Toxins**: a toxin can be considered to be a chemically-active agent of biological origin. Toxins generally have a shorter latency period (hours–days) than the live agents, which may take days or weeks, or even months to exert their effects. Biological agents can be injected (inoculated), ingested, inhaled, or transmitted by contact with an infected patient [2]. The most common cause of health care-associated infectious diarrhoea in industrialized countries is caused by the toxin of *Clostridium difficile*.

Health care workers hands and clothing frequently become contaminated with nosocomial pathogens capable of colonizing the intestinal tract. It is probable that small numbers of these pathogens are intermittently ingested. However, intestinal colonization with detectable levels of antimicrobial-resistant pathogens and *C. difficile* diarrhoea remain uncommon among health care workers, because the indigenous microflora inhibit growth of these organisms [3].

Chemical hazards

Disinfectants

Common disinfectants include isopropyl alcohol, ethyl alcohol, quaternary ammonium compounds, sodium hypochlorite, and iodine. Exposure to these agents can cause irritation of the skin, eyes, and dermatitis. Some of the chemicals can act as carcinogens. Cancers caused by environmental agents frequently occur in tissues with the greatest surface exposure to the agents—lung, gastrointestinal tract, and skin. This process often takes years [4]. Exposure to these materials should be kept to a minimum, and personal protective equipment, including respirators when necessary, should be worn.

Toxic substances are poisonous and can have other qualities, such as being inflammable, combustible, corrosive, or irritant. When evaluating the toxicity of a substance, several factors should be considered—concentration of the chemical agent, duration of exposure, and available ventilation. Absorption happens through the skin or breaks in the skin (cuts, sores), inhalation of contaminated air through the nose and mouth, or by ingesting the substance through eating and drinking.

Substances that can be inhaled in the ICU setting include dust, smoke, aerosols (for example during ventilator disconnection), and gases. The most commonly used chemicals are:

- **Isopropyl alcohol:** a widely used antiseptic and disinfectant. It is used to disinfect thermometers, critical care equipment, and other instruments. Workers should use appropriate protective clothing, such as gloves and face shield, or splash-proof safety goggles.
- **Ethyl alcohol (ethanol)**: most hospitals use 70% ethyl alcohol as a topical application for local skin disinfection. It is highly inflammable in all dilutions when vapour may come in contact with an ignition source. When used topically, it dries the skin and care is needed to avoid dermatitis.

- **Iodine:** used as a general disinfectant and can be mixed with alcohol for use as a skin antiseptic or with other substances for general disinfecting purposes. Exposure can include irritation of the eyes and mucous membranes, headaches, and breathing difficulties. Protective clothing such as gloves and face shields should to be worn.
- **Phenol-based disinfectants:** generally used against a wide range of bacteria and for intermediate level disinfection for tuberculoidal infections. Contact with skin or mucous membranes should be avoided. Characteristic of phenol poisoning are burns of the mucous membranes, weakness, pallor, pulmonary oedema, seizures, and respiratory, circulatory, cardiac, and renal failure. Workers should use protective clothing, including gloves and face shields to avoid skin or eye contact.

Medical waste and sharps

Waste is now classified on the basis of its hazardous characteristics and the point of production. Segregation of waste at the point of production into suitable colour-coded packaging is vital to good waste management. There are hazardous (i.e. infectious waste, cytotoxic and cytostatic medicinal waste, health care chemicals, and other hazardous properties) and non-hazardous waste products (bottles, syringes, unused, but expired vials). There is clear guidance on labelling, disposing, storing, segregating, and handling of these waste products [5]. For example, in the UK there is a strict colour-coded waste disposal system, which is implemented by the health care facility according to the Department of Health regulations. The use of colour-coded receptacles is key to good segregation practice. Clear information, instruction, and training on categorizing waste needs to be provided for everyone working in areas where health care waste arises. It is helpful if posters showing the different waste pathways and types of waste are displayed at appropriate locations.

Chemotherapeutic substances

Some chemotherapeutic drugs pose a potential health risk to health care workers who may be exposed during their preparation or administration. Such drugs require special handling because of their inherent toxicities. Their actions are not specific to tumour cells and normal cells may also be damaged [4]. Health care workers who have been exposed to hazardous drugs have reported acute symptoms, such as skin irritation, sore throat, cough, dizziness, headache, allergic reaction, diarrhoea, nausea, and vomiting [6]. Safe handling of these agents is regulated by the Health and Safety Executive [7].

Radiation

Radiation hazards exist in areas where therapeutic radiology is used. Radiation sources in the ICU arise from bedside imaging procedures, such as radiographs, fluoroscopic placement of enteral feeding tubes, and insertion of vena cava filters. Primary radiation should always be pointed at the patient. No untrained health care worker should hold the patient during the procedure as the lead aprons, although they protect against secondary radiation, offer little protection against the primary beam. Secondary radiation exposure usually results from the scatter of the X-ray beam caused by reflection or deflection from the main beam. Generally, the intensity of scatter radiation 1 m from the patient is approximately 0.1% of the intensity of the useful or primary beam seen at the patient's position [8]. Staff are often anxious about portable X-rays done at the patient's bedside. However, if the X-ray is pointing at the patient and the staff member is downstream from the X-ray beam, 6 feet away from the X-ray source, and wears the appropriate protective apparel, the occupational exposure should be minimal. The 6-foot rule states that, by law, the exposure cord for any portable X-ray unit must be no less than 6 feet in length, in order to give the radiological technologist a minimal safe distance from the radiation source although it is advisable for the health care workers to stay as far away from the patient as possible during the actual procedure time [9]. Natural radiation results in the average person receiving about 125 mrem per year. Workers in health care and the nuclear industry, are typically monitored and restricted to effective doses of 100 mSv every 5 years (i.e. 20 mSv per year), with a maximum of 50 mSv allowed in any given year [10]. There are no reports of radiation sickness in ICU workers regarding acute radiation syndrome.

Radiation: pregnant and breast-feeding employees

The vast majority of medical X-rays do not pose a critical risk to a developing child; there may be a small likelihood of causing a serious illness or other complication. The actual risk depends on how far along the pregnancy is and on the type of X-ray. Most standard X-ray examinations of the abdomen are not likely to pose a serious risk to the child. Some abdominal and pelvic studies such as CT deliver greater amounts of radiation to a developing pregnancy [11]. Scattered radiation resulting from diverse radiological interventions are not posing significant risk to the breastfeeding employee, although exposure should be kept at a minimal level.

Ergonomics

Health care ergonomics is the science to fitting the job to the workers. There is scientific evidence linking the physical environment to staff performance effectiveness, and error reduction [12]. It improves patient safety by reducing staff fatigue. There are several hazards resulting from an inappropriate working environment or failure to provide appropriate equipment. Modern ICU design has shifted from traditional crowded environments with little or no natural light, to large single room units with windows and natural light. Single rooms enhance family presence, staff communication, and patient privacy. Designing exposure to nature through posters, pictures, or windows looking upon natural scenes improves outcomes and reduces costs [13].

Back-related injuries

One of the most common occupational injuries among health care workers is back injury. Only about 5% of back injuries result from a single accident; most are the result of long-term wear and tear on the back. This can lead to disc degeneration and nerve damage [14]. In the critical care setting there are countless ways of damaging the back. These include bed-to-stretcher and bed-to-wheelchair transfer, pulling the patient up in bed, turning the patient over, and transferring to the CT scanner table. In the UK, the Manual Handling Operations Regulations Act 1992 states that employers should provide mechanical assistance—a trolley or hoist for example—to employees when doing heavy lifting wherever reasonably practical. All health care workers need to regularly attend safe lifting and patient handling training.

Slips and falls

Slips and falls are some of the most common patient-related occurrences in health care facilities. Identifying risks, tailoring the hospital environment, i.e. better lighting and better flooring, can reduce risk. Splashed fluids on the floor are major sources of slips. Clear sign-posting of a wet surface is essential. Provide all employees with training related to slip, trip, and fall prevention [15].

Equipment and electrical safety

Injuries related to electrical equipment are mostly avoidable if compliance with the safety measures is observed. The human body responds in several ways to electrical current flowing through it. The sensation of shock is only one such effect and this can be extremely painful. The passage of electric current may cause muscular contractions, respiratory failure, and fibrillation of the heart, cardiac arrest, or injury from internal burns. In the UK, the 1989 Electricity at Work Regulations requires every employer and employee to comply with the provisions of the regulations in so far as they relate to matters that are within his control.

Psychological hazards

Stress

Health care workers on shift work or doing overtime can develop stress and burn-out syndrome. Epidemiological studies suggest a link between stress at the job and cardiovascular disease, with a stressful and demanding job doubling the risk of death from these condition [16].

Dealing with life-threatening injuries and illnesses, even with death, complicated by overwork, understaffing, paperwork, tight schedules, and demanding and dependent patients often leave health care workers feeling lonely, isolated, angry, or frustrated.

Stress contributes to apathy, lack of confidence, and absenteeism. Stress has been associated with loss of appetite, mental disorders, migraines, sleeping disorders, and emotional instability [16,17]. According to Coomber et al., self-reported risk factors include a sense that the responsibility is too great, lack of peer recognition, worry about compromising standards, the effects of stress on home life, distressed relatives, and the pressure to keep up to date with the literature [18].

Preventing stress in the ICU is critical for patient safety. Making the workplace a pleasant environment with natural light, windows, posters, or pictures, and having an appropriate place to take breaks is crucial. Positive thinking, good time management, and interacting and sharing problems with colleagues or friends can improve stress management. Also avoiding unhealthy habits and engaging in regular exercise will reduce some of the emotional intensity by clearing the thoughts and enabling the individual to deal with the problems more calmly.

Noise

Exposure to high levels of noise in the workplace is a common job hazard that is much more serious than it was originally thought. The World Health Organization (WHO) guidelines stipulate a limit of 35 decibels (dB(A)) equivalent continuous sound level (LEq) during the day and 30 dB(A) LEq at night in patients' rooms.

Noise may trigger changes in cardiovascular, endocrine, neurological, and other physiological functions, and hinders communication among workers. One potentially useful strategy when building an ICU is to create a quieter facility by installing high-performance sound absorbing ceilings [19]. Other strategies include reducing noise sources (e.g. providing noiseless paging) and converting to single-bed patient rooms.

Conclusion

Through the chapter we aimed to point out the most common elements causing biohazard risk in an everyday intensive care unit. Safety is equally important not only for the patients, but to the team members as well. We hope to improve that by putting special emphasis on the health care ergonomics and raising attention to factors sometimes less obvious like stress or the noise.

CHAPTER 19

Managing ICU staff welfare, morale, and burnout

Gavin G. Lavery and Linda-Jayne Mottram

Key points

- The intensive care unit (ICU) environment exposes staff to stressful and emotionally-demanding situations, which places them at high risk for burnout.
- Risk factors for burnout can be found at both individual and organizational levels.
- Consequences of low morale and burnout include personal distress for clinicians, poor quality of care for patients, and higher health care costs for organizations and society.
- Staff engagement is emerging as the antithesis of burnout.
- We need to promote a wider recognition among ICU staff regarding risks of burnout and the consequences for both them and the patients in their care.

Introduction

Low morale, stress, and 'burnout syndrome' have been identified as risks for staff working in health care. There is also a link between staff dissatisfaction and poor performance by health care organizations [1]. In the clinical environment, poor performance translates to increased frequency of adverse events, patient harm, and suboptimal outcomes.

Clinical staff are prone to work-related stress for many reasons, including the emotional demands of the job, limited resources, ethical conflicts, and excessive clinical workload. In the critical care environment, treatment is complex, patients' needs change rapidly and 'end-of-life' decisions are relatively common. This represents a working environment that can generate significant stress for staff and, potentially, lead to burnout.

Definitions and terminology

Our aim should be to develop a workforce and a working environment that guards against low morale, stress, and burnout. These are diverse concepts that are linked, but not in a simple cause-and-effect relationship.

Morale

Morale is readily detected in the workplace, but is difficult to define. Workplace morale can be defined as;

- The level of staff satisfaction (based on how they see or value their job).
- Attitudes to the work environment.
- Buy-in regarding the aims and objectives of the organization.

Morale is a measure of staff 'happiness' within an organization. When morale is high, the long-term goals of the department or parent organization become merged with the goals of individual staff members—a high degree of 'buy-in'. High morale leads to increased productivity in an appropriate environment and will support similar performance even when working conditions are difficult. In contrast, poor or low morale is associated with inefficiency and poor quality even when the work environment is optimized. Studies have concluded that care delivered by unsatisfied health care employees (low morale) is negatively affected and this adversely affects patient satisfaction [2]. One would expect that increasing the engagement, satisfaction, and morale of employees may benefit a health care organization, and result in improved patient care and higher patient satisfaction.

Stress

Stress at work occurs when there is an imbalance between the demands of the job, and the worker's capacity and capability to cope with such demands. The latter may be due to lack (or perceived lack) of organizational support. It is interesting to note that, compared with airline pilots, intensive care unit (ICU) doctors are much more likely to report themselves as being able to perform effectively during critical phases of care when they are fatigued and are also less likely to acknowledge the effect of personal problems upon performance at work [3]. However, the symptoms caused by stress are often obvious to the individual affected and/or those around them; over engagement, a sense of urgency, and hyperactivity accompanied by overactive emotions—a state of 'too much of everything'. While stress may lead to burnout, most stressed individuals do not suffer burnout. Indeed, finite exposure to some stressors may enhance performance [4].

Burnout

Burnout is a colloquial term, describing a state of work-related mental exhaustion. The burnout syndrome was first defined by Freudenberger as, 'the extinction of motivation or incentive, especially where one's devotion to a cause or relationship fails to produce the desired results' [5]. By the late 1990s the definition had been expanded [6] to 'a persistent, negative work-related state of mind in "normal" individuals that is primarily characterized by exhaustion, which is accompanied by distress, a sense of reduced

effectiveness, decreased motivation, and the development of dysfunctional attitudes and behaviours at work. This psychological condition develops gradually but may remain unnoticed for a long time for the individual involved. It results from a misfit between intentions and reality on the job. Often burnout is self-perpetuating because of inadequate coping strategies that are associated with the syndrome'.

While burnout is often associated with absenteeism and poor performance at work, it may also lead to 'presenteeism', where the clinician is physically at work, but displays little desire to be there. Thus, in contrast to stress, the hallmark of burnout is 'too little of everything', although prior to exhibiting such hallmarks, individuals may show behaviour such as increased intensity at work, with ideas that no one else (except them) is dedicated (or talented enough?) to provide services/care.

Depression is a separate entity from burnout and pervades all areas of life, not merely professional aspects. Depressed individuals experience affective symptoms (low mood, worthlessness, and guilt), behavioural changes (social withdrawal, agitation, and psychomotor retardation) and cognitive symptoms (difficulty with decision-making or concentration). There may also be somatic features, such as change in appetite, fatigue, and sleep pattern. Depression can follow as a consequence of burnout, but in burnout the dysphoric and behavioural features predominate over somatic symptoms. Depression is common in ICU physicians with a reported prevalence of between 12 and 24% [7].

Burnout: recognition

Burnout is most frequently detected and quantified using the Maslach Burnout Inventory (MBI), a questionnaire covering 27 items within three subscales [8]. MBI scores the presence of the three hallmarks of burnout—emotional exhaustion, depersonalization (cynicism and negativity towards patients, clients, or others), and low personal accomplishment (characterized by feelings of professional insufficiency). Freudeberger proposed the existence of 12 phases within the syndrome of burnout [5], although some suggest that this description is overly focused on personal characteristics, rather than the wider social and organizational factors contributing to burnout [9]. Some, but not necessarily all, of these phases may be identifiable on the journey towards burnout (Box 19.1).

Box 19.1 Potential phases of burnout [3]

- **The need to prove oneself:** often occurring in highly motivated and ambitious individuals.
- **Working harder:** high personal expectations emerge as further work commitments are undertaken.
- **Neglecting personal needs:** no time or energy is reserved for activities or relationships outside the workplace.
- **Displacement of conflict:** the individual is unable to identify the cause for their difficulties.
- **Revision of values:** isolation from family and friends with a solely job-related value system.
- **Denial:** cynicism, aggression, and intolerance of others emerge, leading to isolation.
- **Withdrawal:** social contact at a minimum. May seek respite in alcohol or drugs.
- Behavioural **changes become more apparent to others:** e.g. conflict.
- **Depersonalization**: loss of appreciation for self and **self-worth**. Cannot appreciate future success.
- **Inner emptiness:** may seek an activity to fill the void such as eating, drugs, etc.
- **Depression:** typical affective, cognitive and somatic features are present.
- **Burnout ensues:** complete physical and emotional collapse.

Data from Sexton JB et al., 'Error, stress and teamwork in medicine and aviation: cross sectional surveys', *British Medical Journal*, 2000, **320**, pp. 745–9.

Burnout: frequency

It would appear that severe burnout, as measured with the MBI is present in about half of critical care physicians [10] and one-third of critical care nurses [11] in France. These figures match the findings from studies across Europe in anaesthesia and critical care medicine, which suggest a point-prevalence for moderate or severe burnout (as determined with the MBI, of 30% among nurses and approximately 40–50% among physicians.

While the ICU environment appears psychologically challenging, burnout may be a significant problem other clinical environments. A study of 564 UK general medical practitioners (GPs) found that 46% had high levels of emotional exhaustion, 42% had depersonalization characteristics, and 32% had low levels of personal accomplishment [12]. However, differences in methodology prevent direct comparison. In a study of 351 ICU and general nurses from three US hospitals [13], more ICU than general nurses showed evidence of post-traumatic stress disorder (24% versus 14%).

Burnout: contributing factors or risk factors?

Intrinsic factors

Burnout can occur at any age, but is more likely in younger workers and may be quite common in doctors-in-training [14]. It would appear that maturity and experience are protective. The influence of gender is complex. Many physician studies have suggested that females are more likely to suffer from burnout, but this may reflect differing ability to demonstrate empathy. Women suffering burnout tend to display more emotional exhaustion and men experience more depersonalization, or a cynical attitude to co-workers or patients. Demographics such as single status, childlessness, and personality characteristics such as neuroticism and low self-esteem can increase risk [14].

Extrinsic factors

Six key influences, within the working environment and external to the individual, contribute to burnout.

Workload

The profile/case mix of the ICU may influence levels of reported stress. Larger units, typically those in teaching hospitals, with a more diverse and complex case mix, and higher mortality rates, have higher reported rates of burnout. French intensivist physicians with severe burnout [10] tended to be those with hours of work as a stressor (number of night shifts, and time since last vacation). However, while workload can be stressful; conversely, frustration and stress may arise when workers do not get the opportunity to use their specialist skills or to make appropriate progress in their career.

Choice and control

Working patterns for nurses and junior doctors (length of shifts, breaks between periods of working, and flexibility in working) are all known to affect staff morale. When work–life balance is eroded by rigid rostering, staff turnover and sickness increase. The autonomy of many physicians and the ability of nurse empowered to contribute to clinical decision-making would be expected to have some protection from stress and burnout [15].

Recognition and reward

The belief that one's work is important and appreciated can buffer against low morale and burnout. Staff development and training initiatives demonstrate to workers that they are valued. However, the satisfaction from successfully treating critically-ill patients may not be reward enough for ICU staff, since without critical care follow-up, physicians and nurses may not see the full effects of their care in terms of recovery of function or well-being by the patient.

Work community

There is often a positive sense of community between those working in ICU. However, it is also an enclosed community in which it is difficult to escape from (unresolved) conflict. This may erode workplace relationships, even between individuals who are not part of the problem. Junior staff, faced with stressful clinical situations, will experience significant distress, which may progress to burnout if they are poorly supervised and supported by seniors [14].

Fairness and justice

This relates to fairness in areas, such as rostering and opportunities for training or advancement, or may involve deeply-held beliefs about unfair treatment at work. Effective strategies for conflict resolution and an open ICU culture can promote justice.

Values

Incongruence between the stated values of an institution and cultural practices may the genesis of burnout. Practices that appear to promote cost-saving over high quality care can erode staff commitment, especially when the corporate view does not acknowledge a compromise between resources and cost. Moral distress is a key cause of burnout for critical care nurses. This arises when the ethically right course of action is known, but staff are unable to follow it—for example, the continuation of aggressive, but futile treatment, particularly when there is a perception that patients who are more likely to survive are not being admitted at the appropriate time due to bed pressures.

In the study by Poncet and colleagues [11] of almost 2400 French ICU nurses, four domains were associated with severe burnout:

- Age.
- Organizational factors, such as the ability to choose days off or participation in an ICU research group.
- Quality of working relations.
- End-of-life care related factors.

We should think of these factors as contributing to, or being associated with, burnout, rather than being risk factors, linked by cause and effect.

Burnout: effects

The relationship between burnout and outcomes is complex. Does burnout lead to bad outcomes or do bad outcomes lead to burnout? Can they be due to other influences, e.g. inadequate staffing levels or skill mix? Job demands related to burnout (e.g. long working hours) are known to heighten the chance of junior doctors making serious medical errors [16] and this may provide us with a key insight. It would appear that good outcomes are hampered by the presence (or co-existence) of burnout and/or its risk factors. The search for cause and effect is not only very difficult, but also misses the point. The presence of factors known to promote burnout or evidence of burnout among staff should be tackled—both for the benefit of staff, and the quality and/or experience of care for patients

Burnout: prevention

Established burnout appears to be difficult to treat and has serious long-term potential for further harm. Thus, we require strategies that prevent burnout (or that aid early detection), although there is no consensus on what to do [17]. Health care workers also have a responsibility to manage their own risks for burnout. This includes avoiding personal behaviour that may adversely affect themselves or colleagues, and fully engaging with workplace initiatives designed to improve the environment and reduce avoidable stresses.

While redesigning the working environment and providing training in areas such as stress and time management, relaxation, and assertiveness have been suggested to reduce burnout, there is little supportive evidence. More research is required into the causes of burnout, the interventions that might reduce the frequency of burnout, and the coping strategies that ICU staff use on a day-to-day basis that may protect them. Most pressing is the need to assess the effect of burnout on patient safety and the quality of care.

Despite the lack of certainty, sufficient plausibility exists for the causative factors. As with many intensive care strategies, it is unlikely that one magic bullet will cure the problem. It would seem prudent to pursue interventions targeting both the individual and the workplace (Table 19.1). The greatest early advance might be a wider acceptance of the risk of burnout by ICU staff and recognition of the potential consequences for them and for patients.

Worker wellness and employee engagement

Quality indicators in critical care usually focus on outcomes such as infection rates or compliance with processes. However, high quality care must be patient-centred which encompasses patient satisfaction with their experience of care. The experiences of patients and relatives depend heavily on the attitudes and demeanour of the staff providing care. Some have argued that the well-being of health care staff is a missing quality indicator [18]. Staff suffering from burnout and low morale are less productive, more prone to error and less likely to deliver high quality care. Thus, preventative measures and

Table 19.1 Cross-organizational interventions that may reduce the risk of burnout

Individual	Unit	Organizational
Stress management	Flexible working/rostering	Staff engagement
Involvement in research	Leadership development	Resource provision
Assertiveness training	Collaborative decision making	Policy development
Time management skills	Employee mentorship	Promoting a learning culture
Coping strategies	Teambuilding and social support	Organizational values
Interpersonal skills	Improved end-of-life care	Hospital management style

interventions to reduce burnout should improve efficiency, safety, and motivate the workforce for quality improvement. Health care institutions are increasingly recognizing that quality of care and patient safety are partly dependent on the employee well-being [19].

Many health care organizations have moved beyond prevention of burnout to focus on employee engagement. Indeed, burnout could be viewed as the erosion of engagement [20]. Engaged workers are **energized** not exhausted, **involved** not cynical and **work effectively** as opposed to underachieving. Engagement captures the spirit of 'going the extra mile' in order to improve quality of care and patient safety.

Conclusion

In ICU, failure to provide 'care for the carers' may have unwelcome consequences, not least the risk of adverse events, suboptimal care, and poor outcomes. An unsatisfied and exhausted workforce is less effective both individually and collectively. Assessment of critical care performance should encompass more than survival, infection rates, and process measures. As important as these indicators are, reliable high quality care will remain elusive if the health of the carers is not viewed as important. Failure to adopt such an approach will almost certainly result in increased turnover of the workforce, and the financial burden of training and orientating new staff. Recognition and prevention of burnout in ICU may emerge as an important tool in reducing variability and promoting high quality care.

PART 1.5

Governance

CHAPTER 20

ICU admission and discharge criteria

Julian Bion and Anna Dennis

Key points

- The decision to admit or discharge a patient is the responsibility of the intensive care specialist.
- Decisions will be based on the severity of the illness, chronic health and physiological reserve, and therapeutic susceptibility, and will be informed by the patient's wishes.
- Admission and discharge decisions involve balancing the needs of individual patients against those of society.
- Wide variations in admission and discharge practices between centres and countries probably reflect differences in resources, cultures, and clinician beliefs.
- Outcomes of intensive care are affected by the timing of admission and discharge, and the quality of care outside the ICU.

Background

The decision to admit patients to intensive care or discharge them to a hospital ward (or even directly back home) is a daily task for intensivists, a life-changing event for patients and families, and in aggregate a major strategic issue for health care systems worldwide [1]. Decisions must often be made rapidly in conditions of uncertainty involving substituted judgements about relative risks and benefits, framed by sociocultural factors that are not well characterized. The outcomes of the decision are strongly influenced by available resources, staffing, and skills throughout the patient pathway.

Intensive care developed in response to the polio epidemics in the early 1950s. Survival rates were transformed by concentrating technology and expertise in one location, substituting invasive mechanical ventilation for the iron lung, and introducing the science of physiological measurement. With the progressive eradication of polio, the criteria for admission to intensive care shifted to ventilatory support for other causes of acute respiratory failure, and then to the support of other failing organ systems. Single-speciality high-dependency units (HDUs) were established for patients with isolated non-respiratory organ failures (cardiac, renal, neurological, burns), while intensive care was reserved for those with, or at risk of, multiple organ failure or requiring invasive mechanical ventilation. Over the years, the hospital case mix has become more elderly, complex, and dependent, driven by a combination of demographic changes, cost-containment, and technological advances. As the number of hospital beds has diminished, intensive care has expanded in response to the growing demand for multiple organ support. Additional demands come from elective high-risk elective surgery and, more recently, from the transplant community, for the admission of potential organ donors. One of the most important roles for the intensivist, therefore, is in managing this diverse and competing demand to greatest effect through informed and patient-focused decisions about admission and discharge.

Intensive care is a package of interventions, which consists of specific therapies for the disease, technologies for physiological monitoring and organ system support, and integrated multidisciplinary decision-making. Organ system support is not, in itself, therapeutic. Part of the art of intensive care lies in minimizing its burdens. Admission to intensive care implies that the benefits will outweigh these burdens, and that the potential lost opportunity costs for other patients and society are justifiable. Therefore, the intensivist functions as custodian of a scarce resource, balancing a fiduciary duty to individual patients against the interests of wider society. The manner in which this duty is expressed is influenced by the context in which admission and discharge decisions are taken.

Determinants of admission and discharge decisions

Context

Admission and discharge processes and outcomes vary widely between hospitals and between countries. For example, half of all deaths in England and one-third in the USA occur in hospital, but in England only 10.1% of hospital deaths involve intensive care unit (ICU) admission compared with 47.1% in the USA. Of the ICU deaths, patients over the age of 85 accounted for 1.9% of non-operative and 8.5% of operative deaths in England, but 31.5 and 61%, respectively, in the USA [2]. The USA has 5.7 times the number of ICU beds *per capita* that of the UK [1] and makes greater use of chronic ventilator units outside acute hospitals, facilitating 'discharge', but not necessarily improving outcomes [3]. Patients admitted to ICUs in the UK have a much higher severity of illness, are more likely to be intubated, and those with sepsis are less likely to be admitted directly from the emergency department (ED) [4], transiting instead via the ordinary wards. These different admission pathways impact on mortality. Emergency hospital admissions transferred to a ward and, subsequently, to an ICU have a higher mortality than those admitted directly to ICU from the ED, as do

high-risk surgical patients admitted from a surgical ward, instead of directly from the operating theatre.

Both admission and discharge involve a change of location with the potential for gaps in communication and loss of continuity of care. There is growing research evidence showing that the outcomes of intensive care are affected by the timing of admission and discharge decisions, which in turn are influenced by resource availability in the ICU and probable inexpert care on the ordinary wards. Admission to the ICU from 00:00–07:00 hours, and at weekends is associated with a higher mortality, as is discharge from the ICU to the ordinary ward at night [5]. Readmission to intensive care is associated with a hospital death rate 2–10 times that of non-readmitted patients [6], and can be mitigated by intensive care outreach in the form of intensivist-led rapid response teams [7]. Of high-risk surgical patients admitted to intensive care in 28 European countries, 43% of deaths occurred after discharge to the ordinary ward [8], suggesting substantial opportunities for improving discharge planning and post-discharge care. Unintentional discontinuation of chronic medications is also common following discharge from the ICU, and is associated with adverse patient outcomes [9].

Patient factors

Decisions to admit patients to ICU or discharge them to the ward are determined by the severity of their illness. Severity of illness is a composite of the magnitude of the acute disease, the patient's physiological reserve, and the concurrent level of treatment and organ system support. Of these three variables, physiological reserve is the most difficult to quantify and modify. It is generally assessed using functional capacity, co-morbid disease, and age. Loss of functional capacity is an important predictor of frequent hospitalization and death, and co-morbid disease impacts on ICU and hospital outcomes [10]. The benefits of intensive care for very old patients are uncertain, although there may be an increased risk of disability for the elderly when compared with younger patients [11]. However, chronological age is a poor substitute for 'biological age' when deciding on who to admit to intensive care.

Diagnosis and prognosis are intimately linked to therapeutic specificity, and advances in treatment will alter prognosis. Diagnoses that would once have justified non-admission to intensive care are now much more treatable. Patients with AIDS-related critical illness have better outcomes because of antiretroviral therapy [12]; those with haematological malignancy now have much improved survival rates [13]; and outcomes are improving generally across ICUs.

Patient preferences are fundamental determinants of ICU admission and discharge decisions, and in setting levels or limits on intensity of care. However, loss of capacity caused by critical illness means that substituted decision-making is common and this may contribute to substantial variation in practice between centres. Failure by physicians to understand patient preferences to forego life-sustaining treatments, and failure of the health care system to offer alternatives to hospitalization, result in excess burdens and costs of care. The challenge lies in early identification of patients at risk of critical illness to permit informed discussions with intensive care staff, while the patient still has capacity. With a rapidly ageing population, opportunities should be taken to discuss advance planning in the community; doing so reduces unwanted medical treatment (including ICU admission), and stress and depression in family members.

Decision support

Scoring systems

Physiological severity scoring, in particular the Acute Physiology and Chronic Health Evaluation (APACHE) system, was a transformational concept, introduced as a tool to characterize patient populations and to inform decision-making about individual patients. Physician experience may be a valuable tool for contextualizing population-based prognostic estimates for individual patients, but it is an unreliable device for constructing those population estimates for which large observational databases are far better. Scoring systems based on very large patient numbers capture more population information than the individual clinician can acquire in a lifetime, but the clinician will know more about the individual patient than any scoring system can. For this reason, predictive systems may inform clinical judgement, but cannot replace it. Triage protocols to maximize use of scarce resources in pandemics have been modelled prospectively and retrospectively, demonstrating theoretical value in releasing intensive care beds by denying admission to those categorized as being too well or too sick to benefit.

Several models have been developed to inform safe and timely ICU discharge decisions. Simple univariate risk factors include prolonged length of stay, unstable vital signs including tachypnoea or tachycardias, and poor pulmonary function [6]. Badawi and Breslow [14] have modelled post-ICU mortality and ICU readmission, using data from more than 700,000 patients, incorporating admission diagnosis, severity of illness, laboratory values, and physiological variables in the last 24 hours of the ICU stay. The Stability and Workload Index for Transfer score [15], and a model developed in France [16], have similar predictive precision for ICU readmission. Others have identified the potential for important reductions in mortality had triage models been used to avoid premature ICU discharge. All methods need prospective validation.

Guidelines for ICU admission and discharge

The UK guidelines on admission to and discharge from ICUs and HDUs [17] were developed in response to adverse publicity surrounding the lack of intensive care beds. The working party chose simple criteria based on dependence on organ system support linked to intensive care (level 3) or high dependency care (level 2) (see Table 20.1). The classification has stood the test of time, perhaps because it is permissive, rather than constraining.

The guidelines provided by the Society of Critical Care Medicine in the USA [18] offer four alternative classifications:

- A prioritization model with four categories based on different sets of patient characteristics.
- A diagnosis model.
- An objective parameters model based on physiology or investigations.
- Discharge Criteria linked to physiological stability.

This guidance is currently under review with the publication in 2015 of the Guidelines on the Provision of Intensive Care Services by the UK Faculty of Intensive Care Medicine and the Intensive Care Society [19]. Night-time discharge in particular should be avoided, and if it occurs should be treated as a critical incident, accompanied by measures to protect patient safety [20].

Table 20.1 UK Guidelines on admission to and discharge from intensive care and high dependency units [19]

Intensive care is appropriate for:	High dependency care is appropriate for:
Patients requiring or likely to require advanced respiratory support alone	Patients requiring support for a single failing organ system, but excluding those needing advanced respiratory support
Patients requiring support of two or more organ systems	Patients who can benefit from more detailed observation or monitoring than can safely be provided on a general ward
Patients with chronic impairment of one or more organ systems sufficient to restrict daily activities (co-morbidity) and who require support for an acute reversible failure of another organ system	Patients no longer needing intensive care, but who are not yet well enough to be returned to a general ward
	Post-operative patients who need close monitoring for longer than a few hours

Decision processes

Admission and discharge decisions should be made by the specialist intensivist, and taken in collaboration with the referring team, and the patient and family where circumstances permit. Early involvement of the intensivist permits more effective planning, e.g. rapid response teams (intensive care outreach) have an important role in facilitating end-of-life care discussions in order to avoid futile and burdensome treatments.

The provision of futile care is usually driven by family expectations and lack of agreement among the treating team. Discussions involve value judgements—clinicians should be aware of biases based on their own personal views, family requests, or inadequate resources. While caring for the family is an essential component, the primary duty is to the patient. Outcomes are strongly affected by the degree of trust that can be established between the intensivist, family, and referring team. Decisions not to admit a patient to the ICU on grounds of futility or to discharge a patient for palliative care, should be taken by senior staff following a broad consensus, the reasons clearly documented, and with a support plan in place both for the patient and the family.

In conditions of uncertainty about the best course of action, a formal second opinion should be obtained, and for admission to intensive care, a trial of treatment may be offered with explicit and agreed limits, including the withdrawal of support if no improvement occurs. Trials of intensive care discharge is more problematic, as de-escalation involves a loss of process control, if discharge involves an abrupt change in both location and quality of care. Longer-term ICU patients need a planned and supervised trajectory for progressive restoration of physical and psychosocial independence, to realize the investment of intensive care resources in full. Premature discharge from intensive care carries a significant increase in mortality [5], which cannot be acceptable to a modern health care system.

Outcomes

Effective admission and discharge processes will minimize avoidable morbidity, mortality, and ICU readmissions, and maximize family and patient satisfaction and cost-efficacy. However, reaching the most effective level of practice involves balances and compromises—a permissive admissions policy and conservative discharge policy will increase ICU bed occupancy with the potential for refused admissions and lost opportunity costs elsewhere in the health system. Given the uncertainties that surround decision making, and the balance between sensitivity and specificity of decision-support tools, experienced clinical judgement remains a key element in defining suitability of individual patients for ICU admission and discharge.

Objective benchmarked comparative data linking suboptimal processes, such as night-time discharge [5] or unintentional medications discontinuation [9], with undesirable outcomes (ICU readmission rates or post-ICU mortality [6] should be used to determine the quality of local practices, and from this to identify the changes required in resources or processes of care. These changes will be located along the patient pathway, not just in the ICU, and will include senior involvement in decision making, engagement of intensivists with community care and palliative care medicine, earlier identification of critical illness and involvement of intensive care staff, electronic prescribing and compilation of patient records to bridge changes in patient location, and engagement of families in decision making and the provision of care.

CHAPTER 21

Resource management and budgeting in critical care

Jukka Takala

Key points

- Budgeting should cover short-, mid-, and long-term planning of resources, as well as the continuous monitoring of actual resource use.
- Consider separately the two main production lines of intensive care—unplanned (emergency) intensive care unit (ICU) admissions and planned (elective) ICU admissions.
- Patient turnover rate is a major determinant of resources needed. Increasing resources to reduce the length of stay can reduce the total costs without compromising quality.
- Costs and charges are fundamentally different and should not be mixed—there is no fixed relationship between them.
- The key information needed for budgeting includes the number of patients needing intensive care, their expected length of stay, typical treatments needed for the specific case mix, the number, structure, and costs of personnel needed, and the average material and medication costs.

Introduction

Planning, acquisition, and allocation of resources are core management tasks for the leader of an intensive care unit (ICU). Budgeting should optimize resource use and cover short-, mid-, and long-term planning of resources, as well as the continuous monitoring of resource use. Short-term budgeting focuses on operational planning, whereas mid- and long-term budgeting should have a strategic perspective.

Assessment of resource needs

There is no absolute, quantifiable amount of intensive care services needed. As most developed health care systems have a strong public health care component, a major determinant is political: the health care policy makers (state, regional, and local governments, public health officials, health insurance stakeholders) determine the level of health care financing. The regional and local availability of health care services rarely depends on rational or objective factors alone-rather, structural, historical, cultural, and other 'soft' factors have a major influence. Accordingly, health care resources use *per capita* is highly variable. For example, in the USA, Medicare reimbursement varies several-fold across regions [1]. The use of ICU resources also varies widely between countries of comparable wealth and similar population death rates. In the USA, almost half of all hospital deaths involve an ICU stay, whereas in the United Kingdom, intensive care is involved in one out of five hospital deaths [2].

The need for and spectrum of intensive care services in a specific hospital depend on that hospital's characteristics and role within the health care system. It is useful to estimate the needs for intensive care for the population of the main referral area of the hospital. The presence and resources of other intensive care providers, and the role of other hospitals in the area should be taken into account. The structure of the local health care system and probable changes during the strategic planning period should also be considered when determining the resource needs for an individual hospital and ICU.

It is helpful to consider the two main components of intensive care separately:

- **Unplanned (emergency) ICU admissions:** patients with either acute, potentially reversible, life-threatening organ dysfunction(s) or a high risk of developing such.
- **Planned (elective) ICU admissions:** patients undergoing complex surgical or other procedures that require treatment or monitoring of vital organ function.

The resources needed for emergency admissions within a population are relatively constant as long as the indications for intensive care do not change, or new treatments do not alter the indications for ICU admission. For example, new treatments for cerebrovascular emergencies have increased the need for ICU resources. The local culture and religion can have a fundamental impact on indications for emergency ICU admissions and the resources needed. Key issues include how many resources are allocated to treat patients with little chance of meaningful survival or for patients with very small risk of organ dysfunction or the need for treatment.

In both emergency and elective intensive care, the ICU is part of a multidisciplinary, horizontal care process or production line involving other clinical specialties. The resource availability at any step can be rate limiting. Delays in discharging patients from the ICU due to lack of beds in the intermediate care units or wards may substantially reduce the capacity to admit new patients to the ICU. The impact of lack of resources ('reverse bed pressure') is not limited to actual emergency admissions, but it influences the care of all patients potentially benefiting from an ICU admission. The amount and level of care that can be provided in all the participating units should therefore be considered. As ICU patients often continue to need increased nursing care, monitoring, or both after

ICU discharge, limited availability of resources in the recipient ward may delay discharge. 'High dependency', 'intermediate care', or 'step-down' units provide less intensive monitoring and treatment than the ICU, but more than normal wards. Integration of such beds or units in the ICU may enhance flexible resource management.

The need for emergency ICU admissions fluctuates markedly over short periods of time. Insufficient resources are a serious problem for the whole hospital. Either intensive care must be acutely rationed or unstable patients must be transferred to other institutions—both scenarios increase the risk of suboptimal care and poor outcome. Alternatively, planned intensive care admissions could be cancelled. Although frequently used, this should be considered a failure of resource allocation and an indicator of poor process quality. It does not necessarily indicate insufficient resources in the whole production line—an imbalance of resources (e.g. too much interventional capacity in relation to ICU or ward bed capacity), or a problem in resource utilization (e.g. delayed extubation of ICU patients) is also possible. Cancelling elective operations disrupts a complex production line with interlinked support processes (diagnostics, anaesthesia, etc.) and is a disproportionate waste of resources. If this must be done frequently, care process analysis with ICU involvement is mandatory. Patients needing intensive care must be admitted without delay and, after a sufficient recovery period, discharged without delay.

Patient turnover rate (length of ICU stay), has a major impact on the number of beds needed. Increased ICU capacity may be achieved by more beds, but with a concurrent investment and additional staff. In contrast, reducing length of stay without compromising quality of care can be cost effective. If a smaller increase in staff or a different staff profile can reduce the length of stay, an increase in ICU capacity can be achieved without investment costs and with smaller recurring salary costs, as presented in Table 21.1.

Table 21.1 How to acquire the capacity for 600 further ICU admissions in an ICU with 30 beds (the numbers shown are based on a real example from the author's own institution)

	Option 1	**Option 2**
Average length of stay	3.5 days	2.5 days
Intervention	Additional beds with current number of staff/bed	Increase efficiency by process optimization and adding 24-hour, 7 days a week, in-unit specialist coverage
Admissions produced per bed/year (70% effective occupancy)	73	102
Admissions produced with 30 beds	2190	3060
Additional beds needed to produce 600 admissions	8.2	None—additional capacity for 870 admissions achieved
Investment costs	High, depending on the amount of construction and new equipment needed	None
Additional staff	For 8.2 additional beds: five full-time-equivalent nurses to cover 1:1 nurse:patient ratio for three shifts per day per bed = 41 nurses. 3.5 Full-time-equivalent doctors to provide 1 intensivist and one resident for one shift per day	Additional intensivist staff to cover 24 hours, 7 days a week for two additional shifts = 3.5 full-time-equivalent intensivist salaries
Running costs (salaries)	~2.5 Million euros/year	~0.4 Million euros/year

Cost accounting and budgeting

Costs and charges are fundamentally different and should not be mixed [3]. There is no fixed relationship between costs and charges. In profit-driven systems, the charges include the profits. In public health care systems, charges are typically based on political decisions and do not necessarily represent true service production costs. The relationship between costs and charges can be further distorted by cost-accounting efficiency and charging policies, and cross-subsidization within the hospital. Cross-subsidization can be used, for example, to reduce the costs of low-volume, expensive therapies by assigning part of their costs to high-volume, less expensive interventions—a policy that distorts the costs of both. Unintended cross-subsidization may typically result from insufficient differentiation between costs needed for elective (planned) and emergency (unplanned) interventions. An institution performing mainly elective surgery is likely to have lower average costs per intervention compared with an institution that must treat emergency patients as well, since the latter institution needs to maintain capacity for the emergencies. A fair comparison of costs for elective interventions between such institutions can only be made if the costs of resources for elective interventions versus maintaining emergency capacity can be clearly differentiated. In many reimbursement schemes, lumping together the elective and emergency services puts public institutions at a disadvantage compared with private institutions, which have no obligation to provide emergency services.

The economic costs and accounting costs should be differentiated. Economic costs are the marginal costs for additional services, e.g. the costs of additional resources to perform more renal replacement therapy, which may include disposables, more staff, or an additional device. In contrast, accounting costs takes into account all the costs, including a share of all the equipment costs (depreciation) and other relevant infrastructure costs. These approaches provide distinctly different, but relevant cost perspectives.

Cost finding comes first in cost accounting. From the accounting perspective, the ICU should be a cost centre, where at least all the costs directly created in the ICU can be appropriately allocated. These direct costs typically include all salary, material, and medications costs. The indirect costs represent services provided by others for the ICU, e.g. laboratory, radiology, operations, housekeeping, laundry, etc. Three different approaches to handle these costs include:

- Exclusion from the budget of the requesting unit, and budgeting by the producing unit as their direct costs.

- Expected volume of requested services belongs to the budget of the requesting and producing units.
- Internal billing of services, as part of the budgets of both the requesting and producing units.

For example, the ICU needs radiology services. In the first scenario, the radiology carries the risk of fluctuations in demand and changes in production costs. If the demand increases, their budget may not be sufficient for producing the services. If the demand declines, the resulting overcapacity causes inefficiency (which may go undetected, unless the budget is linked with an expected volume of production) and unnecessary hospital costs.

In the second scenario, the producing unit and the requesting unit agree on the level of services needed, and deviations from this (within an agreed tolerance range) will have budgetary or operational consequences for both units. In this case, the two units share the risk—the absence of a direct financial link makes intervention in case of a relevant deviation difficult.

In the third scenario, an internal 'market' is created. Internal prices are defined for the budgeting period, and the budget contains both the direct and the indirect costs. The mechanisms to control the budget include direct monetary equivalents. The disadvantage is that the internal market often contains monopoly service production, but not true market prices. Free outsourcing with market prices is usually only possible for services without strategic importance for the hospital.

From the perspective of the whole hospital, all costs are equal, i.e. the direct and indirect costs for each department and other services cause costs that need to be met by the specific financing system used, from direct public sector financing to the hospital carrying the full consequences of its finances, selling services at the market price—the latter is rather an exception, since some regulation of the charges is established in most systems. Regardless of the system, each service within the hospital has characteristics of either a 'cost centre' or a 'profit (revenue) centre'. Cost centres typically produce services that are not directly charged from third-party payers, e.g. housekeeping, laundry, and information technology. Some clinical services, e.g. radiology and clinical laboratory, can be regarded as cost centres. The profit centres (e.g. surgical departments) charge directly from the third-party payers, and their charges also include the costs of the cost centres. The ICU can function either as a cost centre, billing internally, or a profit centre charging directly, or a mix of the two. In the latter case, some but not all costs are charged directly, e.g. patients admitted primarily for intensive care and/or discharged directly to other institutions. All costs within the hospital must finally be assigned to profit centres to provide total costs and revenues. The cost and profit centre structure, and internal billing are tools to distribute hospital resources. The calculated profit or loss per department or service tells us nothing about the financial efficiency of a particular service; it reflects the combined effects of the tariffs, production costs, internal allocation of costs, and finally, the efficiency of service production.

ICU cost structure

The ratio between direct and indirect ICU costs can only be estimated roughly due to problems related to the costs and charges of internal services. Approximately 50–60% of the total ICU costs are direct costs. Most of the direct costs, up to 90%, are personnel costs. Accordingly, around half of the total ICU costs are personnel costs. Some costs are fixed, i.e. independent of activity level (e.g. costs of floor space), whereas others are variable depending on the volume and content of care (e.g. costs of materials and medications). Personnel costs are often considered as fixed costs; however, if flexible use of staff depending on the patient load can be achieved, part of the staff costs can be transformed to variable costs, with relevant cost savings.

Cost assignment methods

Once the costs of the ICU have been determined, they need to be assigned to individual patients or groups of patients, in order to help in planning budget and cost consequences of changes in ICU activities.

Two common approaches are using time as a proxy (the *per diem* method, the hourly rate method) and the weighted procedure method [3]. Both these methods can be used for the direct costs only, for the total costs, or for part of the costs in combination with separate costing for specific (usually particularly expensive or uncommon) procedures or products.

The *per diem* method and the hourly rate method

These methods divide the costs of the ICU by, respectively, total patient days and patient hours in order to obtain the cost per unit of time in the ICU. Time as a proxy for costs can function relatively well, assuming that all patients require roughly similar therapeutic interventions and procedures. When the need for time-independent resources (e.g. specific materials or interventions) varies widely between patients, more cross-subsidization between patients will result from using these methods.

The weighted procedure method

This assigns a relative weight for the resource consumption of common procedures and therapeutic interventions. The relative weight should consider the need for supplies, equipment, and personnel. The costs assigned for material and equipment should include the direct costs of material usage, purchase price and depreciation, and the personnel costs related to training, supervision, and maintenance. Once the total costs for all procedures and therapeutic interventions have been determined, a relative value is assigned to each of them. The total costs, including those from the use of other services, are then divided according to the number and relative weight of the procedures and interventions performed.

Several standard methods exist to assign the relative weight for ICU interventions [4–6]. The earliest and perhaps most used is the Therapeutic Intervention Scoring System (TISS) [4]. The original TISS consists of 76 individual therapeutic interventions and monitoring tasks with a weight from 1 to 4, based on the relative intensity of nursing and physician effort required. A shorter version with 28 items has subsequently been developed [5]. Using the TISS score, common ICU interventions can be summarized to a single sum score, which gives a surrogate measure of the cost, including both the material and labour costs—the contribution of each cost component to the cost per TISS score can also be calculated. The weighted procedure method using the TISS or other similar instruments provides robustness at the expense of some cross-subsidization, since the direct relationship between individual interventions and costs varies, and since no such scoring covers all the relevant ICU activities. The scoring per se also requires some effort.

Practical steps in budgeting

The budgeting and financing (reimbursement) systems of ICUs vary widely [7,8]. Regardless of the system used, the same basic information is necessary to estimate the resources needed or, conversely, what can be done with the available resources:

- The number of patients needing intensive care.
- Their expected length of stay.
- Typical treatments for the specific case mix.
- The number and structure of personnel needed.

The average length of stay per patient and the average number of staff needed per patient care day can be used to calculate the personnel costs. For an estimation of material and medication costs, data from the preceding budgeting period and the expected changes in practice need to be considered. Using care day or daily TISS score normalized cost equivalents helps to predict the costs. These cost predictions need to be matched with the resources available from the specific financing system, regardless of whether the financing is primarily revenue or cost-orientated.

Conclusion

Resource management and budgeting are core ICU management tasks and cover optimizing resource use, planning for future needs, and continuous monitoring of actual resource use. The main steps include assessment of resource requirements, acquisition of the resources, cost finding, understanding the cost structure, cost assignment, and cost accounting. Costs and charges should not be mixed.

CHAPTER 22

Costs and cost-effectiveness in critical care

David J. Wallace and Derek C. Angus

Key points

- Overall health care costs and the proportion dedicated to critical care are increasing.
- Cost-effectiveness analysis allows the costs and benefits of different therapies to be directly compared.
- Within a constrained budget, cost-effectiveness analysis can identify the optimal therapies for funding.
- Policy informed by cost effectiveness should improve public health.
- Critical care, with its inherent complexity, frequent innovations, and high cost, is well suited for cost-effectiveness analysis as a basis for improving health care quality.

Introduction

In the USA in 2005, Medicare and Medicaid critical care costs were estimated to be 81.7 billion dollars, representing 4.1% of national health expenditures and 0.7% of the gross domestic product. Compared with only 5 years prior to that, this was a relative increase of 13.7% and a 44.2% increase in absolute spending [1]. Therefore, not only is critical care expensive, but costs are growing. Furthermore, during the same years, the overall number of critical care beds in the USA increased 6.5%, the number of critical care inpatient days increased 10.6% and the proportion of critical care beds to hospital beds increased 5.2% [1]. The shift in physical resources and use comes at a time when the first of the baby-boomer generation is reaching age 65, foreshadowing further demand on a health care system already under strain. These pressures have increased attention on finding the optimal balance between cost and quality for new procedures, protocols, programmes, and therapies, and the methods of cost-effectiveness evaluation.

Definitions

There are four main types of cost studies—cost-minimization, cost-benefit, cost-effectiveness and cost-utility.

Cost-minimization analysis

Cost-minimization studies consider only expenditures and are essentially evaluations of comparable medication costs. Each product is assumed to be equally effective and to equally affect all other aspects of treatment. Medication benefits, such as reduced length of stay, reduced need for other therapies, or improved quality of life after illness, are not considered. The preferred therapy is simply the one that costs less per unit of treatment.

Cost-benefit analysis

For cost-benefit analysis, all costs and benefits are converted into monetary units. Summary costs are then subtracted from summary benefits, resulting in a summary difference. If the result is positive, the benefits outweigh the costs, and the programme or intervention under evaluation is attractive. The difficulty with this approach is that human lives must also be assigned a financial amount, a valuation that is inherently controversial. For this reason, this type of analysis has fallen out of favour in health care cost evaluations.

Cost-effectiveness analysis

Cost-effectiveness analysis is the most common method for health care cost and outcome evaluation. In this analysis, the ratio of net cost difference to net effect difference is calculated for two interventions. The numerator is the marginal cost in dollars between the comparisons, while the denominator represents the change in health status (e.g. number of additional survivors, cases of disease averted, life-years gained, etc.). The expression takes on the form of cost per unit of benefit (e.g. dollars per additional survivor, dollars per case of disease averted, dollars per life-year gained, etc.). This metric is called the **incremental cost-effectiveness ratio**. Alternatively, a simple **cost-effectiveness ratio** can be calculated, which is the cost per unit of benefit for a given therapy or programme, without reference to a comparator.

Perhaps surprisingly, neither the incremental cost-effectiveness ratio nor the cost-effectiveness ratio necessarily indicates whether a therapy or programme under consideration either saves money or is actually cost-effective. The incremental cost-effectiveness ratio of a new therapy may indicate that a new therapy is more expensive than standard care, yet improves outcome. Deciding if this therapy is cost-effective then requires a value judgment regarding how much the patient or society is willing to pay for the additional benefit. At a given cost threshold, the therapy might be considered cost-effective by one person and not by another. This spending threshold varies by health care system. In the USA, its value is somewhere between $50,000 and $100,000 per life year gained, whereas in the United Kingdom it lies in the range of $33,000–50,000. (It is worth noting that in the USA, the Centers for Medicare and Medicaid Services does not formally consider cost-effectiveness in medical coverage decisions, whereas in the United Kingdom the National

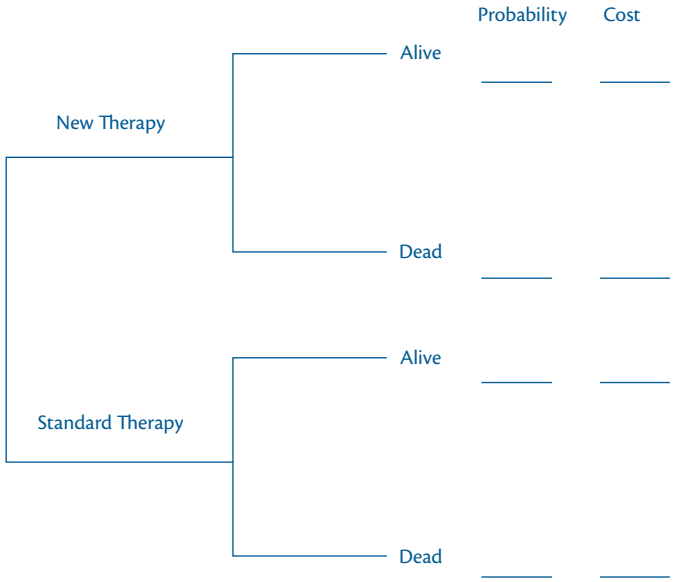

Fig. 22.1 Simple decision tree comparing outcome for patients treated with new therapy versus standard therapy. In order to calibrate the tree, we must estimate: (1) the probability for a given patient to live or die, given whether they received the new therapy or not; and (2) the average costs associated with each of the four branches.

Institute for Health and Clinical Excellence explicitly relies on these analyses to make recommendations regarding medical coverage to the National Health Service.)

A typical cost-effectiveness analysis requires collecting detailed information on costs and effects for both standard care and the new intervention. Based on the complexity of the cost and benefit streams, a **decision analysis model** may be needed to show progressive clinical decisions and outcomes. Branching trees represent these models, where each successive limb has a probability of occurrence and a cost. At its simplest, the tree will contain only branches for treatment allocation (e.g. new or standard therapy) and outcome (e.g. alive or dead). To calibrate the tree, we need to know the probability of living or dying based on each therapy, and the average cost of care for survivors and non-survivors in the two treatment arms (Fig. 22.1).

We could expand this model to include other elements that affect morbidity and cost, or sequela other than death. The new therapy, while expensive alone, may offset its own expense with a reduced need for other supportive care, and may therefore be comparatively more cost-effective than standard therapy. As additional elements are incorporated in the decision analysis model, additional branches must be added to the tree. For each branch, we must know a patient's likelihood of entering a particular branch and the average costs (Fig. 22.2).

Cost-effectiveness analysis is endorsed by both the United States Public Health Service Panel on Cost-Effectiveness in Health and Medicine (PCEHM) and the American Thoracic Society (ATS) as the primary method by which to measure the costs and effects of health care programmes and medical therapies [2,3].

Cost-utility analysis

Cost-utility analysis is a special case of a cost-effectiveness analysis, where benefits are represented as the number of years lived in full health by beneficiaries. These **quality-adjusted life years** (QALYs) are calculated by calibrating the number of years of survival for the 'quality' of that survival. A person living for 1 year with a quality-of-life score of 70% would be 'awarded' 0.7 years of quality-adjusted survival. An advantage of this approach is that it allows comparison of different interventions for different diseases through a common metric. On the other hand, QALYs are more difficult to measure than the monetary summaries of cost-effectiveness analyses. An additional criticism of cost-utility analyses is the implicit bias against older patients, who are will generally have fewer QALYs, as they have fewer overall years of life to live.

Perspective

Each cost-effectiveness method employs cost accounting and adopts a cost-accounting perspective. This perspective is fundamental to the interpretation of the results, as it is the viewpoint from which costs are measured. For example, consider the implications of adding a non-cardiac step-down unit to a hospital that previously had general hospital beds and intensive care beds. One can imagine that, from the perspective of the intensive care unit (ICU), having a step-down unit could reduce ICU length-of-stay, as some patients would be discharged sooner to the step-down unit, rather than waiting until they were well-enough for a general hospital bed. A portion of what would have been the patient's ICU length-of-stay is replaced with presumably less expensive step-down length-of-stay. If outcomes were equivalent, an administrator may be eager to approve implementation of step-down units on these grounds alone. From the perspective of the hospital, however, step-down units may not be associated with clear cost-savings. In fact, unless ICU beds are closed after admissions are diverted to the step-down unit, the overall operating cost of care in the hospital **must** increase. Depending on case mix and payer mix, this **may** be advantageous to the hospital from a financial standpoint, but it is unlikely that it results in a reduced incremental cost-effectiveness ratio from the perspective of society. In other conditions, the costs of care may be transferred out of the hospital itself, such as in the case of long-term acute care hospitals. In that setting, the use of long-term acute care hospitals may lower the costs of care for a transferring facility, but that does not guarantee that the overall cost or quality of care is better for the transferred patient [4]. Both the PCEHM and ATS recommend using the societal perspective for cost-effectiveness studies.

Included costs and cost savings

Accounting for and measuring all cost streams associated with an intervention may appear to be a daunting task. Fortunately, only costs that differ between treatment groups are included in the incremental cost-effectiveness ratio. For example, although PCEHM guidelines identify pain and suffering as relevant costs, they can be omitted from calculations if pain and suffering are equivalent in the two treatment branches. Only unbalanced costs are compared, a feature of the analysis that simplifies the accounting considerably.

Cost savings are also included in cost accounting, although downstream resource use reductions require cautious interpretation. As noted in the step-down unit example, a seemingly intuitive line of reasoning is that if a therapy results in a shorter length-of-stay, it will have a significant reduction in the overall cost of care. Cost perspectives aside, there is also accounting for the actual savings recaptured by reducing the length of intensive care stay to take

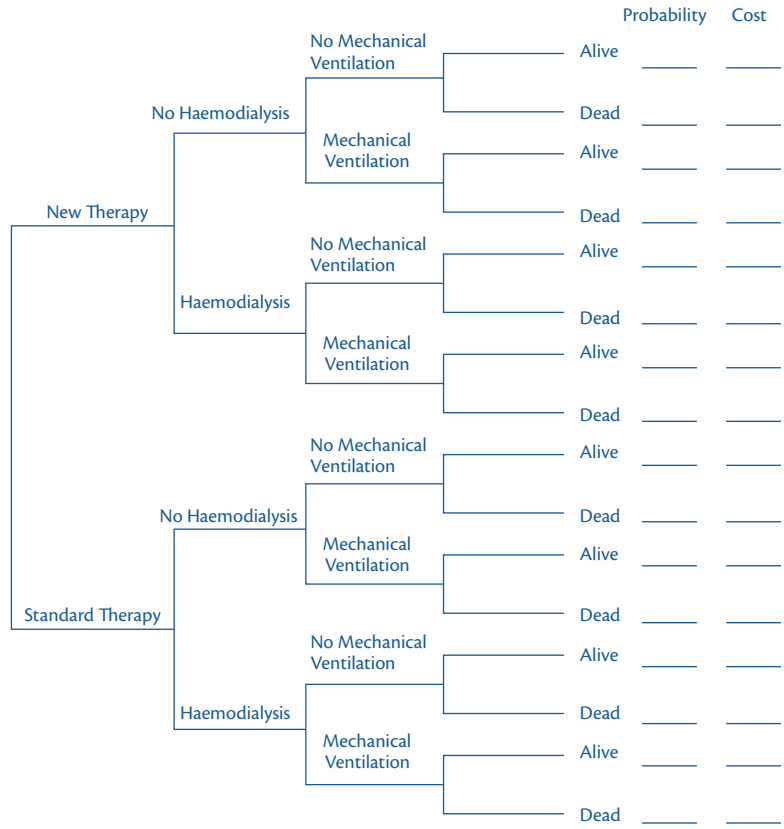

Fig. 22.2 Decision tree comparing outcomes for patients treated with new therapy versus standard therapy, which incorporates the potential to undergo mechanical ventilation and receive haemodialysis. In order to calibrate the tree, we must estimate the probabilities and average costs for 16 separate trees.

into account. Importantly, every day in intensive care is not equivalent to the cost of an 'average' intensive care day. This is because patient costs are usually disproportionally concentrated in the first few hours to days of admission. By the time the patient is transferred out of intensive care, there is a lower intensity of procedures, monitoring, and therapies being performed. Length-of-stay reductions come from this side of the admission, the tail, where costs are inherently lower [5].

Discounting costs and effects

Future costs and benefits are both discounted in health economics, making them worth less than current costs and benefits. As an example, $100 today is worth more than the guarantee of $100 1 year from now. The discount is rooted in uncertainty, economic inflation, and a general preference for immediate gains over those in the future. Likewise, the benefit of one person living 10 additional years is not equivalent to 10 persons each living one additional year. Failure to discount future effects incurs the **Keeler–Cretin procrastination paradox**, wherein we would always favour health care programmes that take place some time in the future [6]. Worldwide economic growth is occurring at approximately 3% per year, and therefore the PCEHM and ATS recommend that costs and effects be discounted at a 3% rate per annum.

Sensitivity analysis

To determine how sensitive a cost-effectiveness analysis is to cost or effect estimates, the completed model may be exposed to a **sensitivity analysis**. Here, cost and effect estimates are iteratively included across the range of plausible values to demonstrate the impact of estimation precision. These values are compared with the **base case**, which uses the best point estimates of cost and effect. As long as the estimates have little effect on the overall conclusions, imprecise estimates are acceptable and the finding is considered robust.

The sensitivity analysis can also be used to determine which model parameters need to be measured most accurately. For example, the cost-effectiveness ratio may be particularly sensitive to estimates of medication costs, but relatively insensitive to expected costs of post-discharge resource use. In this situation, medication costs need to be measured carefully, while post-discharge resource use can be estimated less rigorously. Finally, a sensitivity analysis can be pinned to a cost-effectiveness threshold and then vary other parameters to show the ceiling of costs under which a given therapy would still be considered cost effective. An example of this approach was used in the evaluation of lung-protective ventilation for acute lung injury. Even at an investment level of $9482 per patient with acute lung injury, an intervention that increased adherence to lung-protective ventilation from 50 to 90% would be considered as cost effective [7].

Interpretation

The PCEHM and ATS endorse standardized reporting in cost-effectiveness studies. Studies must generate a reference case, indicate the perspective chosen, determine costs and effects, define the study time horizon, provide measurements of uncertainty,

Table 22.1 League table showing the range of cost-effectiveness ratios for a variety of medical or preventive interventions

Intervention	More favourable scenario	$/QALY	Less favourable scenario	$/QALY
Statins [11]	For secondary prevention with stepped care versus niacin	1600	For primary and secondary prevention versus secondary only	48,000
Neonatal intensive care [8]	Versus standard neonatal care for infants 1–1.5 kg	7100	Versus standard neonatal care for infants 0.5–1 kg	49,000
CABG [12]	For left main vessel disease versus medical management of angina	7100	For one-vessel disease versus medical management	56,000
tPA for AMI [9]	For anterior myocardial infarction versus streptokinase	18,000	For inferior myocardial infarction versus streptokinase	60,000
Air bags [14]	For driver side only versus no air bag	28,000	Dual air bags versus driver-side air bag only	72,000
Implantable defibrillators [10]	ICD-only regimen versus amiodarone to ICD regimen	40,000	Amiodarone to ICD regimen versus amiodarone only	157,000
Lung transplantation [13]	Versus standard care, assuming 10-year survival	44,000	Versus standard care, assuming 5-year survival	204,000

Data from various sources (see references).

and include a sensitivity analysis. This standardized approach allows for comparisons of results across studies. The reference case allows us to make inferences about the cost-effectiveness of lung protective mechanical ventilation compared with a therapy for multidrug-resistant pneumonia. When compiled, these comparisons can be sorted by incremental cost-effectiveness in league tables (Table 22.1). These tables can include interventions against specific disease states (e.g. myocardial infarction, stroke, lung transplantation) [8–13] and interventions designed to prevent injury or illness (e.g. airbags) [14].

Policy implications

To support comparative effectiveness research, the Patient Protection and Affordable Care Act established a non-profit Patient-Centred Outcomes Research Institute (PCORI) [15]. The goals of the Institute were to identify research priorities and fund research that compared the effectiveness of medical treatments. Specifically included were, 'health care interventions, protocols for treatment, care management, and delivery, procedures, medical devices, diagnostic tools, pharmaceuticals (including drugs and biologicals), integrative health practices, and any other strategies or items being used in the treatment, management, and diagnosis of, or prevention of illness or injury in, individuals' [15]. PCORI was fiercely debated throughout its development and, unfortunately, became politically linked to rationing and government restriction on care. In the end, the final version of the bill prohibited the use of QALYs as a metric for comparing therapies. The language was specific, stating that PCORI, 'shall not develop or employ a dollars-per-quality adjusted life year (or similar measure that discounts the value of a life because of an individual's disability) as a threshold to establish what type of health care is cost effective or recommended' [15].

Under the current tax and spending structure, Medicare inpatient and related care funds will be exhausted in the year 2024 [16]. Best evidence from comparative effectiveness is necessary, but not sufficient to improve the quality of the USA health care system. Robust **economic** evaluations of new therapies, procedures, protocols, and interventions are crucial, especially in the complex world of critical care. Currently, the policy debate has focused on effectiveness without cost, while the insurance market has focused on cost without effectiveness. Future directions should look to incorporate incentives that will beneficially influence physician practice, patient preference, and manufacturer investment—directions navigated by careful cost-effectiveness analyses.

Conclusion

The health care industry must improve its return on investment. Critical care, with its inherent complexity, frequent innovations, and high cost, is well suited for cost-effectiveness analysis as a basis for improving health care quality. While cost-effectiveness analyses cannot tell us what proportion of overall resources should be spent on health care, they can tell us what should be considered within a given budget. Ultimately, cost-effectiveness analyses should promote better choices, and in turn, improve the overall public health.

For a more detailed discussion of economic analysis in health care, the reader is referred to texts by Gold and Drummond [17,18].

PART 1.6

Research

CHAPTER 23

Evidence-based practice in critical care

Marius Terblanche and Damon C. Scales

Key points

- Evidence-based practice (EPB) integrates the best available evidence with individual clinical expertise.
- EBP ensures that patients receive up-to-date care proven to be efficacious, safe, and cost effective.
- EBP benefits patients by introducing new treatment approaches where appropriate, by reducing the harm associated with necessary treatments, and by questioning the continued use of ineffective or harmful treatments.
- To practice EBP, clinicians should become acquainted with techniques to stay current with new publications and research findings.
- When high quality evidence is unavailable to answer specific clinical questions, practitioners of EBP still rely on clinical judgment and expertise to decide upon the best treatment strategies for their patients. However, they are wary of the potential harms of unproven therapies.

What is evidence-based practice?

Evidence-based practice (EBP) refers to the integration of the best available evidence with clinical expertise to make decisions about the care of individual patients [1]. EBP seeks to equip clinicians with tools to overcome incorrect decision making by relying on the highest quality empiric evidence. It is not 'cookbook' medicine, since research evidence informs, but does not replace, clinical expertise [1].

In practice, EBP is a process that starts with the identification of a clinical problem or question, and then involves a search and critical appraisal of the literature. The validity and applicability of the available evidence is assessed and, if appropriate, it is then applied to clinical practice. The process concludes with an evaluation of the individual's performance [2].

Generally speaking, the randomized controlled trial (RCT) provides the most rigorous and reliable evidence to inform practice, and the highest level of evidence is achieved if multiple large, well-conducted trials have similar results and reach concordant conclusions [3]. In situations where RCTs are not feasible, for example, when studying uncommon critical illnesses or where ethical issues prevent conducting an individual patient RCT, other research designs can still help inform EBP. These include observational cohort studies, case-control studies, and even case reports. However, EBP practitioners appreciate that these study designs are more vulnerable to problems with confounding and bias, especially when seeking to establish causal relationships, rather than simply describing associations.

Why is EBP important?

EBP is important because all medical treatments, effective or otherwise, have associated risks. Clinical practice entails weighing the risk of a treatment against its perceived benefits. Good clinicians have always tried to make accurate diagnoses and formulate treatment plans using the best available information, guided by their judgment and experience. Unfortunately, clinical experience and judgment alone are vulnerable to heuristics and cognitive biases, in particular the availability heuristics (e.g. estimating the likelihood of a condition based on how easily we can recall similar conditions), base rate neglect (e.g. failing to appreciate the true incidence of a condition), framing (e.g. avoiding options that pose risks, even if such options offer small, but certain gain), overconfidence (e.g. failing to recognize what we do not know), and hindsight bias (e.g. believing we can deduce all the signs and events that led to a particular outcome) [4,5]. Such biases can undermine clinicians' abilities to make a correct diagnosis or develop an effective treatment plan for individual patients. A solid understanding of the true benefits of a potential treatment requires information from research designs like the randomized controlled trial that adequately protect against sources of error, including findings resulting from chance, bias, and confounding [5]. By considering these principles, EBP aims to ensure that patients receive up-to-date care shown to be safe and effective.

EBP is also increasingly important because of the rising cost of health care. The Cochrane collaboration states: 'Because resources would always be limited, they should be used to provide forms of health care which have been shown in properly designed evaluations to be effective'[6]. Pressure towards adopting EBP now often comes from public and private health insurance providers, which in some jurisdictions have even refused coverage of practices lacking in systematic evidence of usefulness. In the future, adherence to EBP may be targeted by pay-for-performance initiatives, although the cost-effectiveness of these schemes has not been adequately studied in critical care [7].

In practice, EBP benefits patients by introducing new treatments or treatment approaches where appropriate, by directly reducing

Table 23.1 How does EBP benefit patients?

Introducing new treatment approaches	*Example: Lung protective ventilation for Acute Respiratory Distress Syndrome (ARDS)* Mechanical ventilation is a cornerstone of ICU treatment approaches for patients with ARDS. In 2000, The ARDS Network demonstrated that using lower instead of higher tidal volumes reduced mortality (31.0% versus 39.8%, $p = 0.007$) and ventilator-free days [9] *Example: Neuromuscular blockers for ARDS [17]* Neuromuscular blockers may help improve oxygenation in patients with ARDS, but may also cause muscle weakness. In a recent RCT, which enrolled 340 patients with ARDS, a 48-hour cisatracurium infusion (compared with placebo) was associated with improved 90-day survival (HR 0.68, 95% CI 0.48–0.98, $p = 0.04$)
Preventing harm associated with necessary treatments	*Example: Central venous catheters* Central venous catheters are ubiquitous in ICUs, but are also associated with serious infections and consequent harm. A study involving all ICUs in Michigan demonstrated that introducing five recommended procedures (hand washing, using full barrier precautions during the insertion of central venous catheters, cleaning the skin with chlorhexidine, avoiding the femoral site if possible, and removing unnecessary catheters) sustainably reduced the incidence rate ratio of catheter-related blood stream infections from 0.62 (95% CI 0.47–0.81) at baseline to 0.34 (95% CI 0.23–0.50) at 16–18 months [18] *Example: Sedation during mechanical ventilation* Sedation practice and approaches to weaning from mechanical ventilation vary widely. Concerns about patient anxiety and discomfort, and uncertainty about the safest approach to wean may introduce unnecessary delays in extubation, thus increasing the risk of complications associated with sedatives and mechanical ventilation. A RCT conducted in four hospitals showed that pairing a daily spontaneous awakening trial with a spontaneous breathing trial increased the time of breathing without assistance compared with an approach in which patients received spontaneous breathing trials alone (14.7 days versus 11.6 days; mean difference 3.1 days, 95% CI 0.7–5.6; $p = 0{\cdot}02$) [19]
Question the continued use of a current treatment or approach	*Example: Aprotinin to prevent bleeding in cardiac surgery patients* Bleeding after cardiac surgery can be a serious and even fatal complication. The antifibrinolytic aprotinin was commonly used to minimize both the risk of bleeding and the use of blood products. A large RCT with three arms compared aprotinin with tranexamic acid and aminocaproic acid. The rate of bleeding was similar comparing the three groups, but aprotinin was associated with a higher risk of 30-day mortality than the other two agents (relative risk 1.53, 95% CI 1.06–2.22) [20]. These findings suggest that aprotinin should no longer be used for this indication *Example: Synthetic colloids for resuscitation* Hydroxyethyl starch (HES) solutions are commonly used resuscitation fluids. Several recent RCTs highlighted the risks associated with these solutions and raise questions about their continued use. In Australia and New Zealand, a large 7000-patient RCT showed that mortality was similar in both groups, but patients receiving HES required renal replacement therapy more frequently than those receiving saline (7.0 versus 5.8%, relative risk 1.21; 95% CI, 1.00–1.45; $p = 0.04$). These findings reinforced the findings of earlier, but smaller RCTs, and suggest that the use of HES should be curtailed

Data from various sources (see references).

the harm associated with necessary treatments, and by questioning the continued use of ineffective or harmful existing treatments (Table 23.1).

The evidence–practice gap

Considering the high mortality of critically—ill patients, it is especially important that eligible patients receive interventions that are known to improve outcomes. Yet the lag between identification and publication of potentially helpful interventions, and their adoption into clinical practice has been well described. For example, a study examined 439 indicators of quality of care for 30 acute and chronic conditions in 12 metropolitan areas in the USA, and found that only about half of patients received recommended care [8]. In critical care, a compelling example of the delayed uptake of research evidence into clinical practice is the slow adoption of lung protective ventilation using lower tidal volumes for patients with the acute respiratory distress syndrome (Table 23.1) [9]. Although this landmark trial was published in 2000, several investigators have shown that many eligible patients still do not receive this treatment, even in academic centres with ample resources [10]. EBP seeks to reduce these practice gaps by ensuring that eligible patients receive timely, appropriate, and up-to-date therapy.

How to implement EBP into a practitioner's clinical setting

We suggest the following strategies to implement EBP into your own practice:

- **Stay current:** despite the challenges of attempting to remain current and up-to-date in a world where information overload is a common challenge, electronic resources have also made it easier to keep abreast of new developments. It is suggested that all practitioners of EBP subscribe to email alerts of table of contents from the leading journals in their field as an initial strategy for keeping up-to-date. This simple task will allow users of electronic devices, e.g. cell phone and laptop computers, to remain current with minimal additional effort.
- **Take advantage of other experts' summaries of existing EBP:** there are many resources that are available to EBP practitioners to help synthesize the existing literature. For example, guidelines from professional societies, including the American Thoracic Society (www.thoracic.org), European Society of Intensive Care Medicine (www.esicm.org), and the Society for Critical Care Medicine (www.sccm.org), have covered a wide range of topics in critical care medicine. These should not simply reflect a summary of experts' opinions, but should be created using recommended

approaches to ensure transparent explanations for the guidelines' recommendations (for example, the GRADE framework of guideline reporting) [11].

- **Learn how to review and critically-appraise the literature:** becoming familiar with the principles of evidence-based medicine and critical appraisal should be considered an essential part of EBP [3]. There are fortunately many resources available to help clinicians without formal graduate training or a degree in Clinical Epidemiology or Public Health. This chapter directs readers to the excellent series entitled 'Users' Guides to the Medical Literature' from the *Journal of the American Medical Association* (http://jamaevidence.com) or 'Critical appraisal check lists' (http://clinicalevidence.bmj.com) from the *British Medical Journal*. Finally, we believe that all clinicians should receive training to conduct a search on a clinical topic using PubMED or Medline (most health libraries provide training resources), and should familiarize themselves with the Cochrane Collaboration topics collection (www.cochrane.org).
- **Evaluate your own EBP:** an important aspect of EBP involves objectively assessing your own practice to ensure it is current and up-to-date. This can pose a challenge, since it involves time and effort and also an appreciation that there may be aspects of one's own clinical practice—unbeknown to the individual—that no longer represent EBP!

Controversies

The current generation of trainees may find it difficult to comprehend that EBP has not always been the dominant philosophy. However, the adoption of EBP principles has been a controversial movement. In a particular, the following areas have generated debate about the limitations and unintended consequences of adopting EBP; we believe these are derived largely from either a misunderstanding of the principles behind EBP or are reactions to their overly rigid application.

What to do when evidence is lacking to inform EBP?

Unfortunately, there are many specific clinical situations for which no evidence exists to guide clinical practice. For example, should patients with cervical spinal cord injury and ARDS receive low tidal volume ventilation? While there is convincing evidence that ICU patients in general should receive mechanical ventilation with low tidal volumes, there are also recommendations that patients with spinal cord injury should receive larger tidal volumes to prevent atelectasis [12]. In situations such as these, a lack of evidence supporting low tidal volume ventilation from RCTs conducted specifically in patients with spinal cord injury obviously does not imply there is no net benefit or harm; the clinician must rely on his/her own interpretation and judgment to arrive at the best treatment approach for an individual patient. This still comprises EBP, but incorporates the ability of the clinician to decide when to generalize treatment approaches. Another challenging situation arises when there is insufficient high quality evidence available to suggest whether a treatment should be adopted, for example, using statins to prevent sepsis. While it may seem that there may be potential benefit based on preliminary research findings for such treatments [13], clinicians should be wary about broadly applying promising, but unproven treatments because many side effects or harms cannot be predicted or evaluated until high-quality RCTs or even population-based surveillance studies are completed.

Does EBP imply clinicians cannot think for themselves?

That is to say, does EBP leave clinicians practicing 'cookbook medicine'? Some critics have raised concerns that the dogmatic application of guideline or research suggestions may have unintended consequences and potentially cause harm [14]. The authors agree, but feel that these concerns are overstated because EBP also requires that clinicians continually re-evaluate their own practice and are able to recognize when research findings may not be generalizable to their own patients.

Are EBP recommendations transparent and free of bias?

Much controversy has arisen surrounding the process for developing guidelines for EBP. In particular, concerns have been raised about industry-sponsored guidelines, especially when these have been guided largely by expert opinion or funded by industry, and without transparent critical appraisal of the literature [15]. The GRADE approach to guideline creation has evolved to help deal with these concerns and enhance the transparency of guideline creation [11], but critics have raised concerns that even this approach itself has not yet been adequately scrutinized [16]. The authors believe guidelines that are created using a comprehensive and systematic search of the literature combined with transparent procedures for developing recommendations are important if these are to guide EBP. However, EBP implies that clinicians critically appraise all sources of information, including guidelines and the processes used in their development, to ensure that they are using the best-available evidence to guide clinical care.

Conclusion

EBP implies that clinicians make clinical decisions and treat patients using principles and therapies that are based on sound scientific research. There is an obligation to patients to provide treatments that are proven to be effective (and are not harmful), and that our own practices should continue to be evaluated to ensure current, up-to-date, provision of EBP.

CHAPTER 24

Research ethics in the ICU

Neal W. Dickert and Scott D. Halpern

Key points

- Barriers to informed consent are unavoidable features of many intensive care unit (ICU) studies and must be recognized and addressed in a context-sensitive manner. This may include alterations to consent processes, the use of surrogates, or exception from informed consent.
- Assessments of equipoise can be complicated in the ICU context. Adequate review and assessment of clinical uncertainty and risk is particularly essential to this determination.
- Choice of control group in ICU trials can be difficult in the context of heterogeneous or non-data-driven practice patterns, but this choice must always be driven by the goal of producing data that will answer the clinical question and have a meaningful impact on clinical practice.
- Quality improvement activities and clinical research can at times be difficult to distinguish. Both should always be evaluated regarding their potential impact on patients and the need for informed consent.
- Improving the ethics of clinical research in the ICU requires innovative, context-sensitive analysis of individual studies and empirical research to determine optimal ways of overcoming ethical challenges.

Introduction

Clinical research in the intensive care unit (ICU) is essential. Patients are at considerable risk for death and disability, and critical care consumes enormous resources (estimated 0.66% of US GDP) [1]. Clinical trials have improved outcomes for many severe illnesses and systems-based research has reduced mortality. However, treatments for many conditions remain inadequate or lack adequate evidence.

Critical care research also presents ethical challenges [2]. Some, such as conflict of interest, are generic to research. Others are more specific, arising from a combination of patient acuity, practice variability, lack of evidence, and consent-related challenges. This chapter focuses on issues with unique manifestations in critical care that warrant specific attention and research.

Challenges to informed consent

Although involving patients in decisions is central to respecting autonomy, many barriers can prevent ICU patients from participating in decisions. Patients are often unconscious, delirious, or in distress or pain, and many require medications that cloud mental status. Mechanical ventilation may complicate communication. Additionally, decisions must often be made quickly. Surrogates are regularly employed in situations of impaired mental status, but time constraints and distress affect surrogates too.

These barriers probably hinder involvement in research decisions even more than in clinical decisions. Clinical trials, particularly in acute settings, are poorly understood. They depart from the norms of clinical medicine prioritizing individual interests, involve complicated concepts such as randomization, involve risks not justifiable by direct benefit, and foster conflation of research with care. For those same reasons, informed consent has an important role in research enrolment decisions when 'stakes are high' in the ICU. Consent is thus most difficult when it seems most important

Although surrogate consent for ICU research is widely employed [3], studies have demonstrated that surrogates' decisions may not reflect patients' choices. Indeed, one recent study found surrogates' predictions were no better than chance [4]. The implications of these findings are unclear. It may, for example, be that patients care more about **who** makes decisions than the '**accuracy**' of substituted judgment [5]. If so, surrogate consent might be justified as a patient-centred process, even if it results in different decisions from what patients themselves may choose. Further research is needed.

There are other challenges with surrogate consent. First, surrogates are typically non-neutral observers (often family), and their distress may degrade decisional capacity. Secondly, surrogates may feel uncomfortable making decisions regarding research. Some investigators have noted, for example, that consent for participating in potentially therapeutic trials is often refused initially, but later granted if the patient fails to improve. This reflects indecision and conflation of research with clinical care. It also may introduce bias by preferentially selecting sicker patients. Finally, it is unclear when patients want surrogates involved. In acute myocardial infarction research, for example, many participants feel capable of making enrolment decisions and often want to do so, despite poor understanding [6].

Barriers to consent in ICU research are thus significant, numerous, and unavoidable. Unfortunately, current regulations continue to require complex documentation that does little to promote informed consent. Shorter, simpler consent materials have been suggested but have not been widely employed or evaluated.

When time constraints are significant (e.g. septic shock, ST-elevation myocardial infarction, or gastrointestinal bleeding), the maximal attainable goal may be to learn whether patients generally accept research enrolment, and a process of informed refusal may be more appropriate [7]. Seeking full consent seems

disingenuous and may delay treatment. However, there is a need for empirical evaluation of the impact of innovative approaches on enrollment decisions, and patients' and surrogates' perceptions of procedural justice.

Exception from informed consent

In the USA and many other countries (including Australia and Canada), regulations allow an exception from informed consent (EFIC) in certain emergency settings. Notably, there is significant heterogeneity across Europe. While the European Clinical Directive contains no provisions to allow for EFIC in emergency settings, many European countries explicitly permit it [8].

The principal requirements in US EFIC regulations are that consent is impracticable within the necessary timeframe, that existing treatment is inadequate, and that studies pose a reasonable risk–benefit ratio. Additionally, there are requirements for community consultation and public disclosure [9]. These regulations have facilitated pivotal studies in conditions including cardiac arrest, status epilepticus, and shock, typically conducted in out-of-hospital and emergency department settings. They may also be appropriate for in-hospital studies of resuscitation or other unpredictable conditions where consent is impracticable. How community consultation processes might differ in inpatient settings warrants exploration. Importantly, EFIC is not appropriate when patients or surrogates can make enrollment in decisions.

Equipoise and critical care

Another set of ethical challenges in ICU research involves study design. Core design elements, such as choice of control, decisions about randomization, and tests or procedures done purely for research purposes, all influence a study's ethical acceptability. These factors determine study risks, the extent to which study care differs from routine care, and the extent to which a study will impact on practice. Given consent challenges and high patient acuity, these issues can be daunting.

Most design issues arise in randomized trials. The prevalent standard for acceptability of randomization is clinical equipoise [10]. Clinical equipoise does not require that individual clinicians be agnostic about which treatment arm they prefer, only that the relevant medical community be sufficiently uncertain. There has been debate about whether this standard is appropriate, but the basic requirement for uncertainty within a field and reasonable risk are intuitively sensible and widely applied. The devil in operationalizing this concept, of course, is in the details.

High acuity clearly raises the stakes. Given that mortality is often a primary outcome measure and not rare in ICU studies, the relative harm of being assigned to an inferior treatment is potentially enormous. Of course, if investigators knew which arms were superior at the outset, the trial would be unethical, but varying levels of evidence may exist to support different treatments. What level of evidence is sufficient to disturb equipoise is a matter of debate. For example, a randomized control trial comparing epinephrine with epinephrine plus vasopressin in cardiac arrest was acceptable because there was significant experience using both drugs, but no evidence of superiority [11]. A study comparing epinephrine with a new compound with encouraging preclinical data, but limited clinical data, may pass a test of uncertainty, but there may be insufficient experience to justify randomization in cardiac arrest. By contrast, a new intervention may have such strong face validity, or accumulated experience may suggest such profound benefits, that some are reluctant to allow randomization to standard interventions. Adaptive designs have at times been employed to minimize the number of patients exposed to inadequate treatment, but these designs require careful consideration of methodological limitations [12].

Although these considerations are not conceptually distinct from similar dilemmas in other contexts, the potential 'costs' of randomization to inferior therapy, coupled with challenges to consent, impose especially rigorous requirements for scientific review. Many institutional review boards (IRBs) are ill-equipped to assess risks of specific comparisons. At a minimum, IRBs should seek confirmation from experts unaffiliated with the trial that comparison arms are reasonable and do not present excessive risks, just as they should seek statistical confirmation that trial designs will answer the clinical question. In large, multicentre trials, review mechanisms may take place centrally, although the locus of responsibility (data safety and monitoring committee versus scientific review committee versus IRBs) can be unclear. The guiding principle of all trials must be to produce evidence that impacts clinical decisions.

Standard of care and control group selection

Another design-related challenge is the choice of control or standard of care. This issue arose, for example, regarding the ARDS Network trial of low versus high tidal volume ventilation for acute lung injury [13]. Investigators chose a 12 mL/kg control, based on available observational data, but critics argued that this control did not reflect community standards and that the trial did not effectively inform practice. They argued that a lower 'high' volume, clinician discretion (no protocol-defined volume), or a three-arm trial should have been employed. While the optimal approach in the context of heterogeneous practices is unsettled, helpful approaches may include systematic surveys of relevant experts to drive a consensus-based choice of comparison [14] or potential inclusion of multiple control groups, one of which does not conform to a particular protocol [15]. The latter, of course, poses logistical hurdles and challenges regarding sample size. These concerns merit careful consideration, because multiple control groups increase cost, and they may delay data production and reduce scientific value if recruitment is insufficient.

Similar dilemmas arise in organizational-level research. For example, one of the authors recently conducted a randomized trial of in-house night-time intensivist staffing versus home-based intensivist availability [16]. Although the latter model was the standard in the ICU where the study was proposed, concerns were raised that it was unethical to randomly assign patients to this model because continuous intensivist coverage had become standard at peer institutions. The trial was ultimately launched after investigators established that this 'standard' lacked evidence, but concerns remained among clinicians who believed the face validity of in-house night-time coverage was sufficiently strong.

System-based studies and quality improvement

Distinguishing between quality improvement and clinical research can be challenging, an issue raised most visibly by a study

evaluating ICU checklists [17]. Investigators did not seek IRB review because their institution considered the study to be quality improvement. Accordingly, informed consent was not sought. The study was eventually halted, as it was determined that it did represent research and prospective consent should have been obtained. However, the study would have been eligible for expedited review and a waiver of consent because of the impracticability of consent and minimal risk involved [18]. The error was thus more in categorization and compliance than in substance. The case nonetheless highlights two key issues. First, it can be difficult to distinguish between quality improvement activities and clinical research, but systematic attempts to generate generalizable knowledge do constitute research and warrant review. More importantly, the ethical acceptability of such activities and standards for consent do not hang on this distinction.

Perhaps the biggest ethical challenge of system-based studies is the inability of individual subjects to decline participation. Informed consent is impractical when randomizing units to checklists or staffing structures; patients cannot choose whether to be admitted to a unit that uses a checklist, and the goal of these studies is to examine the impact of systems. If anything, the absence of consent highlights the importance of review, as significant outcomes are at stake.

Ethical innovation and data-driven research ethics

Two critical elements of advancing understanding of ethics in ICU research are thinking broadly and applying standards of evidence to ethics. A salient example of the former was the first study in humans of glycoprotein IIb–IIIa inhibitors. Because of bleeding concerns, investigators conducted early phase research in brain-dead patients to establish safety before studying the drug in acute myocardial infarction [19]. This approach minimized risk in transitioning new agents into trials in sick patients and represents a model for a context-sensitive approach to critical care research.

Low recruitment is another pervasive problem that delays or prevents important knowledge, and creates inefficiencies in the use of research and health care resources. Incentive payments to patients—long-shunned—have become more accepted in clinical studies as data have suggested that ethical concerns may have been overstated [20]. Broader use of incentives in critical care research, for example, to members of the research team in order to overcome recruitment barriers, may improve enrolment, but these practices raise real ethical concerns. Incentives should thus only be implemented under rigorous empirical evaluation to assess whether beneficial enrol effects can be obtained without adverse consequences. Ethics practices, just like clinical practice, should be data-driven.

Conclusion

ICU research presents unavoidable ethical challenges that must be surmounted to improve care for the sickest patients. This chapter highlighted challenges that are particularly salient or have unique features in the ICU. Approaches to addressing these issues must recognize and be sensitive to the ICU context, maintain commitment to high-quality data, and avoid over-reliance on consent as the *sine qua non* of ethical research. Many of these challenges—and their potential solutions—are amenable to empirical investigation, and it is essential to create a culture of creative thinking and evidence-based research ethics in the ICU.

PART 1.7

Medico-legal and ethical issues

CHAPTER 25

Informed consent in the ICU

Henry J. Silverman

Key points

- In recent years, the overemphasis on autonomy that has led patients and family members feel they have to 'make the decision' by themselves has shifted towards a more balanced approach with the participation of both patients and health care providers, a concept termed 'shared decision making'.
- In order to be deemed legally and ethically valid, there needs to be adequate disclosure of information, the individual must have the capacity to understand and make a decision and the decision needs to be free from coercion, i.e. voluntary.
- Advance directives serve as a mechanism for patients to have their previously stated autonomous wishes followed when they lose decision-making capacity to decide for themselves.
- Ethicists, caregivers, and the legal system recommend that standards for surrogate decision making should include substituted judgment and best interests.
- Patient autonomy has assumed an important status in the provision of health care, but it must be recognized that autonomy is largely a Western concept, which might pose challenges in other cultural settings.

Introduction

Informed consent in the medical setting has evolved during the past 50 years. Previously, most major medical decisions were left exclusively to physicians, as society accepted that physicians not only possessed the detailed technical knowledge required to make medical decisions on behalf of patients, but they were also guided by an overriding principle of beneficence. This paternalistic approach had several benefits, as physicians attempted to make the best decisions possible and they spared patients and their families from the emotional burdens associated with these difficult choices. This paternalism emphasized beneficence to the exclusion of other principles, particularly autonomy [1]. By the mid-1980s, the concept of the paternalistic physician was replaced by developments in health care law and ethics that accompanied the rise of the doctrine of informed consent. This doctrine, intended to promote and respect the autonomy of patients [2], 'flows from the recognition that all persons have unconditional worth, each having the capacity to determine his or her own moral destiny' [3].

In addition to this inherent value of autonomy, an instrumental value afforded to informed consent also arose from the realization that it can be difficult for physicians to determine what is in their patients' best interests [4] and to avoid basing decisions on their unintended biases. [1]. As such, in the late twentieth century, the pendulum swung away from paternalism and towards patient autonomy. Unfortunately, many physicians began to act as impartial agents for their patients and withheld any advice, as they strived to avoid exerting what they believed to be inappropriate influences on the patient or family. This overemphasis on autonomy led to patients and family members being made to feel that they have to 'make the decision' by themselves. However, in recent years, the pendulum has begun to swing back from absolute autonomy towards a more balanced approach with participation of both patients and health care providers, a concept termed 'shared decision making' [5].

Elements of informed consent

Typically, in order to be deemed legally and ethically valid, an individual's consent must be properly informed (i.e. adequate disclosure of information), the individual must have the capacity to understand factual information, appreciate the situation he or she is in, make a decision, and the decision must be free from coercion (i.e. voluntary) [2]. The combination of having the abilities to understand, appreciate, and make a decision is sometimes referred to as having 'competence' on the grounds that what is at issue is 'the ability to perform a task' [3]. It is also sometimes referred to as 'capacity', since the task in question involves the capacity to make a decision [6]. In practice, both words are used interchangeably.

Disclosure of information

Patients must have adequate information if they are to make decisions that reflect their own values and preferences, and physicians play a key role as educators in this process. Accordingly, physicians have a basic duty to disclose enough about the proposed treatments (e.g. rationale for the treatment or intervention, risks and benefits, who would carry out the intervention, and alternative recommendations for treatment) so that the patient becomes sufficiently informed to participate in shared decision making. If physicians fail to do their 'due diligence' in this area of patient–physician communication, patient decisions will be based on incomplete and, possibly, incorrect information, which can lead to unwarranted assumptions by the patient. Furthermore, physicians must do more than just tell patients about a proposed procedure or therapy, and its risks and benefits. They must communicate in a way that the patient can understand, including requesting a language translator if necessary and avoiding medical jargon. Physicians must also ask questions of patients to ensure that they demonstrate a deeper understanding of the treatment proposals, not merely prompt the patient to parrot information back.

There is a debate regarding how much information the patient requires, and physicians might find it difficult to strike a balance between too much and too little information. Communicating every detail is neither possible nor practical. Most of the ethics literature and law in this area suggest one of three standards:

- **Professional community standard:** entails that a physician's duty to disclose information to the patient depends on what the majority of physicians in the community would disclose regarding the **intervention**. This standard allows the physician to determine what information is appropriate to disclose. The concern, however, is that the typical physician would tell the patient very little. This standard is also generally considered inconsistent with the goals of informed consent, as the focus is on the physician rather than on what the patient needs to know.
- **Reasonable patient standard:** entails a duty of disclosure based on what the average patient would need to know in order to be an informed participant in the decision. This standard focuses on considering what a patient would need to know in order to understand the decision that needs to be made.
- **Subjective standard**: entails that the physician tailors the information based on **what** a specific patient needs to know and understand in order to make an informed decision. This standard is the most challenging to incorporate into practice, since it requires tailoring information to each individual patient.

The reasonable person standard seems the most practical and achievable, although practice should be guided by local interpretation of the law and professional society's standards.

Decision-making capacity

In order to give valid informed consent, patients must have the following in order to make a decision—the ability to understand factual information, to appreciate their situation and its consequences, to rationally consider information in light of their underlying values, and to commit to a choice.

- **Understanding of information**: once the information provided is deemed adequate, the physician must be assured that the patient understands the basic factual information. A useful technique for assessing understanding is to ask the patient to summarize what has just been said and to correct as needed.
- **Appreciation**: in addition to understanding basic factual information, commentators agree that patients must also have some **appreciation** of the nature and significance of the decision that they are faced with [2]. Appreciation is a term used to refer to the highest degree of understanding, one that grasps more than just the medical details of the illness and treatment. Very basically, patients must recognize that this is **their** decision to make and that it is **their** life and values and future lives that are at stake. Essentially, patients need to demonstrate what has been termed 'insight' into the circumstances of a given decision.
- **Reasoning**: patients must have the cognitive ability to manipulate information rationally, weigh risks and benefits, consider trade-offs of accepting or not accepting the recommended treatment, and evaluating potential consequences. Usually, asking patients to state their reasons for their decision can serve as a 'window' into their reasoning process.
- **Choice**: patients must be able to commit to a decision or a choice. Unless a patient's preferred choice can be expressed to others in some explicit way, it is impossible to know their intended decision. The condition is not trivial, since some patients might defer decisions or authorize others to make decisions for them. This is perhaps the least mental of the sub-capacities that constitute capacity, which may explain why it is not considered an element of capacity by some authors.

Voluntary decisions

A valid informed consent requires that patients' decisions must be free from controlling influences. The institutional setting of the hospital may be a source of subtle or covert coercion, including a fear, justified or not, that they may not receive future care in some way if they do not follow the physician recommendations. Patients may feel they have little choice, but to agree with 'their' doctor who is 'recommending' a treatment. Also, families may exert considerable pressure on patients.

Informed consent and the capacity to consent

Critically-ill patients may have a diminished capacity to make decisions. Studies have showed that patients with acute illnesses may have limitations in their decision making capabilities due to a number of factors, including the presence of delirium, their underlying illness, or the use of sedatives and analgesics [7–12]. The presence of these factors does not necessarily translate into incapacity to provide a valid informed consent. Indeed, two types of errors can occur in the setting of obtaining informed consent from critically-ill patients. One error involves obtaining surrogate consent for patients who are capable of providing consent, thus depriving such patients their autonomous rights to choose for themselves. The opposite error occurs when physicians obtain informed consent from patients who lack decisional capacity. To minimize such errors, it is crucial for physicians to assess the decision-making capacity of their patients.

Methods for assessing capacity

Currently, there are no universally accepted procedures regarding capacity assessment for critically-ill patients.

Physicians may attempt to gauge a patient's ability to make treatment-related decisions through regular communication during the clinical encounter. Such informal capacity assessments consist of using probing questions to assess patient's ability to understand factual information, their appreciation of their situation, and their cognitive ability to manipulate and weigh the information before coming to a decision. Often, physicians rely on 'experts' (e.g., psychiatrists) to determine decision making capacity. Regardless of who does the capacity assessment, one must realize and accept the inherent subjective nature of such judgments regarding the capacity to make decisions. Also, one is often left with the question of how much understanding and rational decision-making capacity is sufficient to make the determination that a patient has capacity. Conversely, how deficient must a patient's decision-making capacity be, before he or she is declared to lack capacity? Rather than selecting a single standard of capacity, commentators have suggested a sliding scale concept, which paternalistically requires an

increasingly more stringent standard (or greater evidence of capacity) as the consequences of patients' decisions embody more risks or more severe consequences to their welfare [3,6]. In other words, if the consequences of a decision for patient welfare are grave (e.g. refusing ventilator support), the greater would be the need to be certain that the patient possesses the requisite capacities. However, if little in the way of welfare is at stake, a lower level of capacity might be required for decision making [3]. This concept of a sliding scale explains why a greater degree of capacity (or greater degree of certainty) is warranted for a patient to refuse treatment, whereas a lower degree of capacity is required to accept treatment recommendations. These concepts can be applied in the following manner. If a patient is critically ill because of an acute illness that is life-threatening and the available treatment is considered to be effective, low in risk, and there are few or no alternatives available, then a physician may accept a low level of decisional capacity from the patient to accept the treatment. That is, the act of consent to such a treatment is considered to be an informed consent as long as the patient is aware of what is going on. Awareness in the sense of orientation or being conscious of the general situation would satisfy the cognitive requirement of informed consent [13].

However, a high level of decisional capacity would be required if the patient refuses to accept the available treatment. Such decisions can be respected as long as the patients satisfy the most demanding standard of capacity. Patients need not conform to what most rational people would do to be considered as having capacity, but patients must be able to give reasons for their decisions. Patients must be able to show that they have thought through the medical issues and related this information to their personal value systems. Patients' personal reasons may derive from a set of religious beliefs (e.g. Jehovah Witness) or from a philosophical view that is shared by only a small minority, but they should not be purely idiosyncratic or incoherent [13]. If the patient is terminally ill, and the treatment carries great risk or is of less definite benefit (or if there are real alternatives to one or another course of action, e.g. hospice care, rather than lingering illness), then the physician should accept a low level of capacity if the patient refuses the treatment.

A problem with the sliding scale strategy is that health care providers may manipulate it to declare patients who consent to a treatment to be competent and those who refuse treatment to be incompetent.

When patients lack capacity for decision making

When patients lack decision-making capacity to provide their own consent, several mechanisms exist by which their autonomy can still be respected.

Advance directives

Advance directives serve as a mechanism for patients to have their previously stated autonomous wishes followed when they lose decision-making capacity to decide for themselves. There are two types of advance directives. One is an instructional directive, or a 'living will', which specifies the patient's preferences to specific care decisions. Often, such directives contain general statements of not wanting life-sustaining interventions or they describe the values that should guide specific terminal care decisions. Such general statements might not be helpful, as they lack specificity for complex decisions that occur in the critical care setting. Some advance directives enumerate different scenarios and interventions for the patient to choose from and others are designed for use by patients with a specific disease, such as cancer.

Alternatively, a person can select a proxy decision maker, sometimes called a durable power of attorney for health care, to make decisions for them when they lose decisional capacity. Individuals choosing a proxy should make sure that the proxy knows their wishes and values well enough to ensure that decisions made are more likely to be reflect the decisions they would have made. Often, a combined directive includes both instructions and the designation of a proxy. In general, advance directives remain a challenge with their clinical implementation [14] and also with its normative justification in different cultural contexts that define varying roles for family decision making, e.g. individualistic vs. relational understandings of autonomy [15].

Surrogate decision making

If a patient has not legally appointed a health care proxy, family members (or in some cases, friends who know the patient well) may still be able to serve as the patients' surrogate decision maker and make health care decisions for patients. US and European standards require such surrogates to be legally authorized to provide such consent under applicable law.

Standards for surrogate consent

Ethicists, caregivers, and the legal system recommend that standards for surrogate decision making include a substituted judgment and best interests. Substituted judgment holds that the surrogate decision makers should attempt to reconstruct the patients' judgment by analysing prior statements, and their overall values and beliefs, and to make the decision that 'would be made by the incompetent person, if that person were competent . . .' . Most surrogates, even close family members, cannot accurately predict what the patient would want. Therefore, in the absence of specific guidance from the patient, substituted judgment involves surmising what a patient would want, rather than a guaranteed fulfilment of the patient's wishes. Of note, patients who were surveyed in one study varied in the extent to which they want families to strictly adhere to their personal wishes in making end-of-life decisions on their behalf [16].

If the patient's wishes cannot be reliably ascertained, then surrogates should resort to a best-interests standard, which entails that the surrogate should base decisions on a balancing of the treatments' benefits and risks, the medical prognosis, and the patient's present and future interests. The term 'best' is used to denote that the surrogate's obligation is to select from those competing treatments the one in which the benefits maximally outweigh the burdens of treatment. This standard can be considered 'objective', only if there is a 'societally-shared criteria' about what constitutes benefits and burdens. This has proved to be problematic, as benefits and burdens transcends a medical calculus (e.g. pain and discomfort), and usually also include patient values, e.g. religion, any beliefs related to life and death, level of rationality, and concepts of dignity. In the absence of an objective best-interests standard, physicians largely rely on families to decide what constitutes a benefit or burden from their estimation of a patient's personal values, and only object if these decisions seem to demand treatments that seem to be not beneficial or futile. Without a perfect solution to the problems

raised by proxy decision making, this approach may be the most reasonable one in difficult circumstances.

A concern with surrogate decision making in general, is that studies have shown high levels of anxiety and psychological distress in family members of critically-ill patients. This consideration might, at times, call into question the ability of surrogates to make morally adequate decisions for incapacitated patients.

Special situations

Critically-ill patients who lack both decision-making capacity and surrogate decision makers

No formal guidelines exist regarding the process that should be involved with decisions regarding the use of limit life-sustaining treatments for adults lacking both in capacity to make decisions and surrogate decision makers. One study demonstrated that such a situation was present in 16% of patients admitted to the intensive care unit of one hospital. Processes to make decisions regarding life supporting treatments include unilateral physician decision making, involvement of an ethics committee, and institutional or judicial review [17]. Further discussions are warranted to develop optimal guidelines for such patients.

Emergency clinical situations

In general, all invasive procedures require informed consent from the patient or the appropriate surrogate. Exceptions occur when emergent, life-saving procedures are required (e.g. endotracheal intubation), and patients lack decision making and surrogates are not available. Under the concept of implied consent, whereby it is implied that such patients would consent to such treatments, if competent, it would be ethically appropriate to provide treatments to such patients. It is the responsibility of individual units and institutions to establish guidelines for which procedures require formal written consent.

Informed consent in the research setting

A major and complex issue regarding informed consent in the research setting involves the inability of potential research participants to distinguish between research and clinical care [20]. Patients and families have a strong tendency to inaccurately attribute therapeutic intent to research interventions. However, the goal of clinical trials is not to provide direct benefits to subjects, but rather, the primary goal of research is to generate generalizable knowledge for future patients [18]. The term 'therapeutic misconception' is used to describe this phenomenon, a term first reported by Appelbaum and colleagues in 1982 during interviews with patients with psychiatric disorders who participated in clinical trials [19]. There are two major ethical concerns with the therapeutic misconception. First, the failure of patients to appreciate correctly the risks and benefits of potential research participation raises concerns regarding the validity of informed consent [20]. Secondly, the presence of the therapeutic misconception reflects the very real possibility that research participants will see the investigator's role as that of the physician and view an invitation to enrol in research as a professional recommendation, intended to serve their individual treatment interests. Such inappropriate enrolment of patients into research reflects a concern with exploitation. Physician investigators should explicitly refute such a 'therapeutic misconception' and should dispel any notion that a clinical trial is designed to or will provide patients with direct benefits, or that the research substitutes for clinical care. Commentators have given further recommendations for informed consent in the critical care setting [20].

Emergency research

Advancing the field of emergency medicine requires research, but, in emergency circumstances, it is often impossible to obtain consent from patients or their families in time. Several ethicists believe that, because the field of emergency medicine simply cannot progress without research, there should be an exception to informed consent requirements, even for such risky trials, combined with additional safeguards to to ensure that exploitation is prevented.

Conclusion

Patient autonomy has assumed an important status in the provision of health care, but one must recognize that autonomy is largely a Western concept that might pose challenges in other cultural settings. For example, full disclosure might be at variances with cultural beliefs about hope and wellness, autonomous decision making may contradict family-centred values, and uncoerced choices may counter cultural norms of obedience to other family members. Cultural competence in the health care setting is recommended to gain sensitivity to cross-cultural encounters in the medical care setting.

CHAPTER 26

Patient rights in the ICU

Thaddeus M. Pope and Douglas B. White

Key points

- To say that a patient has a 'right' is to say both that the patient has a 'claim' against the clinician for X and that the clinician owes a correlative 'duty' of X to the patient.
- Patient rights are not absolute trumps. They are only *prima facie* (presumptively) valid claims, which must sometimes yield to other sufficiently compelling claims.
- Overriding a right can be either justified (an 'infringement') or unjustified (a 'violation'). Patient rights are sometimes justifiably infringed by distributive justice concerns.
- Patient rights are also sometimes justifiably infringed by clinicians' assertions that the requested intervention violates professional integrity.
- Patient–clinician conflicts can usually be prevented or mediated. When conflict is intractable, it should be resolved through appeal to socially-accepted rules. When this is not possible, the dispute should be managed through a fair process of dispute resolution.

Introduction

This chapter proceeds in seven stages. First, it explains the nature and source of patient rights. Secondly, it analyses the scope of patient rights. Thirdly, it describes five specific patient rights that are particularly relevant to critical care. Fourthly, this chapter turns to discuss several ways in which patient rights might be illegitimately violated. Fifthly, it discusses how patient rights might be justifiably infringed by distributive justice concerns and concerns grounded in professional integrity. Finally, this chapter concludes by describing four leading mechanisms by which patient rights are balanced against clinician rights.

Nature and source of patient rights

The concept of 'rights' is ambiguous, but Wesley Hohfeld [1] famously disambiguated and clarified the concept by distinguishing four types of rights: claim, liberty, authority, and immunity rights. Most relevant, here, are claim rights. To say that a patient has a 'right' is to say both that the patient has a 'claim' against the clinician for X and that the clinician owes a correlative 'duty' of X to the patient. Or one might say that a patient's 'right' is a normative demand, which imposes a constraint on the clinician [2].

Hohfeld's theory of correlative rights concepts has been enormously influential, and it is particularly appropriate in the critical care context. Because of a patient's overwhelming vulnerability and dependency, typically he/she can effectively exercise his/her rights only through or with her clinician. Indeed, the very basis of patient rights (and clinicians' correlative duties) rests to a significant degree on the extreme power imbalance between clinicians and patients. Patient rights are also grounded in the highly-valued principle of respect for autonomy or self-determination.

One need not resort to philosophical axioms to identify patient rights. They are already well-articulated more concretely in state and federal statutes, Medicare conditions of participation, licensing regulations for clinicians and facilities, Joint Commission accreditation standards, professional medical association ethics codes, and international conventions [3–6].

Scope of patient rights

Theoretically, patient rights could be specified in such a way that they would include exceptions and limitations that accommodate competing claims of clinicians and society. With such 'built-in' specification, patient rights would always be absolute. However, anticipating and incorporating all these restrictions would be burdensome, cumbersome, and probably impossible. For example, consider a proposed right to 'treatment within the boundaries of accepted medical practice'. Such a right would be indeterminate, because the boundaries of accepted practice are notoriously fuzzy.

Accordingly, ethicists and political philosophers generally consider rights as only *prima facie* binding. Rather than narrowly defining rights with exhaustive detail, it is better to talk about when a (presumptively broad) right can be 'permissibly infringed' or 'overridden'. Beauchamp and Childress distinguish the 'violation' of a right from the 'infringement' of a right. Violation refers to an unjustified action against a right, whereas infringement refers to justified action overriding a right [7].

Due to the pre-eminence of the principle of respect for autonomy in Western culture, the scope of patient rights is quite broad. Indeed, the claim is basically that medicine should make its skills available to patients to help them achieve their own private vision of the good life. Nevertheless, both through professional standard setting and court rulings, some limits have been established. For example, it is well-settled that patients generally do not have a right to non-palliative treatment in situations of physiological futility, death, anencephaly, or gestation under 22 weeks [8].

Key patient rights

Because some patient rights are human rights, they are inalienable and universal. Other patient rights vary across countries. The

development of patient rights is evolving. We must necessarily generalize across settings with material and minor differences. Still, many patient rights are standard across health care settings. For example, patients typically have the right to privacy and to confidentiality of their health information. They typically have the right to be treated according to the prevailing standard of care. However, particularly notable in critical care are patient rights to informed consent, treatment refusal, non-discrimination, pain management, and non-abandonment.

Informed consent

Patients are usually ethically and legally entitled to informed consent. They have the right to know what their treatment options are and to intelligently participate in decisions about their care. Accordingly, the clinician must provide the patient with information about his/her diagnosis and prognosis, the risks and benefits of proposed procedures and treatments, and the risks and benefits of reasonable alternatives. Furthermore, the clinician must provide all this information in an understandable manner, which is sensitive to the patient's language and cultural needs.

Treatment refusal

A logical corollary of informed consent is the right to refuse treatment. The patient has the right to withhold (not start) treatment that might be offered (e.g. cardiopulmonary resuscitation) and to withdraw (stop) treatment that is already under way (e.g. mechanical ventilation). Moreover, the patient has the right to refuse treatment, even if clinicians regard it as 'medically indicated' and even if such refusal will cause the patient's death. In particular, the patient has the right to have an advance directive with the expectation that clinicians will honour the intent of that directive. However, while patients have the 'negative' right to decline unwanted treatment, it remains less settled whether patients have an 'affirmative' right to demand the initiation or continuation of treatment.

Non-discrimination

Patients are entitled to treatment without regard to their race, sex, colour, ancestry, national or ethnic origin, religious beliefs, sexual or political orientation, marital status, genetic information, age, or disability. While these are the classic grounds of prohibited invidious discrimination, patients are also entitled to treatment without regard to their source of payment, educational background, compliance with social norms, perceived social worth, or, sometimes, even ability to pay.

Pain management

Patients have a right to effective pain management. This includes physical, social, psychological, and spiritual pain management. If requested, clinicians must administer, prescribe, or dispense medications or procedures sufficient to relieve the patient's pain or discomfort, even if that intervention may hasten or increase the risk of death.

Non-abandonment

Clinicians are generally free to choose whom they will serve, but once having undertaken a case, clinicians must not abandon the patient. Clinician-initiated termination of a treatment relationship is particularly serious when the patient is acutely ill. Clinicians must assure the patient's continuity of care. Therefore, clinicians may not discontinue treatment, so long as that treatment is needed, unless adequate care is otherwise available.

Illegitimate violations of patient rights

Unfaithful surrogates

Patient rights are often exercised on the patient's behalf by surrogate decision makers. Because patients in critical care usually lack decision-making capacity, surrogates make most treatment decisions. Accordingly, clinicians usually honour patient rights, such as informed consent and treatment refusal through joint deliberation with the surrogate, rather than with the patient him/herself.

Unfortunately, the very surrogates who are supposed to protect and promote the patient's rights sometimes undermine those rights. For example, surrogates are often unable or unwilling to properly exercise substituted judgment and make the same treatment decisions that the patient would have made for him/herself if he/she had the capacity. Surrogates often do not know the patient's preferences. Moreover, even when they know the patients' preferences, surrogates sometimes fail to follow them faithfully. Sometimes, these are calculated decisions influenced by private gain or personal advantage. Other times, the surrogate lacks the capacity, or is encumbered by emotional or psychological barriers to ideal decision making [9].

Under those circumstances in which the surrogate's decision represents a material contradiction of or a substantial deviation from patient wishes or best interests, it is appropriate for the clinician to remonstrate or even challenge the surrogate. This is not an affront to patient rights. Rather, the clinician actually protects the patient's right to autonomy (informed consent) by challenging a surrogate who seems to be acting inconsistently with the patient's wishes [10].

Poor communication

Patient rights are also threatened by inadequate training or performance at the individual and system-wide level. In particular, poor communication both between team members, and between the team and the family is a common causal factor underlying adverse events. Critically-ill patients and their families have a unique set of issues and concerns that clinicians must address. Unfortunately, effective goals discussions are often confounded by late timing, poor communication, and lack of regularly implemented protocols [11].

Conflicts of interest

Patient rights are also threatened by clinicians' conflict of interest. Different reimbursement models can provide incentives and external pressures that influence the provision of critical care services. For example, a fee for service payment may encourage the overuse of medical procedures relative to patients' actual preferences, while capitated payment models may encourage undertreatment relative to patients' preferences [12].

Misrepresentation and coercion

Sometimes, clinicians engage in misrepresentation or coercion in order to obtain surrogate consent. This can violate the patient's rights to informed consent and treatment refusal. For example, some clinicians intentionally withhold information or prognosticate with varying degrees of certainty [13]. Others write 'slow codes' or 'show codes', the ethical and legal status of which remains unsettled. The risk of infringing patient rights is far greater where

the grounds are not explicit, because unspoken and illegitimate biases may be influencing behaviour.

Personal conscience-based objections

Critical care clinicians are also sometimes faced with situations in which they have a personal, moral objection to providing or disclosing information about a medical service, also known as a conscience-based objection. Such situations may be common in critical care due to the frequency of value-laden decisions with life and death consequences. For example, clinicians may have moral objections to disclosing information about the option of withdrawing nutrition and hydration, to offering or providing palliative sedation to unconsciousness, to participating in organ donation after cardiac death, or to providing advanced life support to patients with a poor prognosis [14].

There are numerous reasons to accommodate clinicians' conscience-based objections, such as by transferring care to an alternate clinician. Doing so allows the objecting clinician to preserve their moral integrity and to avoid moral harm associated with acting contrary to moral beliefs. It may improve medical quality at the population level by allowing a diverse clinical workforce, which is especially valuable in pluralistic society. Moreover, accommodating conscience-based objections may help identify needed changes in professional norms and practices.

However, it would be an illegitimate violation of patient rights if the clinician's CBO resulted in the patient not receiving legal, accepted medical services. Instead, clinicians should continue to provide treatment to the patient until an alternative provider can be found. Although doing so may impose a burden both on the clinician (e.g. feeling complicit in a treatment plan that violates their moral beliefs) and on the patient (e.g. the delays and inconvenience associated with transferring care to an alternate provider), this approach is a compromise that preserves respect for both clinicians' moral integrity and patients' right to legal, accepted medical services [15].

Legitimate infringement and distributive justice

While patient rights are sometimes unjustifiably violated, as mere *prima facie* claims, they are sometimes permissibly infringed. Rationing of critical care is both necessary and unavoidable. For example, it is common to transfer a patient out of an intensive care unit (ICU) when she still might derive some small benefit from ongoing monitoring. Such transfer accommodates the need of sicker patients in the face of a finite number of ICU beds [16].

Distributive justice refers to fairness in the distribution of limited resources. Fairness refers to giving equal treatment to all patients who are similarly situated with respect to relevant characteristics, but there are competing principles to guide such allocation—utilitarian, egalitarian, prioritarian, and the rule of rescue. Because reasonable people may be unable to agree on which principles should guide rationing, these should be determined through a fair process like that described in the section 'Balancing Patient Rights and Clinician Rights'.

Legitimate infringement and clinician rights

Patient rights may be infringed not only by the needs of the community, but also by the rights of clinicians themselves. Clinicians sometimes refuse to comply with patient treatment decisions either on the basis of professional integrity or on the basis of personal conscience-based objections.

Professional objections to medically-inappropriate treatment

Patients sometimes request treatments that either will not work or that clinicians believe are medically inappropriate under the circumstances. Often this is because the clinician judges that the potential benefit is either not probable enough or not great enough to be worthwhile. Clinicians may object to such treatment because they want to avoid patient suffering, to protect the integrity of the medical profession, to avoid moral distress, and/or to promote good stewardship [8,17].

Balancing patient rights and clinician rights

There are four leading mechanisms by which patient rights are balanced against clinician rights—prevention, mediation, established socially-accepted rules, and procedural due process.

Prevention

Clinicians should focus efforts on preventing treatment disputes between clinicians and surrogates, rather than focus on developing policies to manage such disputes once they occur. Most clinician–surrogate disagreements arise not from intractable value conflicts, but from inadequate communication and support in the face of the emotional and psychosocial difficulty of facing death. These conflicts can often be avoided by coordinating effective family meetings, providing family centred communication, and fostering shared decision making.

Mediation

While good preventative efforts can reduce the number of disputes, they will not eliminate conflict altogether. Fortunately, clinician–surrogate disputes are not generally intractable and can be resolved collaboratively through ongoing dialogue. Ethics consultants, social workers, chaplains, ethics committees, legal counsel, ombudspersons, and other hospital resources are quite effective at achieving consensus. Therefore, clinicians should focus on consensus building through counselling, negotiation, and mediation.

Established socially-accepted rules

If a dispute proves intractable, it should ideally be resolved by appeal to established, widely-accepted rules. Such rules (e.g. brain death, prioritization strategies for organ allocation) have normative weight in proportion to the degree that they are:

- Explicit.
- Developed with diverse input.
- Based on explicit, defensible reasons.
- Overseen by groups viewed as legitimate policymakers.

Unfortunately, very few rules have been developed for the types of situations (e.g. critical care for patients in a persistent vegetative state) that commonly produce intractable conflict.

Requests for treatment that the clinician believes is medically inappropriate should not be managed unilaterally, unless the requested intervention is the subject of one of these rules or would

be wholly ineffective at achieving the patient's goals. This is because judging whether a treatment, which could potentially achieve a patient's goals, is nonetheless inappropriate involves complex value judgments at the intersection of medicine, law, and ethics. Individual clinicians may lack the necessary expertise to independently manage such dilemmas. In addition, given substantial diversity in clinicians' attitudes about appropriate treatment near the end of life, allowing individual discretion risks unwarranted treatment variability in which similarly situated patients receive different treatment [18].

Procedural due process

In the absence of a widely accepted rule, when a surrogate requests treatment that the clinician believes is inappropriate, the dispute should be managed through a fair process of dispute resolution. Such a procedural resolution process does not force rigid, predetermined templates onto situations that are often complex and highly nuanced, and may be better addressed in an individualized way.

Such processes should conform to accepted principles of due process. First, the surrogate must be given adequate notice that a process-based resolution procedure has been undertaken, the steps involved in such a process, and the anticipated timeline. Secondly, the review should be undertaken by a multidisciplinary hospital committee that includes representative members of the community as active members. This committee's task is both to evaluate the clinician's judgment about whether the requested treatment is inappropriate and to oversee the remaining steps in the process. This committee should actively elicit the surrogate's input into the process. Thirdly, the clinician and facility should afford an opportunity for transfer to a willing provider. Finally, the surrogate must be afforded the opportunity to appeal the hospital committee's decision to an impartial third party, such as a court or other socially-sanctioned mechanism [19].

Conclusion

The physician charter on professionalism observes that medicine's commitment to patient rights is being challenged by external forces of change within our societies [20]. While patient rights are not absolute, clinicians must not override them without compelling reasons and through fair processes.

CHAPTER 27

Medico-legal liability in critical care

Michael A. Rie

Key points

- Malpractice law arose 1000 years ago from the ethic of fiduciary trust relationships in feudal monarchies of England and Europe.
- This 'Common Law' holds professionals accountable to the trust relationship (doctor–patient or team–patient) and not the beneficiary (patient).
- Legal accountability in democratic nations recognize widely divergent understandings of individual 'rights of consumption' in balance with judicially recognized transparent efficiency and health care outcomes.
- Efficient medical errors management is procedurally changing in 2012 as we move from expensive adversarial legal proceedings to medical disclosure, apology, and preventive settlement offer (Disclosure, apology and offer methodology).
- All critical care medicine (CCM) professionals should educate their respective judiciaries in preserving the ethical integrity of our profession, while preserving public trust in the fiduciary relationship.

Introduction

Contemporary critical care medicine is team-based care. Malpractice accountability and liability (under rule of law) arose from Plato and the Hippocratic tradition. Patient and physician freely met in a relationship of trust for the betterment of the patient's welfare. Neither was obligated to join the endeavour and each could withdraw without external constraint. Although resources were limited, Greek physicians avoided 'rescue' when patients were overmastered by their diseases [1].

To address malpractice negligence and professional accountability we should first ask who is the patient in the eyes of the judicial system, how that image may be changing, and what are the standards of care that society expects, while providing (or failing to provide) necessary resources to produce the care. The past generation has produced a migration of health policy from individual-centred finance and regulation to population-based financial distribution criteria, driven by evidence-based outcomes. Praiseworthy as such goals may be, they will fall short at legal challenge. Much of what we offer patients lacks clear evidence, often requiring unethical clinical trial designs or revision of marginal evidence prior trials [2,3]. The imbalance between the service demand for marginal outcome success and the societal ability to supply services not paid for by individuals produces moral strife of finitude [4,5]. Thus, national policy conflicts of interest are rendered to the patient care delivery level. Within this mayhem, patients and professionals continue to receive and deliver care. We should accept our role in defining limits of individual rights of consumption (under rule of law). Rights require balance with morally prioritized and defined minimal standards of care for those patients cared for by public funds. However, private ownership of money requires ability of the well off to buy more. Such a lawful multi-tiered system of health insurance was created in the Oregon Health Plan in the 1990s [6], and adopted by the Netherlands and other western democracies. Infrastructure for critical care implementation should soon emerge [6–9].

This chapter adopts classical medical ethics [10] as the historical source of judicial authority for professional fiduciary relationships. Developed in medieval times, fiduciary trust relationships define professional duty to the trust relationship and not the beneficiary (patient) [11–13].

Nations differ in judicial enforcement of critical care resource limitation policies when challenged by individual patients [14]. In New Zealand (with few intensive care unit (ICU) beds), the courts have consistently upheld the policies promulgated and adopted by professionals [15]. Such explicit finite resource allocation policies are not developed or codified in the USA or Germany [16] (where more ICU beds exist).

Clarity requires the elimination of politics, religion, national budgets, economic global recession, and other geopolitical sources from Common Law understandings. The English Common Law arose from property law and the creation of contract law (trusts) in the feudal period of absolute monarchy. Preceding creation of the seventeenth-century parliamentary system, the Common Law was retained as to contracts and trusts. Common Law originally applied to nobles responsible for collecting taxes for the King. If a noble died with the oldest son and heir still to be raised to adulthood, 'trustees' were responsible for preserving the estate, raising the future heir (landowner), and collecting the taxes. Failure to do so was held punishable by the King under rule of law. The rise of merchant trades and professions (law and medicine) were incorporated into the laws of contracts and trusts, and continue to the present. It is the courts that interpret the meaning of the patient–doctor relationships, including mutual obligations and limitations. These laws have undergone continuous and slow modification by the

courts as to the definition of obligations owed by physicians to the beneficiary (patient). The present population-based health care methodology remains to be reconciled with the Common Law in all countries that have adopted the Common Law. To better analyse judicial meanings of our fiduciary duties, we begin with the analogy of critical care teams as champion ballroom dancers or Olympic skating pairs. The changing nature of medical care, technology, and drug innovation has led to continuous improvements in the care of patients. What might have been 'standard practice' in year 1 would be obsolete and below the contemporary standard in year 50. However, honest discussions with patients and families would be constant over time eventually including entitlement limits to non-evidence-based service demands. As the ethical and legal foundation of 'professionalism' relies on the trust that individual patients, the public or political and governmental society have in their professionals, all of us and patients must be held to standards of champion ballroom dancers and skaters. We must perform in perfect harmony with patient(s) to achieve the best that can be hoped for and contextually framed by circumstances of resource finitude, innovation and the present state of medical science. However, professionals, health care systems, individual patients, and non-governmental mass demonstrations may not legally disrupt the size of the ballroom, skating rink, or how long the music plays.

This text appears during sustained global economic malaise. Professionals in national health systems (Canada, UK, France, Netherlands, Australia, New Zealand) and the complex American regulated free market all share the necessity to publically articulate intrusions upon professional integrity created by all forces external to fiduciary trust that are not transparent and publically accepted [10].

This ancient principle is clearly enunciated in the Common Law doctrine of the *Parens Patria* ('The State as Parent of the People'). A cornerstone of Common Law predating the American Constitution and British conversion from absolute monarchy to limited democracy, the doctrinal duties are:

- Prevention of homicide.
- Prevention of suicide.
- Protection of innocent third parties (e.g. wards of the state, children of Jehovah Witness parents forbidding necessary blood transfusions to minor children).
- Protection of the Ethical Integrity of the Medical Profession(s).

In this changing world of resources, budgets, and finite funds available for health care, it will be incumbent upon the institutions of health care and our organized medical leadership to articulate our integrity and how it may be threatened by greater societal forces. The need for transparency and the quest of evidence-based truth and its articulation will be the first step [17] necessary to preserve the integrity of medicine and 'critical care rescue medicine' in the coming years. When we lack evidence and rely on 'judgment and experience' in care delivery, it is our moral and legal duty to defend individual and group integrity for all branches of government and the public. When necessary, judicial review and protection may be necessary. Conversely, when we know or should have known that our integrity is threatened by external forces, we should presumably disclose them as a risk management issue beyond our direct control.

While governments differ in payment methodology for drug purchase, hospitals and professionals have experienced widespread shortages of generic injectable drugs that are daily mainstays of our standards of care (e.g. propofol, midazolam, fentanyl, norepinephrine) in the USA, Canada, and other countries, i.e. Greece. Despite obvious disruptions in care delivery procedure, drug errors, and the arrival of underground 'grey markets', professionals, health systems, and health system researchers have not reported the presumed identifiable morbidity and mortality risk, including system inefficiency costs of ongoing shortages. Until such data is disclosed, our professional integrity is at risk; we should have known our patients were at risk, as we passively allowed standards of care to decline.

Case examples over half a century

Case 1

In 1972, a healthy 25-year-old female suffered multi-trauma in a road accident and was admitted to an early trauma centre. Bleeding and intra-abdominal injuries were surgically controlled. Post-operative care for respiratory failure with bilateral chest injury and rib fractures required volume cycled mechanical ventilation with an Emerson Post-Operative Ventilator widely used at the time. Unpredictable and undetected acceleration of ventilator rate resulted in intrathoracic pressurization and bilateral tension pneumothorax with cardiac arrest. Following resuscitation she survived for several years with anoxic ischaemic encephalopathy.

Comment

A lawsuit ensued. Under civil law judicial rules, a breach of the 'standard of care' (legal negligence) requires plaintiffs to carry the burden of proof demonstrating evidence (with reasonable probability) that the defendant was responsible for the injury. An adversarial relationship that previously existed in other areas of negligence law was woven into the culture of medical liability disputes. In this case, causation was attributed to equipment malfunction. No ventilator rate monitors, saturation metres, or pressurization alarms existed. The plaintiff could find nothing in the patient's record mentioning technology failure. Hospital and medical personnel were not forthcoming with explanation of the event. Subsequent plaintiff review discovered an unsigned nurse's note at the cardiac arrest. When located, the nurse divulged that he had been admonished by the trauma surgical director not to come forward with information about what had transpired. When presented to a court of law as evidence, a private settlement followed.

Since the 1970s, the number of malpractice cases has increased with public awareness. In adversarial 'battle of the experts', courts and juries rely on the accuracy and completeness of information supplied by medical experts for either party. The result is costly and prolonged expenses for lawyers, expert witnesses, and insurers before the matters are settled or tried in court. While a minority of cases comes to trial, those privately settled consume vast amounts of resources [18]. Their data suggest that costs of malpractice litigation may be decreased by a new process best described as Disclose, Apologize, and Offer. First developed in Michigan [19], this process is now thought to result in decreased costs of litigation for all parties. Massachusetts (a state moving to system wide value based health care payments) announced a state-wide pilot programme of the non-adversarial approach [20]. The underlying assumption is

to increase patient trust in medical care while decreasing cost and promptly recompensing patients for real errors.

Case 2

In 2008, a 50-year-old woman was admitted to ICU with viral pneumonia. Hypoxaemic respiratory failure followed necessitating intubation and ventilator support. Mentation was stable when not sedated. As weaning was not possible at 2 weeks, a surgical tracheostomy was performed and she returned to the ICU with a stable airway and prior ventilator parameters. That evening, following a bed bath, the patient's nurse noted significant air leak from the tracheostomy and cervical subcutaneous emphysema with decline of tidal volume. A critical care physician examined the patient and ordered a chest X-ray and noted differential diagnoses of airway dislodgement and pneumothorax in the patient's record. The physician's duty shift terminated and he failed to report this patient's precarious situation to the night-time physician. Air leakage continued, the patient became unresponsive and tachycardic with desaturation on pulse oximetry for at least 1 hour. The covering physician was called and arrived during cardiac arrest finding ICU nursing staff bag ventilating the tracheostomy, while performing cardiopulmonary resuscitation. The physician replaced the tracheostomy with an endotracheal tube in a displaced trachea. No breath sounds were heard on the left and subcutaneous emphysema was prominent. A chest tube was placed once oxygenation and vital signs were re-established. The next day the surgeon re-established the tracheostomy within the prior intact tracheal incision. She survived in anoxic ischaemic coma with tracheostomy and gastrostomy in a chronic care centre.

Comment

Extensive review was conducted by experts for both parties. Hospital records showed no available policies and procedures for medical hand-offs in ICU. No policies and procedures consistent with contemporary hospital standards could be identified defining guidelines or parameters for calling physicians when ventilatory or vital function problems developed. Continuous electrocardiographic monitoring station and technician were present, but recordings could not be located for this sentinel event. Evidence was provided explaining the mechanism of airway dislodgement and its necessary re-establishment as the standard of care, which was not followed. One day before trial, the matter was privately settled. Such agreements typically contain non-disclosure secrecy provisions. Little is divulged to shed light on procedural migration to the non-adversarial proposed changes.

Conclusion

Comparing adversarial cases with the evolving disclosure, apology, and offer culture will take time and data. If there has been direct injury from a medical error in a negligence proceeding, the possibilities for improving the efficiency of negligence proceedings (cost containment) and recompensing injured patients promptly may become established. Challenges along the way may go to court by patients. Professionals may also seek court protection when the desired outcomes could not be produced. Resource deficiencies could then be demonstrated as evidence of system-generated invasions of professional integrity. The new frontier of justice is on the horizon.

PART 1.8

Critical illness risk prediction

CHAPTER 28

The role and limitations of scoring systems

Hannah Wunsch and Andrew A. Kramer

Key points

- Severity of illness scores are frequently used in critical care settings to describe patients.
- The most common severity of illness scores use patient data from the first hour to 24 hours immediately after admission to the intensive care unit (ICU) to predict short-term outcomes, such as hospital mortality.
- Severity of illness scores are extremely useful for comparing risk-adjusted outcomes between ICUs, as well as within an ICU over time.
- The use of severity of illness scores must be tempered by the inherent limitations of current systems, including variable performance outside of derivation cohorts, inability to accurately predict outcomes for individuals, and performance decline over time.
- Future systems may include the prediction of long-term outcomes and assimilation of granular data temporally, and at the molecular level that could result in more personalized severity scores to help guide individual care decisions.

Introduction

The concept of scores that provide information on the severity of illness for critically-ill patients and allow for comparison of outcomes between different cohorts of patients is now over 30 years old. The field of critical care has seen a proliferation of scores since then [1–4]. The majority of these scores use information gleaned from patient status on admission or within 24 hours post-admission to the intensive care unit (ICU). Either the severity score itself, or components of the score, can then be used in multivariable models that predict duration of stay or mortality at the end of the acute hospitalization. This chapter describes the most common general ICU scores that were initially developed to predict short-term mortality, uses of these scores, limitations, and future directions.

Main scoring systems in use for intensive care

General ICU scoring systems are complex to develop and require periodic updating. As a result, there are only a few scoring systems in general use today (see Table 28.1). The oldest system is the Acute Physiology and Chronic Health Evaluation (APACHE) score. Created in the 1980s and updated intermittently, APACHE's main score is made up of three components: the Acute Physiology Score (APS), age, and chronic health items indicative of severe underlying disease. The most current published version is APACHE IV [1]. An earlier version, APACHE II, is still widely used [5], probably due to its free availability, as well as its previous application in determining eligibility for recombinant activated protein C use in US patients with severe sepsis [6]. However, the accuracy of APACHE II for contemporary ICU populations is equivocal [7].

The Simplified Acute Physiology Score (SAPS) was initially developed in Europe as an alternative to APACHE's complexity [2]. While using many of the same data items as APACHE's APS, the SAPS requires the worst physiologic value within the first hour post-admission, rather than the first 24 hours, as in APACHE. The Mortality Probability Model (most recently MPM0-III) was developed using USA ICU data from the Project IMPACT database [3]. Like SAPS, variables used to generate an MPM prediction are captured within the first hour after admission to the ICU. Of the equation's 16 variables, 15 are binary responses to items representing a patient's condition, and one continuous variable (age). The idea behind MPM was to arrive at a predictive model that could easily be implemented. Finally, the United Kingdom has its own severity of illness system (ICNARC score), developed using information from National Health Services ICUs in England, Wales, and Northern Ireland [4]; the ICNARC score is very similar to APACHE.

All of the systems except for MPM rely heavily on physiology. APACHE IV and ICNARC have substantially more diagnostic categories than the other systems. The number and type of outcomes that are predicted also differ; most (APACHE II, SAPS, and ICNARC) predict only hospital mortality; MPM also has an equation to measure weighted hospital days. APACHE IV has equations for predicting hospital and ICU mortality, hospital and ICU length of stay, duration of mechanical ventilation, and need for active therapy. As well as generating a score for general use, SAPS 3 also provides different weights for the equation that can be applied in individual regions of the world.

The majority of scores were developed on very large cohorts (>100,000) of ICU patients. While APACHE, MPM, and ICNARC were all developed on data from a single country, the development of SAPS 3 included admissions from ICUs in 35 countries. Other than APACHE II, each system currently in use was developed within the past 10 years, with fairly similar exclusion criteria (Table 28.2). Most notably, the majority of these scoring systems cannot be applied to cardiac surgery patients or burn patients.

Table 28.1 Selected information collected for APACHE II and the most recent versions of the APACHE, MPM, SAPS, and ICNARC scoring systems

	APACHE II [5]	APACHE IV [1]	MPM_0-III [3]	SAPS III [2]	ICNARC [4]
Age	Yes	Yes	Yes	Yes	Yes
Type of patient (medical/surgical or planned/unplanned)	Yes	Yes	Yes	Yes	Yes
Co-morbidities (#)	Yes (5)	Yes (7)	Yes (3)	Yes (14)	Yes (6)
Location prior to ICU admission	No	Yes	No	Yes	Yes
Length of hospital stay prior to ICU admission	No	Yes	No	Yes	Yes
Cardiopulmonary resuscitation prior to admission	No	No	Yes	No	Yes
Mechanical ventilation within the first hour or first 24 hours	No	Yes, 24 hours	Yes, 1 hour	No	Yes, 24 hours
Disease categories (#)	Yes (50)	Yes (433)	Yes (6)	Yes (39)	Yes (709)
Physiology measurements					
Vital signs	Yes	Yes	HR and MAP	All but RR	Yes
Arterial blood gases	Yes	Yes	No	Yes	Yes
Glasgow coma score	Yes	Yes	Yes	Yes	Yes
Albumin	No	Yes	Yes	No	No
Bicarbonate	Yes	No	No	No	Yes
Bilirubin	No	Yes	No	Yes	No
Blood urea nitrogen	No	Yes	No	No	Yes
Creatinine	Yes	Yes	No	Yes	Yes
Glucose	No	Yes	No	No	Yes
Haematocrit or haemoglobin	Yes	Yes	No	No	Yes
Lactate	No	No	No	No	Yes
Platelet count	No	No	No	Yes	Yes
Potassium	Yes	No	No	No	Yes
Sodium	Yes	Yes	No	No	Yes
Urine output	No	Yes	No	No	Yes
White blood cell count	Yes	Yes	No	No	Yes
Outcomes predicted					
Hospital mortality	Yes	Yes	Yes	Yes	Yes
ICU mortality	No	Yes	No	No	No
Hospital length of stay	No	Yes	No	No	No
ICU length of stay	No	Yes	Modified*	No	No
Duration of mechanical ventilation	No	Yes	No	No	No
Need for active therapy	No	Yes	No	No	No
Daily mortality predictions	No	Yes	No	No	No

*Weighted hospital days: weights ICU days more than days on acute care floor.

HR, heart rate; MAP, mean arterial pressure; RR, respiratory rate.

Data from various sources (see references).

Other scoring systems: organ-specific, therapeutic, and disease-specific

Other types of scoring systems focus on organ-specific information that can be examined as a trend to assess the trajectory of a patient, or number and types of interventions required—either as the predictor or outcome [8–10]. Two scores in particular, the Multiple Organ Dysfunction Score (MODS), and the Sepsis-Related Organ Failure Assessment (SOFA) score, include information that characterizes specific organ dysfunction or failure, and may be assessed at multiple times during the ICU stay [8,9]. The benefit of these scores is that they provide more specific information regarding

individual organ function. However, they were not developed to be used as a general scoring system across all critically-ill patients. The Therapeutic Intervention Scoring System (TISS) first developed in 1974 [11], and then simplified to the TISS-28 [10] takes a different approach, focusing on quantifying nursing activities for patients in the ICU, with the idea that the workload required to care for patients is a measure of the severity of illness. Other types of scores help assess the risk of an event occurring, such as prediction of need for organ support in intensive care [12], or may be disease-focused, such as the Ranson criteria for acute pancreatitis [13].

Model performance and use

Model accuracy can be measured in two ways—discrimination and calibration. The former gauges how well a model predicts mortality. It is usually assessed by calculating the area under the receiver operating characteristic curve (AUROC) [14]. This statistic is based on randomly sampling all pairs of patients in which one patient died and another survived. The percentage of pairs in which the patient not surviving has a higher probability of mortality than the surviving patient is the AUROC. All of the models described had an AUROC value >0.80 (good to excellent) for predicting mortality (Table 28.2) [1–5]. APACHE IV and ICNARC had the highest AUROCs, probably due to using single-country data, inclusion of diagnostic group information, and inclusion of physiology variables gathered from data over 24 hours.

Calibration measures the extent to which a model accurately predicts probability across a population. There are many ways of assessing calibration, including the Standardized Mortality Ratio (SMR), graphs of observed versus predicted probability, the Hosmer–Lemeshow statistic, and the Brier score. All of the models described had acceptable levels of calibration when applied to the patient population in which the model was developed.

Severity of illness scoring systems can be used in a variety of ways. Their most frequent use is as a variable in predictive models, which are then employed in benchmarking efforts. For example, hospital mortality for patients in an ICU may be evaluated by taking the number of deaths over a specific time period and dividing that by the predicted number of deaths over the same period (SMR). The SMR for an ICU can be tracked over time to evaluate an ICU's performance. This kind of analysis is usually used for internal quality initiatives. Alternatively, ICU SMRs can be compared with each other to assess comparative effectiveness.

Scoring systems are also used as a descriptive comparator across patient groups in research studies. Most commonly, the severity of illness scores are then included in multivariable models as a method of adjusting for any differences in the severity of illness between groups in studies. The severity score is usually highly significant and, therefore, in outcomes studies the inclusion of case mix adjustment is strongly advised. Finally, the severity of illness scores have sometimes been used as a stratification variable in randomized clinical trials to ensure balanced groups.

Limitations of scoring systems

Scoring systems have many uses, but they also have limitations that must be recognized. Each scoring system attempts to balance the number and type of variables against the accuracy of the prediction. While addition of variables may improve a predictive model,

Table 28.2 Patient populations used to develop current severity of illness scoring systems

	APACHE II	APACHE IV	MPM-III	SAPS 3	ICNARC
Dates of admission to ICU	1982 primarily	2002–2003	10/2001–3/2004	10/2002–12/2002	12/1995–8/2003
No. of admissions	5815	120,345	124,885	16,784	216,626
Location of patients	United States	United States	United States	35 countries	England, Wales, and Northern Ireland
No. of hospitals	13	45	98	NA	NA
No. of ICUs	19	103	135	303	163
Discrimination accuracy (AUROC)	0.86	0.88	0.82	0.85	0.87
Excluded patients

Cardiac diagnosis	CABG patients	None. CABG patients get separate set of predictive equations	Cardiac surgery, acute myocardial infarction	No	No
Burns	Yes	Yes	Yes	Yes	No
Transplants	Yes, except kidney not excluded	Yes, except liver and kidney not excluded	No	No	No
Other	Missing any physiology values. ICU stay <8 hours	ICU length of stay <4 hours	None	None	None

CABG, coronary artery bypass grafting; AUROC, area under the receiver operating characteristic curve.

Data from various sources (see references).

this is offset by the increased data burden necessary to collect that information. All of the scores require accurate data collection on a range of variables associated with an individual patient, which can be a time-consuming process and may require some training [15]. The adoption of electronic medical records may improve the ability to gather these data in a more timely fashion, but this process is still hampered by differences in electronic systems and variations in data input.

Severity scores were initially developed to predict in-hospital mortality. However, changes have occurred in critical care over the past two decades that can affect the measurement of in-hospital mortality as an endpoint. Most prominent is an increase in the discharge of patients to post-acute care facilities [16]. Appreciable mortality occurs well after patients are discharged alive from the hospital and may still be related to the critical illness [17]. For example, in the USA some critically-ill patients—many of whom may still be ventilated and/or requiring vasopressors or inotropes—are now discharged to long-term acute care facilities [16]. These changes in practice may significantly shift reported hospital mortality and SMRs [18].

Current predictive models using severity scores were developed to be applied to groups of patients. Although the accuracy of these systems is quite good at the cohort level, they are not intended for assessing an individual patient's course. This weakness is borne out in head-to-head studies of predictions by clinicians and scores, where the clinicians were equal to or more accurate than the models [19].

The performance of current predictive models on patient populations outside of the cohort used for development (external validity) is modest to poor. Calibration, the accuracy of a model over a patient cohort, usually suffers. As a result the ability to compare risk-adjusted outcomes for patients across different regions or countries is compromised. The SAPS 3 scoring system provides different equations for different regions. While this approach may allow for broader use of the score globally, it still does not address this limitation of comparison between regions.

Finally, even well calibrated models tend to show 'fade' over time [20], most likely due to a combination of changes in case mix and the delivery of care that shift patient mortality. Models, therefore, require recalibration periodically to ensure that the predictions remain robust.

Future possibilities for scoring systems

There are a number of directions that research into scoring systems may move to accommodate changes in the field of critical care. The first is recognition of the continued increased risk of both morbidity and mortality after hospital discharge, leading to new interest in risk prediction models that use end-points such as 6-month mortality, or focus on patient populations that are likely to have high long-term morbidity and mortality. Secondly, current scoring systems implicitly assume that patients are identical in their reaction to physiological distress and response to subsequent treatment. Adding genetic and other molecular markers may result in predictions that are patient-specific in their scope. A final change may be continuous assessment of physiology—incorporation of data from earlier in an illness/hospitalization, updates of predictions as the course of critical illness evolves to allow for adjustment of the original prediction, and assessment of real-time data for overall change and variability across time.

CHAPTER 29

Severity of illness scoring systems

Graeme K. Hart and David Pilcher

Key points

- Severity of Illness Scoring Systems enable meaningful comparisons, and identify 'similarities' within patient cohorts or across diverse care settings.
- It is important to understand the strengths and biases of the available models when selecting a model for a given audit or research purpose.
- Worst in 24-hour models have potential for poorly performing units to have higher severity of illness indices and, hence, lower (better) standardized mortality ratios.
- Large 'big data' administrative data sets may prove useful and with accurate data linkage to intensive care unit (ICU)-based datasets can provide cost-effective longer-term (30–90 days or greater) outcomes.
- The use of risk adjustment models by clinical quality registries or government regulators for hospital peer review and quality assurance is important, but must recognize that statistical signals only identify a potential problem and data quality must be carefully validated before conclusions can be reached.

Introduction

Inter-group comparisons are central to medical science in randomized controlled trials, performance comparisons between hospitals and clinicians, or in assessing changes to care processes within an institution. Case mix and severity adjustment is critical for meaningful understanding. No adjustment system is perfect, and understanding their strengths and limitations helps avoid erroneous conclusions.

Severity of illness scoring and outcome modelling of patients in the groups being compared are used to ensure appropriate adjustments. Selecting the correct outcome measure is important as not all measures have equal reliability, ease of measurement, or validity. Comparators used in health care systems include physical or activity metrics such as institutional size, academic role, procedure numbers (oesophagectomy, prostatectomy, whipples, cardiac surgery), uptake of electronic health records, and case mix. Critical care comparators are based more on the characteristics of the patients than those of the institution, although the latter may be relevant when comparing outcomes across international and social system boundaries. In general, all patients with the same illness should receive the same chance of a good outcome, regardless of their socio-economic standing or care setting. To this end, critical illness scoring systems do not contain elements in the models for these parameters. This is to enable research studies or quality improvement activities to be conducted on an international scale and for systems performing less well to 'benchmark' themselves against others. Pragmatically, care settings within each 'region' compare themselves to peers to promote improvement within given constraints.

Severity of illness scoring systems are most commonly applied in three settings:

- **Randomized controlled clinical trials**: internationally validated scoring systems facilitate the balancing of severity of illness between treatment arms to ensure inadvertent bias does not corrupt the study outcome.
- **Clinical quality data registries**: several regional or national registries have been established to provide quality assurance and peer review of critical care unit performance within their jurisdictional governance frameworks (ANZICS CORE, ICNARC, Dutch National Intensive Care Registry, NICE). Registries use risk-adjustment models to provide meaningful comparisons and identify sites where statistical variation may identify outlier performance requiring further investigation.
- **Quality assurance and improvement**: assessment of an intensive care unit's (ICU's) performance over time depends on the ability to adjust for illness severity and, hence, identify other factors impacting outcomes, such as specific quality improvement interventions or structural change.

Severity scoring systems measure only one attribute of unit performance (ICU or hospital mortality) and other measures of quality and performance may be equally important. Current scoring systems do not measure quality of life, or survival past ICU or hospital discharge.

Severity of illness scoring systems

Systems must ensure the population of interest is clearly defined, a statistical sample size in the development model that provides adequate power, model components that are meaningful for the comparisons to be undertaken, and model elements free of potential for systematic bias that are freely available as part of the care process and represent the impact of the illness as distinct from the impact

of treatment. The individual elements must be robust in their measurement and likely to be used over long time periods. In order to be useful, appropriate training and data quality systems must be in place to ensure acceptable and consistent use of the model.

Models must be validated in diverse settings and purposes to which they will be applied. Periodic recalibration ensures that they remain relevant and adapt to the impact of evolving case mix on the calibration of the model [1,2]. Another area of potential bias in the models relates to the scope of the models prediction. Assessment of mortality at ICU discharge (Simplified Acute Physiology Score (SAPSII)), versus hospital discharge (Acute Physiology and Chronic Health Evaluation (APACHE) II, III, IV) versus 3-month outcomes, allows variation in discharge practice to impact measured performance [3]. As ICU resources are scarce and expensive, there are pressures to discharge patients to the lowest cost care location that can manage them. Patients may be discharged from ICU to die on the ward or at palliative care locations. Survivors may be discharged to long-term ventilation facilities in some countries and, hence, survival or length of stay may be improved compared with countries where such facilities do not exist. Determining impact of ICU care on mortality may be significantly affected by these practices, and will change over time and between hospitals, regions, and countries. The impact of disease processes on ultimate survival can be immediate or long term and there is value when determining trial outcomes or cost effectiveness to examine outcome over longer time periods. This is generally expensive to achieve, however, where there is access to state death registries, this is more easily achieved through data linking technologies. Outcomes also vary depending on the primary disease and are predicted by Organ Failure Scores and APACHE [4]. In cardiac surgical cohorts, the hospital discharge mortality and the 30-day mortality were almost identical with only a 0.6% increase in deaths between the two measures. Mortality at 90 days increased further to 0.9% [5].

APACHE (I–IV)

The work of Knaus et al. [6], at George Washington University, pioneered severity adjustment in the critical care environment. Successive iterations of the APACHE model have refined diagnostic classifications, definitions, and process descriptors, and larger samples in the logistic regression models have increased reliability. The initial APACHE system was developed in five hospitals in the USA with 795 patients in the development set. APACHE IV, by contrast, used 110,558 patients in 45 USA hospitals. The APACHE IV model was derived from ICUs using the APACHE III computerized data collection and analysis system acquired by Cerner Corporation of Kansas City, Missouri, USA. Criticisms of the APACHE III and IV models included commercial ownership, continuous computer-based physiology variable acquisition (increases the score by up to 25% [7] and use of 'worst in 24-hour variables'), rather than admission values. Lead time bias refers to treatment-related changes in physiology to bias results. Poorly-performing units, paradoxically, may have 'sicker' patients and an improved Standardized Mortality Ratios (SMR) [8]. Although APACHE II score is still used in many studies, APACHE II risk of death for routine benchmarking of ICU outcomes is inappropriate, not least because of the dramatic increase in minimally-invasive surgery, which is not represented in the classification framework or prediction algorithm, and lack of recalibration. APACHE III was the first version of the model to include cardiac surgery and persisted with worst in 24 hours post-admission physiology variables. There are 78 diagnostic categories and 20 physiological variables. It was derived in 40 US hospitals from 17,440 consecutive patients. APACHE III has had multiple revisions of its prediction algorithm.

APACHE IV

APACHE IV [9], which expanded and modernized admission diagnoses, included additional pre-admission variables and broadened the range of locations and settings (104 ICUs in 45 North American hospitals, 110,558 admissions in 2002–2003). It uses a non-linear regression model with four spline terms.

SAPS 2

The Europeans, led by Jean Roger Le Gall, aimed to develop and validate predictive models for medical and surgical patients with greater international validity [10]. The models are based on the hospital outcome of 13,152 consecutively-admitted adults (65% development and 35% validation). It uses 17 variables—12 physiology, age, admission type, and three co-morbidities. The sample was derived from 137 units in 12 countries. Areas of potential bias relate to the self-selection of the contributing units, although the performance as judged by the area under the ROC curve was 0.86.

SAPS 3

SAPS 3 updated predictive models and increased international validity [11]. Both ICU and hospital outcome models were developed in 2002 from 19,577 consecutively admitted patients, over age 16, from 307 units in 35 countries. Contributing ICUs were self-selected.

Australian and New Zealand Risk of Death Model

The Australian and New Zealand Risk of Death Model [12] was recently published and derived using 450,000 adult admissions at 140 ICUs in Australia and New Zealand. In contrast to other scoring systems, the only patients excluded are those whose reason for admission to ICU is for palliative care or organ donation. It also employs eight separate prediction equations (one for each major diagnostic group), which allow more appropriate weighting of components (e.g. a higher weighting for Glasgow Coma Score in neurological and trauma patients than in post-operative cardiac surgery patients).

Mortality Prediction Model

Mortality Prediction Model (MPM) was introduced in 1985 and was cognisant of the potential for gaming by developing both admission and 24-hour models. It excluded patients <14 years old, and those admitted for cardiac surgery, coronary care, or burns. The development data was collected in one country from 755 consecutive patients. The MPM0 (admission) model uses seven variables. The MPM24 (24-hour) model used data from 458 patients still in the ICU 24 hours after admission.

MPMII

MPMII is the revised 1993 model [13] developed in patients from 12 countries. There were 12,610 in the development, and 6514 in the validation cohorts, which excluded patients <18 years, and those admitted for cardiac surgery, coronary care, or burns.

The $MPMII_0$ (admission) model uses 15 variables, is treatment independent, and avoids single principle diagnosis categorization. The MPM_{24} (24-hour) model was designed to update the prediction for longer-term ICU patients who are 'different' to those being discharged earlier. It contains five of the admission variables and eight additional variables easily ascertained at 24 hours.

Therapeutic Intervention Severity Score

The ability to reduce treatment bias in the first 24 hours post-ICU admission was raised as one of the benefits of the MPM0 scoring system. Poor ICU performance resulting in worsened physiology could increase the severity score and, hence, paradoxically improve the standardized mortality ratio. Some of the earliest work on severity of illness modelling and resource utilization was based on the therapeutic interventions required to maintain physiological stability as markers of severity. If high doses of inotrope were required to maintain blood pressure, a score based on the dose requirement may actually be more reliable than the blood pressure measure in its own right. This premise was used to develop the Therapeutic Intervention Severity Score, TISS-76, in 1974, which was updated in 1983, incorporating newer interventions and its subsequent simpler version TISS-28 [14]. This system has been used not only for outcome prediction, but also for nursing acuity and activity measures, staffing allocation, and predicting the safety and reliability of discharge from the ICU.

Administrative datasets for use in risk prediction and stratification

Dependence on manual data collection and entry carries risk of inter-rater reliability, systematic data collection bias, training overheads, and cost. Clinical information systems enable automated or semi-automated data entry, but may introduce other problems [7] and require vendors to co-operate for submission to regional clinical quality registries, update prediction algorithms and calculations. Non-'ICU specific' data models supplement ICU-based systems. Administrative databases use abstracted medical records coded after discharge. Intensive care risk prediction modelling can be performed on such data with some degree of confidence. The Critical Care Outcome Prediction Equation (COPE) was developed using ICD10-AM codes for hospital admissions with ICU hours recorded in the Victorian Department of Health Administrative Episode Dataset (VAED). The Area under the Receiver Operator Curve ROC Curve for risk adjusted survival is 0.82 after stratification for hospital level (tertiary, community, regional) [15]. Prerequisites for using administrative data include robust governance around data acquisition standards and audit excluding 'gaming' (as these systems are used for hospital funding). Where funding is based on coding, data quality audits by funding authorities ensure reliability. Such data has been used to demonstrate improved system wide outcomes of critical care interventions such as medical emergency teams (MET) over multiyear periods [16]. Administrative data (death register) set linkages can also enrich ICU risk adjustment models by follow-up to specific censor dates/date of death [4].

Cardiac surgery

Linked Veterans Health Administration and New York Cardiac Revascularization Registry data were used to develop multi-logistic regression models for risk-adjusted outcomes [17]. This model examined potential outcome and cost benefits of directing Veterans to 'High volume, Low mortality' hospitals. The Danish Heart Register (DHR) analysed 7 years of administrative information from the DHR (operation type, comorbidities), the Danish National Patient Register (previous 12 months admissions for specific cardiovascular, metabolic, renal, and pulmonary conditions), and the Centralized Civil Register for long-term mortality outcomes. A multilogistic regression model using 20,078 patients was developed. The additive EuroSCORE predictions contained in the DHR were compared with the new model, which was found to be comparable or slightly better [18].

Organ failure scoring

In the early to mid-1990s, more detailed examination of specific organ system dysfunctions were developed for both sepsis research and mortality outcome prediction. In Europe, the Logistical Organ Dysfunction System, in Canada the MultiOrgan Dysfunction Score [19], and subsequently the Sequential Organ Failure Assessment Score (SOFA) from Europe. Each system had some variations in definitions, and SOFA appears to have become the predominant model in current day use.

SOFA score

The SOFA score [20] was developed to enhance the assessment and time course analysis of critical illness organ dysfunction over the course of illness. Derived from 1449 patients in 40 adult ICUs in 16 countries, during May 1995, patients staying less than 48 hours or after elective surgery were excluded. This study assisted in the description of the time course of organ system deterioration or recovery in critical care illness. The median length of stay was 5 days, mortality 22%. Sepsis-based admissions had higher mortality (28.7%) and in the 544 patients with an ICU stay longer than 1 week, the increase of organ failure score predicated higher mortality rates.

Graphical techniques to identify performance trends and statistical outliers

Severity of illness scoring systems facilitate the comparison of mortality outcomes for an ICU. Graphical displays facilitate understanding of complex statistics. For appropriate analysis of the data, the risk adjustment model should be well calibrated, and the graph should be easily understood by the reader and lead to consistent conclusions. There are two broad types:

- **Cross-sectional risk adjusted charts** (e.g. Funnel Plots and League Tables): SMRs (the number of observed deaths divided by predicted deaths derived from a scoring system) of a group of ICUs are plotted.
- **Continuous charting methods** (e.g. risk-adjusted sequential probability ratio test charts and risk-adjusted exponentially weighed moving average charts) Sequential mortality outcomes of patients are plotted and compared with predicted mortality derived from a scoring system.

Common examples are shown in Fig. 29.1.

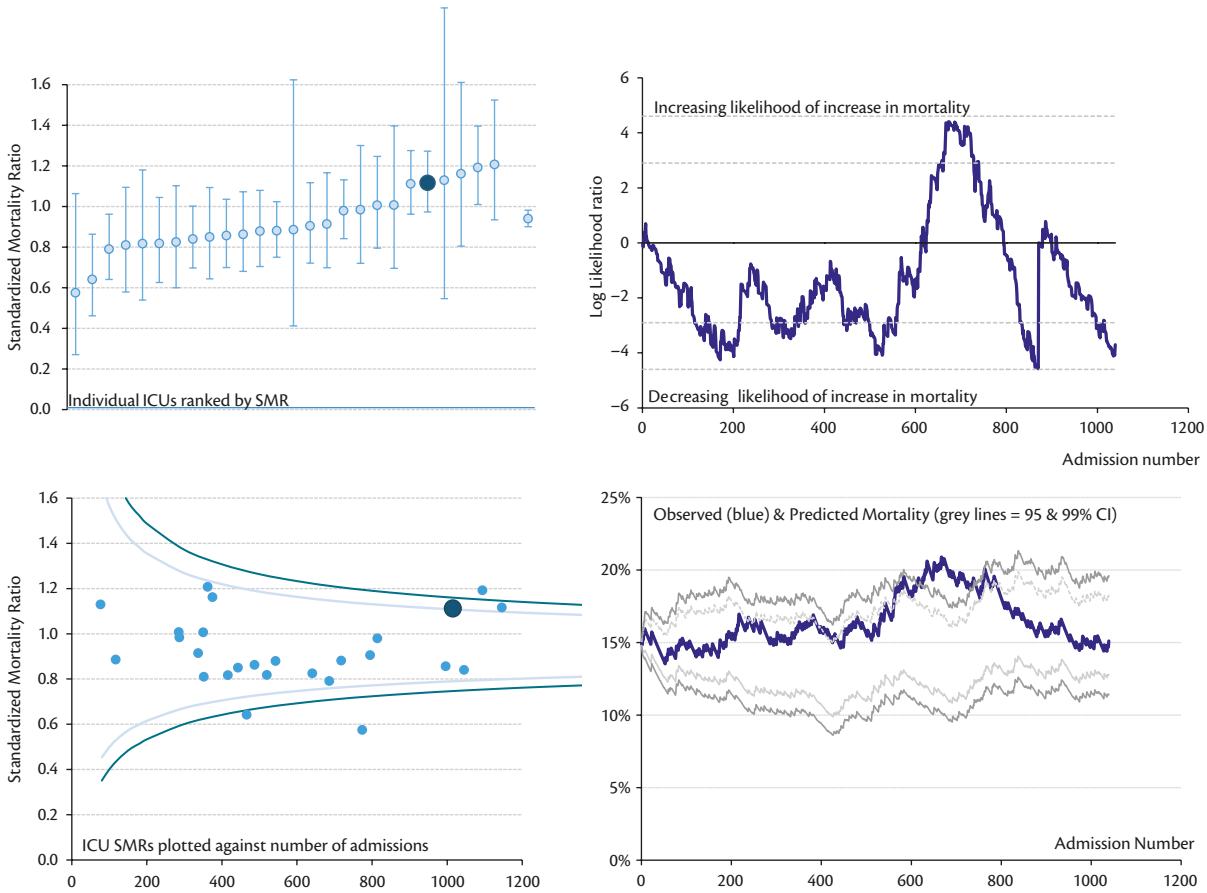

Fig. 29.1 All data from the same hospital showing graphical representation of comparative annual outcomes (SMRs) of one hospital plotted against others on the left of the figure and sequential mortality outcomes monitoring techniques for the same hospital on the right of the figure. This demonstrates a period in the middle of the year when mortality outcomes were above those predicted and thus accounted for the 'relatively high' SMR. (Top left) Caterpillar plot of SMRs arranged as league table. (Bottom left) Funnel plot showing SMRs of the ICUs plotted against number of admissions. (Top right) Risk-adjusted sequential probability ratio test. (Bottom left) Risk-adjusted exponentially weighed moving average chart.

Data from the Australian and New Zealand Intensive Care Society (ANZICS) Adult Patient Database 2011.

CHAPTER 30

Organ failure scoring

Rui Moreno

Key points

- The most commonly used organ failure scores (OFS) are the Sequential Organ Failure (SOFA) score, the Multiple Organ Dysfunction Score (MODs) and the Logistic Organ Dysfunction (LODs) score.
- Organ failure scores (OFS) are designed to describe organ dysfunction, in a sequential (or repetitive) way, during the entire ICU stay, in patients with critical illness.
- OFSs are designed to dynamically describe the patient with critical illness and not to forecast mortality based on a set of variables collected within the first hours or days in the intensive care unit (ICU).
- All OFSs consider organ failure as a spectrum or continuum of organ dysfunction that exists from very mild altered function to total organ failure, which behaves as a dynamic process.
- All the scores widely used nowadays include six key organ systems—cardiovascular, respiratory, haematological, central nervous system, renal, and hepatic.

Introduction

Organ failure scores (OFSs) are designed to describe organ dysfunction, in a sequential (or repetitive) way, in individual patients with critical illness. In the development of organ dysfunction scores, three important principles need to be remembered [1]. First, organ failure is not a simple all-or-nothing phenomenon, but rather a spectrum or continuum of organ dysfunction exists from very mild altered function to total organ failure. Secondly, organ failure is not a static process and the degree of dysfunction may vary with time during the course of disease, so that scores need to be calculated repeatedly. Thirdly, the variables chosen to evaluate each organ need to be objective, simple, and available but reliable, routinely measured in every institution, specific to the organ in question, and independent of patient variables, so that the score can be easily calculated on any patient in any ICU. Ideally, all these scores should be independent of therapeutic variables [2], but this as proven to be virtually impossible to achieve, as all factors are more or less treatment dependent. For example, the partial pressure of oxygen (PaO_2)/fraction of inspired oxygen concentration (FiO_2) ratio (also known as P/F ratio) is dependent on ventilator conditions and positive end-expiratory pressure (PEEP), platelet count may be influenced by platelet transfusions, and urea and creatinine levels are affected by haemofiltration, etc.

Many different scoring systems have been developed for assessing organ dysfunction, since the early 1980s, differing in the organ systems included in the score, the definitions used for organ dysfunction, and the grading scale used. Nowadays, almost all the scores widely used include just six key organ systems—cardiovascular, respiratory, haematological, central nervous system, renal, and hepatic. The three more widely used OFSs (Table 30.1) will be discussed in the following section.

The Multiple Organ Dysfunction Score

This scoring system was developed based on a literature review from 1969 to 1993 performed by Marshall et al. [2]. Optimal descriptors of organ dysfunction were thus identified and validated against a clinical database. Six organ systems were chosen, and a score of 0–4 allocated to each organ, varying from normality (0 points) to the most severe failure (4 points), with a maximum score of 24. The worst score for each organ system in each 24-hour period is taken for calculation of the aggregate score. A high initial Multiple Organ Dysfunction Score (MODS) correlated with ICU mortality and the delta MODS (calculated as the MODS over the whole ICU stay less the admission MODS) was even more predictive of outcome [2]. In a study of 368 critically-ill patients, the MODS was found to better describe outcome groups than the APACHE II or the organ failure score, although the predicted risk of mortality was similar for all scoring systems [3]. The MODS has been used to assess organ dysfunction in clinical studies.

The Sequential Organ Failure Assessment Score

The Sequential Organ Failure Assessment (SOFA) score was developed in 1994 during a consensus conference organized by the European Society of Intensive Care and Emergency Medicine. It is a score designed to objectively quantify the degree of organ failure over time, organ-by-organ, in individuals or groups of individuals [1]. Initially named the sepsis-related organ failure assessment score, the score was then renamed the sequential organ failure assessment as it was realized that it could be applied equally to non-septic patients. In designing the score, the participants of the conference decided to limit to six the number of systems studied—respiratory, coagulation, hepatic, cardiovascular, central nervous system, and renal. A score of 0 is given for normal function through to 4 for most abnormal (for a maximum total of 24 points), and the worst values on each day are recorded. Individual organ function can thus be assessed and monitored over time, and an overall global score can also be calculated.

Table 30.1 Organ dysfunction/failure scoring systems

Organ system	MODS[a]	SOFA[b]	LODS[c]
Respiratory	PaO_2/FiO_2 ratio	PaO_2/FiO_2 ratio Mechanical ventilation	PaO_2/FiO_2 ratio Mechanical ventilation
Cardiovascular	Pressure adjusted HR	MAP Use of vasoactive agents	SAP HR
Renal	Creatinine	Creatinine Urinary output	Creatinine Urinary output Urea
Haematological	Platelets	Platelets	Platelets WBC
Neurologic System	GCS	GCS	GCS
Hepatic	Bilirubin	Bilirubin	Bilirubin Prothrombin time

HR, heart rate; MAQP, mean arterial pressure; SAP; WBC, white blood count; GCS, Glasgow Coma Score.

Data from (a) Marshall JC et al., 'Multiple organ dysfunction score: a reliable descriptor of a complex clinical outcome', *Critical Care Medicine*, 1995, **23**, pp. 1638–52; (b) Vincent J-L et al., 'The SOFA (Sepsis-related organ failure assessment) score to describe organ dysfunction/failure', *Intensive Care Medicine*, 1996, **22**, pp. 707–10; and (c) Le Gall JR et al., 'The ICU scoring group. The logistic organ dysfunction system. A new way to assess organ dysfunction in the intensive care unit', *Journal of the American Medical Association*, 1996, **276**, pp. 802–10.

Based on this score, several derived scores could be derived, that have been shown to provide additional information about the time-course of the disease [4]:

- The admission SOFA (usually computed with the worst values in the first hour after admission to the ICU).
- The daily SOFA.
- The maximum organ failure score (the sum of the worst scores for each of the components, independently from the day they occurred, because the maximum degree of failure for each organ/system usually occurs in different days).
- The amount of organ dysfunction failure appearing after ICU admission (delta SOFA), computed as the total maximum SOFA score minus the admission total SOFA score.
- The maximum daily SOFA (the day in the ICU stay were the aggregated score was maximum).
- The Discharge SOFA Score (which has been shown to be significantly related to mortality after ICU discharge) [5].

A high total SOFA score (SOFA max) and a high delta SOFA (the total maximum SOFA minus the admission total SOFA) have been shown to be related to a worse outcome [4,6], and the total score has been shown to increase over time in non-survivors compared with survivors [6]. It is by far the most widely used of the OFS scores (Table 30.2).

The Logistic Organ Dysfunction System Score

This score was developed in 1996 using multiple logistic regression applied to selected variables from the database of ICU patients used in 1991 to build the SAPS II score [7]. To calculate the score, each organ system received a number of points according to the worst value for any variable for that system on that day. If no organ dysfunction is present the score is 0, rising to a maximum of 5. As the relative severity of organ dysfunction differs between organ systems, the Logistic Organ Dysfunction System (LODS) score allows for the maximum 5 points to be awarded only to the neurologic, renal, and cardiovascular systems. For maximum dysfunction of the pulmonary and coagulation systems, a maximum of 3 points can be given for the most severe levels of dysfunction and for the liver, the most severe dysfunction only receives 1 point. Thus, the total maximum score is 22. The LODS score was designed (due to the constraints of the database used in its development) to be used as a once-only measure of organ dysfunction in the first 24 hours of ICU admission, rather than as a repeated assessment measure. The LODS system is quite complex and the less used of all.

Table 30.2 The Sequential Organ Failure Assessment (SOFA) Score

SOFA score	1	2	3	4
Respiration PaO_2/FiO_2 mmHg	<400	<300	<200 with respiratory support	<100 with respiratory support
Coagulation platelets × $10^3/mm^3$	<150	<100	<50	<20
Liver bilirubin, mg/dL (μmol/L)	1.2–1.9 (20–32)	2.0–5.9 (33–101)	6.0–11.9 (102–204)	>12.0 (>204)
Cardiovascular hypotension[a]	MAP <70 mmHg	Dopamine ≤5 or dobutamine (any dose)	Dopamine >5, or epinephrine ≤0.1, or norepinephrine ≤0.1	Dopamine >15, or epinephrine >0.1, or norepinephrine >0.1
Central nervous system	GCS 13–14	GCS10–12	GCS 6–9	GCS < 6
Renal creatinine, mg/dL (μmol/L) or urine output	1.2–1.9 (110–170)	2.0–3.4 (171–299)	3.5–4.9 (300–440) or <500 mL/day	>5.0 (>440) or <200 mL/day

[a]Adrenergic agents administered for at least 1 hour (doses given are in μg/kg/min). GCS, Glasgow Coma Score.

Reproduced from *Intensive Care Medicine*, **22**, 7, 1996, pp. 707–10, 'The SOFA (Sepsis-related organ failure assessment) score to describe organ dysfunction/failure', Vincent JL, et al., Table 1, Copyright 1996 Springer, European Society of Intensive Care Medicine, and European Society of Paediatric and Neonatal Intensive Care. With kind permission from Springer Science and Business Media.

Comparison of the described systems

The main difference between the three described models is the method chosen for the evaluation of the cardiovascular dysfunction:

- SOFA uses blood pressure and the level of vasoactive support (maximum amount of vasoactive or inotropic drugs in continuous IV perfusion).
- MODS uses a composed variable, the pressure-adjusted heart rate (PAR, the product of the heart rate (HR) multiplied by the

ratio of the central venous pressure (CVP) to the mean arterial pressure (HR × CVP / MAP)).

- LOD score uses the heart rate and the systolic blood pressure.

A comparison among them, suggests that the MODS and the SOFA scores are both reliable outcome predictors, but the cardiovascular dysfunction/failure is better related to outcome with the SOFA score than with the MODS score [8]. It is also easier to compute.

Several mixed models, integrating a combination of OSF and general severity scores have been published [9,10], but they never gained widespread acceptance.

CHAPTER 31

Genetic and molecular expression patterns in critical illness

Anthony F. Suffredini and J. Perren Cobb

Key points

- Global molecular expression patterns have provided important new insights into the host response to critical illness and injury, identifying new genes of interest, key regulation pathways, and novel inflammation paradigms to test.
- The last decade provided tantalizing evidence that omic technology can improve molecular diagnostics, prognostics, and therapeutics, but the promise of clinical benefit for the critically ill and injured has yet to be fulfilled.
- Technological, computational, and expense hurdles have delayed rapid evolution of the field, but the pace of continued advances suggests broader application and improved feasibility for clinical studies.
- Consistency of study design and analysis, in addition to independent corroboration of the major findings, are essential to the success of all omic approaches.
- Analyses of blood are influenced by the composition of cellular populations and the cell phenotype may change with the condition of the patient requiring multiple samples during the course of critical illness. Differences in cell phenotypes in different body compartments (i.e. blood, inflammatory cells within tissues, and parenchymal cells) affect the expression data and may change during the course of an illness.

The omic era

The 1990s brought whole-genome sequencing and microarrays into the clinical domain. These enabling technologies were leveraged first by interdisciplinary collaboratives in the basic sciences that discovered new networks of interacting gene products in single cell organisms. These findings, in turn, fuelled interest in the emerging fields of human systems biology and genomic medicine. Strictly defined, **genomics** describes the potential of the cell to respond to stimuli based on heredity and genetic variation at the level of DNA [1]. **Transcriptomics** describes cellular responses at the RNA level and is used as a proxy for changes in gene transcription or activation (also commonly called 'gene expression profiling') [2]. **Proteomics** studies relative changes in protein abundance and is used to help understand altered gene translation [3]. Finally, **metabolomics** (or metabonomics) characterizes changes in the abundance of metabolites and also reflects aggregate alterations in the transcriptome and proteome [4]. Investigations of critical illness directed at different levels of biological organization provide information that can be integrated horizontally and vertically.

Applying these approaches to a complex critically-ill patient requires an understanding of the technologies and their limitations. Practical assumptions need to be recognized. For example, analyses of circulating blood are influenced by the composition of cellular populations (e.g. leukocyte differential), so that studies often focus on a specific cellular subset, such as monocytes or lymphocytes. The cell phenotype may change rapidly with the condition of the patient, and require multiple sampling during the course of an illness and recovery. Moreover, the phenotype of cells available for sampling (skin, blood, lung airway) may have fundamentally different phenotypes compared with the same type of cells in other organs (i.e. leukocytes or parenchymal cells within tissues). Finally, consistency of study design and analysis, in addition to independent corroboration of the major findings, are essential to the success of omic approaches.

Typically, the output of these investigations are enormous data sets, which cannot be analysed with the statistical approaches familiar to most clinicians [2]. The range of variables analysed—including genes, transcripts, peptides, and metabolites—often number in the tens of thousands multiplied many-fold across patients and the time course of the experiment. In these instances, univariate analysis (e.g. Student's *t*-test) is usually inadequate to find significant results because of the risk of false associations that occur by chance when multiple tests are applied repeatedly to a huge numbers of variables (also known as the 'curse of dimensionality'). One successful analytical method is the reorganization of the data using unsupervised analysis, which makes no assumptions regarding the association of the variables with the patient's clinical state. Examples include hierarchical clustering and principal component analysis. These approaches reorder the data, so that molecules that have similar patterns of expression are depicted near each other. The assumption is that molecules that group similarly are, in some way, biologically related. In turn, these apparent associations must be verified by independent experiments at the molecular level.

This discovery approach is relatively unbiased, but is susceptible to variations in analytical techniques. In contrast, supervised analysis associates variables with a specific medical condition, such as sepsis. While this approach is less sensitive to technical variation, it may be affected by overfitting of the data to match one or more hypotheses.

Transcriptomics

The most illuminating experience with gene expression profiling as a discovery tool in critical care is in the field of sepsis research. For more than a decade, investigators have been motivated by the promise of an accurate sepsis diagnostic, which could determine which patients were infected and which were not, could identify the organism responsible, and could determine the patient's response to therapy. Early advances included pre-clinical data from *in vitro* models and animal experiments that identified a suite of leukocyte RNA markers that could characterize genome-wide cellular response to infectious stimuli. Moreover, it appeared that these changes in leukocyte gene expression could be used to detect the presence of microbes to the point of being diagnostic, differentiating human leukocyte responses to Gram-negative organisms, viruses, and fungi [5]. These discoveries, in turn, fuelled interest in clinical studies, testing the hypothesis that gene expression profiling could be used to diagnose infection.

Because of the novelty, complexity, and expense of human genomic studies, multicentre, interdisciplinary teams were assembled to conduct these investigations, funded by large-scale, collaborative research programmes. Initial studies aimed at addressing a number of theoretical and technical challenges concluded that a national programme for gene expression analysis could reduce unwanted investigative variance present in the clinical setting and enable the detection of gene expression signal reflective of human pathophysiology [6]. Normal human subjects were studied first, testing the ability of circulating leukocyte gene expression profiles to characterize the host response to intravenous bacterial endotoxin, a prototypical inflammatory insult, compared with placebo [7]. The results demonstrated that gene expression profiling could be used not only to track the human systemic inflammatory response, but also to identify inflammation-induced perturbations of highly coordinated gene groups (functional modules), such as leukocyte bioenergetics and gene translation (Fig. 31.1).

Having demonstrated proof of feasibility, attention turned to testing the ability of leukocyte gene expression profiles to diagnose sepsis in patients. Several groups reported that leukocyte gene expression profiles could be used to differentiate the responses of septic patients from those of critically-ill patients that were not septic, both in adults and children [8]. However, in comparing the lists of genes that appeared to be most informational in these studies, little to no overlap was identified, probably due to differences in septic patient cohorts, experimental design, microarray platforms, and analytical methods. The majority of these early investigations compared expression profiles from blood samples drawn at single time points. In contrast, data from longitudinal gene expression studies in septic patients generated a relatively short list of genes associated with ventilator-associated pneumonia (VAP) [9]. Significant heterogeneity of VAP gene expression profiles was observed, associated with differences in patient geographic ancestry, age, and gender. Yet, 85 genes were identified with consistent changes in abundance during the 7 days bracketing the diagnosis of VAP. Consistent with activation of the host response to pneumonia, several of the genes identified were associated with leukocyte pathways related to cellular activation, antimicrobial proteins, and adhesion molecules. Graphs of changes over time in the expression of these 85 genes was used to track the host response to and recovery from infection (Fig. 31.2), similar to the findings from normal subjects treated with endotoxin, as discussed previously. This was the first report demonstrating that disease trajectories derived from microarray expression profiles can be used to quantitatively track the clinical course of acute disease and identify a state of immune recovery. As these graphs are derived from changes in the abundance of ribonucleic acids in circulating leukocytes, these immune trajectory maps are called **riboleukograms** (RLGs) [9].

The ability of RLGs to detect VAP was validated in an independent cohort of 158 severely-injured, intubated patients [10]. Gene expression profiles obtained at frequent intervals up to 28 days after injury validated that 32% of the 85 genes from the initial study were associated significantly with the diagnosis of VAP, but the prediction model based on these 85 genes did not predict pneumonia in this independent patient cohort better than chance. However, a prediction model based on *de novo* analysis of gene expression data from the 158 trauma patients predicted VAP 4 days prior to VAP diagnosis, but the positive and negative predictive values were only 25 and 90%, respectively. Similar results have been reported studying whole-blood gene expression profiles from septic children [11]. Computer-based analysis of gene expression profiles from a derivation cohort of 98 children revealed 100 genes that classified these patients into three sepsis subclasses ('A, B, and C'). A follow-up study of 82 paediatric patients validated these results.

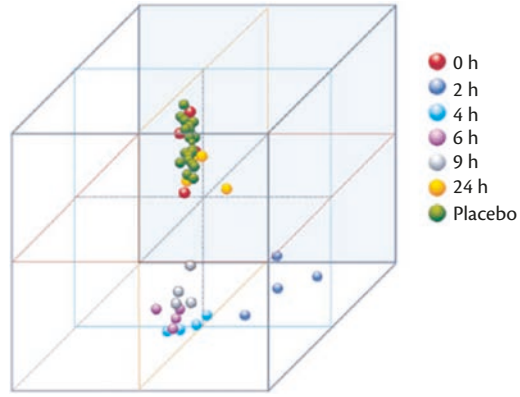

Fig. 31.1 Circulating leukocyte gene expression profiles can be used to track the human systemic inflammatory response. Circulating leukocytes from eight healthy volunteers were tested at baseline (0 hour), and 2, 4, 6, 9, and 24 hours after intravenous administration of endotoxin (four subjects) or placebo (four subjects). Treatment with intravenous endotoxin in this model of systemic inflammation produces flu-like symptoms that resolve spontaneously after 12–24 hours. Significant changes in the expression of 3714 genes were mapped for each sample in three dimensions using principal component analysis. Zero and 24-hour samples in endotoxin-treated subjects mapped similar to samples from placebo-treated subjects at all time points. In contrast, time-dependent changes in the four endotoxin-treated subjects mapped similarly at 2, 4, 6, and 9 hours, returning to baseline at 24 hours.

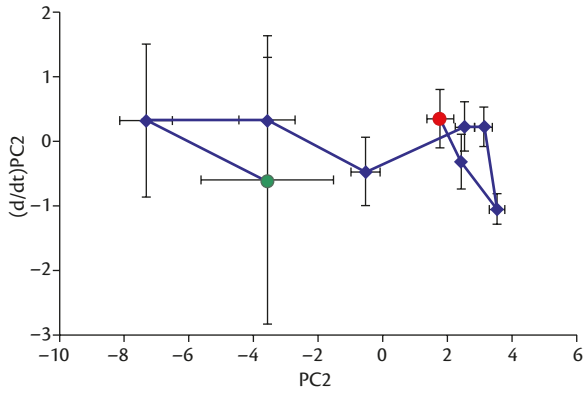

Fig. 31.2 Immune trajectories, called riboleukograms (RLG), from critically-ill patients who developed and recovered from VAP. Buffy coat microarray expression profiles were generated from 11 mechanically ventilated patients every 2 days for up to 3 weeks. Eighty-five genes were found to change in all patients coincident with the development of VAP. Shown is the principal components analysis of these genes. The averaged RLGs appeared to define a general trajectory for the onset and resolution of VAP (the green and red circles indicate where the patients entered and exited the study, respectively). As patients recovered from critical illness complicated by acute infection, the RLGs moved from left to right, converging to a common point concomitant with a decrease in the variance of gene expression (standard deviation of green compared with red circle). These latter findings are consistent with an attractor state of immune health (homeostasis).
PC is principal component, (d/dt)PC is the rate of change of the principal component.

Sepsis subclass A patients were the sickest, based upon higher illness severity scores on average and fewer ICU-free days.

To summarize, gene expression profiling of circulating leukocytes differentiates between the responses of septic and non-septic patients, both in children and adults. Riboleukograms that map changes over time can be used to track the host response to and recovery from septic insults, such as VAP. However, a lack of reproducibility across studies and the number of confounding influences on circulating leukocyte RNA abundance (such as the patient's geographic ancestry, gender, age, and perhaps co-morbidities) have frustrated efforts to date to discover a clinically useful gene expression profile to diagnose sepsis [8]. Reports of human circulating leukocyte gene expression profiles have also raised questions as to the validity of the two-hit model of critical illness and the use of mice to model human disease [12,13]. National efforts to leverage gene expression profiling for clinical benefit should continue as we build on advances in genomic science. For example, the study of enriched populations of circulating leukocytes (granulocytes, monocytes, and lymphocytes), coupled with technical and computational advances (e.g. microfluidics), promise improved signal-to-noise ratios and better discriminatory capabilities that will translate into improved diagnostics.

Proteomics

The proteome encompasses a broad range of molecules that can be classified based on differences in size, post-translational modifications (such as glycosylation), proteolytic cleavage (altering activity), and cellular location. In addition, alternative splicing of mRNA from a particular gene can generate mRNA variants that are translated accordingly into proteins with different amino acid sequences and biological function. Thus, there are far more proteins than there are genes in a genome; for example, there are approximately 21,000 human protein-coding genes, but estimates of the number of human proteins exceeds 100,000. Furthermore, proteins usually found within a cell may leak from a damaged or stimulated cell, and can be found in blood or urine.

The typical approach to identifying proteins in a biological fluid relies on simplifying complex mixtures by sample fractionation—separated typically by size and charge—and then analysing these enriched peptide fractions by mass spectrometry (MS) [3]. Two analytical approaches are typically used [14]. A bottom-up analytical approach simplifies complex mixtures by digesting all the proteins in the mixture and then fractionating them prior to application onto a MS platform. The peptide masses and sequences detected by MS serve as surrogate markers for their respective intact proteins. The thousands of peptide fragments used in this analytical approach create a substantial computational challenge. These peptide sequences are compared with predicted proteins using database searches and the predicted *in silico*-generated fragmentation patterns. An alternative analytical approach is the top-down proteome method in which analysis of intact proteins, their fragments, and post-translational modifications is performed. This approach requires precise, pre-analytic separation of a protein mixture prior to MS, which presents a different set of challenges.

Over the last decade, these approaches have been applied to study critical illness. For example, the application of proteomics to characterize biomarkers is relatively independent of the analytic platform and requires prospective validation in large, independent cohorts [15]. Analysis of the trauma patient plasma proteome exemplifies some of the challenges [16]. The workflow entailed removal of the most abundant plasma proteins, leaving the lower molecular weight proteome for analysis. This fraction was digested and separated into different peptide populations enriched for the presence of cysteinyl peptides and N-glycopeptides. After extensive analysis, over 2000 proteins were identified, including cytokines, chemokines, cell differentiation molecules, and other proteins involved in inflammation and immune responses. The challenges of this type of comprehensive approach include the complexity, throughput, resources, and costs necessary to process and analyse samples. Proteomic analysis of bronchoalveolar lavage is another example that has provided insight into potential biomarkers associated with acute respiratory distress syndrome (ARDS). Patients with ARDS had distinct protein patterns associated with increased levels of apolipoprotein A1 and S100 calcium binding proteins A8 and A9, potentially of use to monitor acute inflammation and the clinical response to therapy [17].

Finally, it is worth emphasizing that the application of mass spectrometry in the microbiology laboratory has revolutionized the rapid identification of microbes. This is based on generating spectral proteomic patterns of the unknown organism and comparing them to a reference database. After relatively simple sample preparation, the results are achieved within minutes, with a high level of accuracy [18].

Metabolomics

Metabolites are small molecules generated as the intermediary products of metabolism, such as signalling molecules, sugars, fatty acids, amino acids, nucleic acids, and vitamins. Metabolomics (the global profiling of metabolites produced in response to different disease states, drugs, or environmental stresses) is an emerging field that complements proteomics and transcriptomics as a means to identify novel biomarkers in critical illness [4,19]. These approaches can be used to identify, in parallel, hundreds of metabolites in biological fluids, utilizing either nuclear magnetic resonance (NMR) spectroscopy or MS coupled to liquid or gas chromatography. NMR has the advantages of a broad interrogation of metabolites with minimal preparation time and high throughput, allowing hundreds of samples to be processed per day. This occurs without destruction of the sample, but this analytical approach is limited by its relative insensitivity due to overlapping metabolite signals and the difficulty of absolute quantification. In contrast, chromatographic separation methods linked to MS have greater sensitivity and reproducibility, but samples are consumed in the process and data analysis is more time consuming [19].

Preliminary work suggests the potential of this approach to define new markers of inflammation in critically-ill patients. Using NMR spectroscopy, plasma from patients with sepsis-induced acute lung injury differed globally from healthy controls, and myo-inositol and glutathione were found to correlate with the APACHE III Acute Physiologic Score [20]. These data confirm the feasibility of this approach in elucidating pathways and potential biomarkers in patient samples.

Respiratory drugs

CHAPTER 32

Oxygen in critical illness

James N. Fullerton and Mervyn Singer

Key points

- Hypoxaemia should be avoided.
- Mortality is increased in intensive care patients with PaO_2 <8–9 kPa.
- Hyperoxaemia is not benign. Observational studies indicate an association with increased mortality in ventilated patients and survivors of cardiac arrest.
- Oxygen is a drug. Commencement and continuation represents a clinical decision. Full prescription, monitoring, and frequent review are required.
- Oxygen therapy may cause hypercapnic respiratory failure in at-risk patients.

Introduction

Oxygen is cheap, widely available, and efficacious in preventing and treating hypoxaemia. Oxygen therapy has long been regarded as integral to the management of critical illness. In the UK, oxygen is administered to over one-third of emergency ambulance patients, while around 15% of in-patients receive oxygen therapy on any given day [1,2]. In critical care, its use is nearly ubiquitous. Despite this, oxygen is a drug. Its use must be accompanied by the traditional stipulations and clinical rigor applied to other therapeutics. However, supplemental oxygen without prescription remains common [2]. In patients with a specified target oxygen saturation range, one-third fell outside [3].

The primary indication for oxygen therapy is actual or suspected hypoxaemia. Sustained hypoxaemia is associated with end-organ damage, most notably to the brain as a result of tissue hypoxia [4,5]. The precise levels of hypoxaemia that are dangerous in given disease states are not known. However, a degree of hypoxaemia may be tolerated in the short term, while gradual acclimatization alters the threshold at which harm occurs [6,7]. Observational studies in mechanically-ventilated patients describe an independent and linear association between hypoxaemia in the first 24 hours after ICU admission and mortality [8,9]. Similar data have been reported in survivors of non-traumatic cardiac arrest [10]. The threshold for harm appears to be around PaO_2 8–9kPa (91–94% SaO_2).

Hyperoxaemia is now recognized as injurious in certain settings. While prolonged exposure to high inspired concentrations of oxygen (FiO_2 > 0.5) has long been known to induce oxygen toxicity with predominantly pulmonary and neurological sequelae [11], more recent research indicates that exposure to lower doses over shorter durations may also be harmful. Data describes an independent association between increasing hyperoxaemia and mortality in both mechanically ventilated patients [8] and survivors of cardiac arrest [10]. Questions remain over whether this contributes to excess mortality after multivariate analysis [9,12]. Harm may arise from cardiopulmonary side effects and deleterious local effects at sites of prior ischaemia or inflammation, e.g. promotion of free radical generation and vasoconstriction (for instance, by promotion of free radical generation and vasoconstriction).

Given the potential for harm, targeted oxygen therapy routinely aiming to achieve normoxaemia and normal tissue oxygen tensions should be the standard of care.

Principles

Oxygen therapy should alleviate both arterial and tissue hypoxia, facilitating aerobic respiration and cellular metabolism. Unfortunately, a simple relationship between FiO_2 and cellular adenosine triphosphate (ATP) generation cannot be assumed.

Maximizing arterial haemoglobin saturation by increasing the FiO_2 represents only one factor that determines oxygen delivery. The oxyhaemoglobin binding characteristics (themselves dependent on pH, 2,3-diphosphoglycerate and $PaCO_2$), haemoglobin concentration, cardiac output, and factors affecting pulmonary gas exchange, peripheral vascular distribution and diffusion from capillary to tissue, also play key roles. A simple dose response relationship (FiO_2 to intracellular PO_2) cannot be expected. To compound the issue, critical illness may also alter or impair mitochondrial aerobic respiration, creating a state of 'hibernation' in organs [13].

Correcting hypoxaemia neither indicates alleviation of tissue hypoxia, nor guarantees oxygen utilization at a cellular level. In the absence of a clinically-relevant measure of intracellular PO_2 and/or mitochondrial function, treatment efficacy must be inferred [14]. Reliance on the correction of arterial oxygen concentration with oxygen therapy, merely because it is achievable and measurable, may not be in the patient's best interests [5]. Modifications of pulmonary physiology, haemoglobin concentration, and a reduction in regional and local barriers to cellular oxygenation (circulatory disturbance, oedema, etc.) may facilitate improved oxygen delivery beyond that afforded by oxygen therapy alone (Box 32.1).

Indications

The main indication for oxygen therapy is documented hypoxaemia (PaO_2 < 8 kPa [60 mmHg], SaO_2 < 92%). Oxygen may also be commenced in emergency situations where hypoxaemia is suspected, but not yet documented. Oxygenation status should be determined as rapidly as possible, a target set, and therapy titrated and/or ceased as necessary. Oxygen is *not* a treatment for dyspnoea.

Box 32.1 Alternative methods to increase oxygen delivery

- Improving and safeguarding the airway: suctioning, manual manoeuvres, airway adjuncts, supraglottic devices or endotracheal tube.
- Optimizing circulating volume to maintain tissue perfusion.
- Enhancing cardiac output.
- Correction of anaemia, increasing oxygen carrying capacity.
- Avoiding or reversing respiratory depressants.
- Establishing and treating the underlying cause of hypoxaemia.
- Non-invasive or invasive ventilation including recruitment manoeuvres.

Adapted from *British Medical Journal*, O'Driscoll R, 'Emergency oxygen use', **345**, 6856, copyright 2012, with permission from the BMJ Publishing Group Ltd.

The normal range for arterial blood oxygen is 11–14 kPa (85–105 mmHg, SaO_2 > 93%). Hypoxaemia is commonly caused by ventilation/perfusion (V/Q) mismatch, resulting in a shunt or dead-space, and hypoventilation. Clinical symptoms of hypoxaemia include restlessness, agitation, confusion, sweating, headache, nausea, paraesthesiae, palpitations, and eventually reduced Glasgow Coma Score (GCS). Signs, are also neither sensitive nor specific, and include cyanosis, tachypnoea, decreased cognitive function and co-ordination, and fluctuating blood pressure (hypertension and subsequent hypotension).

Dosages and monitoring

Hypoxaemia and hyperoxaemia are frequently a result of inappropriate use, dosing, or delivery route of oxygen therapy, in combination with a failure to monitor and titrate therapy. Oxygen commenced out of presumed need is often not reviewed promptly.

Dose

Acutely unwell patients should be prescribed and administered oxygen to achieve target arterial saturations of 94–98% [15]. Patients with risk factors for hypercapnic respiratory failure (Box 32.2) or known chronic hypoxaemia should be set a target range of 88–92% [15]. In specific clinical situations, or if monitoring is unavailable or inaccurate, high-flow oxygen (10–15 L/min) via a reservoir mask may be provided until determination of PaO_2 or SaO_2 can be reliably made with subsequent titration/cessation (Box 32.3). Permissive hypoxaemia may be preferred in certain clinical situations [5].

Box 32.2 Risk factors for hypercapnia

- Chronic obstructive pulmonary disease.
- Chest wall deformities.
- Neuromuscular disorders.
- Morbid obesity.

Adapted from *Thorax*, O'Driscoll BR et al., 'BTS guideline for emergency oxygen use in adult patients', **63**(Suppl. 6), pp. vi1–68, copyright 2008, with permission from the BMJ Publishing Group Ltd.

Prescription

Oxygen should always be prescribed. The delivery device(s) and flow rate range must be specified, along with a target range of saturation or PaO_2.

Box 32.3 Medical emergencies where oxygen is likely to be required

Medical emergencies requiring high concentration oxygen in all cases

- Shock, sepsis, major trauma.
- Cardiac arrest and during resuscitation.
- Anaphylaxis.
- Carbon monoxide or cyanide poisoning.
- Diving and altitude emergencies (specialist input required).

Medical emergencies where patients are likely to need oxygen therapy (ranging from low to high concentration depending on disease severity), with target saturation range 94–98%

- Pneumonia.
- Asthma.
- Acute heart failure.
- Pulmonary embolism.

Medical emergencies where patients are likely to need controlled oxygen, with target saturation range 88–92%

- Acute exacerbation of COPD.
- Acute illness in patients with cystic fibrosis.
- Acute respiratory illness in patients with obesity hypoventilation syndrome or morbid obesity.
- Acute respiratory illness in patients with chronic neuromuscular or musculoskeletal conditions.

Medical emergencies where oxygen is advised only if the patient is hypoxaemic

- Myocardial infarction or unstable coronary artery syndrome.
- Stroke.
- Ongoing management of survivors of cardiac arrest with restored spontaneous circulation.
- Sickle cell crisis or acute anaemia.
- Obstetric emergencies.
- Poisoning (other than above, paraquat is a relative contra-indication).

- Metabolic and renal disorders with tachypnoea due to acidosis (Kussmaul breathing).

Other indications (non-emergency)

- Operations and procedures involving sedation.
- Long-term use in pulmonary disease.
- Assistance in pneumothorax resolution.
- Promotion of wound healing including necrotizing fasciitis.

Adapted from *Thorax*, O'Driscoll BR et al., 'BTS guideline for emergency oxygen use in adult patients', **63**(Suppl. 6), pp. vi1–68, copyright 2008, with permission from the BMJ Publishing Group Ltd.

Monitoring

Documentation of vital signs, including pulse oximetry, is necessary while oxygen is being administered. The delivery device, flow rate, and FiO_2, if known, must be noted. Blood gas sampling (arterial or capillary) is necessary to identify hyperoxaemia and hypercarbia, and to describe hypoxaemia accurately (due to the sigmoid shape of the oxygen dissociation curve). These should be performed routinely in patients at risk of hypercarbic respiratory failure and in ventilated patients (non-invasive and endotracheal). Hyperoxaemia cannot be identified via pulse oximetry or clinical signs so arterial blood sampling is required to facilitate its avoidance.

Routes of administration

Spontaneous respiration

Low-flow devices

The FiO_2 provided by these devices is dependent on the device, mask fit, inspiratory flow rate, and anatomical reservoir. Oxygen is delivered at flows less than the patient's inspiratory flow rate and, due to entrainment and consequent dilution of the oxygen with room air, the concentration delivered to the alveoli will be reduced. FiO_2 >0.8–0.85 cannot be delivered via these devices.

As the inspiratory flow rate rises, the FiO_2 falls. With a constant oxygen flow, a tachypnoeic patient may thus receive reducing and potentially insufficient amounts of oxygen. Equally, with a reduced respiratory rate there is the danger of a rising FiO_2. In patients at risk of hypercapnic ventilatory failure, a vicious cycle may emerge.

Low-flow devices are the most frequently used due to comfort, cost, ease of use and ready availability. They include nasal cannulae or catheters, simple masks (Hudson or MC) and reservoir masks (both partial rebreathing and non-rebreathing). The size of the reservoir (~200 mL with a simple face mask, to 1 L with a dedicated reservoir bag) determines the FiO_2 range that is delivered. Devices with reservoir capacity should be inflated with O_2 prior to use and should neither collapse fully on inspiration nor be utilized at low flow rates. CO_2 re-breathing may occur in this situation secondary to insufficient flushing.

High-flow devices

The FiO_2 supplied is constant (within a range of minute volume) as a prescribed oxygen/air mixture is delivered at flow rates that exceed patient demand.

The most commonly used system is the Venturi valve and mask with either fixed or variable oxygen concentration delivery. The latter is normally linked to a humidification system. The system relies on the Bernoulli principle. Both valve (orifice width) and flow rate must be altered in tandem to provide the desired FiO_2, ensuring the correct amount of room air is entrained.

As inspiratory flow-rate does not alter the FiO_2, these masks represent the first choice in patients who required controlled oxygen therapy.

Mechanically-assisted ventilation

Mechanical ventilation may be used to treat hypoxaemic states, with or without ventilatory failure, that is refractory to standard oxygen therapy. Continuous positive airway pressure (CPAP) or bi-level positive airway pressure (BiPAP) can be delivered via a tight-fitting mask or hood to the alert, spontaneously breathing patient. FiO_2 may be varied between 0.21 and 1.0, dependent on seal.

Hyperbaric oxygen

This has a role in the management of acute carbon monoxide poisoning, arterial gas embolism, severe decompression sickness, clostridial gas gangrene, necrotizing fasciitis, and acute crush injury. Hyperbaric oxygen therapy can be safely administered to critically-ill patients, but specialized equipment and trained personnel are required to operate in chambers. Risk/benefit analysis should be considered prior to transfer and commencement.

Non-spontaneous respiration

Patients with cuffed endotracheal tubes may be provided with variable, accurate, and often high FiO_2 levels via diverse modes of ventilatory support. Severe hypoxaemia in this setting, often secondary to lung pathology, may prompt consideration of extracorporeal membrane oxygenation (ECMO).

Humidified oxygen

The upper respiratory tract is responsible for humidification of inspired air in normal physiology. Administration of non-humidified oxygen at high flow rates for prolonged periods may compromise the mucociliary elevator and, consequently, secretion and pathogen clearance. This insult will be compounded if pathology or an artificial airway determines that the nasopharynx is bypassed. Humidified oxygen offers one means of ameliorating this insult.

Side effects

Oxygen therapy elicits a fall in cardiac output secondary to a vagal nerve-mediated reduction in heart rate and an increase in peripheral vascular resistance. The latter is seen clinically as a rise in both systolic and especially diastolic blood pressure. Prolonged exposure to high FiO_2 may induce long-lasting or even permanent pathological changes.

Oxygen toxicity—cellular mechanisms

Normal cellular respiration generates reactive oxygen metabolites. From the superoxide anion (O_2^-), formed by incomplete reduction of oxygen in the mitochondrial electron transport chain, multiple other reactive species are generated, including perhydroxyl radicals, hydrogen peroxide, and hydroxyl radicals (via redox cycling in the presence of catalytic iron and copper), and peroxynitrite (via

reaction with nitric oxide). These may cause local damage, engaging in destructive oxidation and reduction reactions with cellular constituents, or diffuse insults further afield.

Usually less than 5% of oxygen used metabolically is incompletely reduced to form the superoxide anion. As the intracellular PO_2 rises the law of mass action dictates that this is proportionally increased. In turn, reactive oxygen species increase in concentration, especially in situations where key intermediaries are present (e.g. nitric acid formed by inflammatory cells at a septic site or iron in circulatory stasis). Under normal circumstances protective antioxidants (including glutathione, vitamin A, ascorbate) and 'antioxidant' intracellular enzymes (including superoxide dismutase, catalase, and glutathione peroxidase) exist to eliminate these toxic products. When production increases, these are consumed or overwhelmed.

Oxygen toxicity—clinical manifestations

The key systems affected are the respiratory and central nervous systems, although ocular, endocrine, and diverse other changes are recognized. Symptomatically, patients may experience cough, chest pain, paraesthesiae, visual changes, tinnitus, vertigo, irritability, anorexia, nausea, and vomiting. Seizures may occur. Pathologically, in the lung, a spectrum is seen dependent on both duration of exposure and concentration [11]. An initial endothelial injury-triggered exudative phase, characterized by inflammatory cell infiltration and thickening of the alveolar interstitium, precedes a proliferative phase. This is typified by septal proliferation, alteration of the cellular balance in favour of type II alveolar cells, and deposition of interstitial collagen, elastin, and fibrin. The end-result is fibrosis, similar to the diffuse alveolar damage arising from other pathologies, e.g. smoke inhalation or influenza pneumonia. Physiological changes include reduced gas exchange, V/Q abnormalities, and alteration in lung mechanics (reduced compliance and forced vital capacity).

Multiple drugs may exacerbate oxygen toxicity via increasing tissue oxygen consumption (e.g. epinephrine, norepinephrine) or free radical production (directly or in their metabolism, e.g. nitrofurantoin, bleomycin), or impairing endogenous antioxidant systems (e.g. cyclophosphamide). Several agents show promise in ameliorating oxygen toxicity in experimental models (often focused around 'boosting' the antioxidant system), yet none have entered routine practice. Steroids may have a role in preventing late complications from extended exposure.

Given oxygen's potential toxicity when given at high concentrations ($FIO_2 > 0.5$) for even short periods (>12 hours, no defined cut-off) a policy of titration to need, reduction (where possible), attention to other modifiable factors determining oxygen delivery, and even permissive hypoxaemia should be considered [5].

Summary of other key side effects

- **Ventilatory depression and CO_2 retention**.
- **Absorption (oxygen) atelectasis**: nitrogen washout occurs. At the alveolar level, as oxygen is readily absorbed by haemoglobin, collapse may occur.
- **Depression of lung barrier function**:
  - Ciliary dysfunction, producing decreased tracheal mucous velocity.
  - Lymphocytic infiltration.
- **Vasoconstriction**:
  - *Local*: cardiac and cerebral circulation is of primary concern.
  - *Systemic:* increased vascular resistance and hence cardiac load.

Cautions

There are no absolute contraindications to oxygen therapy. Clinical risk/benefit analysis should determine the target oxygen saturation range and adoption of alternative strategies to maximize oxygen delivery (see Box 32.1) in parallel with selecting a FIO_2 and oxygen delivery system on a case-by-case basis.

Hypercapnic ventilatory failure

The primary concern regarding oxygen therapy is oxygen-induced hypercapnic ventilatory failure in at risk patients (see Box 32.2). Chronic obstructive pulmonary disease (COPD) represents the most prevalent risk factor. In this population, the use of uncontrolled (>35%) oxygen is associated with mortality and requirement for ventilatory support twice that of those receiving targeted (88–92%) therapy [16,17]. Groups not classically associated with 'at-risk' status have also been shown to be vulnerable, including patients with acute exacerbations of asthma [18] and pneumonia [19], reinforcing the need to monitor, titrate, and target therapy. Transcutaneous CO_2 sensors are neither widely available, nor accurate, and the signs of hypercapnia are non-specific, late, and may not be evident in a sedated, ventilated patient. For this reason, arterial blood gases are recommended in all patients at risk of hypercapnic respiratory failure receiving emergency oxygen therapy.

CO_2 retention secondary to an increased FIO_2 is multifactorial. Physiologically, the Campbell theory is most commonly cited, where reduced central hypercapnic drive (secondary to chemoreceptor tolerance after prolonged hypercapnic exposure) places reliance on hypoxaemia for respiratory stimulation [20]. Supplementation with FIO_2 diminishes this drive leading to a falling respiratory rate, CO_2 narcosis, and eventually apnoea. A further significant contribution may come from V/Q mismatching secondary to the release of hypoxic pulmonary vasoconstriction. The pulmonary circulation, in contrast to the systemic circulation, constricts in response to hypoxia. In at-risk patients, increased FIO_2 results in vasodilation in parts of the lung that are poorly ventilated and/or have impaired gas transfer. CO_2 transported in these vessels will not be excreted. Underlying pathology prevents normal compensatory increases in alveolar ventilation with resultant hypercapnia.

In acutely unwell patients, the explanation for a $PaCO_2$ rise in response to oxygen therapy is more complicated. Acute fatigue (often secondary to increased respiratory muscle load, decreased strength, and reduced chest wall compliance) and atelectasis (secondary to weak cough, poor respiratory efforts, increased sputum production, and failed excretion) compounds the physiological factors described previously. In addition, increased CO_2 production as a result of the underlying pathology (e.g. sepsis) or resulting from treatment (e.g. bicarbonate infusion) exacerbates this. Rarely can oxygen therapy be identified as the sole cause of a $PaCO_2$ rise.

Relative contraindications

In the case of paraquat poisoning, bleomycin-induced lung injury and acid inhalation, oxygen therapy may worsen the insult. The decision to initiate oxygen therapy should be made on an individual basis, often encompassing a strategy of permissive hypoxaemia (e.g. SaO_2 90%).

Risk of fire or explosion

Oxygen promotes combustion and poses a fire risk in specific situations

- **Defibrillation**: oxygen sources should either be removed and turned away from the patient or, if a closed circuit is in place, left sealed prior to an electric current being delivered.
- **Bronchoscopic laser-therapy**: risk of ignition.
- **External risk factors**: naked flame, lit cigarette, etc. These are predominantly associated with domestic oxygen use.

CHAPTER 33

Bronchodilators in critical illness

Rajiv Dhand and Michael McCormack

Key points

- Pressurized metered-dose inhalers (pMDIs) and nebulizers are routinely used for aerosol delivery to ventilator-supported patients.
- A complex array of factors influences the efficiency of drug delivery in mechanically-ventilated patients.
- With an optimal technique of administration, drug deposition in the lower respiratory tract of ventilator-dependent patients is comparable with that achieved in ambulatory patients.
- Recommended doses of bronchodilators in mechanically-ventilated patients are higher than in ambulatory patients to compensate for the effects of humidity in the ventilator circuit.
- Despite major impediments to drug delivery during non-invasive positive pressure ventilation (NIPPV), significant responses can be achieved following bronchodilator administration with a jet nebulizer or pMDI.

Introduction

Beta-adrenergic agonists, anticholinergic drugs, and methylxanthines are commonly used in critically-ill patients who are in urgent need of bronchodilation. Beta-adrenergic agonists and anticholinergics are preferably administered by inhalation, whereas methylxanthines can only be administered enterally or parenterally. Intravenous beta-agonists may be used in patients who are refractory to inhaled beta-agonists. The doses of inhaled drugs used in mechanically-ventilated patients are shown in Table 33.1.

Beta-agonists in asthma and chronic obstructive pulmonary disease

Increasing doses of beta-agonists produce greater bronchodilation, but they also increase adverse effects. Usually, 5–10 mg of albuterol produces maximum bronchodilation in severe asthma [1]. Patients who fail to respond to such doses (non-responders) may require hospital admission, whereas responders could be discharged from the emergency department. If pulmonary function does not improve by the end of the first hour of treatment and the asthma attack is severe, continuous nebulization may provide additional benefit [2].

Anticholinergics in asthma and chronic obstructive pulmonary disease

In patients with acute exacerbations of chronic obstructive pulmonary disease (COPD), a pooled analysis comparing fenoterol and metaproterenol with ipratropium found no significant differences in improvement in FEV_1 [3].

Combination therapy is not unequivocally superior to individual drug therapy, but ipratropium can be added when the response to beta-agonists is suboptimal, or if the exacerbation is severe.

Side effects of beta-agonists and anticholinergics

Beta-agonists predictably increase heart rate, and occasional reports of angina and myocardial infarction suggest the potential for myocardial injury. Higher doses of these agents should be used with caution, especially in elderly, hypoxaemic patients. There may be a transient decrease in PaO_2 after beta-agonist inhalation, but not following inhalation of anticholinergic agents. Therefore, a significant fall in PaO_2 can occur during beta-agonist administration and patients with marginal oxygenation should be closely monitored.

Ipratropium and tiotropium do not influence mucus secretion or the rheological properties of mucus, although some reports suggest a decrease in sputum volume. Mucociliary clearance is unchanged with ipratropium use. Dry mouth is the most common side effect, and unilateral mydriasis has been reported with nebulized ipratropium.

Methylxanthines

In acute asthma or COPD, theophylline does not confer additional bronchodilation in patients receiving intensive therapy with inhaled beta-agonists and intravenous corticosteroids [4]. Currently, theophylline is recommended only for patients who fail to respond to beta-agonists, have paradoxical bronchospasm, or have impending respiratory failure. Careful monitoring is required to maintain plasma theophylline levels between 5 and 15 mg/L because these levels could fluctuate with resulting changes in the patient's condition. The frequent occurrence of side-effects with theophylline, especially nausea and vomiting, is a major drawback.

Factors influencing aerosol delivery during mechanical ventilation

In the past, poor efficiency of aerosol delivery to the lungs with pressurized metered-dose inhalers (pMDIs) and nebulizers has meant that much larger doses of drugs than those employed in ambulatory patients are needed in patients receiving mechanical ventilation. With optimized techniques of administration, large increases in the administered dose of a drug may not be necessary to achieve therapeutically meaningful effects [5].

Table 33.1 Doses and duration of action of commonly used bronchodilators in ventilated patients*

Agents	Dose	Time course (onset, peak, duration)	Frequency of dosing
Albuterol (salbutamol)	*SVN*: 0.083% solution, 3 mL (2.5 mg) *pMDI*: 90 mcg/puff, four puffs	5–15 minutes, 30–60 minutes, 4–6 hours	4–6 times daily
Levalbuterol	*SVN*: 0.63 mg or 1.25 mg	15 minutes, 30–60 minutes, 4–6 hours	3–4 times daily
Formoterol	*SVN*: 20 mcg/2 mL solution	1–3 minutes, 1–3 hours, 8–12 hours	2 times daily
Arformoterol	*SVN*: 15 mcg/2 mL solution	1–3 minutes, 1–3 hours, 8–12 hours	2 times daily
Ipratropium	*pMDI*: 18 mcg/puff, four puffs, *SVN*: 0.02% solution, 2.5 mL (0.5 mg)	15 minutes, 90–120 minutes, 4–6 hours	4–6 times daily
Albuterol + ipratropium	*pMDI*: 90 mcg + 18 mcg/puff, four puffs *SVN*: 2.5 mg + 0.5 mg/dose	5–15 minutes, 30–60 minutes, 4–6 hours	4–6 times daily

*Dry powder inhalers are not routinely used in ventilated patients.

pMDI, pressurized metered-dose inhaler; SVN, small volume nebulizer.

Efficiency of drug delivery with pMDIs and nebulizers in laboratory models of mechanical ventilation ranges from 0.3 to 97.5% of the nominal dose depending on the formulation and technique of administration [6]. Obviously, such extreme variability is undesirable and administration techniques that lead to inadequate drug delivery could result in therapeutic failure. Careful attention to several factors is required to achieve consistently efficient drug delivery, including variables related to the aerosol-generating device, the ventilator and ventilator circuit, the inhaled drug or agent, and the patient [6].

With pMDIs, several commercially-available adapters are used to connect the canister to the ventilator circuit, ranging from simple adapters with a port and single nozzle to more complex adapter designs with a chamber and third-party actuator. A pMDI connected to a chamber spacer of about 140 mL volume, placed at a distance of approximately 15 cm from the endotracheal tube provides efficient aerosol delivery in mechanically-ventilated patients, and elicits a significant bronchodilator response [5]. Moreover, pMDI actuation must be synchronized with the precise onset of inspiratory airflow from the ventilator. Even a 1–1.5-s delay between pMDI actuation and ventilator breath can profoundly reduce drug delivery [7]. Furthermore, the pMDI must be appropriately primed before first use or if it has not been actuated for more than 24 hours.

With a jet nebulizer, placement in the inspiratory limb at a distance from the endotracheal tube improves efficiency compared with placement between the 'y' connector and endotracheal tube. The nebulizer brand, nebulizer design, diluent volume, operating pressures and flows, and treatment duration are other factors influencing nebulizer efficiency [8]. Ultrasonic nebulizers are infrequently used for bronchodilator therapy during mechanical ventilation. Likewise, there are limited clinical data with vibrating mesh nebulizers in mechanically-ventilated patients, although bench studies show a 2–4-fold greater efficiency of drug delivery with these nebulizers compared with conventional jet nebulizers [9].

In a ventilator circuit, nebulizers can be operated continuously or intermittently by airflow from the ventilator. The efficiency of some nebulizers is decreased by the lower pressure of gas supplied by the ventilator during intermittent operation compared with continuous operation with gas under higher pressure from a tank or wall outlet at a similar flow rate. Thus, with gas flow from a ventilator, the specific ventilator and nebulizer brand should be tested to determine the aerosol characteristics and efficiency of drug delivery [10].

Other factors that enhance the efficiency of bronchodilator delivery include a tidal volume of 500 mL or more (in an adult), a longer inspiratory time, and slower inspiratory flows [11]. Drug delivery is linearly correlated with a longer duty cycle (T_I/T_{TOT}) for both pMDIs and nebulizers [12].

With jet nebulizers, aerosol delivery is influenced by inspiratory time, pattern of inspiratory flow, and lung mechanics. Delivery is notably lower during pressure-controlled compared with volume-controlled ventilation [13]. Use of flow triggering with a nebulizer could dilute the aerosol and increase aerosol washout into the expiratory limb between breaths.

Circuit humidity reduces drug delivery from both pMDIs and nebulizers by 40% or more compared with a dry circuit [6]. However, removing the humidifier for administration of routine bronchodilator therapy is not recommended. Such a practice would require opening the circuit for each treatment and it may take more than 1 hour after shutting off the humidifier for the circuit humidity to decrease to a level that would enhance drug delivery [14].

A more practical solution is to compensate for the effects of humidity by increasing the bronchodilator dose.

Modifying the density of the gas in the circuit affects aerosol delivery. With helium–oxygen mixtures in the ventilator circuit, drug delivery with a pMDI was 50% greater than with oxygen alone. A practical method to achieve a similar increase in efficiency with a jet nebulizer is to operate the nebulizer with oxygen (6–8 L/min) and to entrain the aerosol into a ventilator circuit containing helium-oxygen [15].

Impaction of aerosol on the endotracheal tube is a major impediment to efficient aerosol delivery, particularly in paediatric ventilator circuits with small endotracheal tubes (internal diameter (ID) 3–6 mm). With larger endotracheal tubes (ID 7–9 mm), the type of aerosol generator and ventilator settings have a greater influence on aerosol deposition within the tube than the endotracheal tube ID per se.

In mechanically-ventilated patients, gamma scintigraphy and measurement of plasma or urinary drug levels also demonstrate that administration technique influences drug delivery.

Bronchodilator therapy

Bronchodilators are among the most commonly used drugs in ventilator-supported patients with acute severe asthma or acute exacerbations of COPD [5,16]. Common indications for bronchodilator therapy in ventilated patients are summarized in Box 33.1. Optimal techniques for bronchodilator administration, based on consideration of various factors influencing aerosol delivery, are shown in Boxes 33.2 and 33.3.

When the technique of administration is carefully executed, the majority of stable mechanically-ventilated patients with COPD achieved near maximal decrease in airway resistance and intrinsic positive end-expiratory pressure (PEEP) following administration of four puffs of albuterol [5]. Patients with acute exacerbations of asthma or COPD may require higher doses of inhaled bronchodilators, but further studies are needed to establish a dosing schedule for such patients. In stable patients with COPD, the bronchodilator effect of albuterol is sustained for 2–3 hours [16]. In ventilator-supported patients with COPD, fenoterol and ipratropium bromide in combination were more effective than ipratropium alone. Although bronchodilators are commonly used in a diverse group of patients receiving mechanical ventilation at considerable additional cost [17], they do not definitely improve clinical outcomes [18].

Box 33.1 Indications for bronchodilator therapy in patients receiving mechanical ventilation

- Severe asthma.
- COPD.
- Acute bronchospasm or wheezing.
- Elevated airway resistance.
- Dynamic hyperinflation/intrinsic PEEP.
- Difficulty in weaning.
- Chronic ventilator-dependence.

Box 33.2 Optimal technique for drug delivery by pMDI in mechanically ventilated patients

- Review order, identify patient, and assess need for bronchodilator.
- Suction endotracheal tube and airway secretions.
- Shake pMDI and warm to hand temperature.
- Place pMDI in space chamber adapter in ventilator circuit.
- Remove heat and moisture exchanger (HME) if used. Do not disconnect humidifier.
- Coordinate pMDI actuation with beginning of inspiration.
- Wait at least 15 seconds between actuations; administer total dose.
- Monitor for adverse response.
- Reconnect HME.
- Document clinical outcome.

This table was published in Egan's *Fundamentals of Respiratory Care*, 8th edn, Wilkins RL et al., p. 795, Copyright Elsevier 2003 [20].

Box 33.3 Optimal technique for drug delivery by jet nebulizer in mechanically-ventilated patients

- Review order, identify patient, and assess need for bronchodilator.
- Suction endotracheal and airway secretions.
- Place drug in nebulizer to fill volume of 4–6 mL.
- Place nebulizer in the inspiratory line 18 in (46 cm) from the 'y' connector.
- Turn off flow-by or continuous flow during nebulizer operation.
- Remove HME (if used) from circuit. Do not disconnect humidifier.
- Set gas flow to nebulizer at 6–8 L/min.
  - Use a ventilator if it meets the nebulizer flow requirements and cycles on inspiration, or
  - Use continuous flow from external source.
- Adjust ventilator volume or pressure limit to compensate for added flow.
- Tap nebulizer periodically until nebulizer begins to sputter.
- Remove nebulizer from circuit, rinse with sterile water and run dry, store in safe place.
- Reconnect HME, return ventilator settings and alarms to previous values.
- Monitor patient for adverse response.
- Assess outcome and document findings.

This table was published in Egan's *Fundamentals of Respiratory Care*, 8th edn, Wilkins RL et al., p. 795, Copyright Elsevier 2003 [20].

Bronchodilator therapy during non-invasive ventilation

Patients receiving non-invasive positive pressure ventilation (NIPPV) for treatment of acute and chronic respiratory failure often require inhaled bronchodilators. Despite several impediments to drug delivery in patients receiving NIPPV, significant bronchodilator responses have been observed after albuterol administration by a jet nebulizer or a pMDI [19].

PART 2.2

Cardiovascular drugs

CHAPTER 34

Vasopressors in critical illness

Daniel De Backer and Patrick Biston

Key points

- Norepinephrine is the agent of choice, especially in cardiogenic shock.
- Epinephrine is associated with more arrhythmias and metabolic undesired events, especially at high doses.
- Vasopressin, at low doses, seems to be a promising alternative to adrenergic agents.
- Nitric oxide inhibition should not be considered.
- Excessive vasoconstriction can compromise tissue perfusion.

Introduction

Vasopressor agents are used to increase arterial pressure in order to improve tissue perfusion. In most cases, these are used in patients with shock of various origins. Less frequently, they can be used to improve cerebral perfusion pressure.

Haemodynamic consequences of vasopressor agents

Vasopressor agents induce arterial vasoconstriction, resulting in an increase in blood pressure; the desired effect may also be accompanied by less desired effects. First, the increase in arterial pressure induces an increase in left ventricular afterload, which may impair cardiac output. Secondly, they may preferentially vasoconstrict some vascular beds, in particular, the skin and splanchnic area.

The haemodynamic consequences of vasopressor therapy vary according to the type of vasopressor agent and the indication for their use. In distributive shock, vasopressor agents help to counteract a markedly decreased vascular tone. Hence, the increase in left ventricular afterload is usually well tolerated. In addition, venous constriction of large capacitance veins decreases unstressed volume and increases ventricular preload [1] so that cardiac output is maintained in most cases. Skin and splanchnic vasoconstriction are usually limited [2]. In haemorrhagic and cardiogenic shock, the situation differs markedly. Regional vasoconstriction will already have occurred to preserve cerebral and myocardial perfusion. Administration of vasopressors further constricts these areas, potentially leading to local ischaemia. Left ventricular afterload increases and may impair cardiac output. The effects on myocardial oxygen balance are difficult to predict. The increase in diastolic pressure improves myocardial perfusion, but on the other hand, myocardial work also increases. Myocardial ischaemia may occur in some patients, especially when heart rate (HR) increases. In haemorrhagic shock, venous vasoconstriction has minimal effect, as capacitance veins are already empty. In cardiogenic shock, venous constriction of congested capacitance veins markedly increases ventricular preload that, combined with the increase in left ventricular afterload, may result in pulmonary congestion in patients with poor ventricular function.

When vasopressors are used to increase cerebral perfusion pressure, the increase in left ventricular afterload and increase in myocardial work are not compensated for by an increase in myocardial perfusion. It may result in myocardial ischaemia or even the Tako–Tsubo syndrome.

The impact on regional perfusion, in particular splanchnic and renal perfusion, also varies according to the indication. In vasodilatory shock, vasopressors usually preserve or even improve regional perfusion, while they further impair regional perfusion in other types of shock or when used to increased cerebral perfusion pressure.

Adrenergic vasopressor agents

Adrenergic agents exert their vasopressor effect through stimulation of alpha-adrenergic receptors. However, the different adrenergic vasopressor agents also variably stimulate beta and sometimes dopaminergic-adrenergic receptors. Stimulation of these receptors results in various haemodynamic and metabolic effects (Table 34.1).

Differences in receptor binding explain the different profiles of the various adrenergic vasopressor agents. Stimulation of beta-receptors is associated with an increase in contractility, HR, and regional perfusion [2], and is also associated with many potential untoward effects. Beta stimulation is responsible for the development of arrhythmias and metabolic effects, such as an increase in temperature, accelerated glycolysis, and hyperlactataemia. Beta stimulation also induces immunodepression [3]. Even though these effects are less pronounced in stress conditions than in healthy conditions [4], they may endanger haemodynamically-unstable critical patients.

Dopaminergic stimulation is associated with an increase in splanchnic and renal blood flow. However, this effect is almost non-existent in critically-ill patients. It also induces depression of the hypothalamo-pituitary axis [5], with suppression of prolactin release that may induce immunosuppression.

Most of the differences in haemodynamic effects between vasopressor adrenergic agents depend on the strength of stimulation of alpha- and beta-adrenergic receptors.

Norepinephrine

Norepinephrine is a powerful alpha-adrenergic agent with minimal beta-adrenergic effect, which results in a large increase in blood

Table 34.1 Main effects of adrenergic vasopressor agents

Receptor stimulation	Effects	Consequences
Alpha-adrenergic	Arterial constriction	Increase in arterial pressure
		Increased in cardiac afterload (= > decrease in cardiac output)
	Splanchnic constriction	Impaired splanchnic perfusion
	Venous constriction	Increase in cardiac preload (= > increase in cardiac output in preload dependent patients)
Beta-adrenergic	Cardiac (inotropic)	Increase in cardiac output
	Cardiac (chronotropic)	Tachycardia/arrhythmias
	Peripheral vasodilation	Hypotension
	Splanchnic vasodilation	Increase splanchnic perfusion
	Metabolic	Hyperthermia, accelerated glycolysis, hyperlactataemia, increased VO_2
	Immunological	Immunosuppression
Dopaminergic	Splanchnic dilation	Increase splanchnic and renal perfusion (questioned)
	Endocrine	Pituitary dysfunction

pressure, while cardiac output is preserved or even increased. It has minimal impact on HR [6].

Phenylephrine

Phenylephrine is a pure alpha-adrenergic agent that markedly increases blood pressure and may decrease cardiac output. The impact on cardiac output depends on relative changes in afterload and preload, and to the position on Starling curve. In preload dependent patients, cardiac output is usually preserved while it decreases in preload independent patients [7]. At a given volaemic state, phenylephrine, compared with norepinephrine, is associated with a decrease in cardiac output and splanchnic perfusion [8]. There are not enough data to evaluate the impact of this agent on outcome.

Epinephrine

Epinephrine results in a marked and proportional stimulation of alpha- and beta-adrenergic receptors, resulting in a combined increase in arterial pressure and cardiac output. As doses of this agent are titrated to its effect on blood pressure, beta-adrenergic stimulation may become excessive at high doses. As a result of this metabolic stimulation, an imbalance between oxygen demand and oxygen delivery may be observed, and this effect is even more pronounced in the splanchnic area [9]. When patients are randomized to receive norepinephrine or epinephrine, similar doses are required to reach the same blood pressure level [10–12]. Usual doses of epinephrine and norepinephrine are between 0.1 and 1.0 mcg/kg/min, but there is no upper dose recommended for either agent (very high doses may be futile, but survival has sometimes been observed in patients treated with doses of 5–10 mcg/kg/min for a few hours). Interestingly, HR, temperature, blood glucose, and blood lactate levels increase in patients receiving epinephrine, but not norepinephrine [10–12]. On the other hand, pH is usually lower in epinephrine than in norepinephrine patients. These differences decrease with time of exposure, but may last up to 2 days. Arrhythmias are more frequent in epinephrine-treated patients. Only one trial compared the effects of epinephrine with a combination of norepinephrine and dobutamine on outcome in patients with septic shock [10]. Mortality at 28 days did not differ significantly between the groups (epinephrine 40% versus norepinephrine 34%, $p = 0.31$), but the trial was not powered to evaluate the 6% difference in mortality rate. In addition, 5 mcg/kg/min of dobutamine was used in all patients in norepinephrine arm, and this dose was tapered down only when mean arterial pressure was at least 70 mmHg, which may have resulted in unnecessary beta-stimulation in many patients. A trial comparing epinephrine and norepinephrine in patients with cardiogenic shock is currently under way in France.

Dopamine

Dopamine has a relatively similar profile to epinephrine, but results in less potent stimulation on both alpha- and beta-receptors. Accordingly, around one-third of shock patients fail to respond to maximal doses of dopamine (20 mcg/kg/min), while most respond to norepinephrine or epinephrine. Compared with norepinephrine, dopamine is associated with a higher HR, while other haemodynamic variables are similar. In addition, there is an increase in arrhythmias, while the other side effects did not differ between the two drugs.

In a large-scale randomized trial comparing dopamine and norepinephrine as the first vasopressor agent, we failed to observe significant differences in day 28 risk of death between dopamine and norepinephrine (relative risk 1.17 [0.97–1.42], $p = 0.10$) [6]. Importantly, in the predefined subgroup of patients with cardiogenic shock ($n = 280$), there was a significant increase in mortality with dopamine (relative risk 1.38 [1.03–1.85], $p = 0.03$). In a meta-analysis focusing on patients with septic shock ($n = 1408$), there was also a significant increase in mortality with dopamine (relative risk 1.10[1.01–1.20], $P = 0.035$) [13].

Vasopressinergic agents

Arginine vasopressin is the most commonly used agent, characterized by a short half-life. Lysine vasopressin can also be used and

seems equally effective as vasopressin [14], but is characterized by a longer half-life and has been studied less. Selective V1 receptor agonists are currently in development. Only arginine vasopressin will be covered here. Vasopressin exerts its vasopressor properties through stimulations of V1 receptors, but also facilitates the response to adrenergic vasopressors. Vasopressin has weak vasopressor effects in normal conditions, but can markedly increase vascular tone in shock states, and especially in septic shock. This accentuated response to vasopressin in shock may be related to decreased endogenous levels of vasopressin, which usually occur after a few days, especially in septic shock, even though endogenous vasopressin levels are usually elevated during the initial phase. Vasopressin receptor stimulation also decreases vascular leakage. Of note, stimulation of V2 receptors favours platelet aggregation. Distribution of vasopressin receptors in the vascular tree is heterogeneous. Accordingly, vasopressin markedly decreases splanchnic perfusion (and portal vein pressure), especially at high doses. In the kidney, it also constricts efferent more than afferent arterioles, leading to an increase in glomerular filtration pressure.

Vasopressin use is mostly proposed in distributive and especially in septic shock. Arginine vasopressin at doses of 0.02–0.04 U/min increases blood pressure and spares adrenergic vasopressor use. Cardiac output is usually preserved, even though HR decreases slightly. Interestingly, urine output and creatinine clearance may increase during vasopressin administration, even though vasopressin is also named antidiuretic hormone [15]. The safety profile of this agent has been reported in several observational trials, but there is only one large-scale randomized trial that compared vasopressin with norepinephrine in the treatment of 778 patients with septic shock [16]. The haemodynamic profile of patients treated by these agents was similar with the exception that HR that was significantly lower in patients treated with vasopressin [17]. Of note, inotropic agents were more frequently used in vasopressin-treated patients. This trial did not demonstrate any difference in outcome in the entire population (28 days mortality: 35% in vasopressin group versus 39%, in norepinephrine group; $P = 0.26$) [16]. There were no differences in the incidence of side effects. In a predefined subgroup analysis, a decrease in mortality reaching borderline statistical significance was observed in the subgroup of patients treated with low doses of norepinephrine (less than 15 mcg/min) at the time of randomization (27 versus 36%, respectively, $p = 0.05$ for unadjusted Chi-square and $p = 0.03$ with log rank statistics), but not in the other patients (44 versus 43%, respectively, $p = 0.76$). These results, although promising, require confirmation. Of note, the criteria defining low severity at baseline is difficult to use at the bedside. It can change over time and, more importantly, patients of different weight receiving the same dose of norepinephrine (expressed in mcg/kg/min) may be classified differently.

Other vasopressor agents

Nitric oxide (NO) inhibition can be considered as NO may be implicated in excessive vasodilation in sepsis and in resuscitated cardiogenic shock. Disappointing results have been reported with non-selective NO synthase inhibitors. In a randomized trial including 797 patients with septic shock, 28 days mortality was higher in the NO inhibitor group compared with the placebo group (59 versus 49%; $P < 0.001$) [18]. A trial in patients with cardiogenic shock was stopped for futility after inclusion of 398 patients [19].

Selective inducible nitric oxide synthase (iNOS) inhibition may be more effective, but no compound has reached the clinical arena.

Methylene blue, as an inhibitor of guanylate cyclase, can blunt the effects of NO and thus improve vascular tone. This compound has only been tested in small trials, but improves arterial pressure and myocardial contractility with a short-lasting effect [20]. The impact on outcome has not been evaluated.

CHAPTER 35

Vasodilators in critical illness

A. B. J. Groeneveld and Alexandre Lima

Key points

- Administration of vasodilators is the treatment of choice for hypertensive emergencies and cardiogenic pulmonary oedema.
- Vasodilating therapy may alleviate pulmonary hypertension, but often at the expense of an increased venous admixture of oxygen in the lungs.
- Vasodilators can be used as potential adjunctive therapy to recruit microvascular perfusion in circulatory shock.
- Vasodilators may precipitate harmful hypotension and tachycardia, and should be carefully dosed.
- Invasive monitoring may be indicated for proper institution and guidance of vasodilator therapy.

Introduction

Vasodilator drugs play a major therapeutic role in hypertensive emergencies, primary and secondary pulmonary hypertension, and acute left heart and circulatory shock. Intravenous administration and titration guided by the haemodynamic response is preferred in the intensive care unit (ICU). There are large differences between individuals and drugs in dose–response relationships. As a rule, the vasodilating effect is greatest in patients with severe vasoconstriction.

Classes and types of vasodilators

The term vasodilator refers to drugs acting directly on the smooth muscles of peripheral vessel walls, and drugs are usually classified based on their mechanism or site of action. Some drugs have a predominant effect on resistance vessels (arterial dilators), while others primarily affect venous capacitance vessels (venous dilators). Although drugs may be classified as 'arterial' or 'venous' vasodilators, most have mixed properties. If the goal of vasodilation is preload reduction, one should target capacitance vessels. This will decrease venous return, and could lead to a fall in cardiac output and blood pressure. If the aim of vasodilation is an afterload reduction, one should target peripheral resistance vessels, which will improve forward stroke volume. Drugs can be divided in two types of pharmacological effects—vasodilator drugs with direct action on smooth muscle and drugs acting indirectly as vasodilators. Drugs with direct action target to relax vascular smooth muscle by interfering with calcium movements across cell membrane inhibiting the smooth muscle contracting process, such as calcium entry blockers. Drugs that interfere with sympathetic nervous system, block renin-angiotensin system, phosphodiesterase inhibitors and alpha-adrenoreceptor antagonists are some examples of drugs with indirect effect. Table 35.1 summarizes the main types of vasodilators drugs commonly used in the ICU.

Vasodilator therapy to control arterial blood pressure and to unload the left heart

Hypertensive emergencies

Drugs used for the treatment of hypertensive emergencies in the ICU include intravenously administered calcium channel inhibitors, sodium nitroprusside, nitroglycerin, phentolamine, and other alpha-adrenergic blockers, diazoxide, hydralazine, and angiotensin-converting enzyme inhibitors. These drugs reduce arterial blood pressure in a relatively short period of time, but effects may be erratic with dangerous episodes of hypotension threatening vital organ perfusion. Intravenous administration of alpha- and beta-adrenergic-inhibiting labetalol has gained popularity. The sublingual administration of both nifedipine and captopril is slightly more rapidly effective than the oral route, and has been shown to be effective initial treatment.

Dissecting aneurysm

Treatment should diminish wall stress by reducing arterial blood pressure and pulse pressure. Vasodilators are often associated with reflex tachycardia and a rise in pulse pressure so should be combined with beta-blocking agents to prevent a rise in wall stress. The short-acting vasodilating beta-receptor blocker esmolol may be an option as is the combined alpha- and beta-receptor blocker labetalol. Trimetaphan, a sympatholytic agent, has been the drug of choice for the acute management of aortic dissection because of a lack of reflex tachycardia and rise in pulse pressure.

Accelerated hypertension in pregnancy

Angiotensin-converting enzyme inhibitors are relatively contraindicated because of the risk of fetal death, while nitroprusside and nifedipine are contraindicated because of fear of toxicity. Preferred drugs are labetalol, hydralazine, ketanserin, and calcium channel blockers.

Post-operative hypertension

The drugs used for post-operative hypertension in the recovery room or the ICU include calcium antagonists, labetalol, nitroglycerin (glyceryl trinitrate), nitroprusside, ketanserin, and beta-blocking esmolol.

Table 35.1 Vasodilators in use in the ICU

	Route	Dose	Onset	Duration	Side-effects
Nitrates					
Nitroglycerin	IV	0.07–5 μg/kg/min	Minutes	5–10 minutes	Tachyphylaxis, flush, headache, collapse, confusion
	Sublingual	0.4–1 mg	20–30 seconds	1 hours	
Isosorbide dinitrate	IV	0.5–3.5 μg/kg/min	Minutes	Minutes	Tachyphylaxis, flush, headache, collapse, confusion
	Oral	5–40 mg four times daily	15–40 minutes	4–6 hours	
Sodium nitroprusside	IV	0.5–50 μg/kg/min	30 seconds	2–3 minutes	Must be shielded from light, thiocyanate, and cyanide toxicity, methaemoglobinaemia, lactic acidosis, vitamin B12 deficiency
Alpha/beta-blockers					
Phentolamine	IV	0.5–15 μg/kg/min	1–2 minutes	1 hours	Flush, vertigo, angina
	IV	1–10 mg bolus			
Labetalol	IV	3–35 μg/kg/min	5–10 minutes	3–6 hours	Bronchoconstriction, heart block
	Oral	100–1000 mg bd	1 hour	6–12 hours	
Calcium antagonists					
Nifedipine	IV	0.1–0.3 μg/kg/min	Minutes	Minutes	Headache, ankle oedema, hyperglycaemia
	IV	5–10 mg bolus	Minutes	Minutes	
	Oral/sublingual	10–20 mg at 1 h or 10–40 mg three times daily	2–5 minutes	3–6 hours	
Isradipine	IV	0.15–0.6 μg/kg/min	Minutes	Minutes	Headache, ankle oedema, hyperglycaemia
	IV	0.5 mg bolus	8 minutes	1–2 hours	
	Oral	5 mg bd	2 hours	5–7 hours	
Nicardipine	IV	1–5 μg/kg/min	5–15 minutes	30 minutes	Headache, ankle oedema, hyperglycaemia
	Oral	20–40 mg tds	1–20 minutes	3 hours	
Nimodipine	IV	0.2–0.5 μg/kg/min	Minutes	Hours	Headache, ankle oedema, hyperglycaemia
	Oral	30–90 mg qds			
Clevidipine	IV	1 mg/h until a maximum of 21 mg/h	2–4 minutes	5–15 minutes	Arrhythmias, fever, gastrointestinal complaints
Angiotensin-converting enzyme inhibitors					
Captopril	Oral/sublingual	12.5–50 mg qds	10–15 minutes	6–12 hours	Renal failure, cough
Enalapril(at)	IV	0.2–0.4 μg/kg/min	15 minutes	6 hours	Headache, ankle oedema, hyperglycaemia
	Oral	5–40 mg/day	1 hours	4–6 hours	
Prostaglandins					
Epoprostenol	IV	5–35 ng/kg/min	Minutes	Minutes	Flush, hypoxaemia
Prostaglandin E_1	IV	20–100 ng/kg/min	Minutes	Minutes	Hypotension, diarrhoea, flush, headache

(*continued*)

Table 35.1 Continued

	Route	Dose	Onset	Duration	Side-effects
Phosphodiesterase inhibitors					
Enoximone	IV	Loading 0.1–2 mg/kg	10–30 minutes	3–6 hours	Arrhythmias, headache, gastrointestinal complaints
		Maintenance 5–20 μg/kg/min			
Amrinone	IV	Loading 0.75 μg/kg	10 minutes	3–6 hours	Arrhythmias, headache, gastrointestinal, thrombocytopenia
		Maintenance 5–10 μg/kg/min			
Milrinone	IV	Loading 50 μg/kg	5 minutes	6–8 hours	Arrhythmias, headache, gastrointestinal complaints
		Maintenance 0.5–0.75 μg/kg/min			
Miscellaneous					
Hydralazine	IV	0.2–5 μg/kg/min	15 minutes	3 hours	Tachycardia, lupus
	IV	5–10 mg bolus			
	Oral	25–100 mg bd	45 minutes	4–24 hours	
Ketanserin	IV	0.7–1.5 μg/kg/min	Minutes	1 hour	Arrhythmias, headache
	Oral	20–40 mg bd			
Trimetaphan	IV	5–50 μg/kg/min	1–5 minutes	10–15 min	Blurred vision, dry mouth, bladder, and gut paresis
Diazoxide	IV	0.7 μg/kg/min	5 minutes	6 hours	Hyperglycaemia
	IV	1–3 mg/kg bolus			
Levosimendan	IV	0.05–0.2 μg/kg/min	10–30 minutes	7 days (due to active metabolite)	Headache, arrhythmias

Acute congestive heart failure

Control of arterial blood pressure may help unload the heart and ameliorate pulmonary congestion. Nitroglycerin lowers the left heart filling pressure more than nitroprusside because of its greater venodilating effect. Unloading can also be performed by intravenous (iv) bolus doses of alpha-receptor blocking agents (such as phentolamine and urapidil) or enalaprilat, and by sublingual or iv doses of nifedipine and other first-generation calcium antagonists, although the latter have negative inotropic properties.

Vasodilator therapy to control pulmonary artery pressure and to unload the right heart

No systemically administered vasodilator has a completely selective pulmonary effect. In cases of shock complicated by pulmonary hypertension, systemic arterial hypotension aggravated by vasodilators may lead to (right) coronary hypoperfusion, further diminishing the right ventricular oxygen supply–demand balance and preventing a rise in cardiac output. Hence, it is better to treat pulmonary hypertension complicated by shock with vasoconstrictors rather than vasodilators [1].

Primary pulmonary hypertension

The treatment of primary pulmonary hypertension is often a matter of trial and error since sensitivity to one vasodilator does not imply sensitivity to another. Sensitivity can be tested in the ICU and this may help in the subsequent choice of vasodilators that can be administered orally on a long-term basis [2]. Acute responsiveness of the pulmonary circulation and long-term lowering of pulmonary artery pressure may improve right ventricular function and thereby ultimate survival [2].

Secondary pulmonary arterial hypertension

Vasodilators have been used to attenuate pulmonary hypertension selectively and unload the right heart. Epoprostenol appears to be a non-selective vasodilator that may lower pulmonary artery pressure and arterial oxygenation, and may not increase tissue oxygen delivery. In contrast, prostaglandin E_1 may have greater pulmonary vascular selectivity and less inhibitory effect on hypoxic vasoconstriction. Its administration in decompensated chronic obstructive lung disease may result in amelioration of pulmonary hypertension, and increased cardiac output and tissue oxygen delivery.

Pulmonary embolism

Some clinical studies have shown the potential haemodynamic and gas exchange benefit of nitric oxide (NO) inhalation in patients with pulmonary embolism [3]. Phosphodiesterase inhibitors and levosimendan have been used to restore right ventricular function in acute pulmonary embolism as a result of a combined pulmonary vasodilation and increased right ventricular contractility effect [3].

Septic shock and acute respiratory distress syndrome

During sepsis and acute respiratory distress syndrome, pulmonary vascular changes are thought to contribute to the diminished ability of the right heart to generate a sufficiently high cardiac output to meet increased tissue oxygen requirements [4]. Pulmonary hypertension can be ameliorated with the serotonin antagonist ketanserin without a rise in venous admixture. The use of (non-selective) nitrovasodilators and phosphodiesterase inhibitors may not increase tissue oxygen delivery due to a limited rise in cardiac output.

Vasodilating prostaglandins have been used as selective pulmonary vasodilators [5]. Prostaglandins may increase cardiac output, dilate pulmonary blood vessels, and maintain or increase PaO_2. Vasodilating prostaglandins have immunomodulating properties that may limit the inflammatory response in the lungs and thereby increase pulmonary gas exchange and patient survival [5]. NO inhalation dilates both airways and vessels locally, thereby improving ventilation-to-perfusion matching in during mechanical ventilation of severe cases of acute respiratory distress syndrome. Although effective on gas exchange and unloading the right ventricle, outcome benefit has not been proved.

Vasodilator therapy to improve the blood pressure–flow relationship

Vasodilator therapy has been used as an adjunct to recruit microvascular perfusion in circulatory shock. A rise in oxygen delivery and uptake may sometimes be accompanied by a rise in oxygen extraction, suggesting improved microcirculatory blood flow with this type of drug [6].

During reperfusion following ischaemia, cells are overloaded with calcium and this is believed to contribute to reperfusion injury. Hence, calcium antagonists have been studied in various models of shock and resuscitation for potentially protective effects on organ function. There is no place for the routine use of calcium antagonists in situations associated with ischaemia and reperfusion, even though the (cerebral) outcome of cardiac arrest was shown to be improved by the administration of the calcium antagonist nimodipine during prolonged cardiopulmonary resuscitation [7].

In subarachnoid haemorrhage nimodipine reduces cerebral vasospasm and subsequent ischaemic necrosis by dilating cerebral vessels and inhibiting cellular calcium overload thereby protect neurones. Adjunctive treatment with such drugs has been shown to improve neurological status and survival following subarachnoid haemorrhage [7].

Specific drugs

Nitrovasodilators

These drugs are the most frequently used vasodilators in the ICU [8]. Although sodium nitroprusside has mainly arterial vasodilating properties, nitroglycerin compounds are predominantly venodilators. At higher doses, they also have an arterial dilating effect and lower arterial blood pressure. The compounds release NO stimulating production of cyclic guanosine monophosphate in the vessel wall, leading to relaxation [8]. When administered intravenously, they have a rapid onset of action that is of short duration. The major limitation is the development of nitrate tolerance, most often seen after long-term continuous administration that can be circumvented by nitrate-free intervals (asymmetric dosing).

The drugs are occasionally used as adjunctive therapy in the treatment of shock, particularly if caused by a low cardiac output (e.g. in cardiogenic shock, after cardiopulmonary surgery, etc.). Nitroglycerin has been the vasodilator of choice to recruit the microcirculation in critically-ill patients. Apart from its quick onset of action (2–5 minutes) with half-life elimination of 1–3 minutes, the specific effect on smooth muscle mainly on the venous side of the vasculature leads to an increase in intravascular pressure gradient and in microvascular blood flow.

The major side-effect of nitroprusside is thiocyanate and cyanide toxicity, a complication that is usually avoided if treatment is limited to 3 days at maximum doses below 3 micrograms/kg/min with normal renal function. Signs of toxicity include central nervous system symptoms. Monitoring of thiocyanate levels in blood is mandatory during prolonged treatment with nitroprusside. The treatment of choice for toxicity is iv hydroxocobalamin (5 mg). Another potential specific side-effect of nitrovasodilators is methaemoglobinaemia.

Alpha-blockers

Some alpha-receptor blockers, such as phentolamine ($alpha_{1-2}$ blockade) are non-selective, and others, such as labetalol ($alpha_1$- and beta-blocker), are selective. Stimulation of the $alpha_1$ receptor causes arteriolar and venous constriction, and stimulation of the $alpha_2$-receptor causes decreased central sympathetic outflow. This type of drug is particularly useful in the treatment of pheochromocytoma crises, hypertension following intracranial hypertension, and pregnancy-induced hypertension [7].

Calcium antagonists

The first-generation calcium antagonists nifedipine, verapamil, and diltiazem have negative inotropic properties rendering these drugs less suitable for patients with (borderline) heart failure or for combination therapy with beta-blockers. The second-generation drugs, which include isradipine, nicardipine, and nimodipine, have fewer side-effects. These drugs have powerful vasodilating properties, and lack significant effects on cardiac conduction and contractility.

Clevidipine, a third-generation dihydropyridine calcium-channel blocker with unique pharmacodynamic and pharmacokinetic properties, is an ultra-short-acting selective arteriolar vasodilator that reduces blood pressure by a direct and selective effect on arterioles. This drug has been shown beneficial in the treatment of hypertensive emergencies and post-operative hypertension [9].

The compounds are commonly used in the ICU for control of arterial blood pressure and vasospasm. Intravenous forms can be used to control arterial blood pressure, and to unload the left heart during accelerated arterial hypertension. Oral and iv nimodipine can be used to prevent and treat cerebral vasospasm during subarachnoid haemorrhage.

Angiotensin-converting enzyme inhibitors

Angiotensin-converting enzyme inhibitors can be used both intravenously and orally. They unload the heart by lowering systemic vascular resistance, and can be useful in the acute (and chronic) treatment of arterial hypertension and cardiac pump failure. They can be administered intravenously or sublingually/orally for the rapid lowering of arterial blood pressure. The relatively slow onset and long duration of action make angiotensin-converting enzyme inhibitor a poor choice for use in a hypertensive crisis. Contraindications for their use include serious disturbance of renal function and the presence of a renal artery stenosis, since administration of these drugs in these situations can lead to severe renal dysfunction.

Phosphodiesterase inhibitors

The mechanism of action of these drugs is inhibition of phosphodiesterase in the heart and vascular wall with accumulation of cAMP. These 'inodilators' increase myocardial contractility without a major rise in heart rate or myocardial oxygen demand, and produce a fall in peripheral vascular resistance without a major blood pressure lowering effect. They may specifically unload the right heart. They increase cardiac compliance and have a prolonged duration of action. They can be used judiciously, mainly as an adjunct to standard therapy in patients in whom cardiac output is (relatively) low, for instance during post-myocardial infarction shock and after cardiopulmonary bypass surgery. Severe hypotension does not usually occur, but can be a major limitation in some patients. The drugs are also used when acute pulmonary hypertension contributes to predominant right heart failure (cor pulmonale).

Miscellaneous drugs

Hydralazine, diazoxide, and phentolamine can be administered continuously and, since the blood-pressure-lowering effect may be relatively prolonged, as a bolus. The ganglion blocker trimetaphan has been used in the past for the treatment of aortic dissection and for controlled hypotension during surgery. This drug, which is continuously infused, acts rapidly and has a short duration of action. It inhibits the action of acetylcholine at autonomic ganglia competitively, thereby blocking sympathetic and parasympathetic pathways. Thus, the hypotensive effect is not accompanied by a baroreceptor-mediated reflex tachycardia.

Levosimendan is indicated to conditions where vasodilation together with enhanced myocardial contractility is needed. Therefore, it is mainly used for haemodynamic support in acute pulmonary embolism or as short-term treatment of acutely decompensated severe chronic heart failure or cardiogenic shock. Its slower elimination and the active circulating metabolites are the main drawbacks of levosimendan [2].

CHAPTER 36

Inotropic agents in critical illness

Abdallah Fayssoil and Djillali Annane

Key points

- Inotropes are pharmacological agents used to improve cardiac contractility.
- Dobutamine is a cardiac beta-receptor agonist and is used as a first line inotrope in patients with severe heart failure and a systolic blood pressure of less than 85 mmHg or sepsis with myocardial dysfunction.
- Levosimendan is a calcium sensitizer agent that has positive inotropic action and vasodilator effect.
- Phosphodiesterase (PDE) inhibitors are inotropic agents that increase intracellular cyclic adenosine monophosphate (cAMP) and are no more used routinely.
- Epinephrine is a non-selective alpha- and beta-agonist agent.

Introduction

In the ICU, inotropes are pharmacological agents that are used for haemodynamic support in patients with shock. Inotropes act on cardiac contractility and improve cardiac output. This phenomenon relies on mobilization of intracellular calcium. Inotropes are mainly indicated in patients with hypoperfusion and low cardiac output. In the Acute Decompensated Heart Failure Registry (ADHERE), an inotrope was administrated in 19% of patients with reduced left ventricular ejection fraction (LVEF) [1]. In the Euro-Heart Failure Survey II (EHFS II), 25% of patients with acute heart failure (AHF) were treated with inotropes [2].

Classification of inotropes according to their mechanism of action

Different inotropes have been described according to their mechanism of action. Inotropes improve cardiac output by an increase in stroke volume and heart rate [3]. Stimulation of beta-adrenergic receptors leads to an increase in myocardial contractility, heart rate (HR), hepatosplanchnic blood flow and results in vasodilation (via beta 2-receptors). Inotropic agents are classified as:

- **Agents increasing intracellular cyclic adenosine monophosphate (cAMP)**: beta-adrenergic receptor (beta-AR) agonists and phosphodiesterase (PDE) inhibitors. These agents increase intracellular concentration of cAMP. The protein kinase A (PKA) is activated and followed by phosphorylation of other proteins involved in myocardial contraction (phospholamban, sarcolemmal calcium channels, troponin I). PDE inhibitors increase cAMP concentration by inhibiting cAMP degradation.
- **Agents increasing sensitivity to intracellular calcium**: e.g. levosimendan.
- **Agents inhibiting Na+/K+ ATPase pump**: e.g. digoxin.

Classification according pharmacological properties

Digoxin

Digoxin is an old drug used in heart failure. Digoxin has positive inotrope effects by inhibiting the Na-K-ATPase pump and increasing intracellular calcium. Inhibition of Na-K-ATPase pump diminishes outward sodium pumping and increases intracellular calcium. According to the European Society of Cardiology (ESC), digoxin is recommended in patients with symptomatic heart failure who are unable to tolerate a beta-blocker (GRADE 1B). Also, digoxin is recommended as a second drug, in addition to beta-blocker, in order to control ventricular rate in patients with inadequate response to beta-blocker (GRADE 1B). Digoxin should be using with caution in patients with renal failure. Furthermore, toxicity is increased in patients with hypokalaemia, hypomagnesaemia and ischaemic disease.

Catecholamines

Dobutamine

Dobutamine acts on **beta 1**- and **beta 2**-receptors with variable action on alpha-receptor. Dobutamine is the most commonly used inotropic agent worldwide. Dobutamine stimulates cardiac beta 1-receptors, thereby increasing stroke volume, HR, and cardiac output. Tachyphylaxis may occur after 72 hours of continuous dobutamine infusion, as a result of down-regulation and desensitization of beta 1-myocardial receptors [4]. On vascular smooth muscle, dobutamine stimulates **alpha 1**-adrenergic receptors and **beta 2**-receptors resulting in vasodilation, particularly at lower doses (≤5 micrograms/kg/min). Dobutamine is recommended in patients with severe heart failure and a systolic blood pressure of less than 85 mmHg[5]. The European Society of Cardiology guidelines recommend initiation of Dobutamine at low dose (2 micrograms /kg/min) and to not exceed 20 micrograms /kg/min in acute heart failure [5]. According to the

Surviving Sepsis Campaign (SSC) [6], dobutamine is the preferred inotropic agent in patients with low cardiac output. The SSC recommend a dobutamine infusion up to 20 micrograms/kg/min or in addition to a vasopressor (if in use) in the presence of myocardial dysfunction as suggested by elevated cardiac filling pressures and low cardiac output, or ongoing signs of hypoperfusion despite achieving adequate intravascular volume and adequate mean arterial pressure (GRADE 1C). Dobutamine increases myocardial oxygen consumption and can cause arrhythmias and myocardial ischaemia.

Dopamine

Dopamine is a precursor of norepinephrine. Dopamine acts on dopaminergic receptors located in mesenteric, renal, and coronary vessels. Dopamine stimulates cardiac **beta 1**- and **beta 2**-receptors. In peripheral vasculature, dopamine stimulates **alpha**-receptors. It is important to note that pharmacological effects of dopamine are dose-dependent. At a dose of <3 micrograms/kg/min, dopamine vasodilates by stimulating dopaminergic receptors (D1) in the kidneys and splanchnic vessels. At doses between 3 and 5 μg/kg/min, dopamine increases myocardial contractility and heart rate by stimulating cardiac beta 1-receptors. At higher dose, i.e. >5 micrograms/kg/min, dopamine vasoconstricts and thereby increases afterload. In theory, dopamine may increase renal blood flow and may improve renal function [7]. In practice, in critically-ill patients, low-dose dopamine showed no evidence for any potential benefits [6]. Dopamine is usually used as a vasopressor agent. In critically-ill patients with shock, a randomized controlled trial showed dopamine was associated with a risk of arrhythmias (24.1 versus 12.4%, $p < 0.001$) when compared with norepinephrine [8]. In a recent meta-analysis, in patients with septic shock, dopamine was associated with higher mortality and a risk of life threatening arrhythmias, compared with norepinephrine [9].

Norepinephrine

Norepinephrine stimulates mainly **alpha**-adrenergic receptors and has modest **beta**-agonist activity. Thus, this drug induces vasoconstriction with less inotropic function. In septic shock, norepinephrine increases venous return and venoconstriction [10]. In post-operative cardiac surgery, norepinephrine may increase cardiac function by veno-constriction [11].

Epinephrine

Epinephrine is a non-selective **alpha**-agonist and **beta**-agonist agent. At a low dose <0.05 micrograms/kg/min, epinephrine stimulates mainly beta-receptors leading to an increase in HR and contractility. At a higher dose, epinephrine stimulates vascular alpha 1-receptors and myocardial beta 1-receptors leading to an increase in systolic and diastolic pressures. In patients not responding to norepinephrine, the SSC [6] recommend the introduction of epinephrine in patients with septic shock to maintain adequate blood pressure (GRADE 2B). Epinephrine may induce arrhythmia and ischemic events. In the CATS trial [12] epinephrine infusion was associated with 12% supraventricular arrhythmias, 7% ventricular arrhythmias, 3% acute coronary events, 1% stroke, and 1% limb ischaemia.

Non-catecholergic agents

Levosimendan

Levosimendan is a calcium sensitizer agent that has a positive inotropic action and vasodilator effects. Levosimendan acts on myocardial contraction via calcium sensitization effects on the contractile apparatus, with a resulting increase in myocardial contraction, and by acting on ATP-dependent potassium channels on vessels with resulting vasodilation. Levosimendan increases cardiac contraction, decreases pulmonary artery wedge pressure, pulmonary artery pressure and systemic vascular resistance. The LIDO trial compared short-term haemodynamic effects of 24-hour intravenous (iv) infusion of levosimendan to dobutamine in patients with severe low-output heart failure [13]. In this trial, the haemodynamic end-point (an increase of 30% or more in cardiac output and a decrease of 25% or more in pulmonary artery wedge pressure at 24 hours) was achieved in significantly more levosimendan-treated than dobutamine-treated patients (28 versus 15%, $p= 0.022$). The SURVIVE (Survival of Patients with Acute Heart Failure in Need of Intravenous Inotrope Support) study compared levosimendan to dobutamine in patients with acute heart failure [14]. At 6 months, there was no significant difference in mortality between groups (26 versus 28%, p 0.40). The ESC guidelines recommend infusion of levosimendan (or a phosphodiesterase inhibitor) to reverse the effect of beta-blockade if beta-blockade is thought to be contributing to heart failure [5] .

Phosphodiesterase inhibitors

Phosphodiesterase inhibitors increase intracellular cAMP by decreasing its degradation. In vascular smooth muscle cells, PDE inhibitors induce relaxation of smooth muscle and lead to vasodilation. Milrinone is a phosphodiesterase 3 inhibitor that blocks the breakdown of cAMP in cardiac cells and vascular smooth muscle leading to inotropic action and pulmonary vasodilation. Milrinone is usually used at doses ranging from 0.375 to 0.75 micrograms/kg/min in acute heart failure. Compared with dobutamine, milrinone causes a greater decrease in systemic vascular resistance, pulmonary artery wedge pressure, and mean pulmonary artery pressure. The effects of iv milrinone for exacerbations of chronic heart failure were investigated in a randomized controlled study that included 949 patients with acute exacerbation of chronic heart failure and low left ventricle (LV) ejection fraction [15]. In this trial, milrinone administration was associated with a significant increase in the rate of hypotension (10.7 versus 3.2%, $p < 0.001$) and of atrial arrhythmias (4.6 versus 1.5%, $p < 0.004$) without survival benefit. Enoximone is another phosphodiesterase inhibitor that can be used in acute heart failure. Enoximone is usually used at dose ranging from 5 to 20 micrograms/kg/min [5].

Potential future inotropes

Cardiac myosin activators

These drugs target myocardial myosin adenosine triphosphate. The result is an increase in the efficiency of actin–myosin cross-bridge formation. This phenomenon induces contractility without affecting intracellular calcium levels.

Istaroxime

Istaroxime is an agent with inotropic and lusitropic effects. This drug induces an inhibition of Na-K-ATPase, leading to an increase in cytosolic calcium and an activation of sarcoplasmic reticulum calcium ATPase isoform-2(SERCA 2). Subsequently, calcium reuptake is enhanced and improves myocardial relaxation (lusitropy). Istaroxime improves left ventricular diastolic function.

SERCA 2A activators

In heart failure, SERCA 2A favours the reuptake of calcium into the sarcoplasmic reticulum. In heart failure, down-regulation of SERCA 2A leads to an increase in calcium in the cytoplasm with subsequently arrhythmia and cardiac dysfunction.

CHAPTER 37

Anti-anginal agents in critical illness

Ajay Suri and Jean R. McEwan

Key points

- A full understanding of anti-anginals and their mechanism of action, possible side effects, contraindications and interactions, and effects of withdrawal is of paramount importance in the critically-ill patient.
- Beta-blockers and calcium (Ca) channel blockers are the usual first-line treatments for angina, but may not be ideal in the critically-ill patient because of their negative inotropic and chronotropic effects.
- Nitrates reduce blood pressure without typically affecting heart rate. Their most common side effect is profound hypotension. Nicorandil has a similar mechanism of action and tends to be given orally.
- Ivabradine, an I_f channel blocker, is a newer anti-anginal. Its primary mechanism of action is to reduce heart rate, while not affecting blood pressure.
- Ranolazine is the one of the newest anti-anginal agents. Its effects are independent of heart rate and blood pressure.

Introduction

Angina is chest pain resulting from the lack of blood supply to the heart muscle. This is usually caused by insufficient blood flow through coronary arteries, most commonly due to obstructive atherosclerotic plaque, although rarely may be due to coronary artery spasm [1]. Other causes of angina include hypertrophic cardiomyopathy, where a combination of increased demand by the hypertrophied muscle and poor tissue perfusion, due to poor flow down small vessels is thought to be the cause of the ischaemic pain. Patients on intensive care units (ICUs) who experience chest pain will usually be bedbound and at physical rest. However, surgical wounding and sepsis increase metabolic demand, and there may be other stresses such as anaemia, so sympathetic drive with increased heart rate will increase the demand on the heart. In addition, the patient with sepsis or who is post-surgery will be pro-thrombotic and at increased risk of thrombus formation on an unstable plaque.

Patients in the intensive treatment unit (ITU) may be sedated, fully anaesthetized or receiving analgesia for other reasons and, in these circumstances, may not complain of pain. Electrocardiogram (ECG) and haemodynamic monitoring, including echocardiographic imaging of function may detect cardiac ischaemia. The angina experienced by ICU patients is correctly considered as unstable, requiring urgent medical treatment to help alleviate distressing symptoms for the patient, and because the chest pain or ECG changes indicates critical coronary perfusion and may herald a myocardial infarction.

Anti-anginals are drugs that are used in the treatment of stable angina and they may also help alleviate ECG, and haemodynamic or echocardiographic signs of cardiac ischaemia. These drugs can be used alone or in conjunction with each other, but are most effective if used with a full understanding of their mechanism of action, possible side effects, contraindications, and interactions. While they may be prescribed in an effort to control new symptoms and signs of myocardial ischaemia in ICU patients, another consideration is that patients who become acutely unwell may experience the effects of sudden withdrawal of long-term medications, such as beta-blockers, prescribed previously for stable angina.

Beta-blockers

Beta-adrenoceptor blockers work as competitive inhibitors of the endogenous catecholamines, adrenaline, and noradrenaline at the β-adrenergic receptors of the sympathetic nervous system. This system mediates the fight-or-flight response and beta-blockers blunt metabolic and cardiovascular pathways that are stimulated in sick patients. There is some evidence that beta-blockade may reduce peri-operative mortality in patients undergoing major non-cardiac surgery, who are also at high coronary vascular risk [2,3]. However, some trials have shown the opposite with increased death and adverse outcomes [4], and currently the best treatment strategy is still debated.

Beta-blockers work on beta 1-, beta 2-, and beta 3-receptors. The anti-anginal effects are mainly through beta 1-blockade. This reduces heart rate and myocardial contractility, while reducing blood pressure and cardiac after-load. As a result, myocardial oxygen consumption and the potential for ischaemia under conditions of sympathetic drive, such as exercise or pain are reduced [5]. Beta 2-adrenergic receptor blockade inhibits smooth muscle relaxation in blood vessels, bronchi, gastrointestinal, and the genito-urinary tract and beta 3-adrenoceptors are known as metabolic receptors, where they mediate lipolysis in adipose tissue. However, evidence is emerging that these receptors are also expressed in human cardiomyocytes and endothelial cells [6], where they are thought to mediate coronary dilatation through the production

of endothelium-derived relaxing factor and endothelium-derived hyperpolarization factors [7].

Beta-blockers can be given orally or intravenously. Metoprolol is the most commonly used short-acting agent, and has readily available oral and intravenous (iv) preparations. Bisoprolol is a beta-1 receptor cardioselective agent and has the advantage of once daily (od) only administration. An additional benefit from beta-blockers comes from their potential anti-arrhythmic effects. The most important side effects of beta-blockers in ICU patients are the ones that may affect haemodynamics, ventilation, or metabolic homeostasis.

Haemodynamic side effects

Beta-blockers may cause hypotension, heart failure, bradycardia, and heart block. Unusually, beta-blocker-induced diarrhoea can cause volume loss and exacerbate hypotension. Bronchoconstriction is a beta 2-related side effect and may be problematic in asthmatics and patients with chronic obstructive pulmonary disease. Other beta 2 side effects include peripheral vasoconstriction. Metabolic side effects include beta-blocker-induced inhibition of both glycogenolysis and gluconeogenesis, resulting in hypoglycaemia [8]. Therefore, beta-blockers should be used in caution in diabetics, as the opening warning sign of tachycardia may be masked. Non-selective and beta 1-selective beta-blockers also affect lipid metabolism by reducing high-density lipoprotein (HDL) possibly through intrinsic sympathomimetic activity. Low-density lipoproteins (LDL) are felt to increase slightly with these agents, as well as triglycerides through unopposed alpha-adrenergic receptor blockade, inhibiting the lipase that acts on triglycerides [9]. Notably, all these side effects are less common in beta 1-selective beta-blockers, but at higher doses, receptor selectivity diminishes.

Of particular relevance to intensive care patients are the more lipophilic beta-blockers, such as propranolol and metoprolol, are much more likely to cross the blood–brain barrier, and could potentiate insomnia, hallucinations, and nightmares [10]. Abrupt withdrawal of beta-blockers may cause rebound hypertension, arrhythmias, and angina.

Ca channel blockers

Ca channel blockers work by inhibiting calcium movement through voltage-gated Ca channels in myocardium and blood vessels [11]. There are two classes of Ca channel blockers. The dihydropyridine Ca channel blockers work primarily by causing dilatation and relaxation of arterial vascular smooth muscle, reducing systemic resistance and blood pressure [12]. Dihydropyridine Ca channel blockers are more commonly used to treat hypertension, rather than angina. They may cause a reflex tachycardia, so this class may be theoretically less useful as an anti-anginal. However, with lower blood pressure the afterload decreases and there is less work for the heart. The stress developed in the left ventricle during ejection is therefore considerably less and myocardial oxygen consumption is decreased. Only dihydropyridines amlodipine, nifedipine, and nicardipine are licensed to treat chronic stable angina.

The non-dihydropyridine Ca channel blockers are further sub-divided into phenylalkylamine (verapamil) and benzothiazepine (diltiazem) groups [12]. Both verapamil and diltiazem treat angina by reducing heart rate and force of contraction, thereby reducing myocardial oxygen demand. Verapamil is more negatively inotropic than diltiazem and, although both have minimal vasodilatory effects, they also slow down the conduction of electrical activity within the heart by blocking the Ca channel during the plateau phase of the action potential of the heart. These Ca channel blockers may be used alone or in combination with other drugs for rate or rhythm control in atrial arrhythmias, such as atrial fibrillation, which may induce angina through tachycardia. Side effects tend to be minor and can be due to its vasodilatory effects, such as flushing and headache. Others include nausea, rashes, tiredness, leg oedema, and dizziness. Sudden withdrawal of Ca channel blockers may worsen angina and also promote tachycardia.

Nitrates

Nitrates have not influenced outcomes (death or cardiovascular events) in clinical trials of myocardial infarction [13], but can be used treat anginal chest pain and manipulate haemodynamics. Nitroglycerin is usually given as a sublingual spray or, less commonly, as a buccal tablet. There is a rapid onset of action as this mode of delivery avoids first-pass metabolism. The effects are short-lived, lasting around 30 minutes. The effects of transdermal patches can last for up to 24 hours. Oral nitrate preparations with a longer onset of action and duration of treatment are isosorbide mononitrate and isosorbide dinitrate. Oral preparations usually require higher doses as they do not bypass first pass metabolism in the liver, but isosorbide mononitrate is not metabolized in the liver and so has almost 100% bioavailability.

In intensive care patients, the most commonly used preparations are iv formulations. These can be titrated to symptoms and also have the added benefit of being able to also treat hypertension and acute heart failure. Intracellular enzymes and sulphydryl groups reduce the drug's nitrate groups to s-nitrosithiol and then to nitric oxide (NO) or directly to NO. Through multiple mechanisms NO cause the relaxation of vascular smooth muscle, which is its primary effect while endogenous. NO also inhibits platelet aggregation, which is the interaction between leukocytes and endothelium, and is anti-inflammatory. Nitrates dilate veins more effectively than arteries and this reduces ventricular preload. In addition, the reduction in diastolic ventricular wall stress helps improve subendocardial blood flow and improves oxygen supply/demand ratio.

The most common side effects of nitrates are headache and skin flushing. More serious side effects are hypotension and reflex tachycardia that may exacerbate angina. Another important consideration is patients with pulmonary hypertension and right-sided heart failure on cyclic guanosine monophosphate (cGMP)-dependent phosphodiesterase inhibitors (e.g. sildenafil, tadalafil) used for the management of pulmonary hypertension and acute respiratory distress syndrome (ARDS), may experience further worsening of angina if nitrate is prescribed concomitantly. The reason for this adverse reaction is that nitrates stimulate cGMP production and cGMP-dependent phosphodiesterase inhibitors inhibit cGMP degradation so when combined, these two drug classes greatly potentiate cGMP levels, leading to impaired coronary perfusion through profound hypotension. Withdrawal from nitrates should always be gradual as sudden cessation may cause angina, myocardial infarction, or even sudden death.

Nicorandil

Nicorandil belongs to a class of drugs known as the K^+_{ATP} channel agonists. It mainly functions as an arterial vasodilator, but has the added property of further arteriolar and venodilatation attributable to a nitrate group of its structure. There is some evidence to suggest that potassium (K) channel activation may also exert a direct cytoprotective effect against ischaemia through pharmacological preconditioning and the activation of K^+_{ATP} channels within myocardial mitochondria, although the exact mechanism remains unclear. Nicorandil is given orally, although there is some experimental evidence for its benefits intravenously. Outcome evidence for this drug is exhibited in the Impact of Nicorandil on Angina (IONA) trial, which showed benefit in stable non-ITU patients with a dose of 20 mg bd [14]. The most common cause for discontinuation of this drug is headache in around 5% of patients, but starting patients at the initial lower dose of 5 mg bd may overcome this. Other side effects include flushing, nausea, mouth ulcers, and palpitations. There is no evidence of an abrupt withdrawal syndrome with sudden cessation of nicorandil.

Ivabradine

This novel agent was first approved in Europe in 2005 and works by selectively inhibiting the I_f channel within the sino-atrial node. In contrast to the other anti-anginals that slow heart rate, this drug is not negatively inotropic and could be useful in sick patients who already have poor cardiac function. The I_f channel is highly expressed in the sino-atrial node and is a mixed Na^+–K^+ inward current channel activated by hyperpolarization and modulated by the autonomic nervous system. Ivabradine blocks this channel in a dose-dependent manner, thereby reducing the cardiac pacemaker activity of the node. The BEAUTIFUL study looked at nearly 11,000 patients across 33 countries and showed that ivabradine significantly reduced the rates of coronary events, myocardial infarction, and coronary revascularization in angina patients with a heart rate above 70 bpm [15]. Ivabradine is therefore used in patients who cannot or should not be on beta-blockers and can be used in combination with beta-blockers in patients with inadequately-controlled chronic stable angina, whose heart rate exceeds 60 bpm on a beta-blocker alone. The SHIFT study also showed that adding ivabradine to optimal heart failure medication decreases both cardiovascular death rate and risk of hospitalization for heart failure [16].

The most common side-effect of ivabradine is a luminous phenomenon described by patients as sensations of enhanced brightness in a fully-maintained visual field, which are often mild, short-lived, and fully reversible. This is probably due to blockage of the I_h ion channels in the retina, which are very similar to cardiac I_f channels. In clinical studies, about 1% of all patients had to discontinue the drug because of these sensations that occurred, on average, 40 days after starting the drug. The next most common problem is bradycardia in 5% of patients on the maximum 10 mg dose. Up to 4.8% of patients report headaches. Other common drug reactions are ventricular extrasystoles, dizziness, blurred vision, and first-degree atrioventricular block. Ivabradine is contraindicated in patients with sick sinus syndrome with both bradycardia and tachycardia, and should not be used concomitantly with inhibitors of cytochrome p450 34A as azole antifungals (ketoconazole and itraconazole), macrolide antibiotics (clarithromycin), chemotherapeutics, and the anti-HIV protease inhibitor drugs, nelfinavir and ritonavir. Importantly, abrupt withdrawal of this drug has not resulted in an exacerbation of angina.

Ranolazine

Ranolazine is thought to have its effects through altering the transcellular late Na current, thereby decreasing Na entry into ischaemic myocardial cells [17]. It is proposed that ranolazine reduces calcium uptake via the Na/Ca exchanger and preserves ionic haemostasis, thereby reducing diastolic wall tension and ischaemia-induced contractile dysfunction [17]. Ranolazine is a partial fatty acid oxidation inhibitor and also shifts ATP production from fatty acid to more oxygen-efficient carbohydrate oxidation [18]. Ranolazine does not affect the heart rate or blood pressure, and so in the sick patient in intensive care this drug may be of benefit where these indices should not be lowered further. Ranolazine is known to prolong the QT interval and, therefore, there is a risk of inducing serious ventricular arrhythmias. It should be used in caution in patients already on drugs that prolong the QT interval. Ranolazine is also contraindicated in patients with any degree of hepatic dysfunction as this drug is metabolized by the liver. Ranolazine is metabolized by the cytochrome CYP3A enzyme, a member of the cytochrome P450 system, and is also partially metabolized by cytochrome CYP2D6. Therefore, drugs that may interact and should have their doses reduced include digoxin, simvastatin, verapamil, diltiazem, azole antifungals, and macrolide antibiotics. Abrupt withdrawal of ranolazine does not worsen angina.

CHAPTER 38

Anti-arrhythmics in critical illness

John LeMaitre and Jan Kornder

Key points

- Cardiac arrhythmias are often the consequence of conditions such as sepsis, electrolyte imbalance, and hypoxia. Correcting the underlying problem should be the first principle.
- No anti-arrhythmic medication has shown mortality benefit. Amiodarone is the most useful acute agent for both ventricular and supraventricular arrhythmias.
- Anti-arrhythmic drugs are still the therapeutic modality of choice in the treatment of cardiac arrhythmias, despite advances in non-pharmacological approaches, such as catheter ablation and the implantable cardioverter defibrillator (ICD).
- Magnesium is useful in torsades de pointes. It may also be useful for refractory ventricular tachycardia (VT) post-myocardial infarction (MI), and VT associated with digoxin toxicity.
- Routine treatment of premature ventricular contractions (PVCs), premature atrial contractions (PACs), and non-sustained ventricular runs is not indicated.

Introduction

Although anti-arryhthmic drugs (AADs) are commonly effective, they are now understood to be pro-arrhythmic and can result in excess mortality. The therapeutic range is frequently narrow, and they often have toxic side effects and deleterious effects on myocardial contractility, conduction, and therefore cardiac output. AADs remain the first-line treatment for situations where haemodynamic instability is dependent on abnormalities of cardiac rhythm and where treatment of the underlying illness is not effective in controlling heart rhythm.

Attention should be first paid to the correction of non-cardiac disease states, such as sepsis, hypoxia, and metabolic derangement, all of which are associated with cardiac rhythm abnormalities. The correction of these may render management of the arrhythmia easier or even unnecessary. Despite correction of any underlying illness, there will remain situations where correction of cardiac rhythm abnormalities using AADs will be necessary.

AADs are traditionally classified using the Vaughan-Williams system, which groups drugs based on similar mechanisms of action at a cellular level (Table 38.1).

Class 1 anti-arrhythmic agents

Class 1 agents block the rapid Na^+ channel slowing conduction velocity. They have varying effects upon the K^+ current and, as such, differing effects upon action potential (AP) duration.

Class 1a drugs

Quinidine affects both atrial and ventricular tissue. It is an effective agent for supraventricular and ventricular arrhythmias, but has fallen out of favour due to risk of pro-arrhythmia. It is increasingly difficult to obtain. A large meta-analysis suggested excess mortality due to drug-induced torsade de pointes (Tdp) [1]. It directly suppresses sinoatrial (SA) and atrioventricular (AV) node conduction, and increases the refractory period of atrial, ventricular, and His-Purkinje tissue. It has a vagolytic effect and may paradoxically increase AV nodal conduction. The most important side effect is Tdp due to early after-depolarizations associated with prolonged AP duration (and hence QT prolongation). Other side effects include diarrhoea, tinnitus, thrombocytopenia, and hypotension due to vasodilatation. The drug may precipitate or worsen digoxin toxicity. It is metabolized in the liver and dose reduction is necessary in patients with hepatic disease.

Procainamide has a similar mode of action to quinidine, but has a very rapid onset. It is generally safe and well tolerated. Long-term administration may result in a lupus syndrome, particularly in slow acetylators. Agranulocytosis is a rare, but serious complication. Tdp is less common. The usual dose is 15 mg/kg body weight at a rate of 50 mg/min. A maintenance infusion of 2–6 mg/min may be required. The plasma half-life is short, requiring multiple daily doses.

Disopyramide is profoundly negatively inotropic, which makes it unsuitable for use in critically-ill patients with impaired myocardial function. Gastrointestinal side effects are generally fewer, but anticholinergic side effects are more prominent. This may cause acceleration of AV nodal conduction and may require co-administration of AV nodal blocking drugs when used for the treatment of supraventricular arrhythmias. It is only available orally and has a rapid onset of action.

Class Ib drugs

The class 1b drugs all share properties of rapid binding/unbinding kinetics, minimal pro-arrhythmic effects and shortening of the AP duration.

Table 38.1 The Vaughan-Williams classification: the major electrophysiological actions of commonly used anti-arrhythmic drugs

Class	Mode of action	Site of action	Examples
I	Membrane-stabilizing agents (fast sodium-channel inhibition)		
	(Ia) Delayed repolarization. Broadened action potential	Atrium ventricle Accessory pathway	Quinidine Procainamide Disopyramide
	(Ib) Decreased action potential duration. Accelerated repolarization	Ventricle	Lidocaine Mexiletine
	(Ic) QRS prolongation. No change in action potential	Atrium ventricle His–Purkinje tissue Accessory pathway	Flecainide propafenone Encainide
II	Beta-blocking agents	Sinus node. AV node	Carvedilol Atenolol Bisoprolol Esmolol
III	Prolongation of repolarization	Atrium AV node. Accessory pathway Ventricle His–Purkinje tissue	Amiodarone Dronedarone Sotalol Ibutilide Bretylium
IV	Ca-channel antagonists	AV node	Diltiazem Verapamil

AV, atrioventricular.

Data from Vaughan-Williams EM, 'Classification of antiarrhythmic drugs'. In: *Symposium on Cardiac Arrhythmias*. Sandoe E., et al. (eds). Sodertalje: AB Astra, 1970, pp. 449–72.

Lidocaine remains the first-line treatment for ventricular arrhythmias, despite the lack of clinical evidence for its efficacy. Like other class 1b drugs, it has no effect on the onset of the AP in normal circumstances and does not slow conduction velocity, but during acidosis, substantial conduction slowing can occur. It suppresses early and delayed after-depolarizations and automaticity. There is little vasodilatory effect. Lidocaine is most appropriately used to treat significant ventricular arrhythmias in the post-myocardial infarction setting, where acute ischaemia is suspected in the pathogenesis of ventricular arrhythmias. It is no longer advocated for the primary prophylaxis of ventricular tachycardia or fibrillation. It is usually administered as a bolus injection (100 mg over 1–2 min) followed by a maintenance infusion of 1–4 mg/min if required, as plasma levels fall rapidly after a single bolus. If a bolus is ineffective, it is unlikely that an infusion will succeed. Toxicity manifests with confusion, twitching, paresthesiae, and epileptiform fits.

Mexiletine is an oral agent with the same electrophysiological actions as lidocaine. It has little haemodynamic consequence with very little myocardial contractility suppression or vasodilatory effect. Unfortunately, it has a narrow therapeutic window and titration of oral dose can take days. Toxic side effects are similar to those encountered with lidocaine.

Class Ic drugs

The 1c drugs have the slowest binding kinetics of the class 1 anti-arrhythmics and slow conduction velocity in both atrial and ventricular tissue. They have little effect upon AP duration.

Flecainide is negatively inotropic and, although very effective at suppressing PVCs, data from the CAST trial demonstrated excess mortality in those treated with flecainide or encainide compared with placebo in the post-MI setting [2]. There is no prolongation of QT interval. Flecainide is useful for cardioversion of atrial fibrillation (AF) and flutter, and maintenance of sinus rhythm, and for treatment of AV re-entrant arrhythmias utilizing an accessory pathway. It should be avoided in patients at risk of developing re-entrant ventricular arrhythmias (e.g. the presence of ischaemic heart disease or other cardiomyopathy) or any situation where the negative inotropic effects are undesirable (e.g. heart failure). For conversion of AF, bolus administration of 1–2 mg/kg (maximum 150 mg) over 30 min is usual, watching for hypotension as a consequence of myocardial depression. Class 1c drugs increase pacing thresholds by up to 200%.

Propafenone prolongs refractoriness and slows heart rate due to mild beta-blocking and Ca^{2+}-channel blocking action. It is less negatively inotropic, but can still precipitate heart failure and should be avoided in those patients at risk of ventricular re-entrant arrhythmias due to its pro-arrhythmic effect. It is effective for the pharmacological conversion of AF.

Class 2 anti-arrhythmic agents: beta-blockers

Beta-blocking agents act by attenuating the effects of catecholamines on the heart and, therefore, exert their maximal effect on areas where the sympathetic innervation is rich. Beta-blockers

suppress automaticity at the SA and AV nodes, slow conduction, and increase refractoriness. Their direct effect on SA and AV nodal tissue also explains their usefulness for re-entrant arrhythmias utilizing these tissues, e.g. AV nodal re-entrant tachycardia (AVNRT) or AV re-entrant tachycardias. They are also useful for catecholamine-dependent VTs and for idiopathic VT arising from the outflow tracts.

In critically-ill patients, catecholamine excess (either endogenously or as a consequence of inotropic support) may be an appropriate and physiological response. Therefore, beta-blockers should be used cautiously in this group.

Carvedilol, atenolol, and bisoprolol have long half-lives, and adverse haemodynamic effects may persist. Carvedilol increases vasodilation through alpha-receptor blockade. In contrast, esmolol, is an ultra-short-acting beta-blocker with a half-life of 9 minutes, enabling transient use of beta-blockade in situations such as post-operative hypertension and where haemodynamic effect is uncertain. The usual dosage range is 50–200 mcg/kg/min.

Class 3 anti-arrhythmic drugs

The class 3 drugs prolong AP duration through the blockade of the potassium (K^+) channels responsible for repolarization.

Amiodarone is an extremely attractive AAD in the setting of the critically-ill patient. It is effective in a wide spectrum of atrial and ventricular arrhythmias, including the post-surgical junctional ectopic tachycardia seen in paediatric patients. The negative inotropic effect is significantly less than that of the majority of AADs. There is less concern in the acutely ill about the extensive long-term toxicity that is seen with chronic oral usage, although acute respiratory distress syndrome due to pneumonitis can be seen at any time during therapy. Amiodarone has a complex mode of action with activity in all Vaughan-Williams classes. It has a delayed prolongation of AP duration, which necessitates aggressive intravenous (iv) loading (usually 300 mg over 30 min followed by a maintenance infusion of 900–1200 mg/24 hours) preferably via central venous access to avoid phlebitis. Acute infusion at high rates may lead to significant hypotension due to an alpha-receptor blocking effect. Even with such loading, effective class 3 anti-arrhythmic action will not be seen acutely and the principle acute efficacy of amiodarone is through beta-blockade. Metabolism is mainly hepatic to desethylamiodarone, which also has anti-arrhythmic action. Amiodarone potentiates oral anticoagulation and increases blood levels of digoxin, quinidine, and flecainide. Although the drug prolongs the QT interval, drug-induced Tdp is less common than with other class 3 AADs. Amiodarone is more effective than sotalol at preventing sudden cardiac death, but less effective than the implantable defibrillator [3].

Dronedarone is an analogue of amiodarone without an iodine moiety. Although beneficial for control of paroxysmal AF, with approximately half the efficacy of amiodarone and no toxic side effects, dronedarone is not recommended for patients with persistent AF or reduced left ventricle (LV) function due to excess mortality [4,5].

Sotalol is a weak non-cardioselective beta-blocker with class 3 action, and is effective for ventricular and atrial arrhythmias, including VT and AF. It is less effective than amiodarone overall, with a higher risk of Tdp. The risk can be reduced by ensuring the QTc does not exceed 500 ms. Sotalol should be avoided in the presence of LV dysfunction in the absence of an implantable defibrillator due to the risk of Tdp [6].

Ibutilide is useful for the conversion of AF or flutter to sinus rhythm, but the same cautions exist regarding the risk of Tdp and the need to avoid the agent in individuals pre-disposed (e.g. hypokalaemia, heart failure). Dofetilide has only class 3 action with close monitoring of QTc required, but is effective for conversion of AF.

Bretylium tosylate is rarely used now. It has a unique mode of action—it concentrates in the terminal sympathetic neurons, causing transient release of stored norepinephrine before blocking further release. The effect is of a chemical sympathectomy, which also gives rise to its major side effect of hypotension. It can be used in patients with ventricular tachycardia refractory to other anti-arrhythmic drugs, although has been superseded by amiodarone, which causes significantly less hypotension. It may cause chemical cardioversion of ventricular fibrillation or facilitate cardioversion of ventricular fibrillation refractory to electrical cardioversion.

Class 4 anti-arrhythmic agents: Ca^{2+}-channel antagonists

The non-dihydropyridine Ca^{2+}-channel antagonists—verapamil and diltiazem—have important anti-arrhythmic action via the modification of the slow Ca^{2+} current responsible for depolarization in the SA and AV nodes. By slowing conduction, these agents may terminate junctional re-entrant arrhythmias and slow the ventricular rate in AF, flutter, or atrial tachycardia. They can be administered by iv bolus—verapamil 5–10 mg over 30–60 seconds, diltiazem 10–20 mg over 30–60 seconds, for acute rate control. Although these drugs have little effect on other atrial or ventricular tissues, certain idiopathic VTs are now recognized to be exquisitely sensitive to Ca^{2+}-channel blockade and verapamil is an effective therapy. For other scar-related VT, however, where significant LV dysfunction exists, these agents should be avoided due to their negative inotropy and vasodilating action. Additionally, SA node dysfunction, either pre-existing or acquired may be exacerbated by co-administration of these agents.

Other drugs

Digoxin

Digoxin is frequently used to control ventricular rate in patients with rapidly conducted atrial arrhythmias, particularly AF. It may be ineffective alone and often requires the addition of other agents, such as beta-blockers or Ca^{2+}-channel antagonists, to gain adequate rate control. In this setting, iv loading with 0.5–1 mg over 24 hours followed by maintenance doses of 125–250 micrograms/day is usual. The therapeutic range is narrow. Arrhythmias seen with toxicity include atrial tachycardia with block, junctional tachycardia, ventricular premature beats, ventricular tachycardia, including bi-directional VT, sinus bradycardia, and varying degrees of AV block. Toxicity may be exacerbated by renal impairment, dehydration, hypokalaemia, many drugs (including amiodarone, verapamil, and quinidine) and old age. In cases of severe overdose, ventricular arrhythmias may require lidocaine or phenytoin, and bradycardia may require temporary pacing. Digoxin-specific antibodies can be administered in extreme cases.

Fig. 38.1 Termination of AVNRT with 12 mg of iv adenosine. Note impaired atrioventricular conduction in beats after successful termination.
Data from Camm AJ and Garratt CJ, 1991, 'Adenosine and supraventricular tachycardia', *New England Journal of Medicine*, 325, pp. 1621–1629.

Although digoxin is by far the most widely used cardiac glycoside, its prolonged onset of action (1–5 hours) may make it unsuitable in the setting of the critically-ill patient. Rarely used, ouabain and deslanoside are only available as iv preparations, but both have a rapid onset of action within 10–30 min.

Magnesium

Intravenous magnesium is a safe and effective therapy in Tdp. Withdrawal of offending drugs, correction of metabolic abnormalities, and pacing, together with iv administration of magnesium sulfate (2–4 g), form the cornerstone of therapy. It may also be of use following cardiac surgery, where significant magnesium depletion can occur in the immediate post-operative period.

Adenosine

Adenosine is an endogenous nucleoside that is capable of causing pharmacological AV block. It has the advantage of having a plasma half-life of only a few seconds. Side effects are usually transient, and include flushing, chest tightness, and bronchospasm, and sustained acceleration of atrial flutter from 2:1 to 1:1 AV conduction has been reported. AV block may persist for several seconds. It has superseded verapamil as the agent of choice for the acute termination of AVNRT and junctional re-entrant arrhythmias. It is administered as a rapid iv bolus of between 3 and 20 mg in an escalating regime (Fig. 38.1) [7].

Adenosine also has a role in the diagnosis of arrhythmias, particularly broad complex arrhythmia, where it may not be easy to distinguish between VT and supraventricular arrhythmias conducted with aberration.

Pro-arrhythmia

Arrhythmia may be worsened in 5–10% of patients taking AADs, sometimes with lethal consequences [8]. Such pro-arrhythmic events are more likely with combinations of anti-arrhythmic drugs and in the presence of metabolic abnormalities, particularly hypokalaemia. Two major patterns of ventricular pro-arrhythmia are seen with anti-arrhythmic drugs. Class 1a and class 3 agents cause QT prolongation and may precipitate Tdp (Fig. 38.2), whereas class 1c agents may give rise to a sinusoidal VT refractory to both pharmacological and electrical therapy.

Conclusion

There is no ideal anti-arrhythmic drug. Considering the diverse mechanisms underlying cardiac arrhythmias, this is not surprising. AADs almost always have adverse effects on haemodynamics and their use in patients who are critically ill must be carefully considered, with correction of underlying disease states likely to be at least as important as the use of AADs.

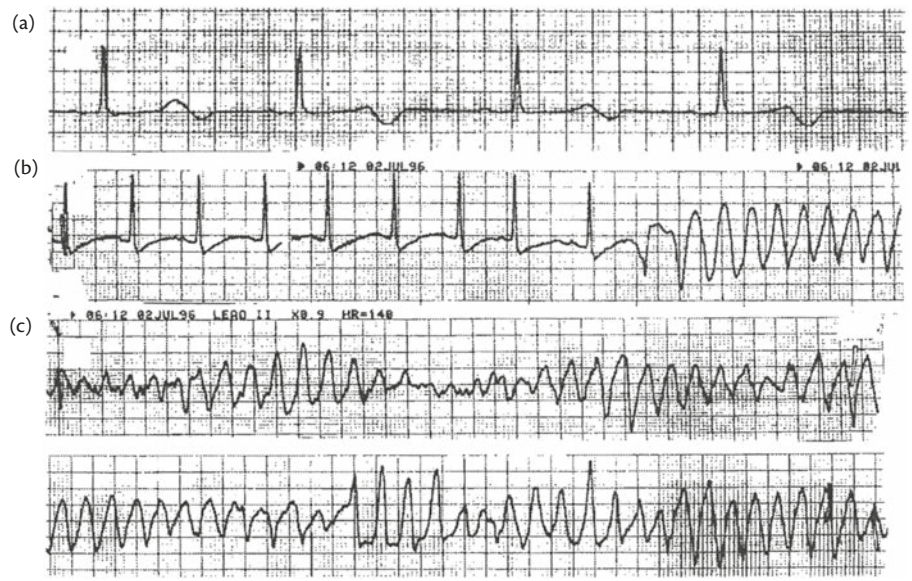

Fig. 38.2 Ventricular pro-arrhythmia from class 3 anti-arrhythmic drugs. (a) Sinus bradycardia with a QT interval of 650 ms in an elderly patient taking amiodarone 400 mg od and atenolol 50 mg od for rate control of atrial fibrillation. (b) Initiation of Tdp with a single ventricular premature beat. (c) Rhythm strip from the same episode showing characteristic twisting of the electrical axis about the baseline. This episode stopped spontaneously and the pro-arrhythmia was treated by drug withdrawal and temporary pacing.

CHAPTER 39

Pulmonary vasodilators in critical illness

Benjamin Chousterman and Didier Payen

Key points

- Pulmonary vasodilators (PV) are used to treat pulmonary hypertension and/or hypoxaemia.
- Inhalation of PV is the most suitable way of administration to treat hypoxaemia.
- The use of systemic PV may lead to a decrease in mean arterial pressure and worsening of hypoxaemia.
- Despite their effectiveness, PV have not shown any benefits in mortality in acute respiratory distress syndrome.
- Rebound of hypoxaemia and/or pulmonary arterial hypertension should be prevented during PV treatment discontinuation with a slow de-escalation protocol.

Introduction

Pulmonary vasodilators (PV) are commonly used in the intensive care unit (ICU). These drugs are prescribed to treat pulmonary hypertension (PH) associated right ventricular overload or failure (RVF) and/or hypoxaemia. PH during critical illness may be new or an exacerbation of a chronic pulmonary hypertension and can be classified according to the 2008 Dana Point conference [1] as PH associated with lung diseases and/or hypoxaemia, PH with left heart disease or PH due to embolic disease. PH is hallmark of acute lung injury (ALI) or acute respiratory distress syndrome (ARDS) in combination with hypoxaemia. Both pressure and hypoxaemia can be an indication to use PV, taking into account the presence or absence of intrapulmonary shunt. Treatment of PH is necessary when it contributes to RVF, especially in ARDS, being a poor prognostic factor. The ideal PV has to:

- Be selective for pulmonary vasculature.
- Maintain hypoxic pulmonary vasoconstriction (HPV), avoiding deterioration of intrapulmonary shunt.
- Be a safe product with pharmacokinetic and pharmacodynamics properties appropriate for acute situations.

Use of PVs

PVs are first considered when there is venous congestion associated with cardiac output limitation due to right ventricular afterload, usually secondary to elevated pulmonary artery pressure (PAP). In addition, due to pericardial constraint the enlarged diastolic right ventricle may impair the filling of the left ventricle, reducing stroke volume and cardiac output. The second reason to use PV is to improve the ventilation perfusion ratio. Dilation of vessels in aerated zones may divert flow from shunt zones, improving ventilation/perfusion matching and PaO_2. Finally, PV-induced reduction in PAP reduces lung microvascular filtration pressure and alveolo-interstitial oedema [2].

Systemic versus inhaled treatment

Pulmonary vasodilating drugs can be used via a systemic route (oral or intravenous) or via inhalation. The decision depends on therapeutic goals, pharmacological properties, and side effects. The systemic route is easier to titrate knowing pharmacokinetics and the dose–response curve. The limitation comes from the systemic effects with a risk of arterial hypotension and/or worsening hypoxaemia when ventilated and non-ventilated area vessels are both dilated. Inhaled treatments increase the flow to well-aerated alveoli selectively (see Fig. 39.1)?

Systemic PV

Phosphodiesterase inhibitors

Cyclic monophosphate nucleotides (cyclic guanosine monophosphate (cGMP) and cyclic adenosine monophosphate (cAMP)) are responsible for smooth muscle cell (SMC) relaxation and are hydrolysed by phosphodiesterases (PDEs) 3 and 5. The inhibition of PDEs by PDE inhibitors (PDEI) leads to an elevation of these molecules' concentrations that results in continued SMC relaxation and, therefore, pulmonary vessel vasodilation. Milrinone is a selective inhibitor of the PDE 3 with inotropic and vasodilatory effects. Milrinone reduces pulmonary vascular resistance (PVR) and RVF. In non-hypoxaemic patients, milrinone increases the cardiac output and DO_2, but could lower the PaO_2 [3]. Inhibition of PDE 5 seems to be more selective for the pulmonary vessels causing less systemic hypotension. Although extensively studied in chronic PH, the data on milrinone use in critically-ill patients are limited.

Sildenafil is a specific PDE 5 inhibitor. It increases cardiac output and reduces PVR. The experience is limited in critically-ill patients. Retrospective studies show a good effect on reducing PAP with a limited fall of MAP after cardiac surgery, but show a decrease in PaO_2 with shunt augmentation in ARDS patients [4].

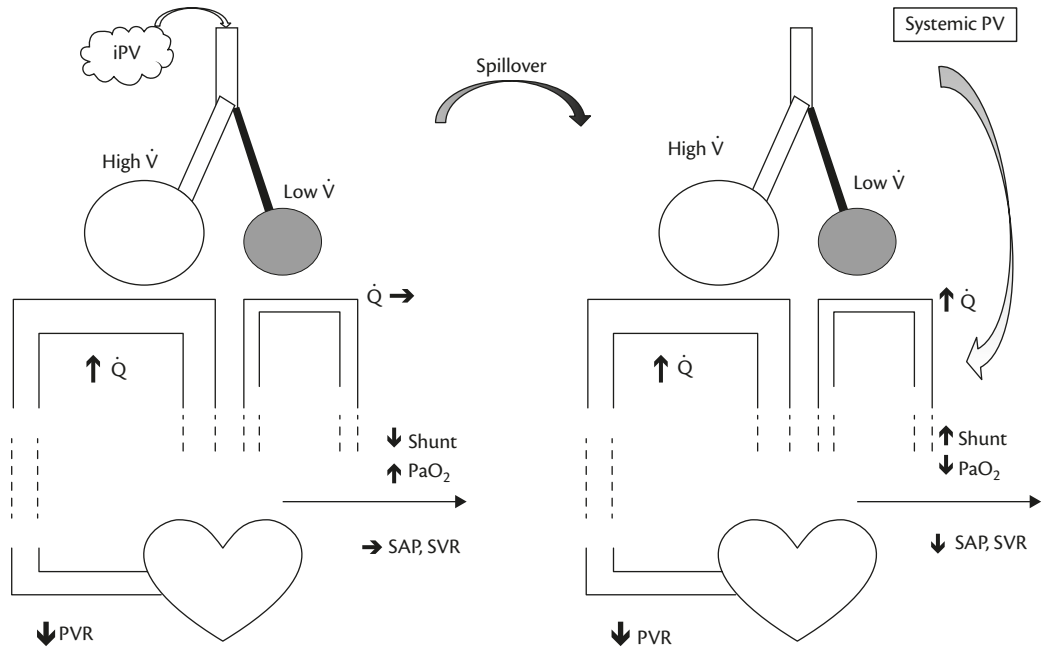

Fig. 39.1 Effects of systemic PVs versus iPV. Systemic vasodilation affects all vascular beds, thereby decreasing MAP and worsening oxygenation by increasing blood flow to poorly-ventilated alveoli, secondary to reversal of hypoxic pulmonary vasoconstriction. iPVs selectively dilate pulmonary arterioles in alveoli that are well ventilated, thus reducing PAP while improving ventilation/perfusion matching and oxygenation. However, 'spillover' of inhaled drugs in pulmonary circulation may lead to systemic effects of iPV.

Q, perfusion; V, ventilation; SAP, systemic arterial pressure; SVR, systemic vascular resistance; PVR, pulmonary vascular resistance.

Data from Siobal MS, 'Pulmonary vasodilators', *Respiratory Care*, 2007, **52**, 7, pp. 885–99 [13] with permission.

PDEIs can be used alone or in combination with inhaled pulmonary vasodilators (iPVs). The haemodynamic effects of sildenafil are observed after 15 minutes of administration, peak at 30–60 minutes, and last several hours. Sildenafil use may prevent the rebound effect associated with inhaled nitric oxide gas (iNO) weaning.

Drug use in clinical practice

Milrinone is usually used as a continuous infusion at doses ranging from 0.25 to 0.75 micrograms/kg/min, with or without a loading dose of 25–75 micrograms/kg. Its half-life is 1.5–2 hours and the optimal blood concentration seems to be around 100 ng/mL. Sildenafil can be administered to patients via a nasogastric tube at doses ranging from 12.5 to 100 mg, bd.

Side effects and pitfalls

Milrinone has been associated with atrial fibrillation and supraventricular arrhythmias. Episodes of thrombocytopenia have also been observed. Sildenafil's side effects are essentially headaches and flushes.

Intravenous prostacyclins

Intravenous prostacyclins (IVPCs) have the same pharmacodynamic properties as inhaled prostacyclins (iPCs) except their pulmonary selectivity is lost causing systemic hypotension and they may worsen hypoxaemia. IVPCs are an essential treatment of chronic PH, but are, nowadays, less frequently used in ICUs. IVPCs are indicated for the treatment of severe PH and/or RVF after cardiothoracic surgery or for patients with pre-existing chronic PH [5]. The observed reduction of PVR is nearly 40% and the cardiac output is 35% improved. Trepostinil, a long-acting prostacyclin analogue, is an effective treatment of PH, but its pharmacodynamic properties make it less suitable for ICU, especially where there is haemodynamic unstability.

Drug use in clinical practice

Epoprostenol should be started at a dose of 1–2 ng/kg/min and titrated, until the desired effect is reached, by steps of 0.5–1 ng/kg/min every 15–30 minutes. Target dose can vary between 5 and 35 ng/kg/min. Alprostenol can be started with a dose of 5 ng/kg/min and titrated by steps of 5 ng/kg/min. Target doses for this molecule range between 20 and 100 ng/kg/min.

Side effects and pitfalls

The side effects of IVPCs are more pronounced than in inhaled prostacyclins (iPCs). The main complication is dose-dependent systemic arterial hypotension. Conscious patients may complain of headaches, nausea, vomiting, and diarrhoea. Extremely severe rebound effects have been observed with the sudden cessation of IVPCs treatment.

Others

Many of the following PVs are indicated for the treatment of chronic PH. Most of them are not selective for pulmonary vessels and should, therefore, be used with caution in ICU patients.

Isoproterenol

Isoproterenol is a beta-adrenergic agonist acting on both beta 1 and beta 2 adrenergic receptors. This molecule has been used to treat PH during cardiac surgery, as well as for its chronotropic effects to increase the heart rate. Isoproterenol increases cardiac output

and, thus, diminishes PVR. The direct effects on PVR are low. Isoproterenol must be used as a continuous IV infusion. The main side effect is arrhythmias and, therefore, this molecule is not suitable as a first-line treatment in ICU.

Nesiritide

Nesiritide is a recombinant form of the brain natriuretic peptide. The main pharmacodynamic effect is to increase the cGMP in SMCs and then induce relaxation with vasodilation. It is mainly used for the treatment of acute heart failure in USA. The effects of neseritide on PH are controversial, but benefits could be observed in case of left ventricular overload or failure (LVF) associated with RVF.

Sodium nitroprusside

Sodium nitroprusside is a member of the nitric oxide (NO) donors family. This short-acting drug is licenced by the US Food and Drug Administration (FDA) as a treatment of acute hypertensive crisis. It has been shown to reduce pulmonary arterial pressure. Some studies have focused on its inhaled administration, which could be effective [6]. The side effects of this molecule are similar to those of NO-like Met-Hb and mitochondrial respiratory chain blockade.

Calcium channel blockers

The most studied molecules are nifedipine, diltiazem, and amlodipine. They are usually used in ICU as antihypertensive treatment. They diminish hypoxic pulmonary vasoconstriction and are associated with worsening hypoxaemia in ARDS patients.

Endothelin-1 receptor antagonists

Endothelin-1 (ET-1) Receptor Antagonists ETA is the only class of molecules acting on the ET-1 pathway. Bosentan is the main molecule studied. It is an antagonist of both endothelin receptors A and B, and is available only for oral use. A new antagonist, tezosentan, available as an IV solution, is under investigation and may reduce PH without a significant effect on MAP.

Inhaled PV

Nitric oxide

The molecule known as the endothelial-derived relaxing factor was found to be NO in 1987 and this discovery opened the field of investigation of the nitrovasodilators. In physiology, NO is synthetized by NO synthase in the endothelium. NO stimulates adjacent SMCs' soluble guanylate cyclase to produce cGMP, which will induce a calcium influx leading to SMC relaxation. It's a major component of vascular tone equilibrium. NO can only be used as iNO. It is delivered to the best-ventilated alveoli with little getting to the poorly-ventilated areas of the lung. NO diffuses through the alveolo-capillary membrane and cause vasodilation of the pulmonary vessels. The duration of effect is only a few minutes. Once NO enters the blood vessel, it is inactivated within seconds by several mechanisms, including the molecule binding to haemoglobin or plasma proteins. This rapid inactivation confers on NO its particular selectivity for the pulmonary vessels without systemic effects. The consequence of iNO administration is a reduction of the PAP and improvement of the PaO_2 via a better ventilation:perfusion ratio in 60% of patients. NO has been used in ICUs since the early 1990s. Despite all its beneficial effects, the use of NO has not shown a benefit in outcome. Five randomized controlled trials (RCT) in ARDS compared the use of NO with placebo and a meta-analysis did not find any benefit in mortality [7]. No RCT have been performed to evaluate the effects of NO in cardiothoracic surgery or RVF. Despite common belief, there is no (or little) alteration of the NO pathway after prolonged use (up to 6.5 days) [8]. However, at the end of NO inhalation, a rebound can be observed with an increase of the PH or hypoxaemia. This rebound can be prevented with the use of a slow NO dose de-escalation protocol. Experts still recommend the use of iNO as rescue treatment in patients with severe refractory hypoxaemia [9].

Drug use in clinical practice

In ICU, NO is usually administered to ventilated patients. It can be added to the air/oxygen mixture before or after the ventilator. NO administration just before the tracheal tube can be done in line with a gas tank containing a known concentration of NO (usually 225 or 450 parts per million (ppm), 1 ppm = 40 nM), in a NO-N_2 mixture. It delivers a precise amount of NO to the inspiratory limb. The amount of NO delivered can be calculated following this formula:

$$CBF = CPP/CVR$$

NO can also be administered to non-intubated patients through a face mask connected to a non-rebreathing circuit. The usual doses used range from 5 to 20 ppm. The peak effect on PaO_2 is observed below 20 ppm (it could be effective at 1 ppm) with the dose–response effect of NO on pulmonary arterial pressure steadily diminishing in a non-linear fashion. To treat severe PH, short course use of higher doses (up to 40 ppm) could be of help.

Side effects and pitfalls

NO is unstable in the presence of oxygen (O_2) with oxidation leading to the generation of nitrogen dioxide (NO_2), which is a toxic gas. Exposure to high levels of NO_2 can cause pulmonary oedema. The final concentration of NO_2 must be less than 1 ppm. Usually, at the doses used in ICU this limit is rarely reached. When NO enters the vessel lumen, it interacts with haemoglobin and forms methaemoglobin (Met-Hb). When high dose NO is used, the level of Met-Hb should be monitored at the 4th hour and daily thereafter; a level of Met-Hb below 4% is acceptable. NO can also cause toxicity by its interaction with reactive oxygen species (ROS), especially the anion superoxide, that will result in peroxynitrite synthesis. Finally, NO causes inhibition of platelet aggregation, and should be carefully used in presence of thrombocytopenia or coagulation disorder.

Prostacyclins

Prostacyclins (PCs; prostaglandin I-2 (PGI2), and prostaglandin E-1, (PGE1)) are naturally occurring prostanoids that are endogenously produced as metabolites of arachidonic acid in the vascular endothelium. While NO stimulates the guanylate cyclase of SMCs, PCs enhance the adenylate cyclase, converting adenosine triphosphate (ATP) to cAMP. Like cGMP, cAMP leads to calcium influx in the SMC producing cell relaxation. By the same mechanism as NO, inhaled PCs (iPCs) reduce PAP and improve arterial oxygenation. iPCs were mainly studied for the treatment of PH and/or RVF, but some studies exist in the ARDS setting [10]. iPCs have also been shown to be anti-inflammatory mediators, PGE1 impairs neutrophil chemotaxis and decreases macrophage

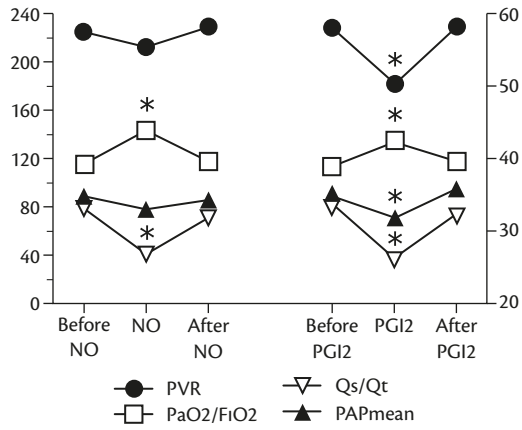

Fig. 39.2 Effects of aerosolized prostacyclin (PGI2) (mean dose = 7.5 ng/kg/min) and inhaled NO (mean dose = 18 ppm) in 16 acute respiratory distress syndrome patients.
PVR = pulmonary vascular resistance, dynes s^{-1} cm^{-5}. PaO_2/FiO_2 = ratio of PaO_2 to fraction of inspired oxygen ratio. PAPmean = mean pulmonary artery pressure, mmHg. Qs/Qt = shunt fraction. *$p < 0.05$.
Data adapted from Siobal M, 'Aerosolized prostacyclins', *Respiratory Care*, 2004, **49**(6), pp. 640–52; and Walmrath D, et al., 'Direct comparison of inhaled nitric oxide and aerosolized prostacyclin in acute respiratory distress syndrome', *American Journal of Respiratory and Critical Care Medicine*, 1996, **153**(3), pp. 991–6 [11].

activation, PGI2 reduces neutrophil adhesion. The main advantage of iPCs is that they are a low-cost alternative to NO. The vasodilator effects of iPCs epoprostenol (PGI2) and alprostadil (PGE1) are similar or better than iNO in ARDS patients [11]. The half-life of these drugs is around 5 minutes. Epoprostenolappears to be more effective than alprostadil in reducing PAP and improving oxygenation. PCs have an antithrombotic effect on platelets and this effect could explain, in part, the effect of these drugs in ARDS patients. Used as aerosolized drugs, iPCs are up to 10 times less potent than their intravenous administration to correct PH. Iloprost is a long-acting PGI2 and is currently the sole PC approved for inhalation by the FDA, although its use in ventilated patients has not been validated. Its effects can last up to 2 hours and it is, therefore, possible to use this drug in intermittent dosing regimens. However, a decrease of the mean systolic arterial pressure was observed with inhaled iloprost, probably due to a spillover of the drug to the systemic circulation. Although good results were obtained in studies focusing on iPCs in clinical practice, the level of evidence is still low and no benefits on mortality have been shown yet (see Fig. 39.2) [12].

Drug use in clinical practice

PCs must be aerosolized. The administration of aerosolized PCs is very inefficient, with only 3% of the nominal dose deposited in the lung. Nebulizers that produce droplets of a few micrometres diameter are optimal; ultrasonic nebulization is also possible. Although usually used in ventilated patients, iPCs can also be considered for non-intubated patients. iPCs, except iloprost, are used in a continuous regimen.

The dose range for inhaled epoprostenol was determined using experimental trials and comparison with iNO and ranges from 10 to 50 ng/kg/min. The starting dose is 50 ng/kg/min (peak benefits) with a slow reduction to the appropriate dose. Experience with inhaled alprostadil is limited in ICU settings; the dose used is 10 ng/kg/min.

Side effects and pitfalls

Systemic hypotension and bleeding disorders are the main side effects of iPCs. Systemic arterial vasodilation can occur for PGI2 doses higher than 200 ng/kg/min. High doses of long-acting PC like iloprost could result in a spillover of the molecule and cause hypotension. While no bleeding events have been attributed to iPCs, their use should be cautious in patients with coagulation disorders. A rebound effect can also be observed and can be prevented by slow weaning. iPCs can cause bronchospasm, especially in patients with bronchial hyper-reactivity.

PART 2.3

Gastrointestinal drugs

CHAPTER 40

Gastrointestinal motility drugs in critical illness

Sonja Fruhwald and Peter Holzer

Key points

- The gastrokinetic domperidone (off-label) has an arrhythmogenic effect related to dose and treatment duration.
- Metoclopramide (off-label) plus erythromycin is a rescue combination therapy in severe gastroparesis.
- Neostigmine is indicated for the management of paralysis and Ogilvie syndrome, but its dosage must be carefully selected.
- Osmotic and stimulant laxatives (polyethylene glycol, bisacodyl) are important options to manage constipation in critically-ill patients.
- Alvimopan (short-term use), methylnaltrexone and naloxegol (off-label) are options to manage constipation associated with opioid analgesic therapy.

Dopamine receptor antagonists

Domperidone

An antagonist of peripheral dopamine D_2-receptors with anti-emetic and prokinetic effects on oesophagus and stomach [1]. The drug can be used in children and patients with Parkinson's disease because it lacks an effect on the brain.

Dosage and pharmacokinetics

Domperidone is only available as an oral preparation and is rapidly absorbed reaching peak plasma levels within 30 minutes. Because of first pass metabolism in the intestine and liver, the bioavailability (13–17%) is low [2]. The recommended dose is as low as possible, not exceeding 30 mg/day.

Adverse effects and drug interactions

- Gynecomastia and galactorrhoea.
- Noteworthy is an arrhythmogenic effect (torsades des pointes) via QT prolongation, guiding the current recommendation of dosage and co-medication with other CYP3A4-metabolized drugs (e.g. ketoconazole, erythromycin, amiodarone, warfarin, and others).

Use in critical care

This is not licensed in the USA and in the EU is restricted to short-term use in nausea and vomiting. Its off-label use in intensive care is limited because of oral administration. It is useful in extubated patients, when longer treatment is necessary, or for prophylactic use in patients with high risk of gastroparesis (Table 40.1).

Metoclopramide

This is a drug with multiple actions—an antagonist of peripheral and central dopamine D_2-receptors, an antagonist of serotonin (5-hydroxytryptamine, 5-HT) 5-HT_3-receptors, and an agonist of 5-HT_4-receptors [1]. It increases lower oesophageal sphincter pressure and stimulates gastroduodenal motility.

Dosage and pharmacokinetics

For use as a gastrokinetic, parenteral administration is preferred. The maximum dose of 10 mg three times daily (tds) needs to be reduced in renal failure; in patients on dialysis 10 mg once daily (od) is recommended [3]. Efficacy declines rapidly over time—in patients with high gastric residual volumes enteral feeding is established in <20% after 3 days of treatment [4].

Adverse effects and drug interactions

- Gynecomastia, secondary to enhanced prolactin release, arrhythmia via QT prolongation. Extrapyramidal motor reactions, such as drowsiness, agitation, irritability, fatigue, and in less than 1% tardive dyskinesia (Table 40.1).
- Extrapyramidal effects appear to be more common in children, young adults, and at high doses.

Use in critical care

In the EU it is restricted to short-term use in nausea and vomiting. The risk for extrapyramidal motor effects increases with treatment duration. Efficacy after traumatic brain injury is doubtful, in patients with post-operative ileus metoclopramide is ineffective.

Macrolides

Erythromycin

Erythromycin binds to motilin receptors and stimulates migrating motor complex and upper gut motility. For efficacy, endogenous motilin levels need to be low.

Dosage and pharmacokinetics

The effective dose is 1 mg/kg intravenously; for practical reasons 100 mg tds is given. Since efficacy is reduced after 3–4 days of therapy, treatment should be limited to 3 days [3,5]. The combination of erythromycin and metoclopramide restores the efficacy of both drugs [4].

Table 40.1 GI motility drugs used in critical care

Substance	Indication	Recommended dose	Side effects	Attention
Domperidone	Gastroparesis	≤30 mg/day orally	Gynecomastia, galactorrhoea, arrhythmia	Off-label use, dose limitation 30mg/day
Metoclopramide	Gastroparesis	10 mg tds iv 10 mg od in renal failure	Galactorrhoea, arrhythmia, extrapyramidal side effects	Off-label use, contraindicated in Parkinson's disease, tachyphylaxis
Erythromycin	Gastroparesis	100 mg tds iv	Diarrhoea, tachyphylaxis, QT prolongation	Tachyphylaxis
Neostigmine	Paralysis, Ogilvie syndrome	0.5–1.5–(2.5) mg short infusion	Bronchospasm, bradycardia	Up to 2.5 mg in Ogilvie syndrome, higher doses inhibit motility
PEG	Constipation	<25–30 mg orally	Flatulence, abdominal pain, diarrhoea	Contraindicated in Ogilvie syndrome
Bisacodyl	Constipation	10–(20) mg/d rectally	Flatulence, abdominal pain, diarrhoea	Contraindicated in Ogilvie syndrome
Naloxone	Constipation, paralysis	3–12 mg tds orally	Symptoms of withdrawal	Inhomogeneous data, not recommended
Alvimopan	Constipation	12 mg BD orally	Flatulence, abdominal pain, diarrhoea	Limited to 15 doses because of cardiovascular side effects
Methylnaltrexone	Constipation, paralysis	8–12 mg sc	Flatulence, diarrhoea, abdominal perforation	Off-label use
Naloxegol	Constipation	25 mg od orally	Abdominal pain, diarrhoea, nausea, headache, flatulence	Off-label use

Data from Fruhwald S and Kainz J, 'Effect of ICU interventions on gastrointestinal motility', *Current Opinion in Critical Care*, 2010, **16**, pp. 159–64.

Adverse effects and drug interactions

Antibiotic resistance is unlikely, but conclusive data are not available. Diarrhoea is common, but unrelated to *Clostridium difficile*. QT prolongation and risk of arrhythmia are characteristic for macrolides.

Use in critical care

In severe gastroparesis, a combination of erythromycin and metoclopramide (Table 40.1) is used as rescue therapy [4]. Since, in the intensive care unit (ICU), a combination of several drugs prolonging the QT interval is common, adequate monitoring is mandatory.

Azithromycin

This macrolide, a relative to erythromycin, has a longer duration of action, comparable prokinetic efficacy, and a more favourable adverse effect profile [6]. Despite a lack of drug interactions via cytochrome P450 enzymes, there is a significantly increased risk of cardiovascular death (hazard ratio 2.88) in patients treated with azithromycin in antibiotic doses [7].

5-HT_4-receptor agonists

5-HT is involved in the regulation of gastrointestinal (GI) motility, secretion, and sensation. Activation of 5-HT_4-receptors, expressed by enteric neurons and smooth muscle cells, leads to the release of acetylcholine from excitatory motor neurons and nitric oxide from inhibitory motor neurons, stimulating GI motility.

Cisapride and tegaserod

Both moderately selective 5-HT_4-receptor agonists were taken off the market. Cisapride was removed because of arrhythmias via hERG-channel stimulation, and tegaserod is now limited to emergency use in the USA, because of an increased risk of cardiovascular adverse events. The mechanism of this adverse effect (calculated as 0.1% risk) is unknown.

Prucalopride

A highly selective 5-HT_4-receptor agonist that stimulates colonic motility, but seems to have limited efficacy in the upper gut [8].

Dosage and pharmacokinetics

Prucalopride (1–2 mg) was approved for women with chronic constipation in whom laxatives are ineffective (Table 40.1). Since 85% of the patients studied were women, prucalopride's efficacy in men awaits to be proven.

Adverse effects and drug interactions

Headache, nausea, and diarrhoea; because of its high selectivity, cardiovascular adverse effects appear negligible. Dose reduction (1 mg) in patients with a glomerular filtration rate < 30 mL/min, severe liver failure, and elderly patients.

Use in critical care

Data on prucalopride's usefulness in the ICU are not available, while beneficial effects on opioid-induced constipation have been reported.

Velusetrag

A highly selective 5-HT_4-receptor agonist with prokinetic effects on the entire GI tract demonstrated in large Phase IIb trials. Of three doses tested, 15 mg has the most favourable therapeutic index and adverse effect profile (diarrhoea, nausea, vomiting, and headache). A metabolite (THRX-830449) is almost as potent as the

parent compound; its elimination half-life is 16 hours after single dosing and 35 hours after multiple dosing [8].

Somatostatin analogs

Octreotide

A synthetic octapeptide, sharing a 4-amino acid sequence with somatostatin. Because of poor bioavailability, it is administered parenterally. As it is excreted renally, dose adjustment is required in renal failure. Octreotide's value as a prokinetic is marginal because low doses stimulate, whereas high doses inhibit motility.

Cholecystokinin agonists and antagonists

Cholecystokinin agonist: ceruletide

A cholecystokinin (CCK) analog with potent prokinetic effects on gallbladder, bile duct, small bowel, and colon, and a stimulant effect on digestive secretion. It also has a beneficial effect in post-operative ileus. Delayed gastric emptying, requiring treatment, is a potential side effect. Ceruletide is currently not available.

CCK antagonists: loxiglumide and dexloxiglumide

These CCK_1-receptor antagonists are of potential value in critically-ill patients with increased CCK levels and gastroparesis, but their efficacy for this indication awaits investigation.

Cholinergic drugs

Neostigmine

This acetylcholine esterase inhibitor increases the concentration of acetylcholine at the receptor and, thus, facilitates parasympathetic and enteric stimulation of GI contractility.

Dosage and pharmacokinetics

Neostigmine has a quick onset (5 minutes) and short duration of action (elimination half-life of 25 minutes). Dose recommendations for short infusions are between 0.5 and 1.5 mg for GI paralysis in the ICU and up to 2.5 mg for Ogilvie syndrome. Care needs to be taken in dosing, because higher neostigmine doses inhibit motility [3].

Adverse effects and drug interactions

Bradycardia, hypotension, and bronchospasm (Table 40.1). In renal failure the elimination half-life is more than doubled. Neostigmine is contraindicated in patients with clinical signs of intestinal perforation.

Use in critical care

Neostigmine is beneficial in post-operative ileus and acute colonic pseudo-obstruction, although its efficacy in critically-ill patients is less pronounced [3], given that the motility disturbances are complex, and involve electrolyte imbalances, hypervolaemia, reduced intestinal secretion, and adverse drug effects (opioids, analgesics, catecholamines).

Acotiamide

Acotiamide is an acetylcholine esterase inhibitor under clinical evaluation. It does not affect gastric emptying in healthy volunteers, but enhances gastric contractility and accelerates delayed gastric emptying in patients with functional dyspepsia [9].

Laxative drugs

Laxatives used in the ICU (bulk-forming, osmotic, or stimulant) either

- Enhance retention of intraluminal fluid by hydrophilic or osmotic mechanisms.
- Decrease GI absorption of fluid due to effects on fluid and electrolyte transport.
- Enhance GI ion/fluid secretion and, thus, stimulate GI motility.

Methylcellulose, psyllium, and polycarbophil

Bulk-forming laxatives are frequently used to relieve constipation, especially if patients are unable to ingest sufficient amounts of dietary fibre. Because of their slow onset of action (up to 72 hours) and the need of adequate fluid intake, bulk-forming laxatives are not recommended in critically-ill patients.

Sorbitol, lactulose, magnesium salts, and polyethylene glycol

Osmotic laxatives draw water into the intestinal lumen and thereby stimulate motility. Of all compounds in this group, polyethylene glycol (PEG) seems to be most efficacious and cost-effective [10].

Dosage and pharmacokinetics

While PEG is inert, lactulose and sorbitol are degraded by colonic bacteria to low molecular weight acids. They increase stool acidity and osmolarity, and cause the accumulation of fluid in the colonic lumen. Recommended doses of lactulose and sorbitol are about 20 mg/day, of magnesium salts between 0.1 mg/kg and 15 g/day, and of PEG between 13 and 30 g.

Adverse effects and drug interactions

Flatulence, nausea, abdominal pain, and diarrhoea. Being renally excreted, magnesium salts should be used with care in patients with renal failure. Contraindications include lactose and sorbitol intolerance (lactulose and sorbitol), renal insufficiency and electrolyte imbalances (electrolyte-enriched PEG), and patients suffering from or being at risk of Ogilvie syndrome (osmotic laxatives in general). On the other hand, PEG is effective in reducing the recurrence rate after Ogilvie syndrome.

Use in critical care

Few studies report on the use of osmotic laxatives in the ICU, with PEG being the most efficacious drug (Table 40.1). PEG is also used prophylactically in opioid-treated patients to avoid constipation and normalize defaecation. One study reports PEG to slightly lower the incidence of Ogilvie syndrome.

Bisacodyl

Bisacodyl is a drug that actively increases the luminal fluid and electrolyte content, and stimulates colonic motility.

Dosage and pharmacokinetics

Taken orally, bisacodyl undergoes enterohepatic circulation before it is activated by esterases in the bowel, which delays the onset of action by up to 12 hours. Doses higher than 10 mg may lead to sudden and powerful bowel movements. Intrarectal administration circumvents enterohepatic circulation and causes laxation within 60 minutes. The maximum dose is 20 mg/day.

Adverse effects and drug interactions

- Bloating
- Light-headedness.
- Nausea.
- Abdominal cramps.
- Discomfort (Table 40.1).

Use in critical care

Although evidence-based data are sparse, bisacodyl (and osmotic laxatives) are recommended for critically-ill patients to improve intestinal motility [3,5].

Lubiprostone

A derivative of prostaglandin E_1, which stimulates fluid secretion by activating CIC-2 chloride channels in colonocytes. Approved for the management of chronic idiopathic constipation (USA, Switzerland, UK), irritable bowel syndrome with constipation and opioid-induced constipation (USA, Switzerland). Studies are ongoing evaluating the effect of lubiprostone on post-operative bowel dysfunction.

Dosage and pharmacokinetics

Lubiprostone accelerates colonic transit and increases the number of spontaneous bowel movements [11]. The recommended dose is 24 micrograms twice daily (bd) for chronic constipation and 8 micrograms BD for irritable bowel syndrome.

Adverse effects and drug interactions

Nausea (20–30%), diarrhoea (13%), abdominal distention, flatulence, and vomiting. The incidence of nausea is reduced when lubiprostone is taken with a meal.

Linaclotide

A peptide analog of guanylin, which activates guanylate cyclase-C, opens cystic fibrosis transmembrane conductance regulator (CFTR) chloride channels, and thus stimulates colonic chloride and bicarbonate secretion and motility. Doses of 145 and 290 μg improve stool consistency and frequency, and reduce abdominal pain. Nausea is a side effect. Linaclotide is currently approved for irritable bowel syndrome with constipation (USA, EU) and chronic idiopathic constipation (USA), the recommended dose is 290 micrograms od. Its usefulness in opioid-induced constipation is under investigation.

Opioid-receptor antagonists

Opioids used in the management of moderate to severe pain frequently cause constipation. Apart from laxatives, peripheral opioid-receptor antagonists can be used to restore GI motility, while analgesia is preserved.

Naloxone

A high-affinity opioid-receptor antagonist. Taken orally, naloxone has low systemic bioavailability due to extensive hepatic first pass metabolism. Doses of 3–12 mg tds are sufficient to antagonize opioid-induced constipation, but too low to have systemic effects. Naloxone is not recommended in critically-ill patients because of insufficient and inhomogeneous evidence.

Alvimopan

A peripheral opioid-receptor antagonist, which inhibits opioid-induced constipation, but does not compromise opioid-induced analgesia. Alvimopan accelerates the time to recovery of bowel function and hospital discharge after abdominal surgery and opioid treatment of post-operative pain (Table 40.1). Because of an increased risk of myocardial infarction associated with long-term use, alvimopan is approved in the USA for the short-term (7 days, 12 mg BD) prevention of post-operative ileus following bowel resection.

Methylnaltrexone

Methylnaltrexone (MNTX) is a peripheral opioid-receptor antagonist approved for the treatment of opioid-induced constipation in patients with advanced illness who do not respond to laxatives.

Dosage and pharmacokinetics

The recommended dose of MNTX is 8 mg for patients weighing 38–61 kg, and 12 mg for patients weighing 62–114 kg. The dose should be reduced in patients with renal failure (creatinine clearance <30 mL/min). No dose adjustment is required in mild to moderate hepatic impairment.

Adverse effects and drug interactions

Flatulence, abdominal pain, nausea, and mild diarrhoea (Table 40.1). Since few cases of intestinal perforation have been reported, MNTX is contraindicated in patients in whom the structural integrity of the gut is compromised.

Use in critical care

There is limited, but promising evidence for a beneficial effect of MNTX in critically-ill patients. Therefore, MNTX is used off-label in the ICU.

Naloxegol

Naloxegol is a PEGylated derivative of naloxone, the PEG moiety making the compound a substrate for P-glycoprotein transporters which limit its entry into the central nervous system. It is thus a peripherally acting μ-opioid receptor antagonist that has been approved in the USA and UK for the treatment of opioid-induced constipation in patients who do not appropriately respond to laxatives [12].

Dosage and pharmacokinetics

Naloxegol is available as tablets, and the recommended dose is 25 mg od. Although the drug is primarily cleared by a hepatic route, no dose adjustment is required in mild renal and mild to moderate hepatic impairment.

Adverse effects and drug interactions

The most commonly reported adverse reactions of naloxegol are abdominal pain, diarrhoea, nausea, headache and flatulence, usually graded as mild to moderate (Table 40.1).

Use in critical care

The use of naloxegol in critically-ill patients has not yet been evaluated.

CHAPTER 41

Stress ulcer prophylaxis and treatment drugs in critical illness

Waleed Alhazzani and Deborah J. Cook

Key points

- Stress-ulcer gastrointestinal (GI) bleeding is less common in critically-ill patients today than years ago.
- Histamine-2-receptor antagonists prevent GI bleeding more effectively than no prophylaxis and proton pump inhibitors prevent GI bleeding more effectively than histamine-2-receptor antagonists (H2RAs).
- The associations of acid suppression with pneumonia are less concerning today than potential associations with *Clostridium difficile*.
- Randomized trials to date in this field, with some exceptions, are of moderate quality.
- The use of stress ulcer prophylaxis should be tailored according to the patient's risk of bleeding and local epidemiological data.

The past, present, and future

Stress ulcer-related gastrointestinal (GI) bleeding was first described in 1969. In 1971, a large case series describing this condition in more detail was published, labelling 'stress-related erosive syndrome' in 300 patients [1]. Many concepts have evolved over the last four decades, practice has changed considerably, and a profusion of studies have been published since the original research.

The story of upper GI bleeding during critical illness is interesting. Table 41.1, outlines past, present, and future trends regarding upper GI bleeding and its prevention. First, the burden of illness has decreased, in that upper GI bleeding acquired in the intensive care unit (ICU) used to be a common problem, but today, the incidence is much lower. Secondly, the mortality associated with upper GI bleeding from stress ulceration used to be high, but the severity of this problem appears to have attenuated. Prevention of GI bleeding was previously universal in the ICU. Eventually, a more targeted approach was adopted, based on risk factors that identified vulnerable subgroups, and the recognition that some patients are at such low risk of bleeding that prophylaxis may not be warranted. While dual drug prevention was previously used, at most, one agent is prescribed today.

Stress ulcer prophylaxis (SUP) has been part of 'standard critical care practice' in many jurisdictions.

Bleeding definitions

Several definitions have been used to describe different manifestations of stress ulcer bleeding. The definition is central to the discussion of this topic because most early literature conflates occult bleeding, trivial bleeding, minor, and more serious bleeding. Across this spectrum, many issues differ:

- Baseline bleeding rates.
- Risk factors.
- Consequences such as transfusions.
- Attributable morbidity and mortality.
- Health care costs.
- The propensity to prophylax.

Definitions used in the literature

Occult bleeding is usually defined as a positive guiac test on a faecal sample without overt GI bleeding. Overt bleeding is macroscopic, usually defined as haematemesis, coffee ground emesis, melena, or bloody nasogastric aspirate. Clinically important bleeding (CIB) is usually defined as overt bleeding plus one of the following four features, in the absence of other causes:

- A spontaneous fall in systolic or diastolic blood pressure of >20 mmHg within 24 hours of upper gastrointestinal bleeding, an orthostatic increase in pulse rate of 20 beats per minute and decrease in systolic blood pressure of 10 mmHg.
- A decrease in haemoglobin of >2 g/dL (20 g/L) in 24 hours.
- Transfusion of >2 units of packed red blood cells within 24 hours of bleeding [2].

Incidence and implications of GI bleeding

There are variable estimates of the incidence of upper GI bleeding due to no standard definition and the heterogeneity of bleeding risk among patients. The incidence of 'mucosal injury' based on endoscopy was reportedly as high as 75–100%, observed within 24 hours of ICU admission [1,3]. The incidence of occult bleeding ranges from 15–50% [4]. The incidence of overt bleeding is 5–25% in

Table 41.1 Stress ulcer bleeding: past, present, and future

	Past	Present	Future
Clinically important bleeding	Common	Uncommon	Rare?
Prophylaxis	Universal	Targeted	Highly selected?
# Prophylactic drugs	2	1	1 or none?
Main drugs	Prostaglandins, anticholinergics, antacids, sucralfate	H2RAs, PPIs	PPIs versus Nil?

ICU patients not receiving prophylaxis [5]. However, overt bleeding does not usually progress to CIB [6]. In two large prospective cohort studies, the incidence of CIB was 1.5 and 3.5%, respectively [2,7]. The mortality of bleeding patients was significantly higher compared with patients who did not bleed (48.5 versus 9.1%) [7].

The incidence of bleeding was also recorded in other populations. In a retrospective review of 526 non-trauma neurosurgery patients in Hong Kong, the prevalence of overt GI bleed and CIB was 6.8 and 2.8%, respectively. Most of the patients with overt GI bleed received a histamine-2-receptor antagonist (H2RA) for prophylaxis [8]. Two prospective cohort studies in cardiac surgery patients included 11,508 and 6186 patients, and found the incidence of CIB to be 0.3 and 0.8%, respectively [9,10]. Temporal examination of the literature suggests the incidence of stress ulcer GI bleed has decreased. In studies published before 1999, the incidence of CIB was between 2 and 6% in patients not receiving prophylaxis; however, in studies published since 2001, the incidence of CIB has reportedly ranged from 0.1 to 4% with or without prophylaxis [11]. This may relate to the overall improvement in critical care, particularly resuscitation, mitigating gastric mucosal hypoperfusion. Trends could also reflect more widespread SUP, since this is now encoded into many ICU admission order sets and practice guidelines. Increasing and earlier enteral nutrition may also play a role.

Bleeding risk factors

A large prospective ICU cohort study showed that need for mechanical ventilation for >48 hours and coagulopathy (platelet count< 50,000/mm^3, INR > 1.5, or APTT > twice the upper limit of normal) were the only independent factors associated with increased risk of CIB in multivariable regression analysis. Of 847 patients who had one or both risk factors, 3.7% developed CIB, while only 0.1% of 1405 patients without either of those risk factors developed CIB [7]. In a subsequent prospective multicentre cohort study of 874 ICU patients, 79 patients (9%) developed overt GI bleeding; however, the incidence of CIB was not reported [12]. In the second study, several factors were associated with increased risk of overt bleeding in multivariable analysis:

- Acute hepatic failure.
- Nasogastric tube placement for over 5 days.
- History of alcohol abuse.
- Chronic renal failure.
- A positive *Helicobacter pylori* serology [12].

In mechanically-ventilated patients acute renal failure was associated with increased risk of bleeding in multivariable analysis performed in another study [13]. The growing prevalence of *Helicobacter pylori* may tend to increase the risk of CIB, although causation has not been determined in critical illness.

Other factors associated with increased risk of GI bleeding include severe head or spinal cord injury, thermal injury involving > 35% of the body surface area, major surgery (> 4 hours duration), high-dose corticosteroids, and acute lung injury.

Prophylaxis options

Antacids, sucralfate, anticholineric agents, and prostaglandin analogues have been studied and used in the past for SUP, but they are rarely used today. The mainstay of SUP is acid suppression in the form of 2 drug classes: H2RAs and proton pump inhibitors (PPIs).

H2RAs versus placebo

A recent systematic review comparing H2RAs to placebo that included 1836 patients from 17 RCTs reported a significant reduction in CIB (OR 0.47; 95% CI, 0.29–0.76; $p < 0.002$) [14]. Neither of the prior meta-analyses nor this one showed a significant increase in the risk of nosocomial pneumonia associated with H2RAs compared with placebo (OR 1.53; 95% CI 0.89–2.61).

H2RAs versus sucralfate

A recent meta-analysis included 10 RCTs with a total of 2092 patients, although there were only three RCTs with CIB as an outcome. Pooled results for CIB were not reported due to significant heterogeneity among trials. For overt bleeding, the six RCTs indicated no difference in bleeding (OR 0.87, 95% CI 0.49–1.53) [15]. The risk of nosocomial pneumonia was not significantly higher in patients treated with H2RA (OR 1.32; 95% CI 1.07–1.64).

PPIs versus H2RAs

A recent meta-analysis included 1720 patients from 14 RCTs, and found that PPIs were more effective than H2RAs in preventing CIB (RR 0.36; 95% CI 0.19, 0.68) [16]. Pre-determined subgroup analyses suggested that choice of delivery (oral versus parenteral) and dosing (od versus bd) did not influence the results. No significant impact on nosocomial pneumonia was demonstrated [16]. Based on the most recent evidence synthesis, PPIs seem to be more effective than H2RAs in preventing CIB and overt upper GI bleeding. The robustness of this conclusion is limited by the trial methodology, few events, and subgroup differences (the biggest effect is in the trials at highest risk of bias). No differences were found between drugs in the risk of pneumonia, death, or ICU length of stay.

Enteral feeding

In animal models, enteral alimentation may protect the gastric mucosa from stress-related gastric mucosal damage. However, no

RCTs compare enteral feeding to H2RA or other drugs. A recent meta-analysis comparing H2RA with placebo examined studies in which most patients (>50%) received enteral feeding; in this subgroup, H2RA did not change the risk of bleeding (OR 1.26; 95% CI, 0.43–3.7). The mortality was higher in patients receiving H2RAs in those studies (OR 1.89; 95% CI, 1.04–3.44; $p = 0.04$) [14]. The findings, however, were derived from only three3 RCTs, two of which were unblinded, and inferences are limited. Whether enteral nutrition represents effective SUP is based on scant quantity and quality of evidence.

To summarize, no prior meta-analyses demonstrated an effect of SUP on mortality or ICU length of stay. Cautious interpretation of all of these results is warranted. The risk of bias was variable across trial quality domains and across trials. Specifically, subgroup analysis suggested that the treatment effect favouring PPIs over H2RAs was higher in trials of lower quality. It is thus possible that suboptimal trial design, especially the lack of blinding, has inflated the observed benefits of PPIs.

Nosocomial pneumonia

Studies suggest that PPI therapy may be associated with increased risk of hospital-acquired pneumonia. The proposed mechanism includes rising of gastric pH, promoting the growth of bacteria in the stomach (particularly duodenal Gram-negative bacilli) with oesophageal reflux and aspiration of gastric contents leading to airway colonization or pneumonia.

The meta-analysis reported earlier [16] showed no difference in the risk of nosocomial pneumonia between H2RAs and PPIs. Also, there was no increased risk of nosocomial pneumonia in the meta-analysis of H2RA versus placebo [15]. Since these trials were not powered to detect a small risk increase in these events, we cannot be certain of the effect. Furthermore, most of these trials were conducted prior to the era of wide spread ventilator-associated pneumonia (VAP) prevention resulting in lower VAP rates than in years past.

Cardiovascular events

The efficacy of platelet inhibition may be reduced by PPIs, causing an increased risk of cardiovascular events [17]. Indeed the, Food and Drug Administration has warned that omeprazole, esomeprazole, and cimetidine should not be prescribed concomitantly with clopidogrel. Other joint guidelines from the American College of Cardiology, the American Heart Association and the American College of Gastroenterology recommend PPI therapy for those on clopidogrel with high risk of bleeding. Most observational studies have shown that PPI therapy is preferentially prescribed to those that have multiple comorbidities and observational data on the harms of PPI therapy may relate to this confounding factor.

Clostridium difficile infection

More recently, questions have arisen about the influence of H2RA and PPI on the incidence of *Clostridium difficile* [18,19]. Gastric acid helps to eliminate ingested bacteria from the digestive tract, and it is biologically plausible that raising the pH of the stomach may result in an increased load of pathogenic microbes and consequently increased infectious risk. Indirect evidence derived from observational studies, both in-patient and out-patient studies, suggest increased risk of *Clostridium difficile* infections in those receiving acid-suppression (OR associated with PPIs was 1.96, 95% CI 1.28–3.00 compared with OR associated with H2RA of 1.40, 95% CI 0.85–2.29) [20]. However, no RCT data are available in critically-ill population about the effect of acid suppression on *Clostridium difficile* infections. Specifically, none of the RCTs comparing PPIs and H2RAs for SUP in ICU patients have reported this outcome.

When deciding to provide SUP, it is often difficult to determine risk:benefit ratios when the quality of evidence is different for the risks versus the benefits. In this case, there is RCT evidence that PPIs are beneficial with respect to lower GI bleeding risk, and observational evidence suggesting an association with *Clostridium difficile*. The association with PPI use and *Clostridium difficile* could be real, or due to residual confounding or other methodological issues affecting observational studies. Large rigorous RCT evidence examining all-cause mortality would help to address these concerns.

Surviving sepsis campaign recommendations

The Surviving Sepsis Campaign underscores how the balance of benefits and risks for SUP depend on the individual patient's characteristics, as well as on the local epidemiology of VAP and *Clostridium difficile* infections. Indiscriminate use of SUP in all ICU patients is not warranted and may be harmful. The guidelines recommend that patients should be periodically evaluated for the need for SUP. It must be acknowledged that many of the smaller RCTs in this field informing the choice of SUP agent are at moderate to high risk of bias.

Guidelines suggest that SUP using H2RAs or PPIs be given to patients with severe sepsis/septic shock who have bleeding risk factors (grade 1B). Secondly, when SUP is used, guidelines suggest the use of PPIs, rather than H2RAs (grade 2C). Thirdly, guidelines suggest a targeted, rather than universal approach to SUP, not prescribing it to patients without risk factors (grade 2B).

On the need for future research

It may be hard to believe after four decades of studies, but more rigorous research is needed on GI bleeding rates, hypothesized to be low in today's practice, potentially reduced recently by optimal resuscitation and/or early enteral nutrition. If true, this would increase the number needed to treat with prophylaxis to prevent a bleed, and correspondingly, increase the cost per event averted. Furthermore, adverse event rates might be changing, as well as GI bleeding rates. For example, VAP rates appear to be decreasing, perhaps due to more effective prevention strategies. This apparent trend could be factitious due to reduced VAP reporting; alternatively, prior VAP rates may have been factitiously high due to non-specific VAP definitions used in the past. By contrast, the risk of *C. difficile* appears to be increasing; this may have as much to do with the bacteria or the community of bacteria comprising the gut microbiome as physician drug prescribing. The role of acid suppression predisposing to *C. difficile* infection in critically-ill patients warrants careful investigation as no trials to date have examined this relationship, and the relationship is heavily confounded by antibiotics in the ICU setting.

Augmenting today's clinical observations with summaries of yesterday's research helps to inform new investigations that may impact on future practice. As critical care evolves, epidemiology appears to change, and the standards for research improve, the international ICU community needs to re-examine practice in the context of the evidence upon which it is founded. Interventions introduced many years ago, which are in widespread use today might not have the same uptake if they were to be introduced anew today.

Large modern observational studies and RCTs would help to re-evaluate baseline risks, and test prevailing approaches to SUP versus no prophylaxis on the full spectrum of clinically relevant outcomes, to determine the risk:benefit and cost:benefit of this aspect of critical care practice today.

Nervous system drugs

CHAPTER 42

Sedatives and anti-anxiety agents in critical illness

Curtis N. Sessler and Katie M. Muzevich

Key points

- Use a structured multidisciplinary approach to managing sedation in critically-ill patients.
- Routinely evaluate level of consciousness using a validated sedation-agitation scale.
- Select sedative and anti-anxiety medications based upon patient characteristics and published literature.
- Routinely apply a protocol to sedation management that targets the lightest effective level of sedation.
- Link arousal from sedation to spontaneous breathing trials and early mobilization.

Introduction

The majority of mechanically-ventilated ICU patients are given sedative medications to promote comfort and improve tolerance of the ICU environment [1,2]. These medications are often combined with opioid analgesic agents since pain, dyspnoea, and other forms of discomfort are common. Additionally, an acute confusional state—or delirium—is frequently recognized as a facet of 'brain dysfunction', and contributes to clouded thinking and anxiety. The ICU environment is poorly conducive to restful sleep because of excessive light, noise, and patient arousal for interventions. Sleep deprivation contributes to heightened perception of pain and anxiety, and is considered a major stressor by ICU patients.

As a result of inadequately managed pain, anxiety, and confusion, some patients develop overt agitation, which is characterized by excessive motor activity associated with internal tension. Agitated behaviour can be dangerous to the patient—with self-removal of critical tubes and vascular catheters—or to care-providers from assault. Agitation is often accompanied by poor coordination between the patient's respiratory efforts and the mechanical ventilator, i.e. patient–ventilator asynchrony. Agitation is typically accompanied by a stress–response characterized by high levels of circulating catecholamines, tachycardia, tachypnoea, and hypertension, and can provoke myocardial ischaemia or increased intracranial pressure. Finally, there is evidence that pain and the stress response can contribute to hypercoagulability, hyperglycaemia, increased catabolism, depressed immune response, and other physiological derangements that can have downstream consequences.

It is clear that effective management of anxiety, pain, confusion, and other forms of distress and discomfort is important for the well-being of critically-ill patients. However, prolonged or deep sedation can have negative consequences, including delayed recovery from respiratory failure. Furthermore, administration of benzodiazepines has been linked to the development of delirium, which in turn, is associated with impaired long-term cognitive function. Accordingly, evidence supports and experts recommend targeting a light level of sedation and minimizing sedation whenever possible [1].

Approach to sedation management

Administering sedative and anti-anxiety drugs to a critically-ill patient begins with an assessment of the goals of therapy and the patient specific characteristics that might influence the approach to therapy [1,2]. A useful starting place is the consideration of the patient's underlying medical issues and home medications. Recognition of home use of benzodiazepine, psychotropic agents, or opioid analgesics is crucial, as is identifying underlying alcohol or substance abuse, which might lead to withdrawal symptoms. Organ dysfunction and medication allergies can impact drug selection. The clinician should also consider other predisposing and causative factors that can influence the presence and severity of anxiety, pain, and delirium [2]. In some cases, non-pharmacological interventions, such as minimizing disturbances during sleep, optimizing ventilator settings, and providing verbal reassurance, can improve patients' comfort.

While providing patient comfort and freedom from distress are universal goals, the patient's condition and interventions influence more specific goals of therapy. For example, development of patient–ventilator asynchrony that results in severe hypoxaemia may prompt targeting sufficiently deep sedation to improve patient–ventilator interactions. The presence of overt agitation requires pharmacological control of these behaviours, and administration of neuromuscular blocking agents (NMBA) mandates concomitant administration of sedative and analgesic agents to prevent unrecognized awareness and/or pain. The specific indications for sedative, and analgesic medications and goals of therapy should be periodically re-evaluated.

Titration of sedative medications should be governed by concerns for safety and effectiveness. Effectiveness is primarily evaluated as successfully achieving the goals of therapy such as adequate control of pain, anxiety, dyspnoea, and tolerance of ICU interventions. Safety includes prevention, recognition, and management of adverse effects of medications together with avoidance of

unnecessarily deep or prolonged sedation. Accurately gauging the level of consciousness is guided by routinely assessing arousal using a sedation scale. A variety of scales have been developed and validated, and useful features of effective scales include:

- Multidisciplinary development.
- Ease of administration, recall, and interpretation.
- Well-defined discrete criteria.
- Sufficient sedation levels for drug titration.
- Assessment of agitation.
- Demonstration of validity and inter-rater reliability [3].

Many scales assign progressive hierarchical numbers corresponding to deeper levels of sedation that are defined by responses (including arousal and cognition) to stimuli escalating from auditory to tactile stimuli. Additionally, some scales address grades of agitation. Among published scales, the Richmond Agitation–Sedation Scale (RASS) [4] and Sedation Agitation Scale (SAS) [5] had superior psychometric properties in comprehensive testing and are recommended in the 2013 guidelines [1].

Sedative and anti-anxiety medication administration

Sedative medications are administered intravenously to most ICU patients, particularly in the setting of mechanical ventilation (MV). The primary agents include the benzodiazepines midazolam and lorazepam, as well as propofol and dexmedetomidine (Table 42.1) [1,2]. Propofol was the most commonly administered agent in a survey of USA ICU patients [6]. A single sedative medication is typically administered in combination with an opioid analgesic, although combinations of multiple sedative agents can have synergistic effects.

Pharmacology of sedative agents

Benzodiazepines are GABA receptor agonists that provide sedation via both anxiolysis and amnestic effects [1,2]. Lorazepam and midazolam are used most frequently, but both agents have the potential for drug accumulation and toxicity. Midazolam is a short-acting agent when bolus doses are given to patients with preserved organ function. However, because it is metabolized via the cytochrome P450 enzyme system, which produces active metabolites that undergo renal elimination, it often has prolonged effects when administered to patients with organ dysfunction. Lorazepam is a longer-acting agent that is metabolized via glucuronidation without production of active metabolites. While the metabolic profile makes it advantageous for patients with organ dysfunction, the parent drug is poorly water soluble requiring the addition of propylene glycol to the intravenous formulation. Propylene glycol accumulates in patients with renal dysfunction and can cause metabolic acidosis. Diazepam is used infrequently for ICU sedation, as it has multiple long-acting active metabolites.

Propofol is a lipophillic sedative drug, which exhibits both GABA-agonism and NBDA-antagonism [1,2]. Like benzodiazepine drugs, it provides sedative effect with both anxiolysis and amnestic effects; however, it is extremely short-acting and does not accumulate in patients with organ dysfunction. Propofol is formulated in a soybean oil lipid emulsion, a significant source of calories

Table 42.1 Pharmacological properties of sedative drugs

	Lorazepam	Midazolam	Propofol	Dexmedetomidine
Usual maintenance dose	0.01–0.1 mg/kg/hour	0.02–0.1 mg/kg/hour	5–50 micrograms/kg/min	0.2–0.7 micrograms/kg/hour
Anxiolysis	X	X	X	X
Amnesia	X	X	X

Accumulation with organ dysfunction		X		
Delirium	X	X		
Hypotension and/or bradycardia			X	X
Hypertriglyceridaemia			X	

GABA, gamma-aminobutyric acid; NMDA, N-methyl-D-aspartate.

Data from Barr J et al., 'Clinical practice guidelines for the management of pain, agitation, and delirium in adult patients in the intensive care unit', *Critical Care Medicine*, 2013, **41**(1), pp. 263–306; and Sessler CN and Varney K, 'Patient-focused sedation and analgesia in the ICU', *Chest*, 2008, **133**, 2, pp. 552–65.

(i.e. 1.1 kcal/mL), and can also cause hypertriglyceridaemia and pancreatitis, especially with high doses and prolonged therapy. Propofol can cause hypotension, and should be used with caution in the haemodynamically unstable patient. Propofol-related infusion syndrome (PRIS) is the most significant potential adverse effect and is thought to be secondary to drug-induced mitochondrial toxicity. PRIS is characterized by metabolic acidosis, rhabdomyolysis, arrhythmias, renal failure, and death. Risk of PRIS increases with higher doses and longer duration of therapy.

Dexmedetomidine is a central alpha 2 receptor agonist, which exhibits sedative and analgesic properties [1,2]. Unlike benzodiazepines and propofol, dexmedetomidine does not cause respiratory depression and can be used as a bridge to liberation from MV. Although an initial bolus dose is recommended, it is associated with hypotension and bradycardia and is frequently omitted. Even without bolus dosing, dexmedetomidine should be used with caution in patients with haemodynamic instability, as it can cause bradycardia and hypotension. Dexmedetomidine is US Food and Drug Administration-approved for durations of up to 24 hours. However, longer durations of therapy have been studied in clinical trials. While dexmedetomidine is generally short-acting (terminal half-life = 2 hours), the potential for accumulation and drug withdrawal exists, especially with prolonged administration.

The choice of the best sedative medication should be individualized, based upon the medication properties, the sedative indication, and patient characteristics. Additionally, general recommendations can be guided by the results of randomized controlled trials (RCTs). In a meta-analysis of 16 RCTs published in 2008 in which propofol was compared with benzodiazepines for moderate-to-long duration sedation, propofol was associated with shorter duration of MV and shorter ICU length of stay (LOS) [7]. Similarly, a 2010 meta-analysis of 24 RCTs demonstrated shorter ICU LOS with dexmedetomidine compared with other agents, although no difference in duration of MV was found [8]. Recent RCTs, performed in the current era, in which a more alert patient state is emphasized are revealing. In an international multicentre RCT, dexmedetomidine was associated with shorter duration of MV and lower prevalence of delirium, but was less potent in comparison to midazolam [9]. A recent multicentre RCT also showed shorter duration of MV, as well as better patient interaction (communication, arousability, cooperation) with dexmedetomidine compared with midazolam [10]. In the same study, dexmedetomidine and propofol had similar outcomes except patients who received dexmedetomidine had better patient interaction as judged by ICU nurses [10]. Patient who received dexmedetomidine had more bradycardia and hypotension in these RCTs. Recent guidelines suggest using non-benzodiazepine agents, such as propofol or dexmedetomidine in preference to benzodiazepines for mechanically-ventilated adult ICU patients (+2B recommendation) [1].

Protocol-based management of sedation

Numerous studies demonstrate that using a structured approach to manage sedation—and analgesia—in the ICU is associated with improved outcomes [11–18]. Most strategies focus on reducing the amount of sedative medication to the lowest effective dose and achieving the lightest level of sedation compatible with effectiveness and safety. Use of a sedation scale to guide therapy has become routine. Specific strategies include:

- Close monitoring of level of consciousness using validated tools and titrating sedative medications to a specific sedation target that is as light as is feasible.
- Administering sedative drugs intermittently.
- Interrupting sedative infusions on a daily basis until the patient is alert or agitated.
- Administering analgesic medications before sedative drugs.

Based upon the recognition that continuous infusion sedation is associated with delayed recovery [19], an early single-centre RCT demonstrated the benefit of a nurse-implemented protocol that focused on administering sedative and analgesic medications intermittently, rather than by continuous infusion [12]. Another early landmark single-centre RCT demonstrated that daily interruption of continuously infused sedative and analgesic medications (DIS) until the patient was sufficiently awake to perform simple tasks or became agitated, was associated with shorter duration of MV, shorter ICU LOS, and other favourable outcomes [13]. These approaches hasten recovery by reducing drug accumulation, plus promoting earlier identification of the ability to breathe independently. In fact, the combination of DIS plus performance of the pivotal component of ventilator weaning protocols—the spontaneous breathing trial (SBT)—was superior to SBT alone in a multicentre RCT [14]. In a recent multicentre RCT, patients randomized to an intermittent therapy-based protocol or to DIS had nearly identical outcomes, although DIS required greater nursing work [15].

It is important to consider that the abrupt cessation of sedative drugs is associated with a surge in circulating catecholamines, tachycardia, and hypertension, and a higher likelihood of agitated behaviour. Accordingly, it is appropriate to avoid or modify the approach in patients with active seizures, active alcohol withdrawal, worsening agitation, recent myocardial ischaemia, elevated intracranial pressure, or receiving NMBA, and to take precautions to avoid self-extubation [14]. Concerns about the potentially negative impact of abrupt awakening on long-term mental health were alleviated by follow-up studies that demonstrated trends for better neuropsychological status several months after DIS [16].

Another approach to reduce sedative drug administration is to focus first on pain control and analgesia, so called 'analgesia-first'. Several clinical trials have demonstrated shorter duration of MV with analgesia-based strategies compared with hypnotic-based sedation [11]. In a single-centre RCT, patients randomized to receive only morphine boluses (no routine sedation) had shorter duration of MV and ICU LOS compared with patients who received morphine plus sedation (propofol × 48 hours, then midazolam), but also had three-fold higher rates of agitation [17]. These results may not be generalizable to all hospitals, since their ICU had a high nurse-to-patient ratio and liberal availability of 'sitters' to prevent patients from injuring themselves. Nevertheless, focusing first on analgesia, then on sedation, received an endorsement (+2B recommendation) in 2013 guidelines [1].

Modern ICU sedation management is clearly enhanced by implementing a protocol that targets light sedation and/or incorporates daily awakening, as recommended in 2013 guidelines [1]. Furthermore, enhanced patient arousal can facilitate ventilator liberation, as well as earlier mobilization and rehabilitation [18]. While many clinical trials that tested various sedation management strategies did not implement them until after 48 hours of MV, a recent

cohort study demonstrated worse outcomes among patients who had deep sedation in the first 48 hours of MV [20]. Accordingly, we encourage clinicians to initiate protocolized patient-focused sedation from the onset of MV. Practical issues for sustained successful protocol implementation includes multidisciplinary development and implementation, incorporation of the protocol into standard practice, provision of care-provider education, and use of pre-printed protocols, order sets, and checklists, as recommended in recent guidelines [1,2,11].

To summarize, the administration of sedative and anti-anxiety medications to critically-ill patients can improve patient comfort, but has the potential to worsen important outcomes. Structured management should be multidisciplinary in design and implementation, and focus on the patient as an individual with unique challenges. Key components of sedation management include:

- Patient assessment, including pre-existing conditions and medications.
- Monitoring sedation using a validated sedation scale.
- Selection of appropriate medications based upon patient characteristics and published research.
- Implementation of a protocol that focuses on maintaining the lightest effective level of sedation.

CHAPTER 43

Analgesics in critical illness

Mayur B. Patel and Pratik P. Pandharipande

Key points

- Pain is common in the critically ill. When it is recognized and treated appropriately the risk of multisystem complications can be diminished.
- Regional analgesia can improve respiratory function, bowel function, mental status, and comfort, but it is limited by local anaesthetic toxicity and invasiveness.
- Non-opioid analgesic classes include non-steroidal anti-inflammatory drugs (NSAIDs), gabapentinoids, ketamine, and α2 agonists. They are used as adjuncts to opioid-based or regional analgesia.
- Opioid analgesia in the intensive care unit (ICU) is commonly infusion-based using fentanyl, hydromorphone, morphine, or recently, remifentanil.
- Naloxone can protect against opioid-related respiratory depression using a low-dose infusion, but in an opioid-tolerant patient it can result in a dramatic and acute withdrawal.

Introduction

Critically-ill patients experience pain from obvious sources like invasive procedures, operations, and trauma. Other under-appreciated sources include routine nursing care, endotracheal tube suctioning, prolonged immobility, and pre-existing chronic pain states.

Irrespective of aetiology, uncontrolled pain can have adverse effects on an already critically-ill patient by increasing sympathetic activity, stressing the cardiovascular system, creating a hypermetabolic state and raising oxygen demand [1]. If left untreated, this may progress to excessive catabolism, decreased immune function, delayed wound healing, impaired physical mobility, increased thromboembolic complications, and increased risk of delirium [2]. Thus, analgesia is a critical component of ICU care.

Mechanism of pain

The word analgesic derives from the Greek word *an*—('without') and *algos* ('pain'). Damaged peripheral tissue is usually the source of pain is related to increased levels of histamine, serotonin, and prostaglandins that activate nerve terminals of C and A delta fibres. This afferent pathway synapses in the spinal cord and activates neurons that originate in the diencephalic portion of the reticular activating system. Available analgesics act at these pre- and post-synaptic sites, and can be targeted individually or as part of a comprehensive strategy aimed at multiple sites for additive or synergistic effects.

Assessment of pain

Pain is sometimes undertreated because of concerns about the adverse respiratory and haemodynamic effects of medications, addiction potential of opioids, and lack of proper knowledge in pain assessment and treatment.

Only 25% of surgical patients in the USA received adequate pain relief. Pain assessments using a self-reporting scale, such as a Visual Analog Scale or Numeric Rating Scale [3], are not always possible in those with delirium or coma, although can be used in patients that are communicative. Routine pain assessment that includes intensity, quality, and location has been associated with lower analgesic and sedative utilization, and decreased time on mechanical ventilation and in the ICU [4].

Analgesia

In managing pain in the ICU, non-pharmacological methods are often ignored despite being effective and safe. These methods include patient repositioning, injury stabilization, removal of noxious or irritating stimuli, and use of heat or cold [5,6]. Repositioning and additional support, especially for the lumbar region, are increasingly important in obese patients. Acupuncture, neurolytic agents, cognitive-behavioural interventions, and transcutaneous electrical nerve stimulation all have roles in pain management, but are beyond the scope of this chapter [5,7].

Non-pharmacological approaches should be attempted before supplementing analgesia with regional or systemic therapy. Analgesics commonly used for the treatment of acute pain are listed in Table 43.1.

Regional analgesia

Regional analgesic therapies target specific areas of the body, while limiting the systemic effects of intravenous analgesics. While these procedures are useful adjuncts to decrease exposure to side effects of potent analgesics, they are not without risk and should only be performed by specially-trained clinicians.

Blockade of an individual nerve or nerve plexus may provide relief of pain localized to one extremity. Continuous peripheral nerve blockade via catheter is associated with lower pain scores [8], facilitating earlier rehabilitation. Post-traumatic or surgical pain in the thoracic or upper abdominal areas can be managed by intercostal nerve blocks, paravertebral blocks, or epidural catheters that can improve respiratory mechanics to reduce the risk of pulmonary compromise or pneumonia [9]. Epidural analgesia is used for the management of pain from thoracic, abdominal, or lower extremity

Table 43.1 Opioid and non-opioid analgesics

Class (prototypical agents)	Routes of administration	Mechanism of action	Side-effects
Local anaesthetics (lidocaine, bupivacaine)	EA/SA, PNB/C, sc, TR	Inhibition of Na channels	Hypotension, motor block, myotoxicity, systemic toxicity (seizure, cardiac dysrhythmias, cardiac arrest)
Opioids (fentanyl, morphine)	EA/SA, iv, sc, TR	μ-receptor agonist	Sedation, nausea, vomiting, pruritis, respiratory depression, immunosuppression
Acetaminophen	po, iv	Uncertain	Hepatic toxicity and liver failure, hypersensitivity
NSAIDs (ibuprofen, ketorolac)	po, iv	Inhibition of cyclo-oxygenase	Gastrointestinal bleeding, platelet inhibition, renal failure, hypersensitivity
Gabapentinoids (gabapentin, pregabalin)	po	Inhibition of voltage-gated Ca channels	Sedation, peripheral oedema, gastrointestinal
α_2 agonists (clonidine, dexmedetomidine)	po, iv	α_2-receptor agonist	Sedation, hypotension, bradycardia
Ketamine	iv, im	NMDA-receptor antagonist	Tachycardia, hypertension, increased secretions, hallucinations

EA/SA, epidural/spinal; PNB/C, peripheral nerve block/catheter; sc, subcutaneous; TR, transdermal; iv, intravenous; po, oral.

operative procedures, and it can provide bilateral analgesia in specific dermatomes. Extrapulmonary advantages include lower pain scores, reduced risk of myocardial infarction and dysrhythmias in high risk patients, and earlier return of bowel function [10]. The most easily blocked nerves are sympathetic, sensory, and motor nerves, in that order. Simple neurological testing of motor function or of sensory deficits shows the extent of the block. Bupivacaine and ropivacaine are the local anaesthetics most commonly used for regional analgesia. However, opioids, clonidine, dexamethasone, and other pharmaceutical adjuncts are often used.

The disadvantages of regional anaesthesia are procedure invasiveness, technical complexity, risks of local anaesthetic toxicity, and infection of in-dwelling catheters. The most common adverse effect, especially for epidural catheters, is hypotension due to the blockage of paravertebral sympathetic nerves. This can be reduced by decreasing the rate of the local anaesthetic infusion by administering fluids and initiating a low-dose phenylephrine infusion [9,10]. General contraindications for regional analgesia include coagulopathy, sepsis, and for epidural placement, alterations in spinal anatomy (injury, instrumentation, or congenital).

Systemic analgesia: opioid analgesics

Opioids are the most commonly used ICU analgesics. Their central nervous system pain inhibition is via μ_1 opioid receptor stimulation. Hepatic metabolism and renal clearance is the basis of opioid metabolism. All opioids have the potential to induce tolerance over time, resulting in the need for escalating doses to achieve the same analgesic effect. The selection of an opioid for systemic analgesia has traditionally depended on the pharmacology of the specific opioid and the probable required duration.

Respiratory depression and sedation is commonly seen with opioid use and co-administration of additional sedative agents. Respiratory rate is typically reduced with the preservation of tidal volume ('slow and deep' breathing). Other side effects include decreased gastrointestinal motility, pruritus, flushing, urinary retention, and delirium. Opioid-induced hyperalgesia, distinct from analgesia tolerance, is a paradoxical response to opioids resulting in increased sensitivity to painful stimuli and possibly related to *N*-methyl-D-aspartate (NMDA) glutamate receptor activation. This difficult-to-diagnose entity can occur with either chronic or acute pain, and may be attenuated by NMDA antagonists [9].

Naloxone, a pure competitive antagonist at μ, δ, and κ receptors, can be used to protect against opioid related respiratory depression at infusion rates of 0.25 micrograms/kg/h [11]. Using naloxone in an opioid-tolerant patient can result in a dramatic and acute withdrawal associated with vomiting, aspiration, and severe agitation, as these patients are not fully awake. The doses used for respiratory depression reversal range from 0.4 to 2 mg intravenously (iv).

Other than central pain inhibition, opioids may alter acute brain dysfunction outcomes. Studies in trauma and burn critically-ill patients have also reported on the beneficial effects of morphine and methadone in reducing the development of delirium [12]. However, meperidine and morphine have been positively associated with increased risk for delirium [13], although meperidine use has declined due to increased seizure potential.

Morphine

Morphine has become second-line opioid treatment in many ICUs due to its histamine release causing more hypotension, tachycardia, and bronchospasm than other newer opioids. Additionally, it has an active, sedative metabolite, morphine-6-glucuronide that requires renal elimination and accumulates during renal failure. In rare pain emergencies in those without iv access, it is the only intramuscularly (im) or subcutaneously (sc) deliverable opioid. Morphine infusions are often started at 1 mg/hour and titrated upwards. Intermittent doses of 1–4 mg iv are administered every 5–15 minutes until the pain is controlled, followed by similar doses on a scheduled basis every 2–4 hours. Longer-acting oral formulations are available for basal and chronic pain control.

Hydromorphone

Hydromorphone is a synthetic, hydrogenated ketone of morphine that is at least five times more potent, has higher lipid solubility and blood–brain barrier penetrance, but similar onset, duration, and glucuronide metabolism as morphine. Hydromorphone is broken

down to two active metabolites that have insignificant analgesic activity, but may have some neuro-excitatory properties. Plasma concentrations are increased in patients with renal failure, thus lower starting doses or longer dosing intervals are recommended. In addition to treatment of acute breakthrough pain, it is an alternative for chronic pain and also severe, painful dry coughing. Both iv and oral (po) formulations are available. Its lack of histamine release and decreased incidence of side effects make it a useful alternative to morphine, with typical dosing ranges of 0.2–1 mg iv every 10–15 minutes until pain is controlled followed by similar doses every 2–4 hours; infusions start at 0.2 mg/hour and are titrated upwards.

Methadone

Methadone is a μ receptor agonist and an NMDA receptor antagonist. It has a slow metabolism and very high fat solubility, making it last much longer than morphine-based drugs, but is less useful in acute pain scenarios. Methadone metabolism ranges widely between individuals. Because of its availability orally in solution form and its long half-life, it is ideal for the ICU patient who is expected to need a long recovery period and helps the shift away from moderate- to high-dose analgesia infusions. Recent data suggest that it may result in a decrease in weaning time from mechanical ventilation, compared with IV fentanyl [14]. Electrocardiogram monitoring of QTc interval is recommended. Starting doses range from 2 to 5 mg staggered every 8–12 hours.

Fentanyl

Fentanyl is a synthetic opioid 100 times more potent than morphine. It has a rapid onset and short duration of action, is not renally eliminated, and releases minimal histamine. It is the preferred opioid analgesic in haemodynamically-unstable patients or those with renal insufficiency. It has a large volume of distribution secondary to its lipophilicity, while its clearance correlates most closely with pharmacokinetic mass (similar to lean body mass). Therefore, significant drug accumulation and a prolonged context sensitive half-life can occur with prolonged infusions. It is vagotonic and, in large bolus doses >400 micrograms, can cause severe bradycardia and chest wall rigidity. It is easily titratable as a continuous infusion, secondary to its short half-life. In general, loading doses of 25–100 micrograms of fentanyl are given every 5–10 minutes until pain is controlled, followed by infusion rates of 25–250 micrograms/hr [15]. Transdermal fentanyl is not recommended for routine treatment of acute pain in opioid naïve patients; iontophoretic delivery of fentanyl, effectively transdermal patient controlled analgesia, is under development [9].

Remifentanil

Remifentanil, a derivative of fentanyl, is a selective μ opioid receptor agonist. Its ester linkage undergoes rapid hydrolysis by non-specific blood and tissue esterases with a terminal half-life of 10–20 minutes, regardless of infusion duration. It is used in peri-operative anaesthesia and non-surgical mechanically-ventilated patients. Hypotension and bradycardia are the most common side effects. As a result of its ultra-short half-life, supplemental analgesic medication is required at the conclusion of a remifentanil infusion. It is utilized primarily as an infusion (0.05–2 micrograms/kg/min) based on ideal body weight or lean body mass.

Remifentanil provided better time at optimal arousal level, necessity of supplemental sedation, duration of mechanical ventilation, and extubation time than morphine in one randomized double-blind study [16]. Remifentanil and fentanyl have displayed equal efficacy in achieving sedation goals with no difference in extubation times. Patients receiving fentanyl required more breakthrough sedatives, but experienced less pain after extubation compared with patients receiving remifentanil [17]. Higher cost and reports of withdrawal and hyperalgesia have limited the widespread utilization of remifentanil in the ICU.

Systemic analgesia: non-opioid analgesics

Non-steroidal anti-inflammatory drugs

Non-steroidal anti-inflammatory drugs (NSAIDs) inhibit inducible and constitutive cyclo-oxygenase enzymes (COX) that are involved in the inflammatory response to injury (COX-2) and protective prostaglandin synthesis (COX-1), respectively. Non-selective NSAIDs, such as ibuprofen and ketorolac), have side-effect profiles that include nausea, gastrointestinal bleeding, inhibition of platelet function, and renal insufficiency, especially in the elderly. Ketorolac is administered at 15 mg iv every 6 hours for a maximum of 5 days. Selective COX-2 inhibitors, such as celecoxib, rofecoxib, or valdecoxib, may be associated with decreased gastrointestinal side effects, but due to imbalance in prostaglandin production, may be associated with cardiovascular morbidity.

Gabapentinoids

Gabapentin and pregabalin were primarily used for anti-seizure activity, but are increasingly used for neuropathic and post-operative pain. They bind to a subunit of the voltage-gated Ca channel, inhibit Ca influx and release of excitatory neurotransmitters. Randomized clinical trial data suggests gabapentin will decrease post-operative pain and opioid consumption, but may increase sedation. There are less data for pregabalin [9]. Gabapentin is generally used as a pain adjunct with opioids at a dose of 100 mg tds, titrated upwards to effect.

Ketamine

Ketamine is a derivative of the hallucinogen phencyclidine (PCP). Its mechanism of analgesic action appears to involve NMDA receptor blockade. The dose for analgesia without loss of consciousness is 0.2–0.3 mg/kg iv, but ketamine can be administered po, rectally, or im. There is increased interest in ketamine's role as an adjunct to opioid administration, as low-dose infusions decrease pain scores and opioid consumption [9]. Ketamine does have sympathomimetic properties, so care must be taken where tachycardia and hypertension would be deleterious.

α_2 Agonists

Clonidine and dexmedetomidine are α_2 agonists that have analgesic and sympatholytic properties, the latter more selective than the former. Clonidine is an anti-hypertensive agent that is associated with rebound hypertension after it is discontinued. Dexmedetomidine is a superior iv short-acting sedative that has brain-protective effects against delirium and coma. It may improve outcome in sepsis [18] and has also been used to control post-operative pain in patients taking the opioid buprenorphine

[19]. Its major side effects are hypotension and bradycardia. Dexmedetomidine infusions start at 0.2 micrograms/kg/min and have been used up to 2.0 μg/kg/min. Clonidine dosing starts at 0.1 mg enterally bd and is longer acting.

CHAPTER 44

Antidepressants in critical illness

Scott R. Beach and Theodore A. Stern

Key points

- Selective serotonin reuptake inhibitors (SSRIs), serotonin norepinephrine reuptake inhibitors (SNRIs), bupropion, and mirtazapine are typically the first-line agents for the treatment of depression in the intensive care unit (ICU) setting given their safety and tolerability.
- Serotonin syndrome is a significant risk in overdose of most antidepressants and can also be seen in the setting of combining more than one antidepressant.
- Stimulants can be used safely and effectively to treat apathy, loss of appetite, and low energy in ICU patients.
- Antidepressants should typically be continued during ICU stays (except in the presence of delirium), as abrupt cessation may produce a withdrawal phenomenon.
- Current evidence does not recommend prophylactic initiation of antidepressants following trauma.

Introduction

Pharmacological treatment of depression began in the late 1950s with the introduction of tricyclic antidepressants (TCAs) and monoamine oxidase inhibitor (MAOIs). Following the introduction of fluoxetine in 1988, the selective serotonin reuptake inhibitors (SSRIs) became the third class of drugs with a proven effect in the treatment of depression, and quickly became first-line agents due to their more benign side-effect profiles and safety in overdose. The past two decades have seen the addition of serotonin norepinephrine reuptake inhibitors (SNRIs) and several atypical compounds that share some, but not all of the pharmacological features of TCAs or SSRIs.

SSRIs

All six SSRIs currently available worldwide (Table 44.1) inhibit the presynaptic reuptake of serotonin. Sertraline, fluoxetine, citalopram escitalopram, and fluvoxamine demonstrate a relative specificity for the serotonin uptake transporter, whereas paroxetine also has anticholinergic and antihistaminergic effects. SSRIs, like other antidepressants, probably exert their effects via downstream consequences on secondary messenger systems, including increased production of proteins such as brain-derived neurotrophic factor (BDNF).

All SSRIs effectively treat depression. They are also commonly used to treat anxiety disorders, including generalized anxiety disorder (GAD) and obsessive-compulsive disorder (OCD) [1]. Occasionally, these agents are utilized in patients with eating disorders or to treat specific symptoms of personality disorders, such as impulsivity.

SSRIs are associated with fewer anticholinergic side effects and less weight gain than TCAs, although all cause some weight gain [2]. Orthostatic hypotension (OH) is not a common side effect of treatment. SSRIs are safe in patients with coronary artery disease (CAD) and may be effective at treating depression in this population. The major side effects are insomnia, gastrointestinal (GI) discomfort, sexual dysfunction, and headache.

In general, SSRIs typically reduce the heart rate by 7–8 beats/minute. Though previously thought to be free of cardiac conduction abnormalities, all except paroxetine have been associated with prolongation of the QT interval at therapeutic doses and in overdose. Citalopram is thought to be the most highly associated with QT prolongation and malignant ventricular arrhythmias like torsades de pointes (TdP), and in 2011 the Food and Drug Administration (FDA) issued a warning that doses of citalopram higher than 40 mg daily should be avoided if possible due to an association with QT prolongation [3].

SSRIs are far safer than TCAs when taken in overdose. Nonetheless, deaths have been reported from overdoses of all agents. Cardiac conduction abnormalities can be seen in overdose.. Serotonin syndrome (with a triad of mental status changes, autonomic hyperactivity, and neuromuscular abnormalities) is also a risk in overdose. Symptoms of serotonin syndrome include tremor, confusion, incoordination, hyperreflexia, diaphoresis, mydriasis, and clonus; it progresses to agitated delirium, muscle rigidity, hypertension, hyperthermia, and shock if left untreated (2). Treatment is largely supportive, including intravenous (IV) fluids, cooling blankets, and benzodiazepines for muscle rigidity, though serotonin antagonists are sometimes also used.

SSRIs and SNRIs

The SNRIs, venlafaxine and duloxetine, are similar in most respects to SSRIs (see Table 44.1). They are used primarily to treat depression, although they may have additional benefits in treating neuropathic pain [1]. Due to their additional action on norepinephrine, these agents are more commonly associated with hypertension, and routine monitoring of blood pressure (BP) is recommended. Headaches may also be a more common side effect than with SSRIs. Duloxetine has been associated with drug-induced liver injury, including cholestatic jaundice and hepatitis in patients with chronic liver disease or cirrhosis [4]. Its use is therefore contraindicated in patients with chronic alcohol use or chronic liver disease. It is important to note that venlafaxine is excreted renally,

Table 44.1 Side effect profiles and available formulations of antidepressants

Medication	Therapeutic dose range (mg/day)	Sedative potency	Anticholinergic effects	Blood pressure effects	Other side effects	Alternate formulations
SSRIs					Insomnia, GI discomfort, sexual dysfunction, akathisia, headache	
Citalopram	20–40	Low	Absent	Minimal		Liquid; dissolvable tablet
Escitalopram	10–30	Low	Absent	Minimal		Liquid
Fluoxetine	10–60	Low	Absent	Minimal		Liquid; enteric-coated weekly fluoxetine
Fluvoxamine	50–300	Low	Absent	Minimal		Extended-release capsule
Paroxetine	10–40	Low	Low	Minimal		Liquid; extended-release capsule
Sertraline	50–200	Low	Absent	Minimal		Liquid
SNRIs					Insomnia, GI discomfort, sexual dysfunction, akathisia, headache	
Duloxetine	20–120	Low	Absent	Minimal		
Venlafaxine	75–375	Low	Absent	Moderate		Extended-release capsule
Desvenlafaxine	50	Low	Absent	Moderate		Extended-release tablet
Milnacipran (not approved for depression in USA)	100–200	Low	Absent	Minimal		
Atypical antidepressants						
Bupropion	100–450	Low	Absent	Minimal	Agitation, headache, nausea, tremor, seizure	Extended-release capsule
Mirtazapine	15–45	High	Absent	Minimal	Weight gain	Dissolvable wafer
Vilazodone	10–40	High	Absent	Minimal	GI discomfort	
Tianeptine (not available in the USA)	37.5	Low	Low	Minimal	Insomnia, vivid dreams	
Reboxetine (not available in the USA)	8–10	Low	Moderate	Minimal	Headache, sweating, insomnia, sexual dysfunction	
Agomelatine (not available in the USA)	25–50	High	Absent	Minimal		
TCAs						
Amitriptyline	50–300	High	High	Considerable	Weight gain, tachycardia	
Amoxapine	50–300	Low	Low	Moderate	Stimulation, EPS	
Clomipramine	50–250	High	High	Considerable	Tremor, GI discomfort, sexual dysfunction	
Desipramine	50–300	Low	Low	Considerable	Palpitations, tachycardia	
Doxepin	25–300	High	High	Moderate	Tachycardia	Liquid
Imipramine	50–300	Moderate	Moderate	Considerable	Tachycardia	
Maprotiline	50–200	Moderate	Low	Moderate	Tremor, seizure	
Nortriptyline	25–150	Low	Low	Minimal	Tremor, headache	Liquid

(*continued*)

Table 44.1 Continued

Medication	Therapeutic dose range (mg/day)	Sedative potency	Anticholinergic effects	Blood pressure effects	Other side effects	Alternate formulations
MAOIs						
Phenelzine	15–90	Low	Very low	Considerable	Insomnia, sexual dysfunction	
Selegiline	6–12	Low	Very Low	Moderate		Transdermal patch
Tranylcypromine	10–90	Low	Very Low	Considerable	Insomnia, tremor	
Stimulants					Insomnia, tremor, decreased appetite	
Dextroamphetamine	2.5–30	Absent	Very Low	Minimal		Liquid
Methylphenidate	5–40	Absent	Very Low	Minimal		Liquid, transdermal patch

GI, gastrointestinal; EPS, extrapyramidal symptoms; SSRIs, selective serotonin reuptake inhibitor; SNRIs, serotonin-norepinephrine reuptake inhibitors; TCAs, tricyclic antidepressants; MAOIs, monoamine oxidase inhibitors.

and its levels therefore increase significantly in patients with renal dysfunction.

Venlafaxine is typically dosed two or three times daily, due to its short half-life, although an extended-release formulation allows for once daily dosing. Duloxetine is generally dosed once or twice daily.

In overdose, SNRIs typically have sympathomimetic effects, including hypertension and tachycardia. Prolongation of the QT interval has been described in case reports with venlafaxine, but not with duloxetine [5,6]. Serotonin syndrome may occur with these agents when used in combination with other serotonergic agents.

Atypical antidepressants

Bupropion is a relatively selective dopamine-uptake blocker that is effective in treating depression (Table 44.1). Its efficacy and side effect profile are similar to those of SSRIs, but bupropion does not cause sexual dysfunction. High doses are associated with an increased risk of seizures [2]. Two distinct extended-release formulations are available.

Mirtazapine is an α_2 antagonist that effectively increases the levels of serotonin and norepinephrine in the synaptic cleft (Table 44.1). It is highly antihistaminergic, leading to prominent side effects of sedation and weight gain. These effects are frequently capitalized upon in medically-ill patients who have poor sleep patterns and low appetite. Mirtazapine has the unusual distinction of causing more antihistaminergic effects at lower doses. Its incidence of sexual side effects is lower than that with SSRIs or SNRIs. Mirtazapine has been associated with prolongation of the QT interval in overdose [7].

Stimulants

Some evidence suggests that dextroamphetamine and methylphenidate may effectively treat depression in elderly and medically-ill patients. Stimulants can also be used safely and effectively to treat apathy and loss of appetite. Although stimulants suppress appetite at higher doses, they tend to improve appetite at low doses. Their onset of effect is much faster than that of SSRIs and TCAs. Caution is warranted with the use of stimulants in patients with untreated hypertension, arrhythmias, or known structural heart defects [8]. Stimulants have the potential to induce or worsen delirium, and should be used cautiously in high-risk patients.

TCAs

TCAs (Table 44.1) effectively treat the neurovegetative signs of depression. Clomipramine is also used to treat OCD. Amitriptyline, clomipramine, and doxepin have a high affinity for muscarinic cholinergic receptors and cause more anticholinergic side effects (e.g., dry mouth, blurred vision, constipation, urinary retention) than the other cyclic compounds. All the TCAs may cause OH, although nortriptyline carries the lowest risk [2]. OH occurs before the therapeutic effect of TCAs.

TCAs cause a predictable increase in heart rate, and all cause prolongation of the QT interval through Na^+ channel blockade, but generally only pose a significant risk of ventricular arrhythmia to patients with pre-existing cardiac disease. Amoxapine has been associated with atrial flutter and fibrillation in case reports. TCAs are not recommended in patients with CAD because of an increased risk of ventricular arrhythmias and myocardial infarction (MI).

MAOIs

Phenelzine and tranylcypromine have traditionally been the two most frequently used MAOIs (Table 44.1). These drugs inhibit both monoamine oxidase isozymes (A and B), which raise the level of norepinephrine, serotonin, and dopamine in the synaptic cleft, as well as the level of exogenous monoamines taken up by the GI tract. The recent development of a transdermal form of selegiline, an irreversible inhibitor of MAO-B, has resulted in resurgence of its use. All MAOIs are primarily used to treat depression, although they are also employed for refractory anxiety and for treatment of specific symptoms, such as impulsivity in patients with personality disorders.

The sympathomimetic pressor amine tyramine, delivered by food to the GI tract, can rise to high levels during MAOI therapy and lead to potentially lethal hypertensive crises, characterized by an elevation of BP, severe headache, nausea, vomiting, and diaphoresis. A tyramine-low diet is recommended in patients taking oral MAOIs, although patients on low-dose selegiline patch do not have

dietary restrictions. MAOIs used in conjunction with other serotonergic agents also carry a risk of serotonin syndrome.

MAOIs have a very low affinity for post-synaptic receptors and, therefore, many of the side effects seen with TCAs are absent. However, insomnia is seen frequently and often requires treatment.

Treatment strategies

The selection of an antidepressant should be based on the side effect profile of the drug and the type of depressive disorder. The SSRIs, SNRIs, mirtazapine, and bupropion are recommended as first-line drugs. Nortriptyline and desipramine are preferred over the other TCAs because of their favourable side effect profile. Amitriptyline and amoxapine are considered third-line drugs because of their propensity to induce significant side effects. The MAOIs are also third-line drugs in the treatment of depression. Stimulants have a rapid onset of effect and can be used effectively in medically-ill patients with prominent apathy and lack of appetite.

Monotherapy is typically the initial treatment strategy. Initiating treatment at low doses and increasing the dose to usual therapeutic drug levels reduces the risk of adverse effects. Monitoring of blood levels is recommended for some TCAs.

If the first antidepressant has not shown a therapeutic effect within 8 weeks, alternative strategies should be considered. Switching to another antidepressant (even of the same class) is reasonable. Augmentation of an insufficient treatment response with a second antidepressant, lithium, a stimulant, or thyroid hormone may also be helpful. Combining pharmacological treatment with psychotherapy is another strategy. Patients who do not respond to adequate trials of antidepressants should be considered for electroconvulsive therapy (ECT).

If the patient recovers from a depressive episode, maintenance treatment should be considered to reduce the significant risk of relapse associated with major depression.

Special issues regarding antidepressant use in the ICU

Use of linezolid with antidepressants

Most antidepressants have the potential to induce serotonin syndrome when used in combination with other agents. One commonly encountered scenario in the ICU involves the use of linezolid in patients maintained on antidepressants. Linezolid is a mild, reversible, non-selective MAOI, and at least 20 case reports have highlighted the potential for serotonin syndrome when used in combination with a serotonergic agent (e.g. an SSRI) [9]. Current recommendations include a washout period of at least 2 weeks for most antidepressants (and 5 weeks for fluoxetine) prior to the initiation of linezolid. This is rarely feasible in the setting of acute infection, however, and a more reasonable guideline may include initiation of linezolid with careful monitoring for signs and symptoms of serotonin syndrome. The decision about stopping the antidepressant should be made after a careful risk–benefit analysis. In the case of a lethal depressive disorder with multiple past suicide attempts, the benefit of continuing the antidepressant may outweigh the relatively low risk of serotonin syndrome. Ideally, an additional washout period of 2 weeks is recommended, following the cessation of linezolid prior to restarting other serotonergic agents.

Special formulations

Many patients in the ICU are unable for a variety of reasons to take pills by mouth, and it is therefore important for critical care physicians to be aware of alternative preparations of these agents (see Table 44.1) [10].

Withdrawal from antidepressants

Another common decision in the ICU involves the continuation of antidepressants. Many critical care physicians favour discontinuation of any non-essential medications. Furthermore, a majority of patients in the ICU will develop delirium at some point during their stay. While most SSRIs, with the exception of paroxetine, are not thought to be highly deliriogenic, all may increase the risk for, or prolong, the course of delirium. The issue is complicated, however, by the fact that an SSRI-discontinuation syndrome has been described in the setting of acute cessation of these agents and is considered to be most significant with paroxetine due to its short half-life [11]. The syndrome is marked by the rapid onset of symptoms that may include anxiety, crying, dizziness, headache, insomnia, irritability, myoclonus, nausea, parasthesias, and tremor. There are currently no guidelines for the maintenance of antidepressants in the ICU setting. In the absence of side effects, it is reasonable to continue these agents, although many would advocate for discontinuing any psychoactive substances should delirium develop. Patients in whom SSRIs are stopped abruptly should be monitored closely for signs of withdrawal.

Starting SSRIs immediately after trauma

Psychiatric consultants are often asked to opine on the utility of starting antidepressant therapy as prophylaxis for depression following a significant trauma. Commonly-encountered situations include a patient who has suffered traumatic para- or quadriplegia or one with a new diagnosis of terminal illness. Although many clinicians assume that anyone in such a situation would become depressed, evidence suggests that in fact, only a minority of such patients develop an episode of major depression. The issue is complicated by the fact that many patients become demoralized, which can mimic depression, but has not been found to be responsive to medication. Given the risks associated with antidepressant medications, there is currently no evidence to recommend empiric initiation of antidepressants patients with catastrophic illness. Instead, patients should be carefully monitored over a period of several weeks for mood changes, with psychiatric involvement as needed.

CHAPTER 45

Antiseizure agents in critical illness

Sebastian Pollandt and Lori Shutter

Key points

- Currently available antiseizure drugs do not affect the development of epilepsy.
- Benzodiazepines are the most effective agents for termination of acute seizures.
- After termination of acute seizures, several effective drugs are available for prevention of seizure recurrence.
- Intravenous (iv) formulations of antiseizure drugs are recommended for management of seizures in ICU populations.
- Drug levels can vary significantly due to drug–drug interactions and co-morbidities, thus frequent monitoring is recommended.

Introduction

Clinical and subclinical seizures are frequent in critically-ill patients, and are often due to intracranial structural lesions, central nervous system (CNS) infections, metabolic derangements, exogenous toxins, or medications [1] that lower the seizure threshold. A full discussion of these issues is beyond the scope of this chapter. The mechanisms of seizure generation and perpetuation are thought to be related to excitatory inputs that exceed inhibition and result in neuronal hypersynchrony. Thus, any disease process that alters the balance of excitation and inhibition has the potential to cause epileptic seizures. Accordingly, antiseizure drugs employ various strategies to either increase inhibition by augmenting GABAergic transmission or reduce excitation, most commonly via Na channel blockade. The most challenging clinical scenario encountered in the intensive care unit (ICU) is status epilepticus, defined as 5 minutes or more of continuous clinical and/or electrographic seizure activity or recurrent seizure activity without recovery (returning to baseline) between seizures [2]. Pharmacological treatment of status epilepticus involves emergent termination of acute seizures with primarily benzodiazepines, followed by rapidly achieving therapeutic concentrations of an antiseizure drug via intravenous (iv) infusion to prevent seizure recurrence.

Agents available for management and prevention of seizures do not prevent development of epilepsy, thus the term 'anti-epileptic' is not accurate. The term anticonvulsant is also imprecise in that it neglects the effects of these drugs on non-convulsive seizures. Agents used for management of seizures will be referred to as antiseizure agents. The choice of an antiseizure agent must be influenced by the clinical situation and potential for drug interactions. Highly protein-bound agents, such as phenytoin, carbamazepine, or valproate, often require monitoring of free plasma levels in the ICU setting.

Benzodiazepines

Benzodiazepines are widely regarded as the agent of choice for emergent treatment of clinical and subclinical seizures [2]. They enhance inhibitory GABAergic transmission via the $GABA_A$ receptor, resulting in hyperpolarization of the membrane. Treiman et al. performed a blinded, randomized, prospective study of four iv regimens, including lorazepam, phenytoin, phenobarbital, and diazepam for primary treatment of status epilepticus. Lorazepam was found to be significantly more successful than phenytoin alone in aborting overt status epilepticus within 20 minutes of therapy, although no treatment regimen was found to be superior in the intent-to-treat analysis [3]. Intravenous lorazepam and diazepam have been shown to be superior to placebo in termination of out-of-hospital status epilepticus, with a trend towards better efficacy for lorazepam [4]. A double-blind, randomized, non-inferiority trial of iv lorazepam versus intramuscular (im) midazolam in the out-of-hospital setting showed non-inferiority for midazolam and a trend towards better results with im midazolam, which may have been related to shorter time to administration [5]. All benzodiazepines are known to result in the development of tolerance, thus dose escalation may be necessary. Propylene glycol is commonly used as a solvent for diazepam and lorazepam, which can cause hypotension and peripheral venous irritation, and may be avoided by modifying the method of administration (slower rate, use of a central venous line). In some countries, diazepam in a lipid emulsion is available for iv and im injections, which has been shown to reduce pain and thrombophlebitis [6].

Lorazepam

Lorazepam is less lipophilic than diazepam and redistribution is slower, resulting in longer duration of action. Lorazepam is administered at an initial dose of 0.1 mg/kg iv up to 4 mg/dose, with a maximum administration rate of 2 mg/min [2]. This dose may be repeated every 5–10 minutes up to a maximum cumulative dose of 8–10 mg, but occasionally higher doses have been used. Common adverse effects include hypotension and respiratory depression, which may necessitate intubation and mechanical ventilation.

Midazolam

Midazolam is soluble in water and available for iv and im injection, as well as buccally or intranasally. It is rapidly redistributed, resulting in a short duration of action. Initial dosing in status epilepticus starts with boluses of 0.2 mg/kg iv, given at a maximum rate of 2 mg/min up to a total of 10 mg. The dosing range for a continuous infusion is typically 0.05–2 mg/kg/hour. For breakthrough status epilepticus, a bolus of 0.1–0.2 mg/kg, together with an increase of the infusion rate by 0.05–0.1 mg/kg/hour every 3–4 hours is recommended [2]. Prolongation of the half-life with sustained infusions has been reported, thus the infusion rate should be decreased if extended use is required [7]. Hypotension and respiratory distress occur, but less frequently than with diazepam or lorazepam. Tachyphylaxis is a known phenomenon and may require switching to an alternative antiseizure agent.

Diazepam

Diazepam is very lipophilic, penetrates quickly into the CNS, but then redistributes rapidly out into peripheral tissues, which can result in a precipitous decline in CNS concentrations and early seizure recurrence. The initial dose is 0.15 mg/kg iv up to 10 mg/dose, which may be repeated after 5 minutes. The administration rate should not exceed 5 mg/min. Diazepam is commonly used in paediatric populations via per rectum administration. The dosing in children aged 2–5 years is 0.5 mg/kg, ages 6–11 years is 0.3 mg/kg, and children older than 12 years should get 0.2 mg/kg [2]. Intravenous formulations of diazepam containing propylene glycol may result in hypotension and respiratory depression.

Clonazepam

Clonazepam is used outside North America in a similar fashion to lorazepam, but the iv formulation is not available in the USA. Multiple studies have found it to be effective in status epilepticus [8].

Barbiturates

Barbiturates exert antiseizure properties by enhancing inhibitory transmission via the $GABA_A$ receptor. Agents used in clinical practice include phenobarbital, pentobarbital, and thiopental. Although highly effective in treating refractory status epilepticus, they have considerable adverse effects, including cardiac toxicity, haemodynamic instability, respiratory depression, ileus, and nosocomial infections. Additionally, iv formulation of both phenobarbital and pentobarbital contain propylene glycol, which is associated with hypotension, renal dysfunction, and cardiac arrhythmias.

Phenobarbital

The initial dose is 20 mg/kg iv administered at 50–100 mg/min. An additional 5–10 mg/kg may be given 10 minutes after the loading infusion [2]. The most relevant adverse effects include hypotension, sedation, and respiratory depression. It has a long plasma half-life of 53–118 hours (mean 79 hours), making it an attractive agent for chronic maintenance therapy.

Pentobarbital

The loading dose is 5–15 mg/kg, with additional boluses of 5–10 mg/kg, typically with the goal of burst-suppression on EEG. This should be administered at 50 mg/min or less. The recommended dosing range for a continuous infusion is 0.5–5 mg/kg/hour. For breakthrough status epilepticus, the recommended treatment is a bolus of 5 mg/kg, followed by an increase in the infusion rate by 0.5–1 mg/kg/hour every 12 hours [2]. Common adverse effects are hypotension, respiratory depression requiring intubation and mechanical ventilation, cardiac depression, and paralytic ileus.

Thiopental

Thiopental is a short-acting barbiturate that is metabolized to pentobarbital. The loading dose is 2–7 mg/kg, administered at 50 mg/min or less. A maintenance infusion is typically dosed at 0.5–5 mg/kg/hour. For breakthrough status epilepticus, the suggested treatment is a bolus of 1–2 mg/kg, followed by an increase of the infusion rate by 0.5–1 mg/kg/h every 12 hours [2] Adverse effects are similar to pentobarbital.

Phenytoin

Phenytoin is a hydantoin and acts by blocking Na channels. It is available in various formulations—immediate and extended release capsules, chewable tablets, oral suspension, and as a solution for injection. Absorption and bioavailability is variable, with close monitoring recommended when switching between formulations. Patients receiving continuous enteral nutrition have lower than expected phenytoin concentrations, and dose adjustments together with more frequent phenytoin concentration monitoring are recommended. The initial dose in status epilepticus is 20 mg/kg iv, given at a maximum rate of 50 mg/min. An additional 5–10 mg/kg may be given 10 minutes after the loading infusion [2]. Phenytoin is indicated for all seizure types, and requires propylene glycol as a solvent. Phenytoin is highly protein-bound (>90%); thus free serum concentrations can vary significantly depending on the patient's nutritional status. Unbound phenytoin is metabolized via a saturable hepatic metabolism, resulting in non-linear kinetics and toxic levels with small increases in dosing. Hypotension is common and often related to rapid infusion rates. Phenytoin is known to exert cardiotoxic effects, and thus requires cardiac monitoring and sometimes external pacing. It is contraindicated in sinus bradycardia, sino-atrial block, second—and third-degree atrioventricular block, and patients with Adams–Stokes syndrome. The most common additional side effects are dizziness, drowsiness, and lethargy. At toxic doses, seizures, coma, and death are possible. Serious skin reactions include Stevens Johnson syndrome, purple-glove syndrome, and toxic epidermal necrolysis.

Fosphenytoin

Fosphenytoin is metabolized to phenytoin and the differences between the two are related to their pharmacokinetic profiles. Fosphenytoin is soluble in water and is dosed in milligrams of phenytoin equivalents (PE). Fosphenytoin may be administered at a maximum rate of 150 PE mg/min.

Levetiracetam

The precise mechanism of action is unknown, but it has been shown to bind to the synaptic vesicle protein 2A (SV2A), which plays a role in release of neurotransmitter. The loading dose is generally 1000–3000 mg iv in adults, while higher doses are used

in paediatric populations (20–60 mg/kg). It is most commonly administered as bd intermittent bolus doses of 500–3000 mg, but has been used as a continuous infusion at 2–5 mg/kg/min [9]. It has minimal drug–drug interactions and is not hepatically metabolized. The dose must be reduced for patients with renal dysfunction, and supplemental doses after intermittent haemodialysis are necessary. In patients on continuous renal replacement therapy dosing is very challenging and thus other agents are more appropriate. Side effects are typically minimal, but psychosis, somnolence, dizziness, agitation, or other behavioural disturbances have been reported. In 2008, Rüegg et al. [10] retrospectively assessed the safety and efficacy of iv levetiracetam in 50 critically-ill patients. The authors reported cessation of seizure activity, or prevention of its recurrence in 41 of 50 patients (82%) without notable adverse effects [10]. Another study retrospectively assessed iv levetiracetam for treatment of refractory status epilepticus. A median daily dose of 3000 mg with a range of 1000–9000 mg was administered as an iv bolus or continuous pump infusion. Status epilepticus was terminated in 69%. Treatment failure was associated with age >80 years, non-convulsive status epilepticus, periodic lateralized epileptiform discharges (PLEDs) on electroencephalography (EEG) and acute lesions, such as stroke, intracranial haemorrhage, encephalitis, or brain trauma [9]. A trial comparing iv clonazepam alone to iv clonazepam plus iv levetiracetam administered by emergency medical services personnel in a pre-hospital setting in generalized convulsive status epilepticus is ongoing [11].

Propofol

Propofol is thought to act by blockade of Na channels and modulation of GABAergic neurotransmission. When treatment is escalated to a continuous propofol infusion, mechanical ventilation is usually necessary. The loading dose is 1–2 mg/kg, followed by a continuous infusion starting at 20 micrograms/kg/min. Maintenance dosing typically ranges from 30–200 micrograms/kg/min. For breakthrough seizures, it is recommended to increase the infusion rate by 5–10 micrograms/kg/min every 5 minutes, or to administer an iv bolus at 1 mg/kg bolus with subsequent titration of the continuous infusion. Caution is recommended for administration of doses in excess of 80 micrograms/kg/min for prolonged periods of time, i.e. greater than 48 hours, due to the risk of propofol infusion syndrome (PRIS), which is a rare, but potentially fatal adverse effect. PRIS is characterized by heart failure, rhabdomyolysis, metabolic acidosis, renal failure, hyperkalaemia, hypertriglyceridaemia, and hepatomegaly [12]. Children are at greater risk for PRIS; thus, propofol is contraindicated in this population. It is also associated with hypotension, particularly with higher loading doses. Due to the short-half-life, a rapid taper of propofol should be avoided to prevent withdrawal seizures. Of note, propofol provides a significant amount of lipid-based calories (1.1 kcal/mL), which should be considered when addressing nutritional needs.

Lacosamide

Lacosamide is a novel antiseizure agent that enhances slow inactivation of voltage-gated Na channels, which is thought to stabilize hyperexcitable neuronal membranes and inhibit repetitive neuronal firing. It also modulates collapsin response mediator protein 2 (CRMP2), a phosphoprotein that is involved in neuronal differentiation and control of axonal outgrowth. The role of CRMP2 in seizure control is unclear. There is some support in the literature for use of lacosamide in status epilepticus [13]. It is administered initially at 200–400 mg iv at a rate of 200 mg/15 min [2], and is subsequently dosed intermittently bd with a total daily dose of 200–400mg/day. Lacosamide and its major metabolite are eliminated from systemic circulation primarily by renal excretion, with approximately 40% excreted unchanged in urine. Hepatic metabolism does play a role in the biotransformation of lacosamide, thus lower doses are recommended in patients with moderate hepatic impairment. It has not been evaluated in patients with severe hepatic impairment. Protein binding is less than 15% and it is effectively removed from plasma by haemodialysis, so supplementation after intermittent haemodialysis is recommended. Lacosamide has no known relevant drug–drug interactions, but may prolong the PR interval and cause hypotension.

Topiramate

The mechanism of action of topiramate remains to be elucidated. It has been shown to block voltage-dependent Na channels, augment GABAergic transmission, exert antagonism at the AMPA/kainate subtype of the glutamate receptor, and inhibit carbonic anhydrase enzyme. It is available for PO administration only and has been used for add-on therapy in the setting of refractory status epilepticus [14]. The initial loading dose of topiramate is typically 200–400 mg po, with maintenance doses of 300–1600 mg/day, divided 2–4 times daily [2]. Common adverse effects include sedation and metabolic acidosis. Topiramate is not extensively metabolized, and about 70% of the administered dose is excreted unchanged in urine. It is also removed by haemodialysis, and a supplemental dose after intermittent haemodialysis is recommended.

Valproate

The mechanism of action of valproate remains unclear, but may be related to increased brain concentrations of GABA. The initial loading dose in status epilepticus is 20–40 mg/kg iv given at a rate of 3–6 mg/kg/min. An additional dose of 20 mg/kg may be given 10 minutes after the loading dose. In paediatric populations, the recommended dose is 1.5–3 mg/kg/min [2]. Valproate has numerous side effects, most notably hyperammonaemia, pancreatitis, thrombocytopenia, and hepatotoxicity, as well as drug–drug interactions. It may be the best choice for patients with primary generalized epilepsy. A randomized study comparing iv phenytoin with iv valproate in status epilepticus refractory to benzodiazepines found both drugs equally effective in termination of seizures without any differences in adverse events [15].

CHAPTER 46

Inhalational anaesthetic agents in critical illness

Laurent Beydon and Flavie Duc

Key points

- Sevoflurane and isoflurane are inhaled agents with interesting pharmacological properties and may be used for sedation in the intensive care unit.
- Sevoflurane and isoflurane require specific administration devices not routinely available.
- Renal toxicity is unlikely despite a sizeable increase in inorganic fluoride level.
- Sevoflurane and isoflurane have been shown to improve patients suffering life-threatening asthma.
- The usefulness of halogenates in status epilepticus is not sufficiently supported to be considered in practice.

Introduction

Inhalational agents are widely used in the operating theatre for general anaesthesia. Their use in the intensive care unit (ICU) is limited as administration requires specific equipment not routinely available. Clinical indications are limited since the use and versatility of relatively cheap competing intravenous drugs only requires conventional peristaltic or syringe pumps. Nevertheless, inhalational agents have also been proposed for short sedation by some authors. Halogenates provide a more predictable dose–response effect, and allow faster awakening than midazolam or propofol. Moreover, they may have therapeutic effects in refractory status asthmaticus or epilepticus.

Administration of inhaled agents in ICU

Three halogenated agents are available currently—isoflurane, sevoflurane, and desflurane. They are all suitable to provide sedation/anaesthesia in the ICU, but require special equipment for their delivery.

Nitrous oxide, a less potent anaesthetic gas shall be considered as an adjunctive agent, which potentiates general anaesthesia. Used alone with oxygen, it allows light sedation and analgesia required for technical and moderately painful procedures (catheter insertion, superficial biopsies . . .). It is available in cylinders mixed to 50% oxygen, ready to be dispensed by a face mask and a demand valve in any place without requiring further equipment.

Xenon, an inert gas with anaesthetic properties cannot yet be considered as a clinically useful means to deliver sedation due to its price and the need for anaesthesia machines specifically compatible with this gas.

Delivery of inhaled anaesthetic agents presents a practical difficulty, which may explain the limited use of inhaled anaesthesia/sedation in ICU practice.

The conventional anaesthesia machine

These large and somewhat cumbersome machines with closed circuit architecture have long been judged as unsuitable for use in ICU. Rarely available outside the operating theatre, it is problematic to remove them from the operating theatre even for short use in ICU. The poor pneumatic performance of anaesthesia machines has traditionally been another limitation for ICU use, but modern devices comprise all the main ventilatory modes, including pressure-controlled ventilation and inspiratory pressure support. All halogenates can be delivered via the integrated evaporators, in the same way as in the operating theatre. Moreover, these machines comprise a sampling gas monitor, which allows closed loop ventilation with CO_2 scavenging via the in-line soda lime canister. This close loop architecture is of major interest as it limits halogenate consumption and costs, and room air pollution. A charcoal scavenging canister fitted to the machine gas exhaust port is recommended when used in ICU to suppress air pollution fully. Using an anaesthesia machine to administer halogenate-inhaled sedation is a straight forward solution. However, one should consider the size of these machines (Fig. 46.1), which, in addition to limited availability, impedes the generalization of their use. The three halogenates routinely used in anaesthesia (isoflurane, sevoflurane, desflurane) can be dispensed by this method.

Reflection HME filter (AnaConDa®)

This reflection HME filter (AnaConDa®, Sedana Medical™, Sundbyberg, Sweden) has been developed to administrate halogenates without the use of an anaesthesia machine (Fig. 46.2). In addition to the 'conventional' HME filter the device includes a carbon layer capturing halogenates from exhaled gas and allowing them to be re-inhaled during inspiration. Halogenate is infused at the patient side of the filter, via an external conventional syringe pump, which controls the inspiratory fraction of the halogenate in use. The intended inspired halogenate fraction is linearly related to the infusion rate (Fig. 46.3). Gas partial pressure (CO_2 and halogenate) can be monitored by an external monitor via a sampling port on the device (Fig. 46.2). Isoflurane and sevoflurane are the two agents

Fig. 46.1 An ICU bed equipped with an anaesthesia closed loop ventilator in order to deliver halogenates. Note the size and room occupancy of this setting.

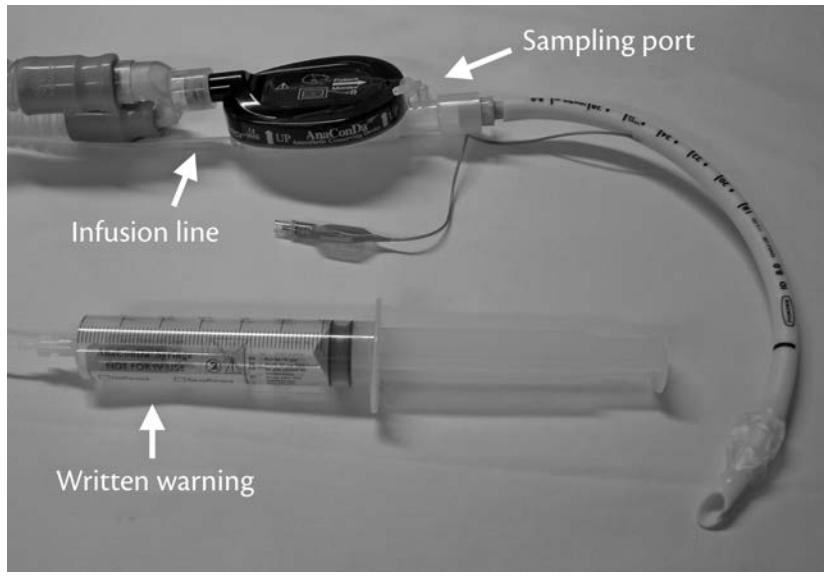

Fig. 46.2 Picture of the AnaConDa® filter showed in a clinical setting.

that can be safely delivered with this system. The rate of halogenate reinhalation (≈90%) is comparable with that of a low flow anaesthesia machine [1]. Any ICU ventilator can be used in association with this dispensing HME filter. These devices have made it possible to reconsider the usage of inhaled halogenate agents in ICU.

Inhalational anaesthetic agents

Sevoflurane, isoflurane, and desflurane

These three halogenated anaesthetic gases are used in anaesthesia worldwide. The vaporization temperature of the desflurane is 23°C, thus requiring a heated evaporator that is only available on anaesthesia machines. Therefore, unlike isoflurane and sevoflurane, desflurane cannot be dispensed with the AnaConDa® HME filter.

Their potency can be summarized by the minimum alveolar concentration (MAC) principle, which is the percentage exhaled fraction at steady state providing immobility on surgical stimulation in 50% of patients (desflurane, 6.0%; sevoflurane, 2.0%; isoflurane, 1.1%). Opiates and nitrous oxide have an additive effect when co-administered with halogenates, and permit reduced concentration and, consequently, side effects.

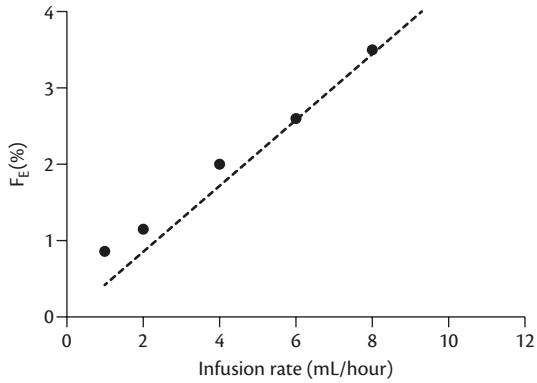

Fig. 46.3 Plot of infusion rate versus expired fraction of isoflurane (F_E%) in the bench study.
Tidal volume, VT = 500 mL; respiratory rate, RR = 12 breaths/minute; respiratory 'duty cycle', Ti/Ttot = 33%; no positive end-expiratory pressure; and constant flow during inspiration. Reproduced from Berton J et al., 'AnaConDa reflection filter: bench and patient evaluation of safety and volatile anesthetic conservation', *Anesthesia and Analgesia*, **104**, 1, copyright 2007 permission from International Anesthesia Research Society.

Isoflurane, sevoflurane, and desflurane are well tolerated with minimal side effects [2]. In short, they moderately depress cardiac output, which is partly compensated by a rise in cardiac frequency. They depress arterial pressure in response to a dose-dependent decrease in systemic vascular resistance [3]. These effects are dose dependent. In addition, sevoflurane may prolong the QT interval [4]. Interestingly, halogenates are cadioprotective when used in cardiac surgery [5]. Isoflurane and sevoflurane decrease airway resistance in cases of bronchospasm, whereas desflurane is irritant to the respiratory tree. Halogenates are also known to potentiate the effects of muscle relaxants and can generate malignant hyperthermia in genetically susceptible patients. When used above 1 MAC, halogenates raise the cerebral blood flow and cerebral blood volume. This contributes to a rise in intracranial pressure in cases of brain damage as the vasodilatatory effect of halogenates is greater than the decrease in cerebral metabolic rate caused. Therefore, halogenates should be used below 1 MAC under moderate hypocapnia, in acute cerebral disease to avoid the deleterious effects of a pharmacologically-induced luxury perfusion. Sevoflurane is known to favour seizure-like EEG activity, especially in children, with possible clonic movements. At the same time, sevoflurane is known to exert neuroprotective effects. Halothane has been shown to be hepatotoxic in rare cases, but this risk in virtually absent in modern halogenates.

Isoflurane and desflurane are not significantly metabolized unlike sevoflurane of which 5% is metabolized via the cytochrome pathway to inorganic fluoride, and hexafluoroisopropanol. These metabolites react with carbon dioxide absorbents (soda lime) in anaesthesia ventilators to form potentially nephrotoxic products where low fresh gas flow is used. No clinically significant renal injury has been documented despite some authors reporting an increase in sensitive markers of renal integrity after sevoflurane anaesthesia [6]. Consequently, sevoflurane should not be used with a fresh gas flow <2 L/min in closed circuit with soda lime, especially for prolonged exposures. This issue has raised concerns about using sevoflurane for sedation in ICU. Insufficient experience has been gained to rule out any renal safety issue when sevoflurane is used for prolonged sedation in ICU. Carbon monoxide is also produced by the interaction between soda lime and desflurane, and to a lesser extent, isoflurane. There are conflicting data on the reproductive hazards related to the exposure of health care workers to halogenates (and nitrous oxide) [7]. When halogenates are used in ICU, charcoal cylinders should be used to suppress air pollution.

Nitrous oxide

Nitrous oxide is not usually available in the ICU, except in the form of 50% N_2O/O_2 cylinders. Accordingly, N_2O may be used to induce light analgesia/sedation for short procedures; in the same way as in office-based surgery. It is an agent of limited potency, but may provide marginal interest in limited cases.

Xenon

For more than 50 years xenon, has been known for its anaesthetic properties at inhaled concentrations around 30% in O_2. Moreover, xenon tends to induce minimal cardiovascular or respiratory depression compared with halogenates. It also allows extremely fast induction and awakening, whatever the duration of anaesthesia, as it is not metabolized and is highly insoluble in blood (blood/gas partition coefficient, 0.115). It has been shown to provide neurological and cardio-protective effects in vivo, which seem promising [8]. It does not induce intracranial hypertension in experimental brain injury, in contrast to halogenates [9]. As a natural compound obtained as a by-product of industrial extraction of oxygen, it does not contribute to atmospheric pollution unlike halogenates and nitrous oxide. However, its price and rarity limits the generalization of its use which is only possible with specific anaesthesia ventilators. Monitoring inspired/expired concentration requires specific technologies (heat conductivity or radiofrequency-based measurement). EEG based monitoring of the depth of anaesthesia can be used in Xenon anaesthesia [10].

At present, its routine use in ICU is out of reach, although some authors foresee applications in cardiac vulnerable patients or after neonatal brain injury.

Inhaled anaesthetics in ICU: a limited experience

Inhaled anaesthetics used for sedation from a few hours to several days has been reported in a limited number of studies. One can summarize these reports by citing the results of several typical studies in order to understand what can be expected from this mode of sedation. Mesnil et al. [11] compared sedation with midazolam (0.1 mg/kg/hour), propofol (2 mg/kg/hour) or sevoflurane (expired fraction: 0.5% with AnaConDa®), in association with remifentanil in 47 ICU patients, for 50 hours, on average. Doses were adjusted to reach the same sedation level according to a sedation scale. Average doses delivered at steady state were: remifentanil: 9–12 micrograms/kg/hour. Awakening duration was shorter with sevoflurane (18 minutes) compared with propofol (91 minutes) and midazolam (260 minutes). Sedation level was more stable with sevoflurane with less hallucinations and a striking reduction in consumption of morphine after extubation. The mean fluoride concentration was 82 μmol/L (range 12–220) with no rise in serum creatinine, aspartate transaminase (AST) or alanine transaminase (cystic fibrosis transmembrane conductance regulator ALT). Sackey et al. [12], comparing isoflurane and midazolam sedation for 96 hours, report a similar shorter time to extubation with isoflurane compared with

midazolam (10 versus 110 minutes). Series of published literature using inhaled halogenates compared with propofol or midazolam has been reviewed with similar findings and no consequence on renal function [13]. Others confirmed the absence of renal consequence after a short sevoflurane sedation (≈ 9 hours) despite a rise in inorganic fluoride levels (average 39 μmol/L) compared with the propofol group [14]. Fluoride level has been shown to return to normal levels by the fifth day after discontinuation of halogenates (isoflurane) [15].

Inhaled sevoflurane [16] and isoflurane [17] have been shown to improve blood gases (decreased pH and $PaCO_2$) and clinical outcome in children ventilated in a state of life-threatening asthma. Refractory status epilepticus has been treated with isoflurane and desflurane, but data are insufficient to recommend their use at present [18].

Xenon (inhaled fraction: 28%) has been used for 8 hours post-operative sedation in comparison with propofol/alfentanil infusion. Haemodynamics were more stable and recovery faster with xenon [19].

Conclusion

Limited experience has been achieved with halogenates and xenon to produce short sedation in ICU. Results seem promising especially because the stability of sedation was achieved with virtually no side effects. However, development of this mode of sedation is limited by the specific devices required to administer these agents. Isoflurane and sevoflurane may be useful to treat life-threatening asthma. Their usefulness in the refractory status epilepticus remains to be confirmed. Xenon, is a difficult to recommend solution as long as its price remains high.

CHAPTER 47

Muscle relaxants in critical illness

Brian J. Pollard

Key points

- Relaxants antagonize the action of acetylcholine. Important factors that may modify the action include acid-base disturbances, electrolyte changes, muscle diseases, and drug interactions.
- The principal differences are in onset, duration, and side-effects.
- Succinylcholine is normally used for rapid tracheal intubation. Rocuronium in a higher dose is also effective.
- Train of four is the most convenient method for monitoring muscle relaxation.
- Indications include tracheal intubation, facilitation of procedures, to assist ventilation, critical gas exchange, tetanus, and transfers.

Physiology

The neuromuscular junction lies between motor nerve and striated muscle. The transmitter is acetylcholine, which synthesized in the cytoplasm of the pre-junctional nerve ending. It is stored in vesicles and released into the junctional cleft in response to a nerve impulse. The released transmitter crosses the space to react with receptors, which lie on the shoulders of the folds of the post-junctional membrane. Each receptor unit is integral with its ion channel and the simultaneous binding of two acetylcholine molecules (to the alpha subunits of the chain) causes the channel to open. Occupation of either or both receptor sites by an antagonist molecule will result in the channel being inactivated, unable to open and thus unable to conduct the impulse onwards. The channels on the post-junctional membrane are selective for small cations; it is the sudden transmembrane flux of Na ions through a large number of channels activated simultaneously that is responsible for the generation of an endplate potential. This is followed by the onward propagation of the impulse across the membrane of the muscle cell.

Receptors also exist in other locations, in particular on the pre-junctional nerve endings and these are involved in modulation of impulse transmission via changes in transmitter mobilization and release particularly at higher frequencies of stimulation.

Pharmacology

The clinical use of the muscle relaxants is regarded as having begun in 1942, although early formulations had been tried out over the previous approximately 40 years. Many different agents have been introduced into clinical practice, some naturally occurring (e.g. tubocurarine) and some totally synthetic (e.g. pancuronium). Only a small number have become established in modern clinical practice, the main reason being issues with undesirable side effects and differences in elimination characteristics.

The principal differences between the available drugs are in their onset of action, duration of action, route of elimination, and side effects.

- Rapidity of onset is important when tracheal intubation must be secured urgently.
- An intermediate duration of action is convenient because it offers better control than a long-acting drug. A short-acting drug might be regarded as better still, although the rate of consumption of a short-acting drug would be excessive if its use is prolonged. A long-acting drug may accumulate.
- Elimination of muscle relaxants is principally through the kidneys and liver. Since impairment of renal and hepatic function are common in the critically ill, any drug used in the ICU should rely as little as possible on either of these organs for its elimination.
- Since many critically-ill patients have significant cardiovascular instability any drug should have minimal effects on the cardiovascular system.

There are a number of medical conditions and pathophysiological changes (acid base, electrolyte) that are common in the ICU patient and which may interfere with the action of muscle relaxants. Acidosis, hypothermia, hypokalaemia, hypocalcaemia, hypernatraemia, and hypomagnesaemia may all potentiate neuromuscular block. Muscular, neurological, and neuromuscular disorders (e.g. myasthenia gravis, myotonias, muscular dystrophies) may also prolong neuromuscular block. In addition, the ICU patient will receive many concomitant drugs and some may interfere with the action of the relaxants, e.g. antagonism by neostigmine, ecothiopate, alkylating agents, trimetaphan, or potentiation by calcium channel blockers, aminoglycoside antibiotics, immunosuppressants, furosemide, and lithium.

Choice of muscle relaxant

Summary information concerning the five non-depolarizing relaxants is given in Tables 47.1 and 47.2.

Table 47.1 Basic pharmacodynamics data for five non-depolarizing relaxants

	ED95 (mg/kg)	Approximate infusion rate to maintain steady state (mg/kg/h)	Approximate duration of one ED95 dose (minutes)
Atracurium	0.23	0.25	20–30
Vecuronium	0.04	0.08	20–30
Pancuronium	0.06	0.03	40–60
Cisatracurium	0.05	0.1	25–35
Rocuronium	0.3	0.5	20–30

Succinylcholine

Succinylcholine remains the only depolarizing agent in current clinical use. Its speed of onset has not so far been surpassed, although there have been many attempts, and its short duration of action has not hitherto been bettered. Its principal use is to secure the airway rapidly. This is of particular advantage when the time of last food intake is unknown, or gastric stasis and a full stomach are suspected. It is often used for this purpose in new admissions to the ICU. It would be unusual to continue to use succinylcholine to continue a block in an ICU patient.

Succinylcholine has a number of unwanted side effects, most of which (e.g. fasciculations, myalgia, masseter spasm) are not of importance in the ICU patient. A dose of succinylcholine may, however, cause a significant increase in the serum potassium concentration and this may be particularly hazardous in the ICU patient. Although this increase is normally of the order of 0.5–1.0 mmol/L in normal patients it may be accentuated in patients with burns, muscle trauma, immobility, and spinal cord injuries. The use of succinylcholine in these patients, or in those with an already raised potassium, may precipitate a cardiac arrest and should only be considered with great caution.

Non-depolarizing relaxants

Pancuronium

This agent is a synthetic steroid based substance [1]. It was first introduced into clinical use in the 1960s and still remains on the formulary in many hospitals. It used to be used as the mainstay of muscle relaxation in the ICU, but has been largely superseded by modern agents. It is a potent relaxant with a relatively slow onset and long duration of action. It is devoid of ganglion blocking activity and histamine release. There is a small rise in the heart rate (by a combination of mild vagal inhibition and sympathetic stimulation) and the blood pressure is well maintained. It is metabolized in the liver and excreted by the kidneys so its action may be prolonged in patients with impairment of one or both of these systems. If pancuronium is used, it is recommended that it should be administered by intermittent bolus doses, not by infusion and to measure the degree of relaxation regularly in order to guard against accumulation.

Table 47.2 Elimination characteristics of five non-depolarizing relaxants. Elimination (beta) half-lives in minutes

	Normal patients	Hepatic disease	Renal disease
Atracurium	20	25	22
Vecuronium	54	90	76
Pancuronium	123	200–270	240–1000
Cisatracurium	29	24	24
Rocuronium	87	97	97

Vecuronium

Also a steroid-based synthetic molecule, its potency is similar to that of pancuronium. It has a very clean cardiovascular profile and does not release histamine. It has an intermediate duration of action and has been a popular choice in many ICUs. It is well suited to administration by continuous infusion or intermittent bolus. It is metabolized in the liver, one of the metabolic products being 3-hydroxy vecuronium, which is also a muscle relaxant with a potency of about 70% of that of vecuronium. Both vecuronium and its metabolites are eliminated in the urine. Its action may therefore be prolonged in patients with renal insufficiency and there are reports of patients where recovery from a block has taken many hours (or days) following an infusion of vecuronium in the presence of renal failure.

Evidence exists for a possible deleterious effect of vecuronium when given by prolonged infusion in the critically-ill patient. Critically-ill patients may develop a myopathy as a part of the critical illness process and this seems to be more prevalent when a vecuronium prolonged infusion has been used. This so-called 'steroid myopathy' is poorly understood, and doubt has been cast on its existence and incidence. Some ICUs do not favour the use of vecuronium for these various reasons.

Atracurium

Atracurium is a racemic mixture and not all isomers have relaxant activity. Another intermediate duration relaxant, it is suitable for administration by continuous infusion. It is virtually devoid of side effects, but histamine release at higher doses has been reported. This does not seem to be a problem in the ICU patient. It has a novel method of metabolism where approximately 60% is broken down by esterases in the liver, while the remainder undergoes spontaneous degradation in the plasma by the Hofmann elimination reaction. This latter reaction is independent of all organ systems and takes place spontaneously at body temperature and pH. Because of this, there is negligible prolongation of its action in the presence of liver or renal disease. Recovery is predictable and it can be reliably expected that the effect of a bolus dose or a continuous infusion will have worn off after about 1 hour.

The metabolites of atracurium have no muscular relaxant action, although they include other substances that may have potentially toxic effects, namely laudanosine and acrylates. Acrylates are potentially hepatotoxic, but are produced in such extremely small amounts so as to be insignificant. Interest has centred around laudanosine, a substance that can cause cerebral excitation in some laboratory animals, although there is no evidence of any toxic effects in humans. Laudanosine is renally excreted and so may accumulate if atracurium is given by a prolonged infusion in the presence of

impaired renal function. It appears unlikely on present evidence that laudanosine is of clinical relevance.

The use of atracurium by prolonged infusion may be associated with a phenomenon of resistance. After a delay of about 2–4 days, it is found that an increase in the infusion rate is needed in order to maintain the same degree of paralysis. As time then progresses, the infusion rate needs to be steadily increased, occasionally to quite remarkable levels. This is not observed in every patient and the mechanism is unclear.

Cisatracurium

Cisatracurium is the component isomer of atracurium with the greatest intrinsic relaxant activity. It is approximately four times more potent than atracurium and so less is required to produce the same degree of block. Otherwise, the side effect profile, suitability for infusion use, etc., are all as for atracurium. As less is required to produce a neuromuscular block then lower concentrations of all metabolites will be produced.

Rocuronium

This is another steroid-based molecule and is an analogue of vecuronium. It is stable in solution and so does not need to be reconstituted just before use. It has a potency of about one-eighth that of vecuronium. The normal intubating dose is 0.6mg/kg, but if given in a dose of 1.0 mg/kg, it produces an onset close to that of suxamethonium at 60–90 seconds. The duration of a normal intubating dose is about 30–40 minutes and higher doses last longer. It can readily be reversed with neostigmine, but also by the specific antagonist sugammadex. Rocuronium has a very clean side effect profile with very little change in cardiovascular parameters and negligible histamine release in clinical doses.

Monitoring neuromuscular blockade in the ICU

It is a general maxim of medicine that whenever a drug is administered to a patient then its effect should be monitored in order to prevent inadequate or excessive effect. In the case of the muscle relaxants, this is relatively straightforward. There are many commercially-available monitoring systems on the market that make use of force displacement or acceleration transducers. These are not necessary for routine clinical use. The use of a simple train of four supramaximal stimuli from a portable hand-held nerve stimulator is recommended. This pattern of stimulation consists of four stimuli each separated by 0.5 seconds from that preceding or following. Two self-adhesive surface (ECG-type) electrodes are placed over the ulnar nerve at the wrist and a stimulus applied. The current needed should be commenced at 20 mA and increased stepwise to a maximum of 70 mA. The movements of the thumb are then detected either visually or by palpation. The number of twitches of the thumb present correlates well with the degree of neuromuscular block ranging from no block with four strong equal twitches to 100% block with no twitches. A useful general rule is to maintain the level of block where the first twitch of the train of four is present and there is a very weak second response with no third or fourth responses. Some hand-held stimulators are also capable of providing a double-burst pattern. Two very short pulses at a base frequency of 50 Hz are given, separated by 0.75 seconds. When there is no neuromuscular block, two strong movements of the thumb can be felt. With increasing neuromuscular block the second movement fades to zero followed by the first. A neuromuscular block with a weak first response only would be a suitable level for most situations on the ICU. If the ulnar nerves are not available then the facial nerve just in front of the ear is commonly used.

It must be remembered the response may vary from day-to-day due to a variety of factors, including changes in skin impedance and the presence of tissue oedema. The electrodes should be changed at least daily, the skin cleaned carefully and the position of the electrodes kept constant. If tissue oedema is present, it is usually possible to reduce the problem by exerting a firm pressure over the electrodes for 1–2 minutes before stimulating.

Indications for the use of a muscle relaxant

At the start of the 1980s, almost every patient on the ICU received a muscle relaxant as a routine part of their sedation regimen, despite these drugs having no sedative action [2]. Use fell markedly over the ensuing 5–10 years. The current situation is that a muscle relaxant is only used where there is a specific indication. Many intensivists nowadays only resort to the use of a muscle relaxant, when all other techniques have been exhausted. Nevertheless, they remain a valuable part of our management strategy when used appropriately. When used by continuous infusion, tachyphylaxis occasionally develops, which may be managed by temporarily changing to a different relaxant.

Tracheal intubation

Tracheal intubation is possible without the use of a relaxant when the patient is weak, has depressed airway reflexes or has received a generous dose of an anaesthetic agent. A bolus dose of remifentanil may also assist in tracheal intubation. The use of local analgesia in the pharynx and larynx may also aid tracheal intubation, and this is usually needed if fibre optic intubation is to be performed. A muscle relaxant is often used to facilitate intubation because it provides completely relaxed muscles of the airway, reduces the potential for trauma, and facilitates a rapid intubation. If speed of intubation is required then the usual drug of choice is succinylcholine. If succinylcholine is contraindicated then a dose of rocuronium at 1.0 mg/kg will produce neuromuscular blockade almost as rapidly as succinylcholine.

Assisting ventilation

It is occasionally not possible for a patient to tolerate intermittent positive pressure ventilation or certain other modes of ventilation when using sedatives alone. The result may be marked swings in intrathoracic, intracranial, and intra-abdominal pressure as the patient attempts to breathe out of phase with the ventilator. This may have significant adverse effects on cardiovascular and other responses. It is often the case that a short period of muscular relaxation will help to establish smooth controlled ventilation after which it can be weaned off. Many consider the use of a muscle relaxant in patients with a raised intracranial pressure to be mandatory.

In patients with a poor lung compliance there may be difficulty in achieving satisfactory gas exchange with sedative agents alone. The addition of a muscle relaxant, possibly for only a short period, often improves oxygenation.

Tetanus

A muscle relaxant will reduce muscle spasms and facilitate positive pressure ventilation. It must be remembered, however, that the relaxant, by masking the spasms, may hinder the overall management and measurements of progress of the patient.

Disadvantages of using a muscle relaxant

Neurological assessment

When a patient has received a muscle relaxant it is difficult or even impossible to perform a meaningful neurological assessment [3]. Focal or localizing neurological signs may be missed leading to delay in treatment, which itself may have potentially serious consequences. Epileptiform seizures may also be masked. If it is decided to use a relaxant then it must be discontinued at regular intervals to allow accurate neurological assessments to be made. Inadequate sedation may be masked by the presence of a relaxant. It is essential to be certain that the patient is adequately sedated when using a relaxant.

Disuse atrophy

Muscle weakness is present in many critically-ill patients as a consequence of their disease process. It is possible that long-term use of a muscle relaxant (particularly a steroid-based one) may exacerbate this phenomenon.

Increased risk of venous thromboembolism

The incidence of deep venous thrombosis and pulmonary embolism has been reported to be more common in the paralysed patient. The evidence is conflicting, however, and with modern prophylactic techniques this is likely not to be a significant issue.

Reversal of neuromuscular block

In the ICU patient, this is normally achieved by stopping the infusion (or intermittent administration) and awaiting metabolism. In some reported cases, recovery has been reported to be prolonged. These include renal failure when pancuronium or vecuronium are used in higher doses. The breakdown of atracurium and cisatracurium is independent of renal or hepatic function, and so either of these drugs may be a better choice in these patients. The use of an anticholinesterase to secure reversal is rarely required.

A new agent, sugammadex, has recently become available as a selective antagonist for rocuronium and vecuronium. It works by chelating and inactivating the molecules in the plasma. Reversal is thus rapid and complete, although such a rapid reversal is unlikely to be required in an ICU. The dose is 2–4 mg/kg up to 16 mg/kg maximum. It can be safely used in patients with some renal or hepatic disease with no dose adjustment. Safety data on its use in patients with severe renal impairment is currently not available.

CHAPTER 48

Neuroprotective agents in critical illness

Jerrold L. Perrott and Steven C. Reynolds

Key points

- For patients with aneurysmal subarachnoid haemorrhage (SAH) pravastatin or simvastatin may be considered to possibly reduce rates of vasospasm, vasospasm-associated delayed ischaemic deficits, and mortality.
- Nimodipine is recommended to reduce the risk of poor neurological outcome and delayed ischaemia in patients with aneurysmal subarachnoid haemorrhage.
- In traumatic brain injury (TBI), and especially for those patients at high risk, phenytoin is recommended to reduce the risk of early seizures, although this intervention does not reduce the risk of seizures beyond 7 days.
- Patients with TBI should not be resuscitated with albumin-based colloids, as these products are associated with increased mortality.
- Corticosteroids should not be given to patients with TBI as they increase the risk of death.

Introduction

Pharmacological neuroprotection following insult to the central nervous system (CNS) has been and remains an enticing goal in the field of critical care medicine. With the exception of certain planned situations, such as neurosurgery or induced cardiac arrest for cardiothoracic surgery, prophylaxis against the primary brain injury is not possible, leaving the target of most interventions as the reduction of secondary injury, and subsequent neuronal dysfunction and death. It is also being increasingly recognized that the neuronal support network, including endothelial, astroglial, microglial, and oligodendroglial cells, play an important role in potentiating and/or mitigating secondary injury [1].

Despite the diversity of mechanisms of primary injury, including traumatic, ischaemic, and haemorrhagic events, it is thought that a number of common pathways converge to result in secondary and ongoing injury [2], many of which offer potential therapeutic targets for intervention (Table 48.1).

Numerous preclinical studies have examined a multitude of agents to address these common pathways of secondary injury with varying degrees of success. More than 30 clinical trials have been conducted with agents targeting single specific pathways, but few have shown positive outcomes. The lack of success with agents targeting single pathways has contributed to a shift in focus, with an emphasis on investigating agents that likely have an effect on multiple pathways. Examples include [2]:

- **Hydroxymethylglutaryl-coenzyme A inhibitors** (statins): may target excitotoxicity, apoptosis, and blood–brain barrier disruption.
- **Cyclosporin:** may target mitochondrial dysfunction, calpain activation, apoptosis, and oxidative stress.
- **Progesterone:** may target inflammation, oedema, oxidative stress, apoptosis, and excitotoxicity.

A representative list of therapeutic classes that have failed to translate preclinical success to positive clinical trials are presented in Table 48.2.

This disappointing lack of success in translating preclinical findings to positive clinical trials of potential medical interventions is common in research in the critically ill. There are multiple reasons, but the most prominent are biological difference between humans and animal models, inadequate animal models, clinical study design, end-point definitions, and recruitment issues [1]. For further discussion of these interventions and challenges, the reader is directed to a number of review articles on the challenges of translating positive preclinical studies to clinical trials on this topic for further information [1,2].

Specific neuroprotective pharmacotherapeutic

Aneurysmal subarachnoid haemorrhage

As opposed to other causes of subarachnoid haemorrhage, specifically trauma and other types of stroke, cerebral vasospasm is the primary driver of secondary neural injury in aneurysmal subarachnoid haemorrhage (aSAH), once the aneurysm has been surgically or interventionally controlled [3]. While arterial vasospasm is arguably beneficial in situations of injury to peripheral vessels to limit catastrophic blood loss, when it occurs in the brain secondary to aSAH, it can induce significant downstream ischaemia and infarct or **delayed ischaemic deficits**.

Two classes of medication have been successfully shown to reduce the adverse sequelae of vasospasm in randomized controlled trials (RCTs)–statins and dihydropyridine Ca channel blockers.

Statins

The mechanism of benefit of statins on vasospasm and outcomes in this population is not well elucidated, but is generally described in terms of their pleotropic effects.

Table 48.1 Potential mechanisms of secondary neuronal injury [2]

Category	Mechanisms and targets
Inflammation	◆ Cytokines ◆ Nitric oxide ◆ Prostaglandins
Blood–brain barrier disruption	◆ Cerebral oedema ◆ Hypoxia ◆ Ischaemia
Cell death	◆ Apoptosis/necrosis ◆ Caspases
Mitochondrial dysfunction	◆ PARP-1 activation ◆ Depletion of ATP and NAD^+ ◆ Calpain activation ◆ Altered membrane permeability
Excitotoxicity	◆ Glutamate → NMDA receptor activation ◆ Ca^{2+} influx
Oxidative stress	◆ Free radicals ◆ Lipid peroxidation

Data from Loane DJ, Faden AI, 'Neuroprotection for traumatic brain injury: translational challenges and emerging therapeutic strategies', *Trends in Pharmacological Sciences*, 2010, **31**(12), pp. 596–604.

To date, four small and one large RCTs have been published on the effect of statin therapy in aSAH. A meta-analysis of the results of the first three of these trials showed a relative risk (with 95% confidence intervals) for statin versus control of incident vasospasm of 0.73 (0.54–0.99), vasospasm-related delayed ischaemic deficits 0.38 (0.17–0.38), and mortality 0.22 (0.06–0.82) [4]. These results translate into a number need to treat (NNT) to prevent incident vasospasm of 6, for delayed ischaemic deficits 5, and for mortality 7. The fourth small pilot study (n = 39) showed non-significant reductions in mortality [5] and the most recent study, the STASH Trial (n = 803), failed to demonstrate any improvements in clinically meaningful outcomes [6]. This most recent trial has introduced significant controversy into the use of statins for aSAH. Statins are generally well tolerated and the regimens used in the published studies, common side effects, and contraindications are presented in Table 48.3.

Table 48.2 Example agents with positive preclinical, but negative clinical trials [1]

Primary injury mechanism	Pharmacological intervention
Stroke	◆ Anti-inflammatory agents ◆ *N*-methyl-D-aspartate (NMDA) antagonists ◆ Dexanabinol ◆ Na channel blockers ◆ Growth factors ◆ Free radical scavengers
Traumatic brain injury	◆ NMDA antagonists ◆ Dexanabinol ◆ Glucocorticoids ◆ Erythropoetin ◆ Ca channel blockers

Data from Faden AI and Stoica B, 'Neuroprotection – challenges and opportunities', *Archives of Neurology*, 2007, **64**, pp. 794–800.

Table 48.3 Statin therapy for the prevention of vasospasm and sequelae [4–7]

Regimen [4–6]	Contraindications Common for all statins	Adverse effects* Common for all statins
◆ Pravastatin 40 mg po daily for 14 days ◆ Pravastatin 40 mg po daily for 14 days or until hospital discharge ◆ Simvastatin 80 mg po daily until ICU discharge ◆ Simvastatin 80 mg po daily for 21 days or until ICU discharge ◆ Simvastatin 40 mg po daily for 21 days or until neurosurgical discharge	◆ Hypersensitivity to drug or component ◆ Acute liver disease ◆ Pregnancy ◆ Breastfeeding ◆ Concurrent use of strong CYP3A4 inhibitors or cyclosporin (with simvastatin)	◆ Hepatotoxicity (including asymptomatic elevations in transaminases through acute liver failure) ◆ Myopathy/rhabdomyolysis ◆ Myalgia ◆ Gastrointestinal (GI) upset or abdominal pain ◆ Headache

*Only ICU relevant, serious, and/or common adverse effects are listed here, see reference for comprehensive list.

Data from Sillberg VAH, et al., 'Do statins improve outcomes and reduce the incidence of vasospasm after aneurysmal subarachnoid hemorrhage: a meta-analysis', *Stroke*, 2008, **39**, pp. 2622–6; Chou SHY, et al., 'A randomized, double-blind, placebo-controlled pilot study of simvastatin in aneurysmal subarachnoid hemorrhage', *Stroke*, 2008, **39**, pp. 2891–3; Kirkpatrick PJ, et al., 'Simvastatin in aneurysmal subarachnoid haemorrhage (STASH): a multicentre randomised phase 3 trial', *Lancet Neurology*, 2014, **13**, pp. 666–75; and Lexi-Comp Online, Lexi-Drugs Online, Hudson, OH: Lexi-Comp, Inc., October 31, 2013.

Calcium channel blockers

Ca channel blockers have been extensively investigated for their potential role in directly mitigating cerebral vasospasm, through their vasodilatory effect, and for preventing secondary injury, through modulation of cellular Ca permeability within the CNS. Nimodipine has the most conclusive supporting evidence, with a Cochrane meta-analysis of RCTs comparing oral nimodipine versus placebo demonstrating a relative risk (with 95% CI) of poor neurological outcome of 0.67 (0.55–0.81) with an associated NNT of 19. It also demonstrated reductions in incident secondary ischaemia and a trend toward reduced mortality. Studies of other Ca channel blockers, including intravenous (iv) nimodipine and magnesium sulfate have failed to demonstrate statistically significant effects on outcomes. The nimodipine regimen used in the published studies, common side effects, and contraindications are presented in Table 48.4 [8].

Traumatic brain injury

The discovery of neuroprotective agents in traumatic brain injury (TBI) remains an ongoing challenge, with very few successful and a number of harmful interventions found to date.

Perhaps the only pharmacological intervention post-TBI that has any proven benefit is the use of prophylactic phenytoin to reduce early post-traumatic seizures (PTS). In the hallmark

Table 48.5 Phenytoin prophylaxis for early seizures post-TBI [7,9]

Regimen	Contraindications	Adverse effects*
Phenytoin 20 mg/kg iv load, then maintenance dose adjusted to maintain serum trough concentration of 40–80 µmol/L	◆ Hypersensitivity to phenytoin or other hydantoins ◆ Concurrent use of delaviridine or other non-nucleoside reverse transcriptase inhibitors	◆ Hypotension ◆ Sinus bradycardia ◆ Heart block ◆ Cardiovascular collapse (especially with rapid iv administration) ◆ Thrombophlebitis ◆ Nystagmus (with supratherapeutic concentrations) ◆ Drug rash with eosinophilia and systemic symptoms

*Only ICU relevant, serious, and/or common adverse effects are listed here, see reference for comprehensive list.

Data from Lexi-Comp Online, Lexi-Drugs Online, Hudson, OH: Lexi-Comp, Inc.; October 31, 2013; and Temkin NR, et al., 'A randomized, double-blind study of phenytoin for the prevention of post-traumatic seizures', *New England Journal of Medicine*, 1990, **323**, pp. 497–502.

paper published in 1990 [9], phenytoin administered within 24 hours of injury and continued for 1 year led to a reduction in early seizures (days 0–7 from randomization) from 14.2% in the placebo arm to 3.6% in the phenytoin arm ($p < 0.001$). However, this did not translate into any statistically significant reductions in seizure risk beyond 7 days. Additionally, the study found no differences in mortality. The regimen used in the study, common side effects, and contraindications are presented in Table 48.5. The Brain Trauma Foundation, in its guidelines, also reports that valproic acid has been shown to offer equivalent efficacy to phenytoin to reduce early PTS, but with a trend towards increased mortality [10]. Certain risk factors are associated with increased risk of PTS, and are often used by clinicians to select patients for prophylaxis. These risks include decreased level of consciousness (GCS<10), cortical contusion, depressed skull fracture, subdural haematoma, epidural haematoma, intracerebral haematoma, penetrating head wound, and seizure within 24 hours of the primary injury [10].

The challenges in identifying effective neuroprotective agents in the TBI population have led to many failed studies, due to lack of effect and at least two interventions that have demonstrated harm. Specifically, these are the use of corticosteroids for the prevention of secondary injury and iv albumin for resuscitation.

The CRASH trial collaborators conducted an RCT examining the effects of iv corticosteroids on mortality in ~10,000 TBI patients [11]. After enrolling approximately half of their target number of subjects, the data safety and monitoring board was forced to recommend discontinuation of the study due to a significant increase in the risk of 2-week mortality with steroids versus placebo of 21 versus 18% ($p = 0.0001$), respectively. As such, it is recommended that steroids be avoided in the TBI population.

Intravenous human albumin has been used as a resuscitation fluid in a number of patient populations. A subgroup analysis of the 460 patients enrolled with TBI into the SAFE trial [12] was published as a separate paper [13]. In this post hoc analysis of critically-ill patients with TBI, the use of albumin versus saline as a resuscitation fluid was associated with an increased risk of mortality of 33.2 versus 20.4% (relative risk 1.63; 95% CI 1.17–2.26; $p = 0.003$). While recognizing the data were from a post hoc analysis of a large RCT, it does still support the practice of using crystalloid and avoiding albumin resuscitation in the TBI population.

Conclusion

Despite significant amounts of preclinical and clinical research, there remain few evidence-based neuroprotective pharmacological interventions available. Ongoing and future research on this topic is eagerly awaited as our understanding of the underlying mechanisms of secondary neuronal injury evolves.

At present, the best therapies we can offer our patients remain nimodipine and possibly statins for aneurysmal subarachnoid haemorrhage, phenytoin for TBI, and avoidance of harmful interventions such as corticosteroids and albumin in TBI.

PART 2.5

Hormonal drugs

CHAPTER 49

Hormone therapies in critical illness

Mark S. Cooper

Key points

- Thyroid function tests are commonly abnormal during critical illness and are part of 'non-thyroidal illness syndrome'. This does not usually indicate a need for treatment with thyroid hormones.
- Specific situations where thyroid hormone therapy has been used include during and after cardiac surgery, and in the preservation of the brain stem dead organ donor. The evidence in support in these situations is weak.
- 'Anabolic' hormones, such as growth hormone have been shown to be detrimental in general critical care patients. However, in the specific situation of burns the use of growth hormone and anabolic steroids has shown a potential benefit.
- Vitamin D deficiency is common in critically-ill patients and is associated with a poor outcome. It is not yet clear whether outcomes can be improved by the administration of vitamin D.
- With acute intracranial injury adrenocorticotropic hormone (ACTH) deficiency is difficult to diagnose and easily missed. In this setting, a low random cortisol should prompt the use of hydrocortisone replacement therapy.

Introduction

A range of hormonal manipulations have been proposed as adjunctive therapies during critical care. Some of these are dealt with elsewhere in chapters of their own ('Insulin and Oral Anti-hyperglycaemic Agents in Critical Illness', 'Steroids in Critical Illness'). This chapter reviews the other hormonal therapies that have been proposed.

Changes in hormonal systems during critical illness

Critical illness is associated with a range of hormonal changes. Many of the early changes are likely to have evolved to be adaptive and protective, but the usefulness of longer-term changes is much less clear. An endocrine disorder could be the primary problem underlying the development of critical illness, or it could develop during critical illness due to the underlying disease or as a side effect of treatment. Since the changes in the endocrine system during critical illness are often profound, it is more difficult to produce reliable 'normal' ranges or to determine with certainty when a test is abnormal. The first part of this chapter considers hormone therapies that might be of use in patients without previously recognized endocrine disorders. The second part will consider hormone therapies in specific disorders that are common or important in the critical care setting.

Hormonal therapy in the absence of a specific endocrine disorder

Thyroid hormones

All types of severe illness are associated with dramatic changes in the hypothalamo-pituitary thyroid axis. These changes are collectively referred to as 'non-thyroidal illness' [1]. Circulating levels of tri-iodothyronine (FT3) levels fall dramatically and remain low until recovery. The levels of thyroxine (FT4) and thyroid-stimulating hormone (TSH) are normal or elevated in the acute phase of illness, but tend to decline with prolonged illness. These changes in circulating levels are due to a combination of altered expression and activity of tissue deiodinase enzymes (which leads to a switch towards inactivation of thyroid hormones), and a reduced central drive towards thyrotropin-releasing hormone (TRH) and TSH secretion. Even though these changes could lead to reduced cardiac contractility and other features considered to be detrimental in critical illness, these changes are thought to be adaptive in the early phase of illness. The use of thyroid hormone treatment in the setting of non-thyroidal illness has been explored in a limited number of studies, primarily focusing on patients post-cardiac surgery. The use of liothyronine (tri-iodothyronine) in adult patients post-cardiac surgery has been explored in several studies. These have demonstrated effectiveness in increasing indices of cardiac output post-operatively, but they have not shown a reduction in mortality or length of stay [2]. Smaller trials in children using the same hormone have also generally demonstrated improved cardiac contractility with no adverse outcomes, but these trials are more heterogeneous in their inclusion criteria and design. In contrast, a trial of levothyroxine therapy in patients with acute renal failure failed to show any benefit in terms of recovery from renal failure and was associated with a three-fold increased risk of mortality [3].

The other critical care setting where thyroid hormone treatment is common is in the maintenance of the brain stem dead organ donor. The use of liothyronine or levothyroxine as part of 'hormone replacement therapy' (methyprednisolone, vasopressin, and

thyroid hormone) is widely recommended in this setting and the combination of all three treatments has been shown to improve the utilization of donor organs. However, the specific benefit of thyroid hormones has been questioned. A randomized trial of liothyronine treatment of cardiac donors failed to demonstrate any haemodynamic effect during the trial, but it is still possible that this therapy has a useful role in maintaining cardiac function once the organ has been grafted [4].

GH/IGF1

Growth hormone (GH) and insulin-like growth factor-1 (IGF1) are important anabolic hormones. GH is released from the anterior pituitary and IGF1 is generated primarily in the liver in response to GH. During critical illness there is a decrease in the level of IGF1. The level of GH increases in the acute phase of illness, but there appears to be a degree of resistance to GH action, possibly due to a down-regulation of GH receptor expression. In prolonged illness, the level of GH also falls. It was previously hypothesized that the changes in the GH/IGF1 axis could be detrimental, since a decrease in their levels could contribute to the catabolic state, thus prolonging recovery from severe illness. Several small randomized trials also supported this concept, demonstrating that GH could reduce the negative nitrogen balance seen in critical illness. However, in a publication that combined two related randomized placebo controlled trials of GH treatment of critically-ill patients a clear, detrimental effect with increased mortality (by approximately 40%) and morbidity in those treated with GH was seen [5]. This was despite an improved nitrogen balance with GH treatment. As such, GH treatment is contraindicated in most critically-ill patients.

A clinical situation where GH could be of benefit is the care of patients with burns. GH supplementation appears to aid skin healing and these benefits might outweigh the possible negatives. A randomized trial of recombinant GH therapy in severely-burned children has demonstrated an improvement in burn healing without an increase in adverse outcomes [6].

Oestrogens, androgens, and anabolic steroids

The normal response of the reproductive system to severe illness is a central decrease in the production of gonadotropin-releasing hormone (GnRH), luteinizing hormone (LH), and follicle stimulating hormone (FSH). In the female, this leads to amenorrhoea and in the male, hypogonadism. Interestingly, however, in the acute phase of critical illness, the levels of oestrogen do not decline, but frequently increase. This is probably due to an increase in the peripheral generation of oestrogen via the aromatase enzyme. Aromatase activity can be stimulated by pro-inflammatory cytokines. Increased levels of oestradiol are associated with an adverse outcome in both women and men in several studies, although it is not clear whether the association is causal [7]. In addition to the possible negative role for oestrogens in critical illness, supplementation with oestrogen in females has generally also been avoided in this setting, given the well-established pro-thrombotic actions of oestrogen.

Due to the negative nitrogen balance and the marked loss of muscle mass seen in critical illness, the use of anabolic steroids might be of use in aiding recovery. However, androgens have also been associated with pro-inflammatory effects in preclinical models. A situation where anabolic steroid therapy might be of benefit is the treatment of patients with burns. Severe burns are associated with a particularly catabolic state. Clinical trials of oxandrolone (an anabolic steroid that has minimal virilizing effects and cannot be aromatized to oestrogen) have demonstrated beneficial effects of therapy, such as reduced hospital stay and improved muscle mass, in adults and children with burns, without any apparent changes in markers of inflammation [8,9]. There were, however, elevations of hepatic transaminases. Although promising, the effectiveness of oxandrolone and related anabolic steroids have not been confirmed in large multicentre randomized controlled trials.

Vitamin D

Recent studies have highlighted a potential link between low levels of vitamin D and adverse outcome in critically-ill patients [10]. Vitamin D deficiency (low levels of 25-hydroxyvitamin D) is particular prevalent in the intensive care unit (and in patients with illness in general). However, randomized trial data are lacking regarding the usefulness of supplementing patients with vitamin D. Clearly, in patients with a level of vitamin D sufficient to interfere with calcium homeostasis, e.g. leading to hypocalcaemia, which in turn leads to bone fragility or muscle weakness, then replacement is required. There has also been recent interest in the role that vitamin D might play in immune responses and, in particular, the role of vitamin D in the response to mycobacterial infection [11]. There is an indication that extra-renal conversion of 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D occurs in immune cells and thus in this setting 25-hydroxyvitamin D is likely to be more effective than 1,25-dihydroxyvitamin D. Currently, it would make sense to give vitamin D to patients who have any features of vitamin D deficiency. In the absence of marked hypocalcaemia, this can be with ergocalciferol or colecalciferol. A regimen of 50,000 units orally once per week or 300,000 units im should be sufficient to raise vitamin D levels to an acceptable level over a few days to weeks [12]. For a more rapid onset of action in patients with hypocalcaemia activated metabolites of vitamin D such as alphacalcidol or calcitriol at doses of 0.5–2 micrograms/day can be used.

Hormonal therapy for specific disorders

Patients with known hypopituitarism

Patients with pre-existing or acquired structural abnormalities of endocrine systems will generally need replacement therapy. Patients with Addison's disease during critical illness need replacement hydrocortisone in stress doses, e.g. 50 mg qds or the equivalent dose as a continuous infusion [13]. Patients with known hypopituitarism will also require an increase in their glucocorticoid replacement in a similar fashion to patients with Addison's disease. Although less important, replacement with levothyroxine can continue at the same dose.

Traumatic brain injury

Hypothalamic and pituitary dysfunction is being increasingly recognized in the acute and chronic phases of traumatic brain injury [14]. Although all pituitary hormonal axes could be affected, the major difficulty in this situation is recognizing hypoadrenalism secondary to ACTH deficiency. This is because the short ACTH (synacthen) test, a common measure of adrenal function, is unreliable in this setting. ACTH acts on the adrenal gland to stimulate acute release of cortisol, but also acts to maintain the integrity of the cortex. With acute ACTH deficiency the adrenal gland is still responsive to exogenous ACTH for 2–3 weeks. As such the

diagnosis of ACTH deficiency can only be made on the basis of a low basal cortisol in these patients. A level of <400 nmol/L is suggestive of deficiency and should prompt replacement hydrocortisone therapy until an ACTH stimulation test can be performed weeks to months later.

Abnormal posterior pituitary responses are also common after brain injury with diabetes insipidus (DI) occurring in up to 50% of patients. Hypernatraemia related to diabetes insipidus is associated with increased mortality emphasizing the importance of appropriate treatment. Treatment is with desmopressin given im. A well-recognized phenomenon in this setting is the triple phase response in which acute DI is followed by hyponatraemia before the patient develops permanent DI. The hyponatraemic phase is thought to be due to the (transient) release of preformed vasopressin from damaged neurones supplying the posterior pituitary. In view of the possibility that hyponatraemia could develop after early DI, desmopressin treatment should be administered by stat doses in this situation to avoid the development of severe hyponatraemia. Similar considerations regarding anterior and posterior pituitary dysfunction apply to patients undergoing pituitary surgery, a situation in which post-operative pituitary dysfunction is highly likely.

Thyroid storm and myxoedema coma

Abnormalities of thyroid function severe enough to cause critical illness are rare. Thyroid storm refers to severe thyrotoxicosis sufficient to cause circulatory collapse. It is usually caused by surgery, infection, or inappropriate use of iodine-containing medications in patients with uncontrolled thyrotoxicosis. Features include tachycardia/arrhythmias, hypotension, and hyperpyrexia. Treatment is with supportive care (hydration and cooling), drugs that block thyroid hormone synthesis (propylthiouracil or carbimazole/methimazole) and cautious use of beta blockers. Propylthiouracil is generally preferred as the thyroid hormone synthesis blocking drug of choice in this setting, since it has an additional action to inhibit the peripheral conversion of FT4 to FT3. Additional therapies, such as lithium and potassium iodide might also be considered after discussion with endocrine specialists. Iodine-containing medications should only be given 2–3 hours after thyroid blocking medications.

Myxoedema coma arises from severe prolonged deficiency of thyroid hormones. This is usually associated with primary hypothyroidism. The common features are hypothermia, respiratory depression, and coma. Since thyroid hormones have a long biological half-life, the response to treatment normally takes days. It is unclear whether initial treatment should be with levothyroxine or liothyronine. Levothyroxine has to be converted to T3 (the active thyroid hormone) in the body and, thus, the response to this will be slow. Liothyronine has the advantage of more rapid action, but it has been suggested that this is associated with a greater risk of developing cardiac arrhythmias [15]. If levothyroxine therapy is used it is advised to give a single loading dose of 500 micrograms followed by a maintenance dose of 100 micrograms/day. Stress dose glucocorticoid replacement should also be given since the risk of adrenal insufficiency in this setting is high.

CHAPTER 50

Insulin and oral anti-hyperglycaemic agents in critical illness

Roosmarijn T. M. van Hooijdonk and Marcus J. Schultz

Key points

- Hyperglycaemia and hypoglycaemia are frequently seen in critically-ill patients.
- Insulin infusion is preferred over oral anti-hyperglycaemic agents for blood glucose control in the intensive care unit.
- Insulin infusion requires frequent blood glucose measurements, a dedicated lumen of a central venous catheter, and trained nurses for adjustment of the insulin infusion rate.
- Hyperglycaemia, hypoglycaemia, and glycaemic variability are all independently associated with mortality and morbidity.
- Whether glycaemic variability can be kept minimal in critically-ill patients is uncertain.

Introduction

Dysglycaemia is frequently seen in the intensive care unit (ICU). Hyperglycaemia may be associated with critical illness or, less frequently, due to diabetic keto-acidosis. Patients who are severely ill may initially present with hypoglycaemia or may develop hypoglycaemia as a result of insulin for glucose control.

Practical aspects of infusion of insulin and the role for oral anti-hyperglycaemic agents in critically-ill patients with critical illness-associated hyperglycaemia are discussed.

Hyperglycaemia in critically-ill patients

For a long time hyperglycaemia was thought to be an adaptive and beneficial response to critical illness. Numerous studies, however, clearly show hyperglycaemia to be associated with increased morbidity and mortality of ICU patients [1,2]. Nowadays, high blood glucose levels are considered acutely toxic for critically-ill patients because of the risk of accentuated cellular glucose overload [3]. Indeed, during critical illness, expression of glucose transporters on the membranes of several cell types is up-regulated, which during reperfusion after ischaemia allow high circulating glucose levels to overload and damage these cells.

Critical illness-associated hyperglycaemia and diabetic keto-acidosis should be seen as different entities. Diabetic keto-acidosis results from a shortage of insulin, in response to which the body switches to burning of fatty acids and producing acidic ketone bodies, which cause most of the symptoms and complications of diabetic keto-acidosis. Critical illness-associated hyperglycaemia is caused, at least in part, by critical illness-dependent insulin resistance. With the disappearance of the critical condition, the insulin sensitivity normalizes. Treatment of diabetic keto-acidosis primarily focuses on normalization of the blood glucose level with insulin, after which home medication is restarted. Treatment of critical illness-associated hyperglycaemia also focuses on normalization of the blood glucose level with insulin, but with disappearance of the critical condition, insulin should be tapered and eventually stopped.

Laboratory assessment

Normal blood glucose levels are from 4.4 to 6.1 mmol/L (80–110 mg/dL). Hyperglycaemia is typically defined as mild or severe, when blood glucose levels are 8.3–10 mmol/L (150–180 mg/dL) or >10 mmol/L (180 mg/dL). Hypoglycaemia typically is defined as mild or severe, when blood glucose levels are 2.2–4.4 mmol/L (40–80 mg/dL) or < 2.2 mmol/L (<40 mg/dL).

Insulin and oral anti-hyperglycaemic agents

Insulin

Insulin is a hormone that affects carbohydrate, fat, and protein metabolism in many ways. Insulin stimulates glucose uptake in liver-, muscle-, and fat tissue. Insulin inhibits glucose production by the liver by inhibiting gluconeogenesis and stimulating glycogen synthesis from glucose. Insulin stimulates lipogenesis, and inhibits lipolysis and release of free fatty acids from adipose tissue. Insulin promotes protein metabolism by stimulating cellular uptake of amino acids. Finally, insulin increases cell wall permeability for several ions, including potassium, magnesium, and phosphate. Insulin analogs are manufactured through the use of recombinant DNA technologies, yielding products that are almost similar to human insulin. The amino acid sequence of insulin can be changed to alter its absorption, distribution, metabolism, and excretion characteristics, thereby making them 'long-', 'medium-' or 'short-acting'.

Notably, while most insulin analogs are registered for sc use, in critically-ill patients insulin is given iv and, in the blood compartment, insulin is always 'short-acting', with a half-life time of minutes. Since effects of subcutaneous administered insulin on blood glucose levels can be slow and sometimes even unpredictable, iv administration is preferred in critically-ill patients. Subcutaneous administration is only preferred in stable ICU patients, who are orally fed and almost ready for discharge to the step-down unit or normal ward.

Oral anti-hyperglycaemic agents

A large variety of oral anti-hyperglycaemic agents are presently available (Table 50.1). Most of them are relatively contraindicated in critically-ill patients, e.g. because of the risk of lactate acidosis. There are several other arguments to favour insulin over oral anti-hyperglycaemic agents for the treatment of critical illness-associated hyperglycaemia. First, the effects of iv infusion of insulin are far more predictable than oral anti-hyperglycaemic agents. Secondly, the biological availability of anti-hyperglycaemic agents in critically-ill patients is uncertain and may change over time, thereby making the effect of these agents on the blood glucose level highly unpredictable. Finally, while insulin has a short half-life time, oral anti-hyperglycaemic agents have longer-lasting effect, which could be unattractive in the critically ill. Although one study of critically-ill patients showed improved glycaemic control with metformin, in addition to insulin infusion [4], further studies are needed before this can be considered standard care.

Infusion of insulin in critically-ill patients

Several trials show glycaemic control aiming for normoglycaemia (4.4–6.1 mmol/L (80–110 mg/dL)) or so-called intensive insulin therapy to benefit critically-ill adult and paediatric patients [5,6]. Subsequent trials testing the efficacy and safety of intensive insulin therapy could not confirm this [7]. While there are numerous alternative explanations about why these later trials did not show beneficial effects of intensive insulin therapy, apart from the possibility that intensive insulin therapy may not benefit ICU patients [7], it has been questioned whether a strategy aiming for normoglycaemia is safe in critically-ill patients. International guidelines, therefore, recommend only treating extreme hyperglycaemia with insulin, aiming at blood glucose levels <8.3 mmol/L (150 mg/dL) [8], or <10.0 mmol/L (180 mg/dL). Whether such an approach is truly safer than intensive insulin therapy (aiming for normoglycaemia) is uncertain, let alone whether this approach is as effective in reducing morbidity and mortality as intensive insulin therapy.

Practical aspects of insulin infusion

A large variety of factors may affect efficacy and safety of any strategy using infusion of insulin (Fig. 50.1). Indeed, insulin titration, independent of the targeted blood glucose level, is a complex intervention that involves several sequential steps that all contain potential sources of variability, including the way the blood glucose level is measured, and the way insulin is delivered and titrated [7].

Blood glucose measurement is one major aspect of glucose control. Blood glucose measurements should be accurate, as inaccurate measurements could lead to potentially life-threatening insulin dose errors. Blood glucose levels can be determined in capillary, arterial, and venous blood. Adequate measurement of the blood glucose level using capillary blood, however, is a challenge and should be avoided [9]. Venous sampling serves as a good alternative, especially when taken from a central venous catheter, but there is a risk of contamination by agents infused through that catheter [9,10]. Arterial sampling, via an intra-arterial catheter, therefore, seems the best option [9,11].

Currently, handheld blood glucose meters or department–based blood gas analysers are the preferred method to measure the blood glucose level in the ICU [9]. Handheld blood glucose meters, however, are far from accurate, especially in the lower ranges of the blood glucose level [11]. Notably, regardless of using handheld meters or blood gas analysers, significant amounts of blood are used and much nursing time is spent. Automatic continuous

Table 50.1 Overview of oral anti-hyperglycaemic agents and its contraindications in the intensive care unit

Class	Mechanism of action	Main side-effects and reasons for caution	Relevant contraindications
Biguanides (e.g. metformin)	Inhibits hepatic gluconeogenesis and glucogenolysis, and increases sensitivity of insulin receptors	Lactic acidosis (rare)	Renal insufficiency, and acute and chronic metabolic acidosis
Sulfonylureas (e.g. tolbutamide (1st generation), or glibenclamide) (2nd generation))	Stimulates the release of insulin from the pancreas	Severe and prolonged hypoglycaemia (particularly in the elderly or those with chronic kidney disease)	Severe renal insufficiency and severe liver failure
Meglitides or glinides (e.g. repaglinide)	Stimulates the release of insulin from the pancreas	Hypoglycaemia	Severe liver failure and diabetic ketoacidosis
Dipeptidylpeptidase iv inhibitors (e.g. sitagliptin, saxagliptin, vildagliptin, and linagliptin)	Increases insulin release and decreases the glucagon concentrations in a glucose-dependent manner	Hypoglycaemia, pancreatitis (for sitagliptin)	Diabetic ketoacidosis
Incretine-mimetics Glucagon-like peptide-1 agonist (GLP1) (e.g. exenatide)	Stimulates insulin release and decreases glucagon concentrations in a glucose-dependent manner, often used in addition with other oral anti-hyperglycaemic agents	Hypoglycaemia, long–acting agents	Renal insufficiency, diabetic ketoacidosis

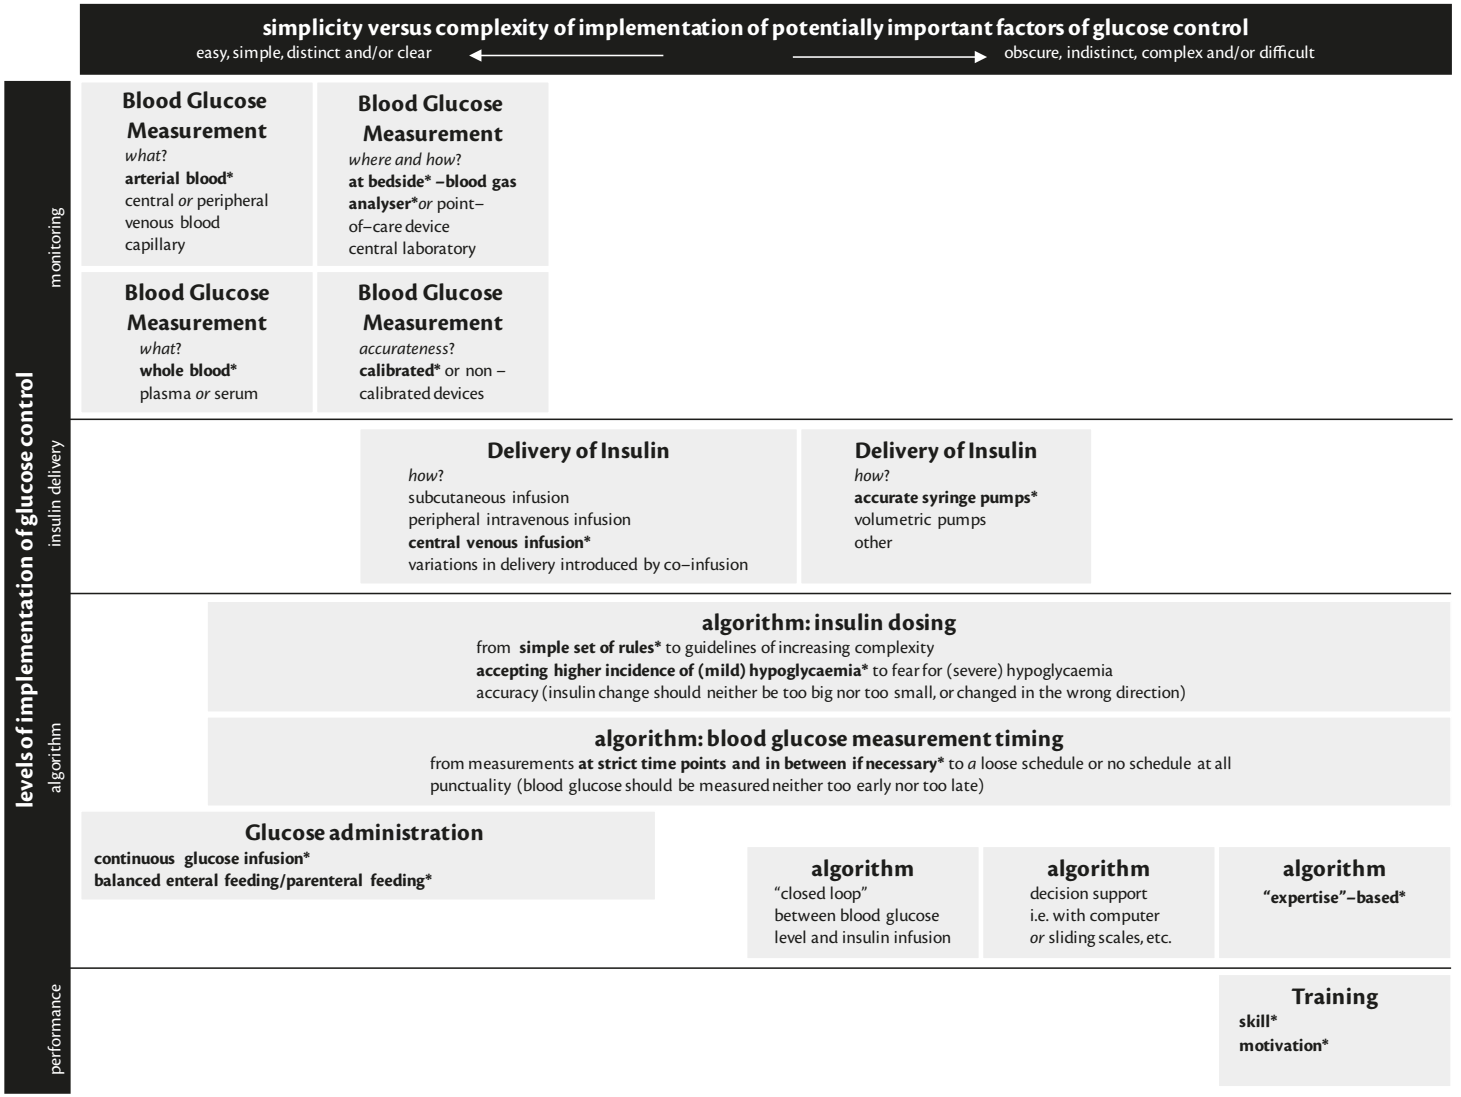

Fig. 50.1 Methodological aspects of intensive insulin therapy, which may contain potential sources of variability in the performance of this strategy. Items are categorized into the following subjects—'monitoring', 'insulin delivery', 'algorithm', and 'experience'. Items are also roughly positioned on a line from 'easy', 'simple', 'distinct', and/or 'clear' to implement towards 'obscure', 'indistinct', 'complex', and/or 'difficult' to translate from one centre to another. Specific elements per item indicated with * are as performed in the single-centre randomized controlled trials of intensive insulin therapy performed in Leuven, Belgium.

glucose measurement systems are being developed but not yet available. Such systems may reduce the amounts of blood used and lower the workload by nurses [12]. In addition, such systems could have the potential to improve safety and precision of insulin titration in the ICU [12].

Accurate insulin delivery is another important aspect of insulin therapy. For insulin therapy reliable, precise, and continuous infusion of insulin is needed [13]. This may include infusion via a dedicated lumen of a central venous catheter and an accurate syringe pump. Next, delicate insulin adjustments need to be performed by ICU nurses trained in using a local algorithm, possibly requiring a high level of intuitive decision-making [7].

Insulin therapy-associated hypoglycaemia and glycaemic variability

Hypoglycaemia is a real risk of insulin therapy in the ICU. Hypoglycaemia is independently associated with mortality and morbidity of critically-ill patients [14]. Whether the association is causal remains unclear. Neuroglycopenia may cause cerebral damage, epileptic insults, or even coma [15]. However, a causal link between hypoglycaemia and mortality has still not been demonstrated. More important, possibly, is that correction of hypoglycaemia with glucose, rather than hypoglycaemia itself may be detrimental [16]. Indeed, brain damage may correlate more to the concentration and amount of glucose used to correct hypoglycaemia [16]. Thus, precautions should be taken against overcorrection of hypoglycaemia, using only small amounts of glucose.

Rapid fluctuations of the blood glucose level, or increased glycaemic variability, is also independently associated with mortality and morbidity of critically-ill patients [17]. Increased glycaemic variability is thought to increase oxidative stress and may be more detrimental than sustained hyperglycaemia [18]. Prevention of glycaemic variability is suggested as a target of insulin therapy in critically-ill patients, in addition to the treatment of hyperglycaemia, and prevention and overcorrection of hypoglycaemia [19]. It is uncertain, however, whether glycaemic variability can be influenced [20]. Another risk of insulin therapy is a shift of potassium from the extracellular to the intracellular compartment, causing hypokalaemia [13]. Therefore, the potassium level should be monitored frequently during insulin infusion.

PART 2.6

Haematological drugs

CHAPTER 51

Anticoagulants and antithrombotics in critical illness

Vickie McDonald and Marie Scully

Key points

- Coagulation is best thought of using the cell-based model of coagulation.
- Patients commenced on heparin therapy should have their platelet count monitored early because of the risk of heparin-induced thrombocytopenia (HIT), which can occur on any type or dose of heparin.
- Emergency reversal of warfarin should be with prothrombin complex concentrate (containing factors II, VII, IX and X) and not fresh frozen plasma.
- New oral anticoagulants have the advantage of predictable pharmacokinetics and do not require routine monitoring, but optimal reversal strategies for these agents are not clear.
- Thrombolytic agents lead to variable degrees of systemic lysis, which may cause haemorrhage including intracerebral haemorrhage.

Introduction

Thrombosis is the formation and propagation of a blood clot within a blood vessel that, under normal circumstances, is a protective mechanism against haemorrhage after injury. Anticoagulant and antithrombotic drugs are used to either treat patients who have developed pathological thrombosis or to prevent thrombosis in those felt to be at high risk. Historically, there have been a limited number available, for example, fibrinolytics for acute, usually arterial or large venous thrombosis, heparin, and warfarin. Recently, newer parenteral and oral anticoagulants targeting thrombin and Xa have been developed. Use of these newer agents present monitoring and reversal challenges, particularly around procedures.

Overview of haemostasis and the coagulation cascade

The coagulation cascade is a complex interaction between coagulation factors, coagulation factor inhibitors, the vessel wall, platelets, and fibrinolytic enzymes. The generation of thrombin is critical to successful haemostasis. Rather than the classical 'intrinsic' and 'extrinsic' pathways, coagulation is now better understood as a 'cell-based' model (Fig. 51.1), whereby coagulation occurs on phospholipid surfaces and is divided into three overlapping phases—initiation, amplification, and propagation [1]. Initiation involves the TF-VIIa complex activating factors IX (FIXa) and X (FXa), and trace amounts of thrombin being generated by FXa. During amplification and propagation, the small amounts of thrombin-generated activate factors leading to the explosive generation of thrombin and formation of a clot.

In-built inhibitory mechanisms to prevent excessive activation of the coagulation system include: Tissue factor pathway inhibitor, antithrombin (which inactivates FIXa, FXa, FXIa, and thrombin); Protein C and S pathways and thrombomodulin. During fibrinolysis, plasmin (derived from plasminogen) digests cross-linked fibrin to form D-dimers and other fibrinogen fragments.

Anticoagulants and antithrombotics

The main anticoagulants and the location of their effect on coagulation are summarized in Table 51.1 and Fig. 51.2.

Heparin

Unfractionated heparin (UFH) is a large glycosaminoglycan that potentiates the effect of antithrombin (AT) and requires adequate AT for therapeutic effect [2]. It predominantly inhibits thrombin and Xa. It is administered parenterally with a rapid anticoagulant effect. It has a short half-life and is fully neutralized by protamine sulfate, so can be used where the risk of bleeding is high. There is dose–response variability due to high non-specific protein binding necessitating frequent monitoring by (activated partial thromboplastin time (APTT)).

Low molecular weight heparins (LMWH) are prepared from UFH and have shorter chain lengths. They have predominantly anti-Xa activity with less anti-IIa activity [2] and adequate AT levels are required for therapeutic effect. They have a more predictable dose–response curve and are administered sc. Because of this, they are used in preference to UFH in most clinical cases. The half-life is roughly 4 hours and only approximately 50% of LMWH is neutralized by protamine. Monitoring via anti-Xa assays is recommended

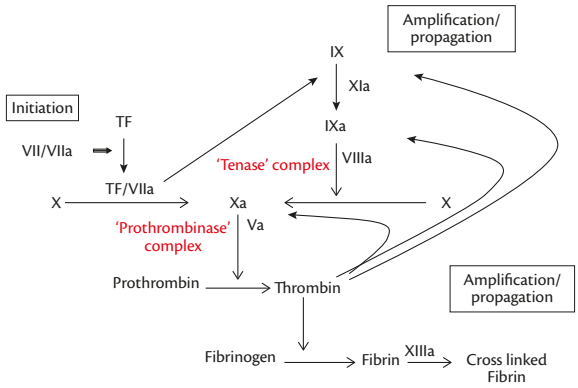

Fig. 51.1 The cell based model of coagulation.

in patients with renal impairment, pregnancy, children, and those with a large body habitus. Both heparin and LMWH are porcine in origin.

Use

- **UFH:** mechanical heart valves and extracorporeal circuits (such as cardiopulmonary bypass, haemodialysis haemofiltration); treatment and prevention of DVT/PE where LMWH are contraindicated; treatment of acute coronary syndromes (ACS) where LMWH are contraindicated
- **LMWH:** treatment and prevention of deep vein thrombosis (DVT) and pulmonary embolism (PE); acute coronary syndromes; LMWH are not licensed for use with mechanical heart valves.

UFH and LMWH do not cross the placenta and are safe in pregnancy.

The APTT or activated clotting time ACT may be used to monitor UFH. In cases where the APTT may not be reliable, such as the presence of a lupus anticoagulant, anti-factor Xa assays should be performed. Specific anti-Xa assays also have to be performed to monitor LMWH. Peak levels should be taken 4 hours after the dose and samples need to analysed promptly (within 2 hours).

Complications

- **Bleeding:** risk factors include recent surgery or trauma, recent intracerebral haemorrhage or large stroke, active peptic ulcer disease, advanced age, or accumulation of the drug (e.g. with LMWH in renal failure). UFH has a short half-life and if severe bleeding occurs, it should be stopped immediately and reversed with protamine sulfate (1 mg protamine sulfate neutralizes 80–100 U heparin, but 10–20 mg is often sufficient) [3]. The response is assessed using the APTT and repeat doses may be needed. LWMH is only partially reversed by protamine. Therefore, in situations associated with a potential risk of bleeding, split dose injections should be considered.
- **Management around procedures:** UFH infusions should be stopped 4 hours prior to surgical procedures and should be started when haemostasis is achieved and maintained—usually 2–4 hours after procedures. Treatment dose LMWH should be stopped 12–24 hours before procedure and restarted 4–6 hours afterwards depending on procedures.
- **Heparin-induced thrombocytopenia (HIT) +/– thrombosis [HIT(T)]:** the immune form of HIT develops as a result of IgG antibody formation to heparin-PF 4 complexes, which activate platelets leading to a prothrombotic condition with a fall in platelet counts [4]. Patients commenced on heparin should have platelet counts monitored. The main features and risk factors are

Table 51.1 Anticoagulant drugs, mechanism of action, routes of administration and monitoring

Drug Class	Drug name	Mechanism of action	Mode of administration	Monitoring tests	Usual target range for therapeutic effect
Vitamin K antagonists	Warfarin Phenindione Acenocoumarol	Inhibits vitamin K-mediated gamma carboxylation of coagulation factors in the liver (II, VII, IX, X)	Oral	INR	2–3 3–4 in certain circumstances
Unfractionated heparin		Potentiate antithrombin leading to inhibition of IIa and Xa	iv or sc	APTT/APTT ratio	APTT ratio 1.5–2.5
LMWH	E.g. enoxaparin, dalteparin, tinzaparin	Potentiate antithrombin leading to inhibition of Xa and IIa	sc	Anti-Xa assay	0.5–1.0 IU/mL
Heparin pentasaccharide	Fondaparinux	Potentiate antithrombin leading to inhibition of Xa	sc	Anti-Xa assay	0.5–1.0 IU/mL
Heparinoid	Danaparoid	Potentiate antithrombin leading to inhibition of Xa	iv, sc	Anti-Xa activity	0.5–1.0 IU/mL
Direct thrombin inhibitor	Argatroban	Directly inhibit free and clot-bound thrombin	iv	APTT/APTT ratio	APTT ratio 1.5–3.0
Oral direct thrombin inhibitors	Dabigatran	Directly inhibits free and clot bound thrombin	Oral	Dilute thrombin time, ecarin clotting time	Not known
Direct Xa inhibitors	Rivaroxaban, apixaban, edoxaban	Directly inhibit Xa	Oral	Anti-Xa assay	0.5–1.0

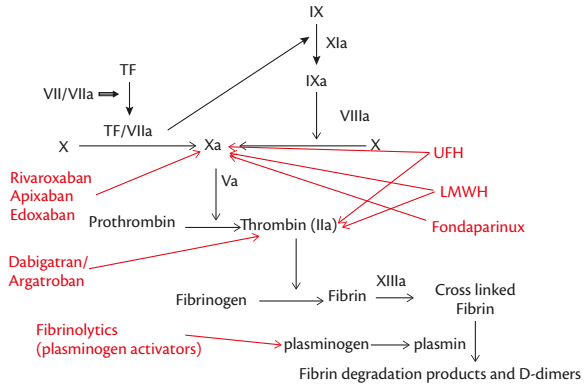

Fig. 51.2 Anticoagulants and antithrombotics. Sites of action of anticoagulants and antithrombotics. Unfractionated heparin potentiates the activity of antithrombin and leads to the inhibition of Xa and IIa. LMWH also act via antirhombin, but have relatively more anti-Xa activity than anti-IIa activity. Fondaparinux has anti-Xa activity only. Rivaroxaban is a direct inhibitor of Xa and dabigatran and argatroban are direct inhibitors of IIa. Fibrinolytic agents increase the conversion of plasminogen to plasmin which in turn degrades cross-linked fibrin leading to clot resolution.

shown in Box 51.1. It occurs after both therapeutic and prophylactic heparin (including heparin in catheter flushes).

The probability of HIT being the explanation for low platelets in ICU is approximately 1/100. If a diagnosis of HIT is suspected, heparin must be stopped and an alternative anticoagulant started [5]. Forty per cent of patients without thrombosis at the time of diagnosis of HIT develop thrombosis within 10 days of stopping heparin if no alternative anticoagulant is given. Patients who require longer-term anticoagulation should not have vitamin K antagonist therapy started until the platelet count has recovered. There is reportedly no amnestic response, therefore, patients with a history of HIT may be considered for heparin 90 days from the last heparin exposure. However, expert advice should be sought.

Fondaparinux

Fondaparinux is a synthetic pentasaccharide subunit of heparin. It inhibits Xa activity and is, therefore, is not reversed by protamine. However, it has a similar efficacy profile to LMWH for treatment of thrombosis, with a slightly increased risk of bleeding. It can be used for thromboprophylaxis of DVT/PE in patients undergoing orthopaedic surgery where the dose is 2.5 mg daily. The dose for treatment of DVT/PE is typically 7.5 mg daily, adjusted for extremes of body weight and renal function [6]. It is as effective as LMWH in ACS [7] and it has been used in HIT but is not licensed for this indication.

Danaparoid

Danaparoid is a heparinoid indirect (i.e. antithrombin dependent) Xa inhibitor that is administered intravenously (loading dose followed by continuous infusion). It has a long half-life (25 hours). It is predominantly renally excreted and patients with renal impairment require dose modifications. Monitoring is with anti-Xa assay. Danaparoid is licensed for the treatment of HIT, but approximately 10% of HIT antibodies cross-react with danaparoid.

Argatroban

Argatroban is a direct thrombin inhibitor administered iv as a continuous infusion. It is predominantly excreted by the liver and requires dose modification in liver disease, but not in renal impairment. Plasma levels of the drug correlate well with the APTT. Initial dosing for HIT is 2 micrograms/kg/min, titrated to target APTT. In critical care, lower initial starting doses should be used because of the increased risk of bleeding. If haemorrhage occurs,

Box 51.1 Summary of risk factors, manifestations, diagnostic tools, and treatment modalities for HIT

Risk factors associated with development of HIT

- **Type of heparin**: UFH > LMWH (PROTECT study showed reduced HIT in ICU patients given dalteparin compared with unfractionated heparin [20]).
- **Duration of heparin**: >6 days increases risk.
- **Type of patient**: surgery > medical > obstetric.
- **Surgery type**: cardiac > other.
- **Age**: middle to old age > young.
- **Sex**: female > male.

Clinical manifestations of HITT

- Thrombocytopenia.
- Shortening of the APTT.
- **Venous thrombosis**: DVT, PE, other sites such as cerebral sinus are rare.
- Arterial thrombosis.
- **Skin lesions**: erythema or necrosis at injection site.

4T's scoring system

- **Thrombocytopenia**: >50% fall in platelet count.
- **Timing**: fall begins 5–14 days after exposure.
- **Thrombosis**: presence of thrombosis or other manifestations, such as skin erythema at injection site and allergic reactions to heparin.
- **Other**: other cause for low platelets more likely.

Assays

- **Immunological**: ELISA—detect antibodies by binding to plates coated with platelet factor 4.
- **Functional**: platelet aggregation, serotonin release, flow cytometry.

Treatment modalities

- **Danaparoid**: but contains heparin sulfate and 10% cross-reactivity with heparin-PF4 antibodies.
- Fondaparinux.

4 T's score: Adapted from Lo GK et al., 'Evaluation of pretest clinical score (4 T's) for the diagnosis of heparin-induced thrombocytopenia in two clinical settings', *Journal of Thrombosis and Haemostasis*, 2006, **4**, 759–65. Wiley, copyright 2006 International Society on Thrombosis and Haemostasis, with permission.

the drug should be stopped. Due to a short half-life (<1 hour), the APTT usually comes down to normal within 2–4 hours. There is no specific reversal agent, but prothrombin complex concentrate may help in life-threatening bleeding. Argatroban may prolong the prothrombin time (PT) so caution is required with concurrent warfarin.

Warfarin

Vitamin K is essential for the γ-carboxylation of glutamic acid residues on clotting factors II, VII, IX, and X (and proteins C and S). Warfarin and other vitamin K antagonists block regeneration of vitamin K from its epoxide, thereby reducing γ-carboxylation and, in turn, function of the vitamin K-dependent factors.

Warfarin is rapidly absorbed from the gastrointestinal tract and has a half-life of approximately 40 hours in the circulation. The effect of warfarin is influenced by many factors, including compliance, vitamin K content of diet, liver function, concurrent illness, drugs, and genetics. The drugs that commonly influence the effect of warfarin are shown in Table 51.2.

Use

- Long-term anticoagulation.
- Warfarin is teratogenic in the first trimester of pregnancy and is difficult to manage around delivery, so is not recommended in pregnancy.

The (international normalized ratio (INR), based on the prothrombin time, monitors the effect of vitamin K antagonists on the haemostatic system. Despite regular monitoring, patients may be outside of therapeutic range for up to 40% of the time.

Table 51.2 Drugs that influence the effect of vitamin K antagonist (VKA) drugs (e.g. warfarin)

Effect of concurrent medication on warfarin and anticoagulant control	
Increased effect of warfarin (or other VKA)	*Reduced effects of warfarin (or other VKA)*
◆ Alcohol	◆ Alcohol
◆ Allopurinol	◆ St John's Wort
◆ Amiodarone	◆ Carbamazepine
◆ **Anti-platelet agents**: aspirin, clopidogrel, dipyridamole	◆ Primidone
◆ **Antibiotics**: ciprofloxacin, clarithromycin and erythromycin, metronidazole, sulphonamides, norfloxacin, cephalosporins, tetracyclines, trimethoprim, and penicillins*	◆ Griseofulvin
◆ **Anti-fungals**: fluconazole, itraconazole, ketoconazole, voriconazole	◆ Azathioprine
◆ Cranberry juice	◆ Mercaptopurine
◆ Entacapone	◆ Oestrogens and progestogens
◆ Esomeprazole and omeprazole	◆ Vitamin K
◆ Iloprost	
◆ Cimetidine	
◆ NSAIDs	
◆ Prolonged paracetamol use	
◆ Quinidine	
◆ SSRIs	
◆ Sodium valproate	
◆ Thyroid hormones	

*No laboratory effect, but clinical reports.

Complications

- **Bleeding:** the risk of major bleeding is around 2% per annum, with a case fatality of 20% and is increased when the INR is >5 [8]. Management is determined by the severity of the bleed and the INR. Vitamin K 5–10 mg iv has an initial onset of action after 4–6 hours, but is not maximal for at least 24 hours and, therefore, additional measures are required. Prothrombin complex concentrates that contain factors II, VII, IX, and X are now recommended as first-line for warfarin reversal [8], which is achieved within 30 minutes of infusion. Recommended dosing is 25–50 IU factor IX/kg body weight. These concentrates carry the potential risk of inducing thromboembolism; therefore, caution should be exercised when using these products in high-risk groups. In the absence of prothrombin complex concentrates, fresh frozen plasma FFP (12–15 mL/kg) can be used, but is not satisfactory as very large amounts of plasma (1–2 L) may need to be infused, and the concentration of factor IX is only minimally increased by treatment with FFP. In the absence of bleeding, over-anticoagulation with warfarin is managed by omitting the drug for a few doses and restarting when the INR is within the desired range. Administration of small doses of oral vitamin K (1–2.5 mg) may also be needed if the INR is >5.0.
- **Management around surgery:** warfarin therapy is suspended and substituted with LMWH therapy for most surgical procedures excepting minor dental surgery. For elective procedures, warfarin is stopped approximately 5 days prior to the procedure, LWMH started the day after stopping warfarin and the INR checked the day before the procedure. For emergency surgery vitamin K (5–10 mg) with/without prothrombin complex concentrate should be administered.

New oral anticoagulants

New oral anticoagulants targeting either Xa or IIa have been developed, which have fewer drug interactions, no dietary interactions, and more predictable pharmacokinetics negating the need for routine monitoring.

Rivaroxaban, apixaban, and edoxaban are Xa inhibitors. Rivaroxaban is renally excreted and has a half-life of 4–9 hours (13 hours in the elderly or when there is renal impairment). It is contraindicated if the creatinine clearance is <15 mL/min and with severe hepatic impairment. It has been shown to be non-inferior to standard anticoagulant therapy in the treatment of acute DVT and PE, in atrial fibrillation, and DVT/PE prevention after elective hip and knee replacements [9–12]. There are ongoing studies in acute coronary syndromes.

Apixaban has a half-life of 12 hours, with 25% renal elimination. Doses may need to be reduced in the elderly and those with low body weight. It is a licensed alternative to standard anticoagulant therapy in atrial fibrillation, and DVT/PE prevention after elective hip and knee replacements [13–15].

Dabigatran etexilate is a pro-drug metabolized to the active ingredient dabigatran, which binds free and clot-bound thrombin. It is predominantly renally excreted. The peak plasma concentration is achieved in 1.5 hours, with a half-life of 14–17 hours. Dabigatran has been shown to be equivalent to enoxaparin 40 mg od in elective

hip and knee surgery. It has also been shown to be effective in the prevention of stroke in AF [11,16].

The increased risk of bleeding with concurrent non-steroidal anti-inflammatory drug use still applies. There are no ideal monitoring assays for these drugs. For dabigatran, increased APTT and PT can be an indication of anticoagulation, but cannot be used for monitoring, so the dilute thrombin time (Hemoclot®) and ecarin clotting time should be used. For rivaroxaban an anti-Xa assay can be used to monitor therapeutic effect.

Complications

- **Bleeding:** at present, there are no specific reversal agents (although they are in development). Prothrombin complex concentrates and rVIIa have been suggested to treat bleeding with rivaroxaban, apixaban and dabigatran [3]. Charcoal administration reduces the absorption of dabigatran, and in cases of intractable haemorrhage, dialysis will reduce drug levels of dabigatran. Dialysis does not effectively remove rivaroxiban, which is 95% protein bound.
- **Management around surgery [17]:** in patients with normal renal function and a standard bleeding risk, discontinuation of dabigatran 24 hours before surgery will decrease plasma levels to approximately 25% of steady-state trough levels, reducing to approximately 12–15% of trough levels 36 hours before surgery and approximately 5–10% 2 days (48 hours) before surgery. In patients at higher risk of bleeding or in major surgery where complete haemostasis may be required dabigatran should be stopped 2–4 days before surgery and LMWH substituted where required. A similar regimen may be adopted for rivaroxiban.
- **Neuraxial anaesthesia [18]:** removal of the catheter must be delayed by an interval of at least two half-lives (i.e. <25% of the drug remains active) after the prophylactic anticoagulant has been administered. Therefore, it is suggested that with rivaroxaban, the catheter should not be removed for at least 20 hours after the previous dose and the next dose should be given no sooner than 6 hours after catheter removal. With dabigatran, recommendations are different. It has been proposed that the catheter should not be removed until 36 hours (two half-lives) have elapsed from the previous dose and the subsequent dose be given no sooner than 12 hours after catheter removal.

Thrombolytic agents

Thrombolytic agents are plasminogen activators that generally cause a state of systemic lysis by converting plasminogen to plasmin. This, in turn, leads to cleavage of cross-linked fibrin and the generation of fibrin degradation products that are cleared by the kidney and reticuloendothelial system. In excess, activators of the fibrinolytic system can lead to degradation of fibrinogen, as well as cross-linked fibrin. First generation thrombolytic agents, such as streptokinase, are more likely to induce systemic lysis than second (rtPA (alteplase)) and third generation (r-PA (reteplase), TNK-tPA (tenectaplase)) agents. These drugs are administered systemically and protocols for use in acute coronary thrombosis, stroke, peripheral arterial occlusion, and venous thrombosis and massive pulmonary embolism with haemodynamic compromise exist. Contraindications to thrombolysis are shown in Box 51.2.

Box 51.2 Contraindications to thrombolysis

Absolute contraindications

- Recent neurosurgery, head trauma or CNS haemorrhage.
- Intracranial/intraspinal neoplasm or aneurysm.
- Stroke within 6 months.
- Active or recent internal bleeding.
- Uncontrolled hypertension.
- Suspected aortic dissection.

Relative contraindications

- Surgery in last 2 weeks.
- Recent trauma (including CPR).
- Infective endocarditis, pericarditis.
- Pregnancy or recent delivery.
- Haemostatic defects.
- Active peptic ulcer disease.

Laboratory tests such as the thrombin time and fibrinogen levels will detect the presence of a systemic lytic state, but they do not predict the bleeding risk. Haemorrhage complicating these agents is most commonly local (e.g. at the site of catheterisation in the groin). However, intracranial (0.5–1.0%) or gastrointestinal bleeding may occur. Cryoprecipitate, fibrinogen concentrate or FFP can be given to treat the coagulopathy and red cells may be required. Antifibrinolytics may provide some benefit and patients who are also receiving heparin should receive protamine. Acylated plasminogen-streptokinase activator complex (APSAC), has a longer half-life of 90 minutes. A scoring system for predicting bleeding in patients receiving thrombolysis for stroke (haemorrhage after thrombolysis—HAT—score) can help to risk stratify patient bleeding risk before undertaking thrombolysis [19].

CHAPTER 52

Haemostatic agents in critical illness

Beverley J. Hunt

Key points

- Antifibrinolytics have been shown to reduce bleeding and blood transfusion during surgery.
- Tranexamic acid is recommended over aprotinin in view of concerns about the safety of the latter.
- In bleeding trauma, tranexamic acid reduces mortality by 9% and should be given as early as possible after injury.
- Desmopressin may have a place in reducing bleeding in those with uraemia.
- The efficacy of rFVIIa in off-licence 'rescue therapy' is uncertain and it is associated with an increased rate of arterial thrombosis especially in the elderly.

Introduction

Pharmacological agents are used in two ways, either to prevent excessive bleeding or to treat established bleeding. The agents used can be broadly classified into three groups—antifibrinolytics, desmopressin, and the recombinant prohaemostatic factors, such as recombinant activated factor VIIa (rFVIIa).

Antifibrinolytics

These include the lysine analogues, tranexamic acid (TA) and epsilon-amino caproic acid (EACA), which are competitive inhibitors of plasminogen binding to fibrin and plasminogen receptors; and aprotinin, a serine protease inhibitor, which has a powerful direct antiplasmin effect and inhibits a number of other haemostatic enzymes, including kallikrein. Although *in vitro* TA has approximately 10 times the antifibrinolytic activity of EACA, TA, and other lysine analogues have similar clinical efficacy in reducing bleeding and blood usage peri-operatively [1]. However, the withdrawal of aprotinin due to safety concerns, and demonstration that TA reduces mortality in patients with traumatic bleeding [2] has pushed TA to the fore, as an efficacious, safe, and cost effective agent.

Tranexamic acid in traumatic bleeding

The CRASH-2 study was a randomized controlled trial (RCT) of TA versus placebo in the management of bleeding after trauma and recruited 20,000 patients worldwide [2]. The primary outcome was death in hospital within 4 weeks of injury. All-cause mortality was significantly reduced with tranexamic acid: (1463 (14.5%) versus 1613 (16.0%) placebo; relative risk 0.91, 95% CI, 0.85–0.97; $p = 0.0035$). The risk of death due to bleeding was significantly reduced by 9% (489 (4.9%) versus 574 (5.7%); relative risk 0.85, 95% CI, 0.76–0.96; $p = 0.0077$). TA was also was shown to be safe, as there were no adverse events and, importantly for a drug that affects haemostasis, there were no increased thrombotic events. Indeed, there was a trend to a lower rate of arterial events in those receiving TA. Further analysis of the data showed benefit was greatest the earlier that TA was given after injury and that there was a possibility of negative benefit when given after 3–6 hours from injury [3].

The estimated incremental cost per life year gained of administering TA is $48, $66, and $64 in Tanzania, India, and the UK, respectively, making it highly cost effective [4]. The WHO has recently classed it as an essential drug.

CRASH-2 recruited patients who had or were at risk of significant bleeding, and included patients with massive bleed loss. The majority of lives saved were those who had significant bleeding, but did not have massive blood loss at presentation. A recent publication [5] confirmed the same reduction of mortality applied to this latter group, i.e. there was no evidence of heterogeneity in the effect of TA on different groups. Thus, TA should not be restricted to those with the most severe injuries or those with hyperfibrinolysis changes on their thromboelastography trace, for although this would save about 20,000 lives a year worldwide, this would deny benefit to the majority of patients who would benefit. Recent work has shown that activation of fibrinolysis is present in most trauma patients and thromboelastography only detects the most severe activation of fibrinolysis [6]. If tranexamic acid is given to all bleeding trauma patients worldwide there is a potential to save 120,000 lives a year.

Treatment of established bleeding and prevention of peri-operative bleeding with the lysine analogues

Since the withdrawal of aprotinin, TA has been widely used to reduce bleeding in cardiac surgery, but it is now also used in other types of surgery. A systematic review in 2012 [7], identified 129 trials that included 10,488 patients, carried out between 1972 and 2011. In this meta-analysis, TA reduced the probability of receiving a blood transfusion by a third (RR 0.62, 95% CI 0.58–0.65; $p < 0.001$). This effect remained when the analysis was restricted to trials using adequate allocation concealment (RR 0.68, CI 0.62–0.74; $p < 0.001$). Fewer deaths occurred in the tranexamic

acid group (RR 0.61, CI 0.38–0.98; $p = 0.04$), although when the analysis was restricted to trials using adequate concealment there was considerable uncertainty (RR 0.67, 0.33 to 1.34; $p = 0.25$). The authors concluded that cumulative meta-analysis showed reliable evidence that TA reduces the need for transfusion.

Another systematic review of 104 randomized trials examined whether the effect of TA on blood loss varies with the extent of surgical bleeding. The results suggest that, despite variation in the magnitude of blood loss between procedures and the heterogeneity of the studies included, the use of TA was associated with an overall reduction in surgical bleeding by about a third. This reduction in bleeding with TA is almost identical to the reduction in the risk of receiving a blood transfusion with TA suggesting, as expected in the closely monitored environment of an operating theatre, that unlike traumatic bleeding in CRASH-2, blood transfusion use was closely titrated to blood loss [8].

The dose of TA recommended by Kerr et all was 1–2 g in an adult patient, their analysis of all trials concluded there was no increased efficacy in using a higher dose. Indeed extremely high doses of TA (100 mg/kg or more) peri-operatively, have been associated with seizures, especially in patients with renal failure and older than 75 [9].

Aprotinin

Aprotinin has long been used in doses of 500,000 kallikrein inhibitory units (KIU) and greater as a treatment to reverse established fibrinolytic bleeding. In the 1980s, it gained a license for reducing bleeding high risk cardiac surgery by giving 2 million KIU to the patient, 2 million KIU to the cardiopulmonary (CPB) circuit and 50,000 KIU/hour during CPB. The original trial reduced post-operative drainage loss by 81%, and total haemoglobin loss by 89% [10]. Since aprotinin is a bovine protein that can provoke an immunological reaction, a test dose is required. By inhibiting kallikrein, aprotonin prolongs in vitro tests of the intrinsic system, including the activated clotting time (ACT), which is used to monitor heparin during cardiopulmonary bypass. In order to allow for adequate levels of heparin to run in patients receiving a high-dose aprotinin regimen, the ACT measured with a celite activator should be kept higher than the normal level of 500 seconds (ideally at 750 seconds) to compensate and allow for 'normal' heparin levels. Kaolin is used as an activator in some ACT tubes [11]. Since it is less affected by aprotinin kaolin ACTs can be monitored in the normal way.

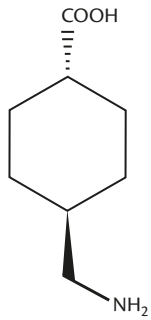

Fig. 52.1 The structure of tranexamic acid.

Aprotinin can also be used in established fibrinolytic bleeding. A good antiplasmin dose is 500,000 KIU iv.

The assumption that had been used for many years—that a reduction in blood loss is a surrogate marker of reduction in premature mortality has been shown to be false. A large open study of the use of antifibrinolytics in cardiac surgery suggested that although aprotinin reduced bleeding, it was associated with increased risk of death and renal dysfunction compared with other antifibrinolytics [12]. A prospective RCT comparing aprotinin versus EACA versus TA was halted by the data monitoring committee due to concerns about the death rate in patients receiving aprotinin [13]. A total of 74 patients (9.5%) in the aprotinin group had massive bleeding, compared with 93 (12.1%) in the TA group and 94 (12.1%) in the EACA group (relative risk in the aprotinin group for both comparisons, 0.79; 95% confidence interval (CI), 0.59–1.05). However, at 30 days the rate of death from any cause was 6.0% in the aprotinin group, as compared with 3.9% in the TA group (relative risk, 1.55; 95% CI, 0.99–2.42) and 4.0 in the EACA group (relative risk, 1.52; 95% CI, 0.98–2.36). The relative risk of death in the aprotinin group as compared with that in both groups receiving lysine analogues was 1.53 (95% CI, 1.06–2.22). There was voluntary suspension of marketing aprotinin. Subsequently, the use of aprotinin has declined and TA has replaced it's indications in most countries.

Mechanism of antifibrinolytics

TA and EACA are synthetic lysine analogues (see Fig. 52.1 for structure of TA), which bind to the lysine binding sites and thus prevent plasminogen from binding to fibrin, fibrinogen and plasminogen receptors as a competitive inhibitor. By preventing the generation of plasmin, and by blocking activation of plasminogen receptors on leucocytes and endothelial cells it probably has a weak anti-inflammatory effect and possibly minor antithrombotic effect. This area is the subject of current research.

In high doses (150–200 KIU), aprotinin inhibits kallikrein and the licensed regimen achieves blood levels of about 200 KIU/mL. However, even in lower concentrations, aprotinin is a plasmin inhibitor, which appears to be the main mechanism for its effect on bleeding; its molar potency in vitro is 100 and 1000 times that of TA and EACA [14].

Antifibrinolytics may also have a minor effect in preserving platelet membrane receptors by inhibiting plasmin-mediated degradation.

Desmopressin

Desmopressin acetate (DDAVP) is a synthetic vasopressin analogue. It increases the plasma concentrations and activity of von Willebrand Factor (vWF) 2–5-fold by inducing the release of vWF from Weibel Palade bodies in the endothelium. It also stimulates endothelial release of tissue plasminogen activator and promotes platelet activation.

Desmopressin shortens the bleeding time in patients with von Willebrand's disease, platelet function defects and uraemia and so is used for these indications, alongside tranexamic acid or EACA to prevent excess fibrinolytic activation.

Despite the success of early trials, a Cochrane systematic review of all 18 RCTs, where desmopressin was given to reduce perioperative bleeding concluded that there was no benefit [15], although it

may be helpful in the platelet defect in renal failure and in some types of platelet dysfunction. Side effects include flushing and an antidiuretic effect.

Recombinant activated factor VIIa

Recombinant activated factor VII (rFVIIa) is approved for the management of haemophilia A or B with inhibitors; acquired haemophilia; congenital FVII deficiency; and Glanzmann's thrombasthenia with refractoriness to platelet transfusion with antibodies to GPIIb/IIIa and/or HLA antigens.

However, rFVIIa has also been used widely as an 'off-label' treatment in patients with platelet dysfunction, thrombocytopenia, and massive transfusion after major surgery or trauma in patients without a pre-existing coagulopathy. Initially, the body of evidence for these indications was disappointingly mainly from case reports [16] and case series, but now data exists from 25 RCTs [17].

Mechanism of action of pharmacological doses of rFVIIa

About 1% of circulating factor VII is in the activated form, but the amount of circulating rFVIIa required to have an effect in haemophilia is much larger. There is disagreement whether rFVIIa has an effect independent of tissue factor. It has been demonstrated *in vitro* that rFVIIa is able to bind weakly to activated platelets and cause activation of FX. The need for binding of rFVIIa to activated platelets may explain why rFVIIa has an effect only at the site of bleeding. Others hold the view that VIIa binds to tissue factor in the normal way. Whatever the mechanism, coagulation activation with rVIIa only occurs locally at the site of bleeding without disseminated activation.

rFVIIa has a half-life of approximately 2.7 hours in adults. Even though the recommended dosage is 90 micrograms/kg in haemophiliac patients with inhibitors, it is clear the optimal dose and dosing intervals of rFVIIa in this group have not been established with certainty. Higher doses up to 300 micrograms/kg have proved to be more clinically efficacious in some patients.

Monitoring of rVIIa activity with routine assays is not possible. The prothrombin time (PT) and activated partial thromboplastin time (APTT) are shortened after pharmacological doses of rFVIIa, but they are only indirect correlates of its action. The measurement of FVII clotting activity (FVIIa:C) in the treatment of haemophilia-related bleeding has led to a recommendation of a minimum level of 6–10 IU/mL and peak levels of greater than 30–50 IU/mL when giving iv boluses. The use of thromboelastography and thrombin generation has also been explored, with limited success, in trying to find an *in vitro* measure that correlates with clinical response.

Platelet dysfunction occurs in uraemia and with aspirin, clopidogrel, and glycoprotein (GP) IIb/IIIa inhibitors in acute coronary syndromes. rFVIIa has been reported to control bleeding anecdotally in these situations.

Off-license use in patient groups other than haemophilia

Many bleeding patients without haemophilia have now been treated, off-license, with rFVIIa [17]. The patients' settings are very diverse, including surgery, gastointestinal bleeding, liver dysfunction, and intracranial and obstetric haemorrhage and trauma. Patients with liver dysfunction often have disproportionately low factor VII levels compared with the other vitamin K-dependent factors. rFVIIa normalizes the PT in liver disease with a single dose of 5–80 micrograms/kg.

Data from 25 RCTs enrolling around 3500 patients have now evaluated the use of rFVIIa as both prophylaxis to prevent bleeding (14 trials) or therapeutically to treat major bleeding (11 trials), in patients without haemophilia. When combined in meta-analysis [17], the trials showed modest reductions in total blood loss or red cell transfusion requirements (equivalent to less than one unit of red cell transfusion). For other endpoints, including clinically relevant outcomes, there were no consistent indications of benefit, and almost all of the findings in support of and against the effectiveness of rFVIIa could be due to chance (the exception was thromboembolic events). Other limitations applied in many trials, for example, uncertainty about the protocols for use of blood components.

Boffard et al. led the first randomized placebo-controlled trial of rFVIIa in blunt and penetrating trauma after patients had been transfused eight units of red cells suggested trends to requiring less red cells in those with penetrating injuries, without differences in thromboembolic but the findings were not replicated in a larger trial [18]. The trauma trials showed that rFVIIa is less effective in those who are acidotic or in severe shock. As for trauma, in the studies of patients with intracranial bleeding, although there were promising results in earlier therapeutic studies, the findings were not replicated in subsequent larger trials.

In both prophylactic and therapeutic groups of trials, there was a trend to increased thromboembolic events [19], with the increase in arterial thromboembolic events reaching statistical significance. Thromboembolic disease is multifactorial and for many of the patients in the clinical settings of the included studies, a higher risk of thrombosis might be expected. Underestimation of the rates of thromboembolic events from the RCTs compared with current hospital practice is also likely, as a history of thrombosis or vaso-occlusive disease was a common criterion for exclusion in most of the included studies. Levi et al. looked at published RCTs of rVIIa and company data [19]. There was no increased rate of venous thromboembolism, but significantly higher rates of arterial events, for example, 2.9% of those who had rVIIa had coronary thrombosis compare with 1.1% of controls. Rates of arterial events were particularly high in those over 65 years (9% versus 3.6%, $p = 0.003$), the rates were especially high in those over 75 years (10.8% versus 4.1%, $p = 0.02$). Concerns about the thrombotic risk, especially increased rate of arterial events associated with the off-license use of rVIIa led to a Black Box warning from the FDA in the USA early in 2010. Because of concerns about its benefit and safety, many guidelines are now recommending that rVII is only used as part of a clinical trial.

PART 2.7

Antimicrobial and immunological drugs

CHAPTER 53

Antimicrobial drugs in critical illness

A. P. R. Wilson and Preet Panesar

Key points

- Meningitis should be treated with cefotaxime or ceftriaxone +/– vancomycin.
- Piperacillin/tazobactam or ceftazidime are appropriate for treatment of ventilator-associated pneumonia more than 2 days after intubation.
- Meropenem or imipenem should be reserved for infections resistant to other agents and used first-line only when the risk of a multiresistant nosocomial infection is high.
- Teicoplanin is less likely to cause nephrotoxicity than vancomycin when used in combination with aminoglycoside.
- Some hospitals exclude cephalosporins and quinolones because of concern not to promote *C. difficile* infection, but a diversity of antibiotics is probably more effective.

Introduction

In critically-ill patients, the pharmacokinetic behaviour of many antibiotics is unpredictable, and clinical trials are difficult to perform and interpret. Antibiotic dose has to be modified repeatedly according to the observed renal or hepatic function. Pharmacodynamic factors are important, i.e. the rapidity of bactericidal effect, the post-antibiotic effect (the length of suppression of bacterial growth after antibiotic concentrations have fallen below inhibitory levels), and the serum half-life and tissue penetration of the antibiotic. The intravenous (iv) route is used because intramuscular administration is affected by changes in tissue perfusion. The penicillins, glycopeptides, and cephalosporins act against the cell wall of the organism and bacterial killing depends more on the time during which the minimum inhibitory concentration (MIC) is exceeded than the absolute tissue concentration, provided that the lowest concentration is at least four times the MIC. The aminoglycosides and quinolones require high peaks because bacterial killing depends on concentration rather than duration of exposure. The area under the curve of serum concentration (AUC) versus time and over the MIC (area under the inhibitory curve AUIC) can be used to predict efficacy: AUIC = (AUC0 – 24 hours)/MIC. The AUIC is predictive of bacterial eradication in vivo and hence pseudomonal pneumonia should be treated with a dose of 400 mg of ciprofloxacin every 8 hours and not 200 mg every 12 hours [1]. Vancomycin, teicoplanin, the aminoglycosides, the cephalosporins, and the penicillins are all excreted by the kidneys and will accumulate when creatinine clearance falls below 30 mL/min. Erythromycin, clindamycin, chloramphenicol, fusidic acid, and rifampin (rifampicin) are metabolized in the liver and, although safe in renal failure, should be avoided in liver failure. Clearance by haemodialysis or haemofiltration depends on the type of machine, the flow rates, and the duration [2]. Aminoglycoside and vancomycin dosage must be determined by serum assay. The cephalosporins are eliminated slowly, but dosage is usually reduced by at least half. The glycopeptides need only be given every 3–7 days after loading.

Empirical treatment

Antibiotic treatment should be started as soon as cultures have been taken, without waiting for the results to be reported. Treatment should be reviewed every 1–2 days and stopped at 5 days unless there is continuing sepsis. Maintaining a choice or diversity of empirical therapy or rotating antibiotic choice is used to delay the appearance of resistant strains [3].

Local susceptibility patterns should determine empirical antibiotic choice. For community-acquired infection, co-amoxiclav or a parenteral cephalosporin (cefuroxime, cefotaxime, ceftriaxone) are appropriate. For hospital-acquired infections, piperacillin/tazobactam, ciprofloxacin or ceftazidime can be used. For suspected vascular catheter infection or methicillin-resistant *Staphylococcus aureus* infection, teicoplanin or vancomycin should be used. Meropenem or imipenem should be reserved for second-line treatment if initial therapy fails. Table 53.1 shows the use and choice of antimicrobials in critical care [4–8].

Patients with febrile neutropenia will usually already be treated with antibiotics on arrival in ICU, usually piperacillin-tazobactam, meropenem, ceftazidime, or ciprofloxacin and, if catheter infection is suspected, a glycopeptide. Antifungals, usually caspofungin, fluconazole or liposomal amphotericin, are used if fungal infection is suspected, especially after 2–3 days antibacterial treatment.

Prophylaxis

For the prevention of surgical wound infection, sufficient antibiotic must be present in the tissue to kill the bacteria likely to contaminate the wound. Antibiotics given after surgery do not provide any additional benefit, and risk the emergence of resistance or acquisition of MRSA. For gut or respiratory tract procedures, a second generation cephalosporin and metronidazole is a common choice. Antibiotics for prophylaxis should be different from those used for treatment.

Table 53.1 Dosage, route of administration, adverse effects, contraindications [4–8]

Drug	Pathogen treated	Dose + route	Contraindications	Adverse effects
Benzylpenicillin (Penicillin G)	Streptococci, *N. meningitidis, C. perfringens, T. pallidum*	2.4–7.2g iv 4–6-hourly (up to 14.4g/day)	Penicillin allergy	Hypersensitivity, seizures with large doses in renal impairment
Flucloxacillin	*Staphylococcus aureus* (MSSA), *Streptococcus pyogenes*	1–2 g iv/po 4–6-hourly	Penicillin allergy Flucloxacillin-associated jaundice	Hypersensitivity, seizures, cholestatic jaundice with high dose and long course
Amoxicillin	Enterococci, *Listeria*, some Gram-negative species (mostly non-ICU)	1 g iv/po 6–8-hourly Meningitis/endocarditis: 2g IV 4–6-hourly	Penicillin allergy Glandular fever and lymphatic lymphoma	Hypersensitivity, maculopapular rash, seizures with large doses in renal impairment
Ampicillin	Enterococci, *Listeria*, some Gram-negative species (mostly non-ICU)	1–2 g iv 4–6-hourly	Penicillin allergy Glandular fever and lymphatic lymphoma	As for amoxicillin
Amoxicillin-clavulanate (co-amoxiclav)	*Escherichia coli*, *Klebsiella* spp., *Staph. aureus, Haemophilus influenzae, Neisseria gonorrheae*, and *Moraxella catarrhalis*	1.2 g iv 8-hourly	Penicillin allergy Penicillin-associated jaundice/hepatic dysfunction	As for other penicillins, cholestatic jaundice, maculopapular rash
Piperacillin-tazobactam	Gram-negative species including *Pseudomonas*, Enterococci	4.5 g iv 6–8-hourly	Penicillin allergy	As for other penicillins, risk of convulsions in renal impairment
Cefuroxime	*E. coli*, *Proteus* sp., *Klebsiella* sp., streptococci, and *Staph. aureus* (not MRSA)	750 mg–1.5g iv 6–8-hourly	Immediate and/or severe hypersensitivity reaction to β-lactam antibiotics	Risk of *C. difficile* infection, particularly in elderly
Cefotaxime	Gram-negative species, *Staph. aureus* streptococci, not enterococci	Up to 12 g daily in 3 or 4 divided doses	Immediate and/or severe hypersensitivity reaction to beta-lactam antibiotics	Risk of *C. difficile* infection, particularly in elderly
Ceftriaxone	Gram-negative species, *Staph. aureus*, streptococci, not enterococci	2–4 g iv 24-hourly	Immediate and/or severe hypersensitivity reaction to β-lactam antibiotics; Premature neonates with jaundice, hypoalbuminaemia	Risk of *C. difficile* infection, particularly in elderly, biliary obstruction, calcium ceftriaxone been mistaken for gallstones
Ceftazidime	Gram-negative species including *Pseudomonas*. Not enterococci	1–2 g iv 8-hourly	Immediate and/or severe hypersensitivity reaction to β-lactam antibiotics	Risk of *C. difficile* infection, particularly in elderly
Vancomycin	MRSA and other Gram-positive bacteria	Loading dose by weight: 1–2 g then 0.5–1.5 g iv 12–48-hourly by renal function Maintain trough level 10–15 mg/L (15–20 mg/L for less sensitive MRSA) *C. difficile*: 125 mg (up to 500mg) po qds 10–14 days	Care in renal insufficiency Avoid if previous hearing loss	Rapid infusion can cause flushing of the upper-body ('red-neck syndrome'), Nephrotoxicity, Ototoxicity
Teicoplanin	MRSA and other Gram-positive bacteria. VanB vancomycin-resistant enterococci	6 mg/kg iv 12-hourly for 3 doses, then 6 mg/kg 24-hourly 10–12 mg/kg for endocarditis/osteomyelitis	Caution in patients known to be hypersensitive to vancomycin	High doses can cause drug fevers and thrombocytopenia
Linezolid	MRSA, VRE, and other Gram positive bacteria	600 mg po/iv 12-hourly	Avoid concomitant use with MAOIs and SSRIs	Myelosuppression—monitor blood counts, serotonin syndrome, peripheral neuropathy, convulsions, optic neuritis

(*continued*)

Table 53.1 Continued

Drug	Pathogen treated	Dose + route	Contraindications	Adverse effects
Gentamicin	Gram-negative bacteria and staphylococci	Use ideal body weight for obese patients 1–1.5 mg/kg iv 8-hourly. Trough level <2 mg/L, peak level 5–10 mg/L or 7 mg/kg iv 24-hourly, but adjust by Hartford nomogram	Myasthenia gravis Keep duration as short as possible	Nephrotoxicity Ototoxicity
Amikacin	Gram-negative bacteria and staphylococci	15 mg/kg/day iv (max 1.5 g daily). Maintain trough <5 mg/L	Myasthenia gravis	Nephrotoxicity Ototoxicity
Imipenem/ cilastatin	Streptococci, staphylococci, *Pseudomonas* and other Gram-negative bacteria, and anaerobes; not MRSA or *Stenotrophomonas maltophilia*	500 mg–1 g iv 6–8-hourly	Hypersensitivity to any other β-lactam	Seizures with large doses in renal impairment
Meropenem	Streptococci, staphylococci, *Pseudomonas*, and other Gram-negative bacteria, and anaerobes; not MRSA or *Stenotrophomonas maltophilia*	500 mg–1 g iv 8-hourly Meningitis: 2 g iv 8-hourly	Hypersensitivity to any other β-lactam	Less potential to induce seizures than imipenem
Ciprofloxacin	*Pseudomonas* and other Gram-negative bacteria, limited staphylococci and streptococci	Oral: 500–750 mg 12-hourly iv: 200–400 mg 8–12-hourly	History of tendonitis Avoid in children, pregnant or breast-feeding women	Lowers seizure threshold, increases QT prolongation, hepatic failure reported, haemolysis in G6PD deficiency
Ofloxacin	*Pseudomonas* and other Gram-negative bacteria, limited staphylococci and streptococci	200 mg–400 mg IV / PO 12H	As for ciprofloxacin	As for ciprofloxacin
Erythromycin	Streptococci, *Corynebacterium diphtheriae, Staph aureus, Mycoplasma, Chlamydia, Legionella*	Oral or **Prokinetic**: 250–500 mg iv / PO 6H **iv**: 50 mg/kg/day (max 4g/day)	May aggravate myasthenia gravis Use with caution in patients with prolonged QT interval	Gastrointestinal upset, iv dosing can cause hearing disturbances
Clarithromycin	As erythromycin but better against *Haemophilus*	500 mg iv/po 12-hourly	As for erythromycin	As for erythromycin Less gastrointestinal adverse effects than erythromycin
Clindamycin	Anaerobes, staphylococci, streptococci. With primaquine, Pneumocystis	**po:** 300–450 mg 6-hourly **IV:** 600 mg–4.8 g/day in 2–4 divided doses		Risk of pseudomembraneous colitis
Co-trimoxazole (trimethoprim/ sulfamethoxazole)	Staphylococci, streptococci, Gram negative bacteria, *Pneumocystis*, not pseudomonas or anaerobes	**PCP**: 120 mg/kg daily in 3–4 divided doses for 3 days, then 90 mg/kg/day in 3–4 divided doses for 18 days	Avoid in liver parenchymal damage	Thrombocytopenia Skin rash Haemolysis in G6PD deficiency
Chloramphenicol	Gram positive and negative bacteria, anaerobes, Rickettsia, not Pseudomonas	12.5 mg/kg po/iv 6-hourly	Monitor levels in neonates, <4 years of age, elderly, and in renal and hepatic impairment	Bone marrow depression Optic and peripheral neuritis 'Grey syndrome' in infants and neonates
Sodium fusidate	*Staph aureus* (in combination)	500 mg iv/po 8-hourly	Regular monitoring of liver function	Pancytopenia Hepatotoxicity with iv

Doxycycline	Gram positive and negative bacteria, Lyme, Rickettsia	200 mg po on first day, then 100 mg po 12-hourly	Avoid in pregnancy, breast feeding and <12 years	Photo sensitivity
Metronidazole	Anaerobes, Giardia, Amoebae, parasites	**Oral**: 400 mg 8-hourly **iv**: 500 mg 8-hourly	Avoid in acute porphyria Disulfiram-like reaction with alcohol	Taste disturbances Peripheral neuropathy with prolonged therapy (>2 weeks)
Rifampicin	Staphylococci, corynebacteria, *Moraxella, Legionella*, M tuberculosis	**po**: 450–600 mg 24-hourly **iv**: 0.6–1.2 g iv daily in 2–4 divided doses	Jaundice Concurrently receiving saquinavir/ritonavir therapy	Hepatitis, flu-like syndrome, reddish colour of urine, sweat, sputum, and tears
Isoniazid	*M tuberculosis* and other mycobacteria	300 mg po 24-hourly	Drug-induced liver disease	Peripheral neuropathy Hepatitis
Pyrazinamide	*M. tuberculosis* and other mycobacteria	<50 kg–1.5 g po 24-hourly >50 kg–2 g po 24-hourly	Avoid in acute porphyria	Can precipitate gout, hepatotoxicity, rash, and photosensitivity
Ethambutol	*M tuberculosis* and other mycobacteria	15 mg/kg po/iv 24-hourly	Optic neuritis, poor vision	Optic neuritis and colour blindness, peripheral neuritis
Streptomycin	*M. tuberculosis* and other mycobacteria	15–20 mg/kg/day im (max 1 g per day)	Avoid in myasthenia gravis	Nephrotoxicity, ototoxicity, rash
Liposomal amphotericin	*Candida, Cryptococcus*, Histoplasma, *Aspergillus*, Leishmaniasis, not *C tropicalis*	Test dose 1 mg over 10 minutes, then 3 mg/kg iv 24-hourly (max 5 mg/kg—unlicensed)	Anaphylaxis reported so test dose recommended	Fever and chills/rigors, renal impairment, electrolyte disturbances
Caspofungin	*Candida; Aspergillus* (if not responded to other antifungals)	**<80 kg**: 70 mg iv on 1st day, then 50 mg iv 24-hourly **>80 kg**: 70 mg iv 24-hourly		Rash, pruritus, or bronchospasm Hepatitis
Fluconazole	*Candida, Cryptococcus*	400 mg iv on 1st day, then 200–400 mg iv 24-hourly (max 800 mg iv 24-hourly)	Acute porphyria	Hepatotoxicity Increased risk of QT prolongation
Voriconazole	*Aspergillus, Candida, Fusarium*	**po:** >40 kg—400 mg 12-hourly for 2 doses then 200 mg 12-hourly; <40kg—200 mg 12-hourly for 2 doses then 100 mg 12-hourly. **iv:** 6 mg/kg 12-hourly for 2 doses, then 4 mg/kg 12-hourly	Acute porphyria, avoid iv in renal impairment as increased risk of convulsions	Increased risk of QT prolongation, hepatotoxicity, blurred vision and optic neuritis, exfoliative cutaneous reactions, bone marrow depression
Aciclovir	*Herpes simplex, Varicella zoster*, not CMV	5 mg/kg iv 8-hourly (10 mg/kg in immunocompromised and encephalitis)		Adequate hydration of the patient should be maintained
Ganciclovir	CMV	5 mg/kg iv 12-hourly for 14–28 days	Potential carcinogen and teratogen—avoid in pregnancy and lactation	Bone marrow depression
Foscarnet	CMV, *Herpes simplex*	CMV disease 90 mg/kg iv 12-hourly 14–28 days	Pregnancy and lactation	Nephrotoxicity, electrolyte disturbances, rash
Oseltamivir	Influenza A and B	75 mg po 12-hourly for 5 days		Headaches and vomiting usually resolve after 1–2 days
Zanamivir	Influenza A and B	IV: 600 mg iv 12-hourly for 5 days (unlicenced) Inhaled: 10mg inh 12-hourly for 5 days	Risk of bronchospasm in asthma / COPD	Neuropsychiatric events especially in children and adolescents

iv, intravenous; po, oral; MAOI, monoamine oxidase inhibitor; SSRI, selective serotonin reuptake inhibitor.

Penicillins

The penicillins interrupt bacterial cell wall synthesis and are bactericidal. They penetrate well and reach high concentrations in the urine and the lung. Penicillin G (benzylpenicillin) is quickly excreted and another dose is needed after 4 hours. Allergic reactions develop in up to 10% of patients and can include drug-induced fever. Interstitial nephritis is suggested by a raised eosinophil count. High doses given to patients with meningitis and severe renal failure risk the development of seizures. Isoxazoyl penicillins (oxacillin, nafcillin, flucloxacillin, cloxacillin) have a synergistic interaction with aminoglycosides and are used to treat penicillin-resistant staphylococci. Methicillin-resistant *Staph. aureus* (MRSA) infections must be treated with glycopeptides. Hepatitis or cholestatic jaundice can occur during prolonged use of penicillins. Supplemental doses are required after haemodialysis. Amoxicillin has a longer half-life than ampicillin. Allergic reactions, particularly rash, are common. Co-amoxiclav is a combination of amoxicillin and clavulanic acid, which prevents the action of ß-lactamase. *Pseudomonas* species are resistant. It can be used as an alternative to cefuroxime in most infections and produces high urinary concentrations [9]. Ticarcillin–clavulanic acid is a similar combination agent with activity against some strains of *Pseudomonas* species.

Piperacillin is usually given in combination with a ß-lactamase inhibitor tazobactam. Piperacillin–tazobactam is a common choice in hospitals where cephalosporins and quinolones are discouraged, and is used in intra-abdominal (e.g. biliary) infections, respiratory or urinary infections, and septicaemia. Temocillin is increasingly used instead of carbapenem as it active against some beta-lactamase producing Gram-negative bacteria (except *Pseudomonas*).

Cephalosporins

The cephalosporins have relatively low toxicity and a broad spectrum. They inhibit bacterial cell wall synthesis. They are not effective against enterococci or methicillin-resistant staphylococci. Cephalosporins are frequently used in surgical prophylaxis and may be given in combination with gentamicin in bacteraemic shock. However, its popularity has declined as overuse in some hospitals has been linked to the emergence of MRSA and *Clostridium difficile* infections. Cefuroxime can be used in abdominal wound infections (with metronidazole) or orbital cellulitis. Pyelonephritis can be effectively treated by cefuroxime, cefotaxime, or ceftriaxone without an aminoglycoside. Vomiting and allergic reactions are the most common adverse effects. Oral (po) cephalosporins have poor activity against Gram-negative bacteria and are not po equivalents of cefuroxime. They should only be used for infections that do not respond to cheaper agents. Cefuroxime is used in a wide range of community-acquired or post-surgical infections. It is not recommended in meningitis. Thrombophlebitis and hypersensitivity are the only common adverse effects. Cefotaxime or ceftriaxone are given as empirical treatment of meningitis. Ceftriaxone is reduced in dosage only in severe renal failure or if there is liver and renal impairment. It is highly concentrated in bile and can produce biliary sludge, causing abdominal pain and vomiting. Ceftazidime penetrates the lung well and is commonly used in the treatment of ventilator-associated pneumonia, provided that staphylococcal pneumonia is excluded. It is used to treat febrile episodes in neutropenic patients and pseudomonal urinary infections.

Glycopeptides

Vancomycin and teicoplanin are the agents of first choice to treat infections caused by MRSA. Both are excreted by the kidneys and dosage reduction is necessary. Oral vancomycin (125 mg every 6 hours for 10 days) is used to treat antibiotic-associated colitis. Teicoplanin can be given iv as a bolus dose, but vancomycin requires a slow infusion over 1 hour to avoid flushing and hypotension. Teicoplanin has a longer half-life, allowing od doses. Neither reliably penetrates the cerebrospinal fluid. Fever in neutropenic patients is treated with glycopeptides when there is evidence of catheter infection or failure of empirical treatment. Vancomycin concentrations in serum can be monitored to maintain troughs of 10–15 mg/L to ensure a therapeutic level and avoid nephrotoxicity, particularly when used in combination with aminoglycosides. Teicoplanin does not require monitoring for toxicity, but to ensure therapeutic levels, for example, in staphylococcal endocarditis, when the trough should be over 20 mg/L, in renal failure, and in drug abusers. Ototoxicity and nephrotoxicity are rare using vancomycin alone, but there is a synergistic effect when it is combined with an aminoglycoside. Both glycopeptides can cause a rash.

Aminoglycosides

Aminoglycosides are bactericidal agents that bind to bacterial ribosomes. They are synergistic in combination with penicillins except when there is high-level resistance. Penetration into the lung is poor, but they are well concentrated in the urine. Their use is limited by nephrotoxicity and ototoxicity. Serum concentrations have to be assayed daily in the ICU to determine dosage. A course should be up to 3–5 days; longer courses should only be used exceptionally (e.g. endocarditis). In patients with normal renal function, administration of a large single daily dose (7 mg/kg) has been found to reduce toxicity without affecting efficacy [10]. A single assay is taken 6–14 hours after the dose to determine the next dosage interval. Aminoglycosides are used in severe infections when resistance to penicillins or cephalosporins is likely. Amikacin can be used in gentamicin-resistant infections.

Carbapenems

Imipenem is a carbapenem antibiotic with an extremely broad spectrum of activity. It is combined with cilastatin, which is an inhibitor of dehydropeptidase, an inactivating enzyme of the renal brush border, which ensures adequate urinary concentrations. Meropenem has similar activity, but does not require an enzyme inhibitor. The carbapenems are inducers of ß-lactamase and should not be combined with other ß-lactams. Penetration is good into most tissues. Excretion is predominantly renal. Bacteraemia, severe respiratory or urinary infections, febrile neutropenic episodes, and abdominal sepsis are common indications. Nausea and vomiting are common and fits develop in 1% of patients given imipenem. Patients allergic to penicillins may be allergic to carbapenems. Superinfection with resistant pseudomonads or fungi can develop.

Fluoroquinolones

Ciprofloxacin, levofloxacin, and ofloxacin are available for po or iv use. However, resistance is increasing, particularly in *Pseudomonas aeruginosa* and MRSA. Like the cephalosporins, some hospitals have

withdrawn them in the belief that avoidance will reduce *C. difficile* and MRSA rates. They inhibit bacterial DNA gyrase and are bactericidal. Excretion is via the kidney. They are used to treat complicated urinary infections and prostatitis, but should be avoided for community-acquired pneumonia. They are first-line agents in severe *Salmonella* and *Shigella* infections. Osteomyelitis and soft tissue infections caused by Gram-negative bacteria, and gonorrhoea are other indications. Gastrointestinal symptoms, rash, and occasionally convulsions occur. Quinolones are not recommended in children, unless there is no alternative, because of their potential effect on growing cartilage.

Macrolides

Erythromycin acts on protein synthesis at the ribosome. Erythromycin is excreted by the liver and should be avoided in severe liver disease. It is used in the treatment of mycoplasmal and chlamydial pneumonia, legionnaires' disease, whooping cough, diphtheria, and *Campylobacter* infections. Nausea and vomiting are common adverse effects. Cholestatic jaudice (with estolate) and reversible ototoxicity are reported. Clarithromycin and azithromycin are used in respiratory tract and sexually-transmitted infections. Gastrointestinal symptoms are less common than with erythromycin.

Clindamycin

Clindamycin inhibits ribosomal protein synthesis. Clindamycin penetrates tissues well, particularly bone and pleural fluid (but not the meninges) and is excreted by the liver. The dose should be reduced in liver failure. It is an alternative to metronidazole for abdominal sepsis and is used to treat osteomyelitis aspiration pneumonia and lung abscess. Necrotizing fasciitis and other severe infections caused by *Streptococcus pyogenes* can be treated with clindamycin. Diarrhoea is a well-recognized adverse effect.

Chloramphenicol

Chloramphenicol has a very wide spectrum of activity. It penetrates well into most tissues and is metabolized in the liver. Reversible bone marrow suppression can develop at dose of 4 g/day or on long courses. Serum concentrations should be measured in the very young and should not rise above 20 mg/L to avoid gray baby syndrome (vomiting, cyanosis, collapse). In rare cases (1 in 30,000) a fatal aplastic anaemia develops. The principle uses of chloramphenicol are treatment of meningitis in patients allergic to cephalosporins, brain abscess, and rickettsial infection.

Trimethoprim and trimethoprim-sulfamethoxazole (co-trimoxazole)

Trimethoprim and sulfamethoxazole act at different parts of the same pathway of synthesis of bacterial folate. Their long half-lives allow both to be given at 12-hour intervals. Trimethoprim can be used for urinary tract infections, but in hospital-acquired infections susceptibility needs first to be demonstrated. Rash, nausea, vomiting, and diarrhoea are common, and occasionally Stevens–Johnson syndrome occurs. Administration in pregnancy is contraindicated.

Tetracyclines

Tetracyclines are bacteriostatic antibiotics with a wide bacterial spectrum, but resistance is common. They are an alternative treatment for atypical pneumonia. Doxycycline has the longest half-life and is the only one that can be used in renal failure. Tetracyclines interfere with growth and development of bone, and must not be given in pregnancy or to children under 8 years old.

Metronidazole

Metronidazole is as well absorbed by the po or rectal route as by iv route. It should not be used in pregnancy. It is used to treat anaerobic bacteraemia, intra-abdominal sepsis, and brain abscess. Aspiration pneumonia can be treated by metronidazole with a cephalosporin, or clindamycin. Oral metronidazole is used to treat mild to moderate antibiotic-associated colitis. The dose should be reduced in severe renal or hepatic failure. Peripheral neuropathy may develop during prolonged courses.

Rifampin

Rifampin is a bactericidal antibiotic, which inhibits protein synthesis by binding RNA polymerase. Resistance will emerge rapidly if it is used in isolation. It is a first-choice agent in treating tuberculosis and *Mycobacterium avium intracellulare* complex disease. In staphylococcal endocarditis, rifampin may be used in combination with a glycopeptide with or without an aminoglycoside. Fever, rash, and hepatotoxicity are the most important adverse effects. The antibiotic antagonizes the effects of warfarin, cyclosporin, verapamil, and po hypoglycaemics.

Other antituberculosis agents

Isoniazid is metabolized in the liver and dosage is not reduced in renal failure. Hepatitis occurs in 1% of patients, but peripheral neuropathy can be prevented by giving pyridoxine. Pyrazinamide is often combined with rifampin and isoniazid. It is given po and can be used to treat meningitis. Hepatotoxicity can occur. Ethambutol is bacteriostatic and is widely distributed after po administration. The dose is reduced in renal failure. Optic neuritis (loss of colour vision) is an important adverse effect, which prevents its use in the unconscious. Streptomycin, like other aminoglycosides, is ototoxic and nephrotoxic, and serum levels must be assayed.

Antifungals

Amphotericin B

Amphotericin B remains the most common choice for the treatment of systemic fungal infection. It is a polyene, which acts by increasing the permeability of the fungal cell membrane. It is highly tissue bound, particularly in the liver, spleen, kidney, and lung. No dose modification is necessary in renal or hepatic failure. Amphotericin B is not removed by haemodialysis. Amphotericin is often used to treat acute cryptococcal meningitis. Adverse effects are renal failure, fever, chills, headache, hypotension, phlebitis, hypokalaemia, anaemia, and hepatitis. Liposomal, lipid complex, and colloidal dispersion amphotericin B have been produced to reduce toxicity. High doses can be given safely, but they are less potent than the original preparation.

Caspofungin

Echinocandins such as caspofungin are indicated in treatment of invasive candidiasis and *Aspergillus* if refractory or intolerant to amphotericin. They are not effective in fungal meningitis.

Imidazoles and triazoles

Voriconazole is the treatment of choice for aspergillosis, including central nervous system infection. Miconazole, ketoconazole, fluconazole, and itraconazole are active against most fungi except *Aspergillus* species. They act by inhibiting the production of the fungal cell membrane. Fluconazole is well absorbed po and can be given iv. Its long half-life allows od dosing. It penetrates most tissues and is excreted renally, largely unchanged. Dosage must be reduced in renal failure. Adverse effects are rare. It is highly effective in mucosal candidiasis. Itraconazole is given po and is distributed throughout the body except the cerebrospinal fluid. It is used to treat histoplasmosis, paracoccidiodomycosis, and blastomycosis, and can be given to patients with invasive aspergillosis in the presence of immune suppression.

Antivirals

Aciclovir

Aciclovir is an analog of guanosine. The iv route is most reliable and it is distributed to all tissues including the meninges. Aciclovir is excreted by the kidneys and dose reduction is necessary in renal failure, although it is removed by haemodialysis. For the immune-suppressed patient, aciclovir prevents dissemination and reduces shedding. It is effective in the treatment of herpes simplex encephalitis. Chickenpox in adults should be treated with aciclovir to reduce the morbidity associated with pneumonia. Phlebitis, reversible renal impairment, and elevation of transaminases are minor side-effects.

Foscarnet

Foscarnet is used to treat herpetic infection that does not respond to aciclovir. It is nephrotoxic.

Ganciclovir

Ganciclovir is usually administered parenterally and penetrates the lung and liver. Dose should be reduced in renal failure, but it is removed by haemodialysis. Ganciclovir is used to treat cytomegalovirus retinitis in AIDS patients and is also effective in cytomegalovirus gastrointestinal disease. The presence of cytomegalovirus in the lungs of AIDS patients may not be the cause of clinical disease and is usually not treated. Myelosuppression is common, and mucositis, fits, and rash can occur.

Oseltamavir and zanamivir

These agents inhibit viral neuraminidase of influenza A and B. They should be used within 48 hours of onset of symptoms to reduce the risk of complications in the elderly or those with chronic underlying illness.

CHAPTER 54

Steroids in critical illness

Didier Keh

Key points

- Critical illness-related corticosteroid insufficiency (CIRCI) is caused by adrenal insufficiency and tissue corticosteroid resistance. It is characterized by insufficient corticosteroid effect to counterbalance an exaggerated and protracted pro-inflammatory response.
- Moderate-dose hydrocortisone should be considered in severe septic shock with poor response to fluid and vasopressor therapy. Shock resolution is earlier and survival probably improves in patients with high risk of death.
- The indication for use should be based on clinical judgement and not on cortisol measurements.
- A continuous infusion and slow weaning from corticosteroids may be preferable to bolus applications and abrupt withdrawal to avoid side effects, such as rebound of inflammation and shock, glucose variability, or respiratory failure.
- There is some evidence of beneficial effect with prolonged moderate-dose methylprednisolone in early severe acute respiratory distress syndrome (ARDS), but further studies are needed for confirmation.

Introduction

The role of corticosteroids in systemic inflammatory diseases such as sepsis and/or acute lung injury (ALI)/acute respiratory distress syndrome (ARDS) is unclear. There is consensus that short therapy with high doses (up to 42 g hydrocortisone equivalent/day) is harmful. The benefit of prolonged use of moderate doses (200–300 mg/day hydrocortisone or 1–2 mg/kg/day methylprednisolone) remains controversial.

In response to inflammation, the hypothalamic-pituitary-adrenal (HPA) axis is stimulated to release cortisol (hydrocortisone), which protects against exaggerated inflammation. Cortisol or exogenous glucocorticoids activate cytoplasmic glucocorticoid receptors (GR), which positively or negatively regulate transcription of proteins (genomic effect), or modulate immune responses by non-genomic pathways, e.g. induction of endothelial nitric oxide production [1]. Glucocorticoids can attenuate inflammation very effectively by inhibition of nuclear factor kappa B (NF-κB), which regulates multiple cytokines, chemokines, adhesion molecules, effector cells, and other mediators.

In critical illness, the HPA-axis may become dysregulated. Triggered by cytokines and toxins, cortisol release and function may be impaired due to reduced corticotropin release, adrenal dysfunction, or resistance to corticosteroids. It has been recommended to describe the dysfunction of the HPA-axis as critical illness-related corticosteroid insufficiency (CIRCI), and to avoid terms like absolute or relative adrenal insufficiency [2]. The latter was used in patients with septic shock to describe poor adrenal response to 250 μg corticotropin stimulation [3,4]. Currently, the best cut-offs for diagnosis of adrenal dysfunction, which was found in about 60% of patients with severe sepsis and septic shock, are a delta cortisol <9 μg/dL ('non-responders') or a random total cortisol <10 μg/dL [2]. However, measuring cortisol is currently not recommended to define eligible patients for corticosteroid therapy [2,5]. There is uncertainty about assay-variability to measure cortisol in septic serum, or to define valid cut-offs for free (biological active) cortisol in the critical ill. CIRCI is not restricted to adrenal dysfunction, but describes an insufficient GR-mediated down-regulation of pro-inflammatory transcriptions factors, such as NF-kB, resulting in persistent inflammation. CIRCI may be transient during critical illness, caused by insufficient cortisol availability or resistance to corticosteroids due to fewer or low-affinity of GR-receptors, as known from chronic inflammatory diseases (e.g. chronic obstructive pulmonary disease). It has been postulated that the acute inflammation-induced resistance to glucocorticoids may be reversed by quantitatively adequate and prolonged glucocorticoid supplementation [2].

There is concern that moderate-dose corticosteroids suppress the immune system beyond the desired attenuation of inflammation. Currently, there is no evidence from immune-monitoring studies for severe immunosuppression or immunoparalysis. There is some evidence that moderate doses in acute systemic inflammation immunomodulating features. In septic shock, hydrocortisone was found to decrease pro-inflammatory interleukin 6 and 8, and inducible nitric oxide synthesis, but did not increase anti-inflammatory interleukin 10, or suppressed HLA-DR on monocytes (antigen presentation) [6]. There is also evidence from in vitro and in vivo studies that moderate doses support innate immune responses and improve opsonisation [2].

Uses

Sepsis

Based primarily on two larger randomized controlled trials, hydrocortisone should be considered only in adult septic shock patients who respond poorly to fluid resuscitation and vasopressor therapy [2,5].

In the French study (n = 299) a significant reduction of 28-day mortality (53% versus 63%, p = 0.04) was observed in

non-responders, but not in responders or in the whole population [3]. Similarly, a significantly faster shock resolution of about 3 days was observed in non-responders.

In the CORTICUS study (n = 499) there was no significant difference of 28-day mortality in the whole group treated with hydrocortisone or placebo (34 versus 32%), in non-responders (39 versus 36%), or in responders (29 versus 29%) [4]. There was a significantly faster shock resolution of about 2.5 days, but in contrast to the French study, irrespective of adrenal dysfunction.

There had been differences between both studies.: In the French trial, patients had a higher mortality in the control group (61 versus 31%), and a higher severity of septic shock. A post-hoc subgroup analysis of CORTICUS patients with similar shock severity revealed a comparable 11% reduction of 28-day mortality. The additional use of fludrocortisone had no effect on mortality in a recent trial [7].

In a meta-analysis of six studies (n = 965) in patients with septic shock, prolonged use of moderate-dose hydrocortisone did not reduce 28-day mortality (relative risk: 0.92, 95% CI, 0.79–1.06, p = 0.25). However, shock was reversed until day 7, irrespective of response to corticotropin stimulation (relative risk: 1.39, 95% CI, 1.24–1.55, $p < 0.0001$) [2]. In another meta-analysis of 12 studies (n = 1228), including patients with severe sepsis, 28-day mortality was reduced in patients who received prolonged moderate-dose corticosteroids (relative risk: 0.87, 95% CI, 0.77–0.98, p = 0.02). Survivors had a shorter length of stay in the intensive care unit (ICU) of about 4.5 days when treated with moderate-dose corticosteroids. Although the combined data suggest possible beneficial effects in severe sepsis, heterogeneity of study populations, small patient numbers in single studies, and different trial designs limit generalization. Due to lack of data from larger randomized controlled trials, use of hydrocortisone is currently not recommended for the treatment of patients with severe sepsis without shock [2,5].

ALI/ARDS

Moderate-dose glucocorticoids have been considered as a management strategy in early severe ARDS (PaO_2/FiO_2 < 200) and before day 14 in unresolving ARDS [2]. In a study of late (>7 days) ARDS (n = 180), 60-day-mortality was not reduced by 2 mg/kg/day methylprednisolone (both groups about 29%). However, patients treated before day 14 had a shorter time on mechanical ventilation and reduced mortality (36 versus 27%) [8]. In another study with early (<72 hours) ARDS (n = 91), patients treated with 1 mg/kg/day methylprednisolone had significantly improved lung function and significantly more ventilator-free days, shorter ICU stay, and reduced ICU-mortality (21 versus 43%) [9]. Combined data from five trials (n = 518) showed an improvement of lung function and reduction of ICU stay. Patients treated before day 14 and for at least 7 days had about 5–6 more ventilator-free days, and a significantly reduced mortality (relative risk; 0.62 95% CI, 0.43–0.90, p = 0.01) [2]. Another meta-analysis included four randomized controlled trials (n = 341) and 5 cohort studies (n = 307) of patients with ALI/ARDS [10]. There was a significant reduction of mortality in pooled data (relative risk: 0.62 95% CI, 0.43–0.91, p = 0.01), but not when cohort and randomized studies were analysed separately. Cohort studies had a higher weight on mortality reduction. There was a consistent improvement of lung function and reduction of organ dysfunction, duration of mechanical ventilation and ICU stay. Taken all together, there is evidence of beneficial effects of moderate-dose steroids in ALI/ARDS, but high heterogeneity of studies, small sample sizes, and subgroup analyses limit a definite conclusion. There is a need for confirmatory trials in early ALI/ARDS.

There are preliminary data suggesting beneficial effects of prolonged use of moderate doses of hydrocortisone in severe community-acquired pneumonia, liver failure, pancreatitis, cardiopulmonary bypass, weaning from mechanical ventilation, severe head injury, and trauma, however, further studies are needed for confirmation [2,11].

Dosages

In patients with septic shock, hydrocortisone should be given in a dose of 200 mg/day in four divided doses or as a bolus of 100 mg, followed by a continuous infusion at 10 mg/hour (240 mg/day), and for at least 7 days before tapering [2]. Although treatment for more than 1 week may be justified following the concept of ongoing inflammation, there is no experience from larger studies in patients with septic shock. With regard to side effects, a continuous infusion and tapering with stepwise reduction every 2–3 days seem preferable; if the clinical situation deteriorates due to tapering, increasing the dose again should be considered.

The best time to start therapy is uncertain. With regard to attenuation of inflammation, early therapy would be obvious. Interestingly, the time window until use of hydrocortisone was much shorter in the French trial (8 hours) [3] than in the CORTICUS trial (72 hours) [4]. In a recent cohort study, there was a significant difference in 28-day mortality between patients treated with hydrocortisone within 6 hours after onset of septic shock, compared with later therapy (32 versus 51%, p = 0.013) [12].

In patients with early ARDS, 1 mg/kg/day methylprednisolone as a continuous infusion for at least 14 days followed by slowly tapering is currently regarded as the optimal treatment procedure [2]. The recommendation is based on a study in which patients with ARDS received the aforementioned dosage early (<72 h) until day 14 followed by tapering up to day 28 [9].

Routes of administration

In critically-ill patients, glucocorticoids should be administered intravenously, either via a central catheter or peripheral access. Fludrocortisone has to be administered orally.

Side effects

Secondary infections

High doses of corticosteroids should be avoided since several trials have shown they were ineffective, harmful, or increased the risk of secondary infections in patients with septic shock, ALI/ARDS, pneumonia, or severe head injury [2,5,13,14].

Evaluating the risk of moderate doses is more challenging. A higher number of secondary infections, including new sepsis and septic shock in the analysis, was reported in the CORTICUS study (33 versus 26%; relative risk 1.27, 95% CI, 0.96–1.68) [4]. In other studies, patients with septic shock [3] and/or ALI/ARDS [8,9] had (significantly) less secondary infections when treated with corticosteroids. Four meta-analyses concluded moderate-dose corticosteroids did not increase the risk in severe

sepsis/septic shock [15], pneumonia or ALI/ARDS [10,13], and one Bayesian analysis of patients with septic shock described an increased risk [16]. Notably, in a trial with hospital-acquired pneumonia as the primary endpoint, patients with severe trauma who received hydrocortisone had a decreased risk of pneumonia (35.6 versus 51.3%; hazard ratio 0.51, 95% CI, 0.30–0.83, $p = 0.007$) [11]. There is currently no clear evidence that moderate-dose corticosteroids increase the risk of secondary infections. However, infection surveillance should be intensified when patients are treated with steroids [2].

Critical-illness polyneuromyopathy

Corticosteroids are often cited to induce critical-illness polyneuromyopathy (CIPNM), which may lead to weaning failure and prolonged mechanical ventilation. In a systematic review of 24 studies, the main risks factors for CIPNM were sepsis, multiple organ failure, and protracted mechanical ventilation (immobilization), but not corticosteroids [17]. Several studies in patients with ALI/ARDS [8–10] or trauma [11] reported more rapid ventilator-weaning with moderate-dose corticosteroids. That muscle weakness may be triggered by systemic inflammation is supported by the observation of high interleukin-6 levels as a risk factor for early myopathy [18]. A higher risk for muscle weakness was reported when patients with ARDS were treated late with higher doses than those currently recommended [8]. Overall, there is currently no clear evidence that early-administered moderate-dose corticosteroids induce CIPNM, whether inhibition of inflammation is protective requires further investigation. Notably, none of the recent studies emphasized CIPNM as a major outcome measure, probably underestimating the incidence of CIPNM. The combination of muscle relaxants and corticosteroids was associated with an increased risk of muscle weakness and should be avoided [2].

Other side effects

Moderate-dose corticosteroids may increase the risk of hyperglycaemia (relative risk 1.16, 95% CI, 1,07–1.25, $p < 0.001$) [15]. Beside the absolute glucose value, glucose variability gains increasing attention as a risk factor for mortality. A continuous infusion of corticosteroids may be advantageous to repetitive bolus applications, which were associated with more glucose undulation and staff workload to maintain an aspired glucose level [19,20]. Due to the intrinsic mineralocorticoid activity of hydrocortisone, there is an increased risk for hypernatraemia (relative risk 1.61, 95% CI, 1.26–2.06, $p < 0.001$) [15]. Abrupt cessation of corticosteroids may produce immunologic (inflammation) and haemodynamic (shock) rebound effects [6], and the need of re-intubation due to respiratory failure [2,8]. The risk of gastrointestinal bleeding is not increased [15].

CHAPTER 55

Immunotherapy in critical illness

Hans-Dieter Volk and Levent Akyüz

Key points

- There is a clear need for immunological stratification of critically-ill patients for improved efficacy of immune modulation.
- Immunostimulation cannot be recommended without immune monitoring.
- Immune modulation is a promising approach, despite many disappointing results, particularly with anti-inflammatory approaches.
- Some immunostimulatory cytokines are able to restore the immunocompetence.
- The reduction of hyperinflammation by broad inhibition of key pro-inflammatory transcription factors is not very promising.

Immunotherapy

The immune system plays an important role in the treatment of critically-ill patients. Adequate immune response is essential for wound healing and control of invading pathogens and, consequently, reducing immunosuppression in critically-ill transplant patients suffering from severe infection/sepsis aids pathogen control. However, this can be a dangerous approach if no immune monitoring is used to guide adequate immunosuppression dependent on individual immune competence/failure ('immunoparalysis'). Moreover, there are some promising pilot studies on immunostimulation granulocyte colony stimulating factor (G-CSF), granulocyte-macrophage colony-stimulating factor (GM-CSF), interferon-gamma (IFN-g) in non-immunosuppressed septic patients with 'immunoparalysis' that require prospective validation in multicentre trials [1–3].

On the other hand, there is no doubt that overwhelming inflammation can result in multiple organ failure and shock [4]. Unfortunately, all approaches to target inflammation (steroids, anti-tumour necrosis factor (TNF) monoclonal antibody (mAb), etc.) have failed, probably because of failure to stratify patients immunologically. This also demonstrates that our animal models are poorly predictive for the clinical course.

The goal of immunotherapy is to readjust the patient´s individually imbalanced immunological responsiveness.

Presently, immunotherapy in critically-ill patients is at a clinical experimental level—no therapy is approved so far. The treatment can include enhancement, suppression, or induction of the immune system. The decision starts with the question whether the therapeutic selection matches the clinical (immunological) need. To develop a potential therapeutic strategy we need to know the pathogen, the immune status of the patient, and the interaction between the particular pathogen and immune cells. The right treatment at the correct time point is crucial for a better outcome and the best economic use of resources is a difficult decision.

The best personalized immunotherapy is dependent on the available biomarker for the selection of the right patient and the right time point. Therefore, future studies on new immunotherapeutic approaches in critically-ill patients can only be interpreted in combination with immunological biomarker analyses.

Enhancement of the immune system by immunostimulatory therapeutic drugs

Inhibition of hyperinflammation

Trauma, major surgery, stroke, and sepsis induce an inflammatory response by activating pattern recognition receptors (PRRs) on cells of the innate immune system (e.g. Toll receptors) that can be amplified by stimulation of lymphocytes. Lymphocytes can be triggered both antigen-specifically (via T-cell receptor) or non-specifically (bystander activation via cytokine receptors). In preclinical experiments TNF-α, interleukin-1 (IL-1), and downstream products play a key role in the pathogenesis of systemic inflammation, organ failure, and shock. Consequently, targeting hyperinflammation seems to be a promising option to improve septic multi-organ failure, further supported by promising in vivo preclinical data (in the wrong models). However, the results are very disappointing.

Systemic glucocorticoids block the cytokine response. Glucocorticoids cross the cell membrane and down-regulate inflammatory mediators by modifying the transcription factors NF-κB and activator protein-1. This can be mediated by direct and indirect interaction by stimulating inhibitory factors, like IκB, and by blocking the DNA-binding of transcription factors, respectively.

The production of inflammatory cytokines, such as TNF-α and IL-6 are thus diminished [5]. This physiological property with the capacity to counteract hyperinflammation was used in many clinical studies and the treatment of critically-ill patients. Studies with high doses of glucocorticoids show no benefit in mortality or adverse events [6]. The trend was even higher in mortality in steroid-treated groups. A link between high dose and higher mortality has been shown in meta-analyses [7]. Treatment with low dose hydrocorticoids is still suggested, but only to treat adverse effects without beneficial in survival.

Controlling the immunoresponse under hyperinflammatory conditions was the aim of several clinical studies. To summarize,

Table 55.1 Some anti-inflammatory agents used in clinical trials of ICU patients

Drugs	Routes of administration	Function	Target
Hydrocorticoid	iv	Reduction of local and systemic inflammation, restore haemodynamic stability	Various cells
Eculizumab	iv	Monoclonal antibodies against C5	Complement activation downstream C3b
Afelimomab, Adalimumab	iv	Monoclonal antibody against TNF-alpha	TNF-α
Anakinra	iv	IL-1 receptor antagonist	IL-1
Tocilizumab	iv	Monoclonal antibody against IL-6 receptor	IL-6

iv, intravenous.

the reduction of hyperinflammation by broad inhibition of key pro-inflammatory transcription factors is not very promising.

However, specific targeting of key cytokines TNF-alpha and IL-1, both key players in (not so relevant) preclinical models, by specific biologics (antibodies, fusion proteins) revealed similar disappointing results.

Targeting TNF-α as a therapeutically approach showed beneficial results in animal model studies [8]. However, the large human clinical studies with monoclonal antibodies or soluble TNF-receptor fusion proteins as well as IL-1RA, generally failed to improved survival [9].

Another approach is to modulate the host innate response by targeting pattern recognition receptor (PRRs), like Toll-like receptors (TLRs). TLRs sense bacterial compounds, like lipopolysaccharide (LPS) or microbial nucleic acids, as well as damaged cells to trigger the innate inflammatory response. Targeting TLR to reduce inflammation by blocking TLR-4, however, failed in septic patients [10,11].

Interestingly, promising results could be observed in a proof-of-concept trial using the selective immunoabsorption of LPS, IL-6 and complement-activation product 5a (C5a). Reducing these factors in critically-ill patients leads to an increased monocytic HLA-DR expression (recovery from 'immunoparalysis') and improved organ function. The beneficial outcome on survival in patients with sepsis has to be demonstrated in a larger well-controlled study [12]. Moreover, it is not clear whether the decrease in C5a alone or the combination of targeting C5a, LPS, and IL-6 was most important for the beneficial effects in this proof-of-concept trial. C5a seems to be a key player in mediating negative effects of systemic inflammation. Monoclonal antibodies, such as eculizumab, against C5 are a promising therapeutic tool to treat critically-ill patients infected with pathogens like enterohaemorrhagic *E. coli* (EHEC) or haemolytic uremic syndrome–associated enterohaemorrhagic *E. coli* (HUSEC) [13]. Guidelines suggest a plasmapheresis within 24 hours to remove complement components C5a or the treatment with the monoclonal antibody targeting C5, eculizumab (Table 55.1).

Restoration of immunocompetence

As suggested in Table 55.1, the phenomenon of immunodepression, sometimes called compensatory anti-inflammatory syndrome (CARS) with its most severe form, 'immunoparalysis', is well recognized in critically-ill patients. It has a major impact on the competence of pathogen defence, wound healing, and tissue regeneration. It can be detected by standardized immune parameters, such as quantitative monocytic HLA-DR expression, ex vivo Toll-receptor triggered cytokine response, ex vivo T-cell responsiveness, and recently revealed molecular markers. There are some immunostimulatory cytokines that are able to restore the immunocompetence.

Both IFN-g and GM-CSF recover the monocytic HLA-DR expression and cytokine release [14]. Proof-of-concept trials demonstrated the power of these cytokines for recovery from 'immunoparalysis' [2].

Immunostimulation cannot be recommended without immune monitoring. Dependent on the individual immune responsiveness, the treatment might be beneficial or harmful. Treatment with IFN-g or GM-CSF during the dominant hyper-inflammatory phase might result in amplification of inflammation associated with enhanced multiple organ failure. Treatment during the phase of an exhausted immune response ('immunoparalysis') might help to readjust the immune system. Therefore, stratification of patients is a key issue.

Stress response induces inhibition of the innate responsiveness (e.g. drop of monocytic HLA-DR and cytokine release) and targets an adaptive response by inhibiting type I T-cell response or

Table 55.2 Some candidates for immunostimulation tested in critically-ill patients

Drugs	Routes of administration	Function	Target	Side effects
IFN-g	sc, iv	Increased expression of MHCI and II, anti-viral activity, activation of macrophages	Various cells	Fever, diarrhoea, muscle soreness
GM-CSF	sc	Granulocytes recruitment, monocytes, and eosinophil differentiation	Stem cell	Bone pain, mylagia, alopecia, fever

sc, subcutaneous; iv, intravenous.

inducing T/B cell apoptosis. IFN-g can replace some of the missing T-cell functions, but there is no drug to reconstitute specifically adaptive immune systems. The beneficial effects of removing T-cell targeting drugs (like calcineurin inhibitors) in critically-ill transplant patients suffering from severe infection demonstrate the need of sufficient adaptive T-cell response for recovery. A novel approach might be adoptive transfer of specific T cells, as shown in murine stroke models, but the proof is still missing (Table 55.2).

To summarize, immune modulation is a promising approach, despite many disappointing results particularly with anti-inflammatory approaches. There is a clear need for immunological stratification of critically-ill patients for improved efficacy, and the search for new clinical endpoints in surviving patients with medical and health-economical impact.

PART 2.8

Fluids and diuretics

CHAPTER 56

Colloids in critical illness

Andrew Webb

Key points

- An adequate circulating volume must be provided before considering other methods of circulatory support.
- The use of fluid to restore circulating volume is essential before resorting to inotropes in the hypovolaemic patient.
- Smaller volumes of colloid than crystalloid are required for resuscitation leading to quicker resuscitation.
- No mortality benefit has been demonstrated between patients resuscitated with colloid or crystalloid.
- The volume required for correction of hypovolaemia can be determined by the haemodynamic effect of small aliquots of plasma substitute.

Introduction

Intravenous (iv) fluids used for volume replenishment in critical care practice encompass a range of crystalloids and colloids. Colloids include: albumin, dextran, gelatin, and hydroxyethyl starch.

Pharmacology

Colloid solutions are homogenous mixtures of large molecules suspended in a crystalloid solution. They intend to substitute some properties of plasma, particularly increasing the capillary colloid osmotic pressure, thus increasing the intravascular retention of plasma.

The efficacy of colloids as volume substitutes or expanders and length of effect are determined by their physicochemical properties, which determine the number of colloid particles in solution and their persistence.

Albumin

Albumin is the fraction of plasma that provides the major part of the circulation's colloid osmotic pressure, and therefore it has been used as a plasma substitute. Although it is naturally occurring, there is a certain amount of heterogeneity in circulating albumin. Albumin for infusion is virtually free from disease transmission since it is heated to 60°C for approximately 10 hours following fractionation. The fractionation process contributes further heterogeneity since the final product contains some dimers and longer-chain polymers. Storage of albumin solutions may produce further heterogeneity through the formation of unstable polymers, which may affect *in vivo* characteristics.

Albumin is the main provider of colloid osmotic pressure in the plasma. The solution has a net negative charge, which helps retain colloid molecules within the vascular space by repulsion from the capillary endothelium and enhances the colloid osmotic pressure by the Gibbs–Donnan effect [1]. Albumin has a number of other functions [2]:

- Transport of various molecules.
- Free-radical scavenging.
- Binding of toxins.
- Inhibition of platelet aggregation.

Human albumin solutions have been used successfully as plasma substitutes and, in view of their natural occurrence, are often considered as the standard with which synthetic plasma substitutes are compared. The major limitations to the use of human albumin solutions are their high production costs and limited supplies.

Gelatin solutions

Gelatin is a degradation product of animal collagen and, therefore, is inexpensive and readily available. Gelatin polypeptides are chemically modified to reduce the gel melting point, while retaining sufficient molecular size for intravascular retention. In the manufacture of urea-bridged gelatin (polygeline) polypeptides of molecular weight 12–15 kDa are formed by thermal degradation of cattle bone gelatin and, subsequently, cross-linked by hexamethyl di-isocyanate. In the manufacture of succinylated gelatin polypeptides of molecular weight approximately 23 kDa are produced by thermal degradation of calf skin collagen. These polypeptides are reacted with succinic acid anhydride to replace amino groups with acid carboxyl groups. No cross-links are formed, but the increased net negative charge on the molecule produces a conformational change to open coils, as well as an enhanced colloid osmotic pressure by the Gibbs–Donnan effect [1]. Although little increase in molecular weight is produced by this reaction, molecular size is increased, allowing better intravascular retention. Urea-bridged gelatin (polygeline) is a 3.5% solution and contains calcium (6.25 mmol/L). The calcium content prevents the use of the same administration set for blood transfusions. Succinylated gelatin is a 4.0% solution with a slightly longer effect. This and the lack of calcium in solution make this a more useful solution than polygeline for short-term plasma volume expansion. Gelatins are largely excreted unchanged via the kidneys with minimal metabolism by proteases.

Dextran solutions

Dextrans are high molecular weight polysaccharides. They are natural substances produced by the action of the enzyme dextran sucrase during the growth of various strains of the bacteria

Leuconostoc in media containing sucrose. After partial hydrolysis of raw dextran (molecular weight between 10^4 and 10^5 kDa), the resulting hydrolysate is fractionated to produce dextran molecules of average molecular weight 70–75 kDa. Since 1953, *Leuconostoc mesenteroides B512* has been the strain used for the manufacture of clinical dextrans. Other strains have been shown to produce dextran molecules with greater degrees of branching, and these molecules were associated with more immunological reactions. Over 90% of the branches in dextran molecules produced by *L. mesenteroides B512* are α1–6 glucosidic bonds, giving relatively few side-chains [3].

Dextran 70 is available as in an isotonic solution or a hypertonic saline solution intended for small volume resuscitation. Dextran 40 is hyperoncotic, but is largely excreted without metabolism.

Hydroxyethyl starch solutions

Unmodified starch is unsuitable as a plasma substitute since it is broken down rapidly by amylase. The hydroxyethylation of starch protects the polymer against breakdown by amylase. Waxy starches consisting of 98% amylopectin are used in the manufacture of most hydroxyethyl starches although potato starch, consisting of 75% amylopectin is used for manufacture of some tetrastarches [4]. After hydrolysis of amylopectin, which is a highly-branched polysaccharide resembling natural glycogen, to reduce viscosity, the solution is treated with ethylene oxide in the presence of sodium hydroxide as a catalyst. Thus, glucose units are substituted with hydroxyethyl groups at positions C2, C3, and C6. The characteristics of hydroxyethyl starch solutions are dependent on the range of molecular weights, the degree of substitution of glucose units by hydroxyethyl groups, and the ratio of C2–C6 substitution. In general, higher molecular weights, higher degrees of substitution, and a high ratio of C2–C6 substitution are associated with more prolonged effects. As experience has been gained with hydroxyethyl starch solutions a balance between the safety profile of solutions and effective volume expansion has been sought by reducing molecular weight and degree of substitution while maintaining higher C2:C6 substitution ratio [5]. Smaller hydroxyethyl starch molecules are excreted unchanged in the urine, but larger molecules must be metabolized by amylase first. As larger molecules are broken down the colloid osmotic effect is maintained, since it is dependent on the number of particles. However, a recent systematic review of trials of lower molecular weight hydroxyethyl starch versus human albumin or crystalloid in sepsis showed no advantage in safety [6].

Uses

Correction of hypovolaemia

Colloid solutions are generally used for the maintenance of plasma volume and acute replacement of plasma volume deficit. Early administration of fluid often corrects features of shock, such as hypotension or oliguria. Hypovolaemia must be treated urgently to avoid the serious complication of progressive organ failure. Indeed, milder degrees of hypovolaemia are associated with the pathophysiological changes leading, ultimately, to organ failure or dysfunction.

Most studies have failed to demonstrate a mortality advantage for resuscitation with colloid, rather than crystalloid and some have demonstrated additional morbidity with colloid [7–10]. However, the CRISTAL trial showed a 90-day mortality advantage for resuscitation with colloid in patients predominantly presenting with hypotension and lactaemia [11]. The ALBIOS trial also showed a mortality advantage in a post-hoc analysis in septic shock patients at 90 days [9]. Resuscitation by smaller volumes is quicker and easier. Plasma substitutes maintain plasma colloid osmotic pressure, but they contain no clotting factors or other plasma enzyme systems.

Where blood loss is the cause of hypovolaemia, it would seem logical to use blood as the replacement fluid. However, while whole blood would achieve an adequate increase in circulating volume, the high haematocrit of packed red cells will correct red cell volume with less effect on plasma volume. Therefore, it is appropriate to consider replacing the plasma volume deficit with a plasma substitute.

It should be noted that plasma substitutes are carried in 0.9% saline or balanced electrolyte so that the majority of critically-ill patients will not require salt-containing crystalloid infusions if colloid solutions are used.

The volume required for correction of hypovolaemia is determined by the haemodynamic effect of the fluid given. Most colloid solutions are subject to maximum limits suggested by the manufacturers on the basis of available research and safety data.

Fluid challenge

The fluid challenge is a method of safely restoring circulating volume [12]. The response of central venous pressure (CVP) and stroke volume should be monitored during a fluid challenge (Fig. 56.1). The change in CVP after a 200-mL fluid challenge depends on the starting blood volume. A significant rise in CVP (3 mmHg) is probably indicative of an adequate circulating volume. However, a positive response may sometimes occur in the vasoconstricted patient with a low blood volume. In addition, it is important to assess the clinical response—if it is inadequate, it is appropriate to monitor stroke volume response, a rise of 10% after a 200-mL fluid challenge being indicative of fluid responsiveness.

Other disease states

Colloids have been used in a number of specific disease states, although in most cases their use has not been justified by evidence.

Nutritional supplementation

Despite the association of hypoalbuminaemia and high morbidity [13], the Cochrane Injuries Group meta-analysis demonstrated an increased mortality in patients who received albumin supplementation to correct hypoalbuminaemia [14]. There is no evidence that maintenance of plasma albumin levels, as opposed to maintenance of plasma colloid osmotic pressure with artificial plasma substitutes, is advantageous [2].

Cirrhosis and acute liver failure

In cirrhotic liver disease there has long been a tendency to give iv albumin infusions during paracentesis. Studies have shown that this practice has no benefit over infusion of synthetic colloids [15]. In-patients with cirrhosis and spontaneous bacterial peritonitis, renal function frequently becomes impaired. This impairment is probably related to a reduction in effective arterial blood volume and is associated with a high mortality. A randomized controlled study patients with cirrhosis and spontaneous bacterial peritonitis showed a reduction in the incidence of renal impairment and death in patients who received iv albumin and antibiotics in comparison

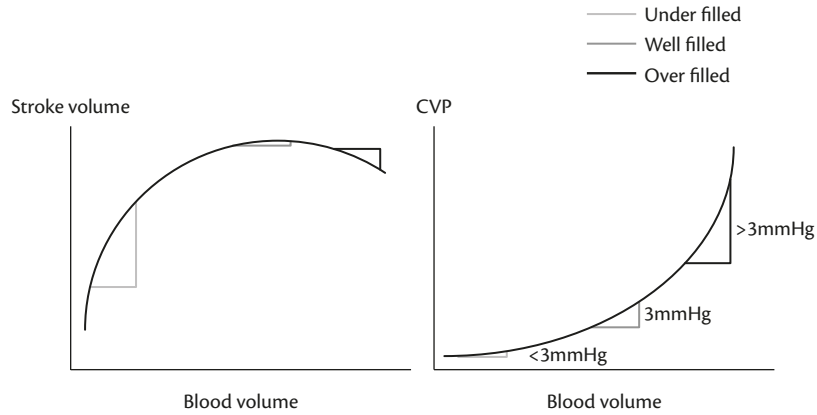

Fig. 56.1 The response of stroke volume and CVP to small-volume fluid challenges. In the hypovolaemic patient, an increase in stroke volume with no significant rise in CVP would be expected. In the optimally-filled patient a rise in CVP with no significant rise in stroke volume would be expected.

with patients who only received treatment with an antibiotic alone [16]. The mechanism by which albumin exerted such a beneficial effect is unclear. It remains possible that the effect of the albumin was simply expansion of the intravascular volume. Whether that effect is specific for albumin infusion or would be achieved with other fluids was not addressed.

Albumin is also used in the dialysate in extra-corporeal albumin dialysis for cirrhosis and acute liver failure. The procedure removes toxins bound to albumin in the blood as well as water-soluble, dialysable. The albumin in the dialysate is 'regenerated' by being passed through an anion exchange resin and activated charcoal. Although biochemical improvements have been demonstrated with the technique survival benefit has yet to be demonstrated [17].

Adverse effects

Adverse reactions include the infusion of excess volume, which may be associated with oedema. Oedema formation may occur despite infusion of apparently appropriate volumes, particularly in capillary leak states. Conversely, the consequences of the minor side-effect of oedema may be necessary to ensure adequate resuscitation.

Allergic phenomena are associated with all colloid fluids [18]. These may range from urticaria (the most common effect seen with gelatins) to severe anaphylaxis with cardiovascular collapse (more commonly seen with dextrans). Reactions may be classical IgE-mediated or complement-mediated and delayed in onset. The incidence of allergic reactions is low with any of the colloid solutions (0.01–0.15%). With longer-acting colloid solutions (e.g. high molecular weight hydroxyethyl starch), anaphylactoid reactions may require prolonged support.

Haemostatic defects include dilution coagulopathy associated with any plasma substitute. In addition, dextrans reduce the activities of factors V and VIII, fibrinogen, and prothrombin, decrease platelet adhesion, and prolong bleeding time. These effects are exploited in microsurgery, where dextran 40 is often used as an anticoagulant. Hydroxyethyl starch solutions also reduce factor VIII activity and platelet aggregation (rather than adhesion), again particularly with higher-molecular-weight fractions [7]. These effects are rarely associated with clinical bleeding.

Hydroxyethyl starch solutions have been associated with an increased incidence of acute kidney injury in sepsis, renal transplant and cardiac surgery patients [7,8]. Non-allergic pruritis has also been associated with tissue storage of hydroxyethyl starch, again more commonly with higher molecular weight fractions [7]. Both effects appear to be dose related.

CHAPTER 57

Crystalloids in critical illness

Karthik Raghunathan and Andrew Shaw

Key points

- A revised Starling model describes fluid distribution across body compartments with the endothelial glycocalyx playing a central role in determining fluid disposition.
- Crystalloids produce important negative consequences with both inadequate and excessive resuscitation.
- During critical illness, crystalloid dose may be based on functional measures such as pulse pressure variation.
- Balanced crystalloid solutions may be advantageous over 'normal' (isotonic) saline.
- Crystalloids may have significant effects on immune and renal function, beyond their direct effects on cardiovascular function.

Background and epidemiology

Fluids are central to the management of critical illness, yet are rarely afforded the same degree of consideration as other drugs in the intensive care unit (ICU). Current estimates, based on a recent survey across 25 countries, suggest close to 40% of ICU patients receive resuscitation fluids each day [1]. Practice patterns show wide variations in the type and volume of fluid used in ICUs [1].

'Crystalloid' conventionally refers to solutions of crystalline substances that can pass through a semipermeable membrane and distribute widely in body fluid compartments. Typical solutions include isotonic 'normal' (0.9%) saline or fractions of 'normal' saline (such as half or quarter normal saline, 0.45 or 0.225% saline, respectively) with or without glucose, and other physiological or balanced solutions with electrolyte concentrations closer to plasma.

The 'crystalloid versus colloid' debate has raged for decades. Most large randomized controlled studies [2] have consistently found no survival advantage with colloids. However, the recently published CRISTAL trial reported that colloids may indeed have an advantage when used for resuscitation in acutely hypovolaemic patients [3]. However, ICU surveys prior to this have shown that colloids were administered to more patients during more resuscitation episodes than crystalloids [1] and this practice variation reflected local preferences, rather than differences in the patient-mix. Recent evidence [4,5] suggests the efficacy of volume expansion (i.e. the fraction of infused fluid retained within circulation that potentially augments cardiac output) depends on the underlying volume status, capillary pressures, and/or the patient's pathophysiological state. Optimal ICU outcomes often result from interventions beginning well before ICU admission. Pre-emptive haemodynamic optimization in patients undergoing major surgery favours colloids [6], since direct comparisons between goal-directed colloid therapy versus goal-directed crystalloid therapy are limited. Crystalloids tend to load the interstitial space in this setting. However, during resuscitation in shock states there is little apparent benefit of colloid use. Crystalloids have been shown to be equivalent and in several settings (e.g. traumatic brain injury) superior to colloids. In addition, crystalloids have variable electrolyte concentrations, volumes of distribution, and consequently have variable effects on plasma pH. The strong ion difference for various crystalloid solutions may vary widely ranging from 0 through 50. Since within-group differences may exceed between-group differences global crystalloid-colloid comparisons are inappropriate.

Pathophysiology

According to the classic Starling model, total body water (TBW) accounts for 60% of the lean body weight (LBW) in adults and is proportioned into: intracellular (IC, 40%) and extracellular (EC, 20%) spaces. EC volume is further divided into intravascular (5% of LBW) and interstitial fluid (ISF) compartments (15% LBW). Crystalloids are expected to distribute across these compartments proportionately, based on their composition. Transvascular exchange is based on the balance of opposing hydrostatic and oncotic forces acting across semi-permeable barriers. Net filtration occurs based on these pressure differentials as per the Starling–Landis equation:

$$J_v = k_f\left[\left(P_c - P_i\right) - \sigma\left(\pi_c - \pi_i\right)\right]$$

where J_v is net fluid movement, k_f is the capillary filtration coefficient, $P_c - P_i$ is the capillary hydrostatic pressure—ISF hydrostatic pressure, σ is the reflection coefficient and $\pi_c - \pi_i$ is the capillary oncotic pressure—ISF oncotic pressure]). Based on these assumptions, only about 7% of an infusion of electrolyte-free water (glucose solutions) should remain intravascular and if an isotonic saline solution is used, the expected efficacy of plasma volume expansion is about 20%. The classic Starling model might allow for fluid recruitment into the vascular compartment from the ISF, if capillary oncotic pressures are adequate to overcome the outward hydrostatic gradient. Colloids might also be predicted to be superior for the resuscitation of hypoalbuminaemic critically-ill patients. However, observations of fluid behaviour during critical illness are not consistent with these predictions [2,5].

To address inconsistencies, a revised Starling model has been developed incorporating a central role for the endothelial surface layer (ESL). This interface between blood and the capillary

wall resists fluid and solute filtration to varying degrees depending on the continuity of and fenestrations in the endothelium [5]. Different types of tissue capillary arrangements exist with sinusoidal tissues essentially continuous with plasma (marrow, spleen, and liver), glomerular filtration occurring via open fenestrated capillaries and continuous non-fenestrated capillaries acting as intact barriers to filtration in most tissue (muscle, lung, connective tissue). The glycocalyx, a key part of the ESL, is semi-permeable with an oncotic gradient across it, rather than across the vessel wall. Plasma proteins, including albumin, leak into the ISF via a relatively small number of large pores. There is *no* net fluid *absorption* across the capillary wall and filtered fluid is returned into circulation as lymph. Transvascular filtration is based on capillary pressures and is determined, in part, by the underlying volume status of the patient. With supranormal capillary pressures, crystalloid infusions will lower oncotic pressures (secondary to a dilutional effect) with resulting greater transvascular filtration into compliant ISF spaces. Therefore, in the presence of an intact endothelial glycocalyx layer (EGL) and euvolaemia, colloid infusions may sustain plasma expansion better (e.g. with pre-emptive goal-directed optimization in surgical patients). At lower capillary pressures during hypovolaemia, volume expansion with crystalloids is effective since transvascular filtration decreases linearly. Also, crystalloids may be more efficient plasma expanders than expected because the actual EC space available for equilibration is limited (by rigid structures or fibrous capsules). Crystalloid retention increases during hypovolaemic states, while the clearance is significantly reduced. Lower arterial pressures also reduce crystalloid clearance, while infusions of alpha-adrenergic agonists significantly accelerate this clearance. Overall, this revised model supports crystalloid utilization in most critical care settings where the ESL is disrupted and supports limiting colloid use to euvolaemic resuscitation at higher capillary pressures with an intact ESL [5].

During critical illness or with systemic inflammation, the ESL is compromised with increased vascular permeability and significant transcapillary escape of albumin [7,8]. There is 'no net absorption' explaining why attempts to raise the capillary oncotic pressure—with the aim of 'recruiting' interstitial fluids into circulation—are not successful. Crystalloid accumulation occurs in compliant loose connective tissues, such as with extravascular lung water (EVLW) and, in muscles or gastrointestinal mesentery, but not in other non-compliant tissues (marrow, liver, spleen, kidney). When the ESL is damaged, colloids are not retained within the intravascular space and would not offer any significant haemodynamic advantage. Thus, the context in which crystalloids are used is a key determinant of its disposition. When hypotension is a result of heart failure or vasoplegia, continued crystalloid use, as opposed to appropriate inotrope or vasopressor use, will result in decreasing clearance and increasing fluid sequestration. Thus, the continued administration of crystalloids in a volume non-responder is especially deleterious.

'Volume kinetics', based on the mathematical modelling of fluid disposition analogous to drug pharmacokinetics, describes the peak effects, distribution, and clearance of crystalloids. A two-compartment model has been developed and appears to fit observed kinetics. Three model parameters are described—volume of distribution, inter-compartmental transfer, and an elimination constant. From a clinical perspective, the elimination of a large, rapidly infused volume of saline is independent of the infused volume. The implication is that rapid crystalloid accumulation occurs after large fluid boluses are administered and the use of fluids under disrupted ESL conditions will result in undesirable accumulation (e.g. EVLW). The relationship between volume overload and poor ICU outcomes is well recognized. Consequently, the titration of crystalloid therapy based on functional dynamic parameters is warranted.

Dosing

The key to dosing crystalloids in the ICU is to address ongoing losses and the need for circulatory support (avoiding under-resuscitation), while continually assessing the need for 'routine maintenance' avoiding the replacement of unmeasured presumed fluid deficits (avoiding over-resuscitation). Threshold central venous pressure (CVP) values continue to be advocated in critical care settings (particularly in septic patients) as targets for early goal-directed fluid therapy in mechanically-ventilated and spontaneously breathing populations [9]. Such CVP-guided crystalloid therapy may be inappropriate and even harmful [10]. Decision-making regarding fluid therapy should be based on objectively-defined individualized functional dynamic parameters, such as the pulse pressure variation (PPV) [11,12] or flow-based/cardiac output related measures [12]. These measures can distinguish between volume responders and non-responders in mechanically-ventilated patients, and resuscitation and de-resuscitation can be guided by such measures in a 'gray zone' approach [11]. Fluids may be given or withheld based on the relative position of each patient on their Frank–Starling curve and the clinical context. Crystalloids dosed in this manner are based on individual assessment of left ventricular pre-load responsiveness balancing 'too little' against 'too much'. Patients may receive diuretics when appropriate, for instance, in the mechanically-ventilated patient with acute lung injury in a normal sinus rhythm with a PPV below 10%. The accumulation of crystalloids as in EVLW may be reduced with this approach. Conversely, early in sepsis a PPV of 12% or higher might indicate the continued need for aggressive crystalloid boluses [11]. Formulaic crystalloid administration especially in surgical populations (such as hourly maintenance rates, based on actual body weight) should be rejected in favour of minimal crystalloids for the replacement of measured losses. Post-operative replacement of 'third space losses' following major abdominal surgery with large volume hourly maintenance crystalloid infusions is especially detrimental.

Key limitations of PPV should be acknowledged including its lack of discriminant ability in spontaneously-breathing patients, in patients with significant arrhythmias, or in those receiving low tidal volume ventilation with reduced lung compliance. In such scenarios, the use of minimally-invasive techniques (such as oesophageal Doppler measures, echocardiographic measures of inferior vena cava collapsibility, etc.) coupled with reversible volume challenge manoeuvres, such as passive leg raising (PLR) might uncover 'recruitable stroke volume'. Cardiac output may be appropriately maximized with crystalloid therapy if PLR manoeuvres or mini-fluid challenges augment circulation. Optimal timing needs to be defined as well. Randomized trials suggest that early crystalloid resuscitation (i.e. within 6 hours of the onset of systemic inflammatory response syndrome) [9] with late restriction and 'de-resuscitation' (beyond 72 hours into critical illness) improves outcomes [13].

Composition

Plasma pH, according to Stewart's approach to acid-base disorders, is influenced by the composition of the crystalloids administered. In this sense, crystalloid administration is an acid-base intervention. Crystalloid loading causes dilution of plasma weak acids raising the plasma pH (alkalosis). On the other hand, crystalloids with a low strong ion difference (SID, approximated by the difference between sodium and chloride concentrations) will narrow the plasma SID driving the pH down (acidosis). Crystalloids with higher SID will tend to minimize this acidotic effect. Although no major clinical trials in the critically ill have compared different types of crystalloids (with SID differences) head-to-head, pre-clinical and observational data suggest that solutions with a low SID and high chloride concentrations (isotonic saline or its variations) may be associated with worse outcomes than balanced solutions. Balanced crystalloids will allow the plasma SID to fall just enough (causing acidosis) to counteract the alkalotic effects of plasma weak acid dilution [14].

In shock states, plasma SID is decreased with metabolic acidosis caused by lactataemia. Isotonic saline has a chloride concentration 1.5 times higher than plasma and has a SID = 0. Resuscitation with saline might be predictably lower the plasma SID resulting in further acidosis. When isotonic saline is given as the primary resuscitation fluid, the result is a predictable hyperchloraemic metabolic acidosis. Such acidosis may give rise to adverse effects including immune [15], gastrointestinal [16], and renal dysfunction [16]. Electrolyte abnormalities are seen more commonly in saline-treated patients and significant fluid replacement with saline (such as during trauma resuscitation) may induce sufficient changes in plasma acid-base balance to affect the immune response. Hyperchloraemia induces intrarenal vasoconstriction in humans and decreased renal function is associated with neutrophil dysfunction and decreased bacterial clearance [17]. A large observational study comparing patients undergoing major open abdominal surgery receiving exclusively saline versus a calcium-free balanced crystalloid on the day of surgery, found greater resource utilization, and risk of infectious and renal complications in the saline group [18]. These differences were especially marked in those undergoing emergent surgery, a population that typically receives care in the ICU post-operatively. Worsening acidosis, due to a saline-based resuscitation strategy, may be mistaken for inadequate tissue perfusion in the setting of septic shock [19]. Unwarranted corrective measures may involve further aggressive volume loading to remedy the presumed perfusion deficit. Such misguided attempts to reverse or correct acidosis may result in increased morbidity and mortality. In summary, there are plausible adverse effects of hyperchloraemic acidosis from saline administration. The routine use of saline for resuscitation and favour the use of alternate balanced solutions with a strong ion difference closer to plasma is cautioned against. It is suggested that saline use be restricted to co-administration with blood products, for the treatment of hydrochloric acid loss and of brain injured patients, as there is evidence that using colloidal solutions or hypotonic solutions results in suboptimal outcomes in this population [20]. Regardless of the chloride concentration, crystalloid solutions with SID (such as glucose-containing solutions, saline, 'half-normal saline', etc.) are going to lower plasma pH. The use of solutions that are closer to plasma in electrolyte concentration and SID are likely to be associated with better outcomes. Thus, the goal of crystalloid use must be to administer the right type of crystalloid at the right time and in the right amount.

CHAPTER 58

Diuretics in critical illness

Marlies Ostermann and Ruth Y. Y. Wan

Key points

- There is no role for diuretics to improve renal function or outcome in patients with acute kidney injury, although an increase in urine output may be achieved, which may be beneficial in patients who are fluid overloaded.
- Diuretics are often prescribed to patients with acute heart failure, but may be harmful since many patients are not fluid overloaded despite the presence of pulmonary oedema.
- Combination therapy with different diuretics is often necessary in resistant oedema, including advanced heart failure and chronic liver disease.
- In chronic kidney disease, the thiazide metolazone is commonly prescribed with furosemide to maintain fluid balance, but there is little data to suggest a mortality or morbidity benefit.
- Effective diuresis is easier to achieve with continuous infusion of loop diuretics compared with bolus therapy, but there is no evidence of better outcome.

Introduction

Diuretics are most commonly used in conditions characterized by fluid overload (including heart failure, acute and chronic kidney disease, nephrotic syndrome, and chronic liver disease) and chronic hypertension. Despite their frequent use, there is uncertainty regarding optimal dosing, route of administration (oral (po) versus intravenous (iv) bolus versus infusion) and the role of combination therapy, especially in the critical care setting.

Types of diuretics

Diuretics can be classified in terms of their site of action and behaviour along the nephron (Table 58.1). Diuretics act from within the tubular lumen. With the exception of spironolactone and mannitol, they are protein bound and are delivered to their site of action by secretion via organic anion transporters in the proximal tubular cells. The intrinsic secretory capacity of the proximal tubule controls the quantity of diuretic that enters the tubule. Patients with an estimated glomerular filtration rate (GFR) of 15 mL/min/1.73 m^2 secrete only 10–20% of the amount of loop diuretic that is secreted into tubular fluid in patients with a normal GFR receiving similar doses. As a result, they need a higher dose to elicit a similar diuretic response. In addition, a reduction in GFR reduces the filtered load of extracellular fluid and Na^+, which also limits the maximum achievable response to any diuretic.

Other factors that influence tubular secretion and drug availability include actual dose administered, absolute bioavailability (for orally administered drugs), renal blood flow, and potential competition for tubular secretion due to metabolic acidosis or co-administration of drugs.

Indications for diuretics

Acute kidney disease

Experimental data suggest that furosemide reduces the oxygen and metabolic requirements of tubular cells, and increases oxygen concentration in the medulla [1]. This led to the hypothesis that furosemide may be beneficial in early acute kidney injury (AKI), and prevent progression and/or reduce its severity. Three meta-analyses concluded that the use of diuretics in established AKI did not improve renal function, speed up recovery, or change mortality, but carried a significant risk of side-effects, including electrolyte derangement, ototoxicity, and vestibular dysfunction [2–4]. There is also no evidence that diuretics are effective in restoring renal function in patients on renal replacement therapy (RRT) [5]. However, diuretics may have a role when treating patients with AKI and significant fluid overload, especially if RRT is not immediately available.

Most of these data stem from small studies. A large randomized controlled trial is currently recruiting patients to evaluate the role of furosemide in AKI (SPARK Study) [6]. The aims of this study are to compare the efficacy and safety of a continuous infusion of furosemide versus placebo in early AKI on progression of kidney injury. Secondary endpoints include fluid balance, the need for RRT, electrolyte and acid-base balance, total duration of AKI, rate of renal recovery, and mortality. Pending the results of this study, there is no evidence in favour of the use of diuretics to treat AKI.

Chronic kidney disease

Patients with chronic kidney disease (CKD) are often (not always) characterized by progressive sodium and water retention. Patients vary in the amounts of urine produced independently of CKD stage. Diuretic therapy usually starts with furosemide as the preferred loop diuretic, since thiazide diuretics (with the exception of metolazone) cease to be effective when estimated GFR falls to <30 mL/min/1.73 m^2. Metolazone is still effective in worsening CKD, but as renal function deteriorates and patients respond less well, RRT may need to be considered for management of fluid overload.

In the critically ill with acute on chronic kidney injury, iv furosemide is widely used. As with AKI, there is no evidence that this strategy improves renal recovery or shortens the duration of AKI.

Table 58.1 Characteristics of different diuretics

Type of diuretic	Site of action	Physiological effect	Most common indication(s)	Most important side effects
Loop diuretics: organic anions	Thick ascending limb loop of Henlé	Blockade of $Na^+/K^+/Cl^-$ cotransport system Inhibition of Na^+ reabsorption	Acute kidney injury, chronic kidney disease, acute heart failure, congestive heart failure, and chronic liver disease	Otoxicitiy Hyperuricaemia Electrolyte disorders Drug hypersensitivity
Thiazides: organic anions	Distal tubule, in the case of metolazone affects the loop of Henlé also	Blockade of Na^+/Cl^- transport system Inhibition of Na^+ reabsorption	Hypertension, chronic kidney disease (metolazone)	Hyperglycaemia Drug hypersensitivity Cholestatic jaundice, hepatitis Agranulocytosis
Aldosterone antagonists	Aldosterone receptors in the distal tubule	Prevention of aldosterone induced Na retention	Mobilization of ascites in chronic liver disease Congestive heart failure	Gynaecomastia Gastrointestinal Drug hypersensitivity Agranulocytosis
Osmotic agents: e.g. mannitol	Filtered in the glomerulus and not reabsorbed along the whole nephron	Reduced passive reabsorption of water	Cerebral oedema ?Rhabdomyolysis	Skin necrosis (in case of extravasation) Renal failure Seizures
Carbonic anhydrase inhibitors: e.g. acetazolamide	Proximal tubule	Inhibition of carbonic anhydrase Increased HCO_{3-} excretion, followed by increased Na^+, K^+ and water excretion	Correction of severe metabolic alkalosis Glaucoma	Drug hypersensitivity Metabolic acidosis Agranulocytosis
Potassium sparing diuretics: e.g. amiloride, triamterene	Late portion of the distal tubule and cortical collecting duct	Inhibition of K^+ secretion	To minimize K^+ loss with loop diuretics or thiazides	Hyperkalaemia
ANP/BNP: e.g. nesiritide	Afferent and efferent glomerular arterioles	Increase in GFR by dilation of afferent glomerular arteries and constriction of efferent arteries	?Acute heart failure	Renal failure Skin necrosis (in case of extravasation)

GFR, glomerular filtration rate; ANP, atrial natriuretic peptide; BNP, B type natriuretic peptide.

Acute decompensated heart failure

Most patients with acute decompensated heart failure present with symptoms related to fluid overload, which may be complicated by concomitant renal dysfunction. For decades, the administration of iv loop diuretics has been the mainstay of therapy to reduce congestion, decrease ventricular filling pressures, and improve clinical symptoms. However, many patients with acute heart failure are not substantially volume overloaded despite the presence of pulmonary or peripheral oedema [7,8]. In these cases, removing volume may reduce the necessary preload of a poorly functioning heart and may actually be harmful. There are other theoretical risks with administering loop diuretics in this situation, including the risk of neurohormonal activation, systemic vasoconstriction, electrolyte disturbances, and impairment of renal function.

Nesiritide (B type natriuretic peptide) has an effect on renin-angiotensin-aldosterone system resulting in smooth muscle relaxation [9]. Despite the potentially beneficial effects, there are currently little data to support its use in acute heart failure.

Congestive heart failure

Appropriate diuretic therapy controls fluid in most patients with mild to moderate chronic heart disease, leading to the resolution of pulmonary and peripheral oedema. Although diuretics may induce a decrease in ventricular filling and fall in cardiac output, this is usually not clinically important unless the patient is over-diuresed. A Cochrane review concluded there was evidence from 14 controlled studies (n = 525 patients) that conventional diuretics in congestive heart failure reduced the risk of worsening heart failure and death when compared with placebo [10]. Diuretics also increased the ability to exercise by 28–33% compared with other drugs. However, most studies had small numbers with a follow-up period of only 4–24 weeks and the use of diuretics was not standardized.

Patients with advanced heart failure may become less responsive to conventional oral doses of a loop diuretic due to reductions in renal perfusion and increased secretion of sodium-retaining hormones (i.e. aldosterone, angiotensin II), and may need increasing doses of diuretics or combination therapies.

Chronic liver disease

Spironolactone is used in escalating doses for the removal of ascites with the usual starting po dose of 100 mg daily. There are two therapeutic strategies for large-volume ascites—paracentesis and the administration of diuretics at increasing doses (maximal doses, 400 mg of spironolactone per day and 160 mg of furosemide per

day) until loss of ascitic fluid is achieved. The results of randomized trials comparing these two approaches support paracentesis as the method of choice [11]. Although there is no difference between the two strategies with respect to long-term mortality, large-volume paracentesis is faster, more effective, and associated with fewer adverse events than diuretic therapy. Regardless of the strategy used, diuretics should be included in the maintenance therapy to prevent recurrence of ascites.

A common complication of both acute and chronic liver failure is hepatic encephalopathy presenting with raised intracranial pressure. Treatment with mannitol boluses 1 g/kg has been shown to improve survival in liver patients with cerebral oedema and normal renal function [12]. More commonly, a dose of 0.5 g/kg is used as a bolus (100 mL 20% mannitol) and repeated after an hour, if necessary. The resulting hypovolaemia can paradoxically cause an increase in intracerebral pressure. Plasma osmolality should be maintained at <320 mOsomol/L, while a mildly hyperosmotic state should be targeted to minimize cerebral oedema. Accordingly, serum sodium should be maintained at least within high normal limits. Hypertonic saline administered to achieve serum Na 145–155 mmol/L may be considered in patients with intracranial hypertension refractory to mannitol [13].

Rhabdomyolysis

The main reason for considering diuretics in rhabdomyolysis is to remove myoglobin from the tubular lumen. However, the use of any diuretic in this situation remains controversial and should be restricted to patients who are not fluid deplete. As an osmotic agent, mannitol may increase urinary flow, promote the flushing of nephrotoxic agents through the renal tubules, and facilitate the shift of fluid from injured muscles into the vascular space. Mannitol is also a free-radical scavenger.

No randomized controlled trial has supported the evidence-based use of mannitol in humans. In addition, high accumulated doses of mannitol (>200 g/day or accumulated doses of >800 g) have been associated with AKI due to renal vasoconstriction and tubular toxicity.

If mannitol is used to prevent and treat rhabdomyolysis-induced AKI and to relieve compartmental pressure [14], plasma osmolality and the osmolal gap should be monitored, and therapy discontinued if adequate diuresis is not achieved or if the osmolal gap rises above 55 mOsmol/kg. Loop diuretics also increase urinary flow and may decrease the risk of myoglobin precipitation, but no study has shown a clear benefit in patients with rhabdomyolysis.

Hypertension

In chronic hypertension, diuretics are one of the dominant drug classes used. However, diuretics should be used with caution during a hypertensive crisis in the critically ill, as volume depletion may already be present in these conditions, putting the patient at risk of AKI. Furthermore, in acute hypertensive crises, there is a role for stronger antihypertensives than diuretics.

Management of resistant oedema

Combination of diuretics

Combinations of different diuretics may be necessary and may avoid side effects from a single drug given at high dose.

In chronic liver disease, dose titration of spironolactone to 300 mg daily is limited by hyperkalaemia. For this reason, loop diuretics are often added to aid faster mobilization of moderate ascites. Maximum doses of spironolactone 400 mg daily and furosemide 160 mg daily is achievable in combination. Amiloride (10–40 mg/day) can be substituted in patients suffering from spironolactone-induced gynaecomastia, although amiloride is less effective. Eplenerone, a newer aldosterone receptor blocker without the side effect of gynaecomastia has not been studied in the setting of cirrhosis and ascites. Other combinations include triamterene, metolazone, and hydrochlorothiazide [15].

In patients with congestive heart failure, the RALES (Randomized Aldactone Evaluation) trial showed that spironolactone (25–50 mg daily), in combination with an ACE inhibitor and a loop diuretic, with or without digoxin was associated with a significantly reduced mortality at 24 months and significant reduction in hospitalization for heart failure [16].

In CKD, the thiazide metolazone is commonly added with furosemide to maintain fluid balance. However, there is little data to suggest any mortality or morbidity benefit when using this combination.

In patients with cerebral oedema, aldosterone antagonists such as spironolactone or potassium canreonate (canrenone) have been used in conjunction with mannitol to minimize the risk of cardiac arrhythmias precipitated by hypokalaemia [17].

Intravenous bolus versus continuous infusion therapy

A randomized controlled trial comparing furosemide infusion versus bolus administration in 59 critically-ill patients with fluid overload, showed patients in the bolus group needed a significantly higher total dose to achieve target diuresis [18]. Mean urine output was significantly higher in the infusion group, but there was no difference in hospital mortality, the number of patients requiring ventilatory support, change in serum creatinine, or change in estimated GFR. Current data suggest diuresis is easier to achieve with a continuous infusion, but there is no evidence of better outcomes.

Combination with albumin

In situations of fluid overload associated with severe hypoalbuminaemia, such as nephrotic syndrome or advanced chronic liver disease, diuretic resistance can occur. Albumin is considered to be necessary to deliver furosemide to the kidney, and severe hypoalbuminaemia is associated with impaired furosemide secretion into the tubular lumen. Diuretics bind to albumin in the tubular fluid, which decreases the amount of unbound, active drug that is available to interact with the tubular receptor. When urinary concentrations of albumin are >4 g/L, up to 65% of the diuretic that reaches the tubular fluid is bound to albumin.

A mixture of loop diuretic and albumin is occasionally used if the patient is severely hypoalbuminaemic (serum albumin <20 g/L). Data to support this strategy are conflicting. In a study including patients with cirrhosis and ascites, the administration of premixed loop diuretic and albumin (40 mg of furosemide and 25 g of albumin) did not enhance the natriuretic response [19]. In contrast, a randomized controlled crossover study in 24 patients with CKD and hypoalbuminaemia showed a significant increase in the increment of urine volume with furosemide and albumin [20]. However, at 24 hours, there were no longer any significant differences.

SECTION 3

Resuscitation

PART 3.1

Respiratory management

CHAPTER 59

Airway management in cardiopulmonary resuscitation

Jerry P. Nolan and Jasmeet Soar

Key points

- In the context of cardiopulmonary resuscitation (CPR), airway obstruction is common.
- The most appropriate strategy for managing the airway depends on the skills of the rescuer.
- Tracheal intubation is generally accepted as the optimal method for securing the airway, but only when undertaken by a highly skilled individual.
- In the absence of a skilled intubator, insertion of a supraglottic airway device (SAD) is probably the best way of managing the airway during CPR.
- Use of waveform capnography is mandatory whenever tracheal intubation is attempted, but will also provide useful information about the effectiveness of CPR, and an early indication of return of spontaneous circulation (ROSC) even when used with a SAD.

Introduction

Establishing and maintaining a clear airway is a fundamental component of cardiopulmonary resuscitation (CPR), but there is some controversy about precisely how this should be achieved [1]. Patients requiring resuscitation often have an obstructed airway, usually caused by loss of consciousness, but occasionally it may be the primary cause of cardiac arrest. Immediate restoration of airway patency enables ventilation of the lungs and oxygenation of the blood. Without adequate oxygenation it may be impossible to restore a perfusing cardiac rhythm. Tracheal intubation is generally considered to be the optimal method for maintaining a clear airway, but this is likely to be true only when undertaken by individuals highly skilled in the technique. In the absence of a skilled intubator, use of a supraglottic airway device (SAD) will provide a more reliable airway than simply using a bag-mask and oropharyngeal airway.

Causes of airway obstruction

Airway obstruction can occur at any level from the nose and mouth down to the level of the carina and bronchi. In unconscious patients, the commonest site of airway obstruction is at the soft palate and epiglottis. Vomit, blood, or foreign bodies can also cause airway obstruction. Laryngeal obstruction may be caused by oedema from burns, inflammation, or anaphylaxis. Upper airway stimulation or inhalation of foreign material may cause laryngeal spasm. Obstruction of the airway below the larynx is less common, but may be caused by excessive bronchial secretions, mucosal oedema, bronchospasm, pulmonary oedema, or aspiration of gastric contents. Extrinsic compression of the airway may also occur above or below the larynx, e.g. as a result of trauma, haematoma, or tumour.

Recognition of airway obstruction

In partial airway obstruction, air entry is diminished and usually noisy—inspiratory stridor is caused by obstruction at the laryngeal level or above, and expiratory wheeze suggests obstruction of the lower airways, which tend to collapse and obstruct during expiration. Signs of complete airway obstruction in a patient who is making respiratory efforts include paradoxical chest and abdominal movement (see-saw breathing), use of accessory muscles of respiration, intercostal and subcostal recession, and tracheal tug. Airway obstruction must be relieved rapidly otherwise irreversible brain injury will start to occur within a few minutes. High concentration oxygen is given during attempts to relieve airway obstruction because this will increase arterial blood oxygen saturation (SaO_2) values more rapidly once airway patency is restored.

Basic techniques for opening the airway

The head tilt, chin lift (Fig. 59.1), and jaw thrust (Fig. 59.2) can be used to relieve upper airway obstruction.

Airway manoeuvres in a patient with suspected cervical spine injury

If spinal injury is suspected the head, neck, chest, and lumbar region are maintained in the neutral position during resuscitation. When there is a risk of cervical spine injury, establish a clear upper airway by using jaw thrust or chin lift in combination with manual in-line stabilization (MILS) of the head and neck. Establishing a patent airway takes priority over concerns about a potential cervical spine injury.

Adjuncts to basic airway techniques

Oropharyngeal and nasopharyngeal airways will overcome soft palate obstruction and backward tongue displacement in an unconscious patient, but head tilt and jaw thrust may also be required. The appropriate size for an oropharyngeal airway corresponds to the vertical distance between the patient's incisors and the angle of the jaw. In patients who are not deeply unconscious, a nasopharyngeal airway is better tolerated than an oropharyngeal airway—sizes 6–7 mm are suitable for adults.

Oxygen

During CPR, the lungs are ventilated with 100% oxygen until return of spontaneous circulation (ROSC) is achieved. After ROSC is achieved, high-flow oxygen is given until the oxygen saturation of arterial blood (SaO_2) can be measured reliably. Animal data indicate an association between high SaO_2 (hyperoxaemia) after ROSC and worse neurological outcome [2], but clinical data from observational studies are conflicting [3,4]. Current recommendations are that when blood oxygen saturation can be measured reliably, oxygen saturations should be maintained between 94% and 98%; or between 88 and 92% if the patient has chronic obstructive pulmonary disease [5].

Ventilation

A detailed discussion on ventilation during resuscitation, including use of a bag-mask device, is covered in Chapter 60.

Supraglottic airway devices

In comparison with bag-mask ventilation, use of SADs may enable more effective ventilation and reduce the risk of gastric inflation. They are also easier to insert than a tracheal tube and can generally be positioned without interrupting chest compressions. Alternative airway devices are used generally by those unskilled in tracheal intubation or as part of a back-up plan if a skilled operator is unable to intubate. Once a SAD has been inserted it is often possible to ventilate the patient's lungs without pausing the chest compressions—this reduces the 'no flow' time (when there is no blood flow to vital organs).

Laryngeal mask airway

Successful use of the laryngeal mask airway (LMA) by nursing, paramedical, and medical staff during resuscitation has been documented, although these are generally observational studies. The need to resterilize the reusable LMA Classic™ makes single-use LMAs more suitable for resuscitation, but the performance of some single-use devices is inferior to the Classic version. In the presence of high airway resistance or poor lung compliance, there is a risk of hypoventilation caused by a significant leak around the cuff. Once an LMA is inserted it is reasonable to attempt continuous compressions (i.e. not pausing the chest compressions during inspiration) initially, but abandon this if persistent leaks and hypoventilation occur.

The LMA ProSeal®

The LMA ProSeal® is a modified LMA: it has an additional posterior cuff, a gastric drain tube (enabling venting of liquid regurgitated gastric contents from the upper oesophagus and passage of a gastric tube to drain liquid gastric contents), and incorporates a bite block. There are no studies of its performance during CPR, but it enables ventilation at higher airway pressures (up to 35–40 cm H_2O), which may enable adequate ventilation during uninterrupted chest compressions. A disposable version, the LMA Supreme (Fig. 59.3), has been used very successfully during resuscitation following out of hospital cardiac arrest [6].

i-gel® airway

The i-gel® has a preformed cuff that does not require inflation. The stem of the i-gel incorporates a bite block and a narrow oesophageal drain tube (Fig. 59.4). Its ease of insertion and favourable leak pressure (20–24 cmH_2O) make it theoretically very attractive as a resuscitation airway device for those inexperienced in tracheal intubation. It has been introduced widely into United Kingdom ambulance services [7] and is about to be compared with tracheal intubation in out of hospital cardiac arrest in a large cluster randomised controlled trial.

Fig. 59.4 I-gel®.
This photograph is reproduced with kind permission by Michael Scott and the Resuscitation Council (UK).

Laryngeal tube

The laryngeal tube (LT) is a single-lumen tube with both an oesophageal and pharyngeal cuff (Fig. 59.5), which are inflated simultaneously via a single pilot balloon. A double lumen LT with an oesophageal vent, and a disposable version are available. There are several observational studies that document successful use of the LT by nurses and paramedics during prehospital cardiac arrest.

Outcomes with supraglottic airway devices

There are no high-quality randomised controlled trials powered for mortality comparing SADs with either tracheal intubation or mask and oropharyngeal airway. Several large observational studies that have documented the association between outcome after out-of-hospital cardiac arrest (OHCA) and use of a variety of SADs. The results of such studies are mixed with some showing better outcome associated with use of a SAD, while others show better outcome with tracheal intubation. Most observational studies show an association between the use of any advanced airway device (SAD or tracheal intubation) and worse outcome after OHCA compared with those patients managed with a bag-mask airway [8]. A large study from North America has also documented lower long-term survival among those OHCA patients with a SAD compared with a tracheal tube [9]. The problem with observational studies is that, no matter how sophisticated the risk adjustment, the possibility of significant confounders remain; for example, some SADs are inserted only when attempts at tracheal intubation have failed. More commonly, a SAD is used as part of a stepwise approach to airway management making it very difficult to ascertain the contribution of any particular airway to outcome after cardiac arrest [7,10]. There are very few data relating to airway management during in-hospital cardiac arrest and it is likely that extrapolation from OHCA studies is invalid; for example, patients with in-hospital cardiac arrest are much more likely to have respiratory disease, and an airway or breathing problem as the cause of their cardiac arrest.

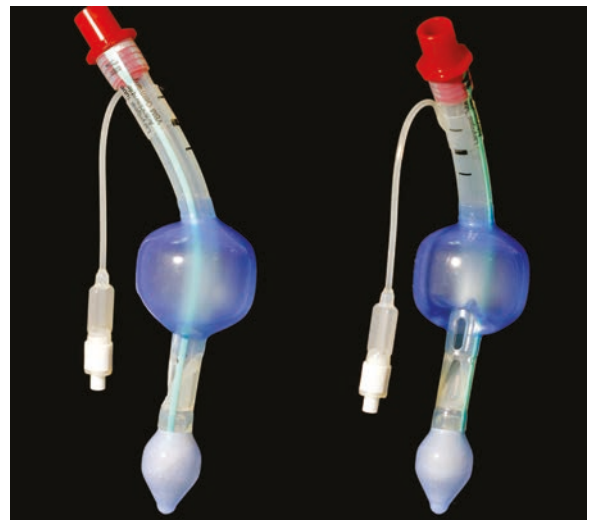

Fig. 59.5 Laryngeal tube.

Tracheal intubation

Tracheal intubation should be attempted during resuscitation only by personnel who are able to carry out the procedure with a high level of skill and competence. No prospective study has shown improved outcome with tracheal intubation compared with bag-mask after cardiac arrest. Some observational studies document an association between tracheal intubation and worse outcome [11].

The perceived advantages of tracheal intubation over bag-mask ventilation include maintenance of a patent airway, which is protected from aspiration of gastric contents or blood from the oropharynx, the ability to provide an adequate tidal volume reliably even when chest compressions are uninterrupted, the potential to free the rescuer's hands for other tasks, and the ability to suck-out airway secretions. The use of a bag-mask is more likely to cause gastric distension, which is, theoretically, more likely to cause regurgitation and the risk of aspiration. This theoretical risk has yet to be proven in randomized clinical trials.

The perceived disadvantages of tracheal intubation over bag-mask ventilation include the risk of an unrecognized misplaced tracheal tube (up to 17% in some OCHA studies, although a recent high-quality Scottish study documented a rate of 2.4%) [12], a prolonged time without chest compressions while tracheal intubation is attempted, and a comparatively high failure rate. In one study involving prehospital intubation of 100 cardiac arrest patients by paramedics, the first intubation attempt accounted for a median interruption in CPR of 45 seconds and in one third of cases it exceeded 1 minute [13].

Personnel skilled in advanced airway management should be able to undertake laryngoscopy without stopping chest compressions. A brief pause in chest compressions will be required only as the tube is passed through the vocal cords. Alternatively, to avoid any interruptions in chest compressions, the intubation attempt may be deferred until ROSC. Attempted tracheal intubation should not interrupt chest compressions for more than 5 seconds, otherwise, bag-mask or bag-SAD ventilation is recommenced. After tracheal intubation, tube placement must be confirmed and the tube secured adequately.

Confirmation of correct tracheal tube placement

Unrecognized oesophageal intubation is the most serious complication of attempted tracheal intubation. Routine use of primary and secondary techniques to confirm correct placement of the tracheal tube will reduce this risk.

Clinical assessment

Primary assessment includes observation of chest expansion bilaterally, auscultation over the lung fields bilaterally in the axillae and over the epigastrium. Secondary confirmation of tracheal tube placement by use of a colorimetric carbon dioxide detector or waveform capnography will reduce the risk of unrecognized oesophageal intubation.

Carbon dioxide detectors

Unless cardiac arrest has been very prolonged (more than 30 minutes), chest compressions will produce sufficient pulmonary blood flow to produce detectable exhaled carbon dioxide (CO_2) concentrations. Following a tracheal intubation attempt, if exhaled CO_2 is not detected, the tube is probably in the oesophagus. Carbon dioxide detector devices measure the concentration of exhaled carbon dioxide from the lungs. There are broadly three types:

- Disposable colorimetric end-tidal carbon dioxide ($ETCO_2$) detectors use a litmus paper to detect CO_2, and these devices generally give readings of purple ($ETCO_2$ <0.5%), tan ($ETCO_2$ 0.5–2%), and yellow ($ETCO_2$ > 2%).
- Non-waveform electronic digital $ETCO_2$ devices measure $ETCO_2$ using an infrared spectrometer and display the results with a number.
- End-tidal CO_2 detectors that include a waveform graphical display (capnograph) are the most reliable for verification of tracheal tube position during cardiac arrest.

When tracheal intubation is undertaken <30 minutes after the onset of cardiac arrest, waveform capnography has 100% (95% CI 98–100%) sensitivity and 100% (95% CI 97–100%) specificity to verify placement of the tube in a major airway. The Royal College of Anaesthetists and Difficult Airway Society National Audit Project 4 (NAP4) included a case of unrecognized oesophageal intubation in which a flat capnograph trace was interpreted as being due to cardiac arrest [14,15]. If tracheal intubation is delayed by >30 minutes, pulmonary blood flow can be so low during CPR that CO_2 is undetectable, despite the tracheal tube being correctly placed [5]. Waveform capnography is the most sensitive and specific way to confirm and continuously monitor the position of a tracheal tube in victims of cardiac arrest, but will not discriminate between tracheal and bronchial placement of the tube—careful auscultation is essential.

During CPR, the use of waveform capnography is also valuable to provide feedback on the quality of chest compressions (better chest compressions will generate higher end-tidal CO_2 values) [16], to predict which patients are likely to achieve ROSC (those with an end-tidal CO_2 value >10 mmHg) [17], and to provide an early indication of ROSC (if the end-tidal CO_2 increases suddenly during CPR) [18]. Waveform capnography works best in the presence of a tracheal tube, but can also be used during ventilation with a SAD [6] or a bag-mask. End-tidal CO_2 values will vary if an inadequate seal causes a leak.

Existing portable monitors make capnographic initial confirmation and continuous monitoring of tracheal tube position feasible in almost all settings, including out-of-hospital, emergency department, and in-hospital locations where tracheal intubation is performed. Ideally, waveform capnography should be available wherever tracheal intubation is performed.

Cricothyroidotomy

Occasionally, it will be impossible to ventilate an apnoeic patient with a bag-mask, or to pass a tracheal tube or other airway device. This may occur in patients with extensive facial trauma or laryngeal obstruction caused by oedema, e.g. anaphylaxis. In these circumstances, a surgical cricothyroidotomy provides a definitive airway that can be used to ventilate the patient's lungs until semi-elective intubation or tracheostomy is performed. Needle cricothyroidotomy is a much more temporary procedure providing only short-term oxygenation. It requires a wide-bore, non-kinking cannula, a high-pressure oxygen source and may cause serious barotrauma. It is also prone to failure because of kinking of the cannula, and is unsuitable for patient transfer. The NAP4 study documented a high failure rate (60%) when airway rescue was attempted with needle cricothyroidotomy [14,19]. In contrast, all surgical cricothyroidotomies achieved access to the trachea.

CHAPTER 60

Artificial ventilation in cardiopulmonary resuscitation

Jasmeet Soar and Jerry P. Nolan

Key points

- Cardiopulmonary resuscitation (CPR) should be started with chest compressions.
- The need for ventilation during CPR is determined by both patient and rescuer factors.
- Rescuers who are unable or unwilling to provide effective ventilation, whilst awaiting expert help should use compression-only CPR.
- Ventilations are necessary during CPR in children and those with a primary respiratory cause of cardiac arrest.
- A high inspired oxygen concentration should be given during CPR, but once circulation has been restored, inspired oxygen should be adjusted to maintain normoxaemia.

Introduction

Traditionally, as soon as possible after cardiorespiratory arrest occurs, artificial ventilation (rescue breathing) is started as part of the ABC (Airway, Breathing Circulation) approach in order to maintain adequate oxygenation and remove carbon dioxide (CO_2). Current guidance advocates starting cardiopulmonary resuscitation (CPR) with chest compressions first. The provision of ventilation is determined by the training of rescuers, their ability, and willingness to provide rescue breaths, patient characteristics, and the underlying cause of the cardiac arrest. There is a greater urgency and need for ventilation when cardiac arrest results from a primary respiratory problem; in such cases it may be impossible to restore a perfusing cardiac rhythm without adequate ventilation and oxygenation. This chapter addresses the need for ventilation, how much ventilation and oxygen to give, ventilation techniques, safe use of oxygen during defibrillation, and how to monitor ventilation during CPR. Ventilation requires an open airway, and techniques for airway opening and maintenance are described in Chapter 59.

Are ventilations needed during CPR?

When performed by laypersons chest compression-only CPR during the first few minutes of a primary cardiac arrest can result in equivalent or superior survival to standard CPR [1]. In primary cardiac arrest arterial blood can remain saturated with oxygen for several minutes [2]. If CPR is started early, myocardial and cerebral oxygen delivery is determined by cardiac output rather than lack of oxygen in the arterial blood. Also, rescuers are often unwilling or unable to provide effective mouth-to-mouth ventilations. Even if they provide effective mouth-to-mouth ventilations, the typical prolonged pause in chest compressions when ventilations are given can reduce the chances of survival. Importantly, ventilations are needed for the treatment of cardiac arrest in children [3], when the arrest is from a primary respiratory cause or during a prolonged cardiac arrest [4]. However in adults, chest compression-only CPR is better than no CPR if a rescuer is untrained in CPR, is untrained and receiving instructions over a telephone from an ambulance dispatcher, or is unwilling or unable to perform rescuer breaths [2].

In the presence of an open airway, chest compressions generate air-flow into and out of the lungs although the measured tidal volumes are small and generally no more than the anatomical dead space [5]. Airway opening and high-flow face-mask oxygen and passive ventilation chest compressions for the first 6 minutes of CPR is used by some ambulance services for primary adult cardiac arrests. Improved outcomes have been reported with this 'minimally interrupted' CPR approach although further study is needed [6].

How much ventilation?

Current guidelines recommend two ventilations after every 30 chest compressions in adults, and after every 15 compressions in children [2]. Once the airway is secured with a tracheal tube, ventilations should be given at 10 breaths/min without any pause in chest compressions. Pauses in chest compressions for ventilations and other interventions reduce coronary and brain perfusion, and worsen the chances of survival [7]. High ventilation rates increase intrathoracic pressure and decrease coronary perfusion during CPR [8]. In clinical practice, rescuers often ventilate patients' lungs at much higher rates. In a single centre US study of in-hospital cardiac arrest, the observed ventilation rate was above 20/min over 61% of the time [9].

The optimal ventilation strategy during CPR is not known and current recommendations are based on limited evidence. As lung blood flow is reduced during CPR, a lower minute ventilation

is needed to maintain an adequate ventilation-perfusion ratio. A larger tidal volume (e.g. 1 L) in patients with unprotected airways produces more gastric distension than a smaller tidal volume (e.g. 500 mL). Effective oxygenation and ventilation can be maintained during CPR with a tidal volume of approximately 500 mL given over an inspiratory time of 1 second.

After a brief duration of cardiac arrest patients usually recover consciousness, maintain their airway safely, breathe adequately, and do not require ventilator support. Patients who remain comatose or agitated with a decreased conscious level, and those with respiratory compromise will require tracheal intubation and mechanical ventilation. In these patients, once return of spontaneous circulation (ROSC) has been achieved ventilation should be adjusted to achieve a normal partial pressure of carbon dioxide ($PaCO_2$) guided by arterial blood gas analysis and capnography. Hypocapnia is associated with decreased cerebral blood flow, and increased excitatory amino acid release causing neurotoxicity [10].

How much oxygen?

Rescuers should give supplemental oxygen in as high a concentration as possible during CPR in order to rapidly correct tissue hypoxia. Once ROSC has been achieved the inspired oxygen should be adjusted to maintain arterial oxygen saturation between 94 and 98% [11,12]. Recent observational studies in adults and children suggest that both hypoxaemia and hyperoxaemia in the first few hours after ROSC are associated with worse survival and neurological function [13,14]. Hyperoxaemia is thought to worsen free radical-induced mitochondrial injury during neuronal perfusion.

Ventilation techniques

The ventilation technique used during CPR and after ROSC will depend on the skills and training of rescuers and the equipment available.

Mouth-to-mouth ventilation

The expired oxygen concentration is only 16–17%, but mouth-to-mouth ventilation has the benefit of not requiring any equipment. Rescuers are often reluctant to perform mouth-to-mouth ventilation due to panic, fear of harming the patient, risk of infection, presence of vomit, blood, or the victim being unkempt. There are very few reports of individuals acquiring infections after providing CPR. Tuberculosis and severe acute respiratory distress syndrome (SARS) infections have been reported [15]. Mouth-to-mouth ventilation is rarely used in clinical settings as current guidelines recommend CPR is started with chest compressions alone. This allows time for airway and ventilation equipment to arrive.

Pocket mask

The pocket resuscitation mask is similar to an anaesthetic face mask and enables mouth-to-mask ventilation through a unidirectional valve (Fig. 60.1). Some masks have a port for the addition of oxygen. If oxygen is available, it should be added via the port at a flow of 10 L/min. If there is no oxygen port, supplemental oxygen can be given by placing oxygen tubing underneath one side and ensuring an adequate seal.

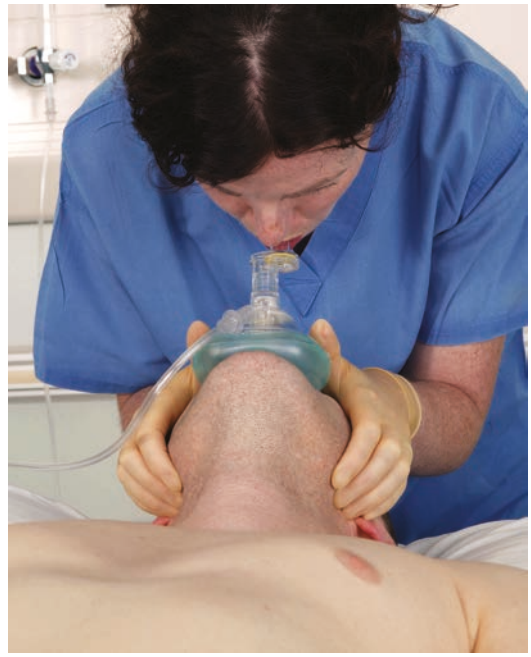

Fig. 60.1 Pocket mask ventilation.

Self-inflating bag

A self-inflating bag can be connected to a face mask, tracheal tube, or supraglottic airway device to enable positive pressure ventilation when the bag is squeezed (Fig. 60.2). On release, expired gas is diverted to the atmosphere via a one-way valve. The bag

Fig. 60.2 Ventilation with self-inflating bag and facemask.

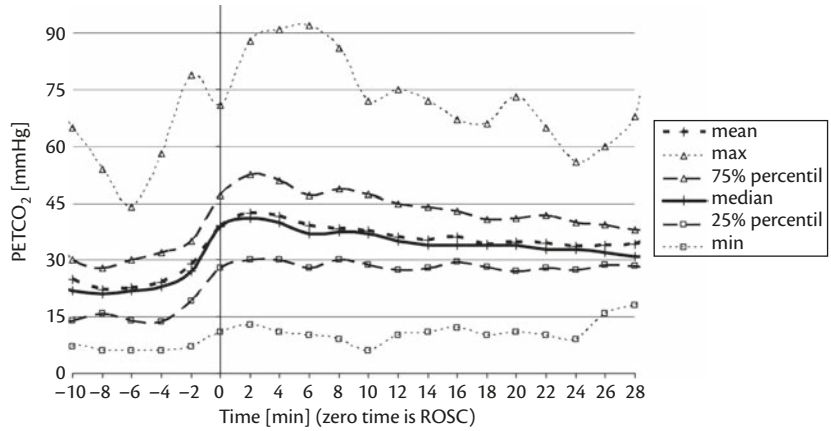

Fig. 60.3 End-tidal carbon dioxide ($PETCO_2$) values recorded before and after ROSC in 59 patients.
Reprinted from *Journal of Emergency Medicine*, **38**, 5, Pokorná M et al., 'A sudden increase in partial pressure end-tidal carbon dioxide (PETCO2) at the moment of return of spontaneous circulation', pp. 614–21, Copyright 2010 with permission from Elsevier and the American Academy of Emergency Medicine.

then refills automatically via an inlet at the opposite end. Without supplemental oxygen, the bag ventilates the patient's lungs with ambient air. Inspired oxygen concentration can be increased to about 45% by attaching high flow oxygen directly to the bag. An inspired oxygen concentration of approximately 85% can be achieved if a reservoir system is attached and the oxygen flow is maximally increased. As the bag re-expands it fills with oxygen from both the reservoir and the continuous flow from the attached oxygen tubing.

Oxygen safety during defibrillation

Sparking from a defibrillator can cause fire and patient burns in an oxygen-enriched atmosphere. The use of self-adhesive pads for defibrillation instead of manual paddles decreases this risk. The Resuscitation Council (UK) recommends the following precautions to minimize risk of fire during defibrillation [16]:

- Remove any oxygen mask, nasal cannulae, or disconnected ventilation bag and place them at least 1 m away from the patient's chest.
- Leave a ventilation bag connected to the tracheal tube or supraglottic airway device, no increase in oxygen concentration occurs in the zone of defibrillation, even with an oxygen flow of 15 L/min.
- If the patient is connected to a ventilator, leave the ventilator tubing connected to the tracheal tube during defibrillation. If the ventilator tubing is disconnected, ensure that it is kept at least 1 m from the patient. Better still switch the ventilator off.

Monitoring ventilation during CPR

Prompts and, or feedback devices can be used to ensure correct ventilation during CPR [17]. Ventilation rate can be monitored by recording changes in the transthoracic impedance through adhesive defibrillation electrodes [18].

Waveform capnography is now recommended to monitor correct tracheal tube placement during CPR [19]. In addition, it can be used to help guide ventilation rate during CPR. Increased depth and quality of chest compression will increase end-tidal CO_2, and a sudden steep rise in the end-tidal CO_2 may be an indicator of ROSC during CPR (Fig. 60.3) [20].

PART 3.2

Circulatory management

CHAPTER 61

Pathophysiology and causes of cardiac arrest

Peter Thomas Morley

Key points

- Sudden cardiopulmonary arrest (CPA) is the commonest cause of death globally.
- Most CPAs are due to cardiac causes, except in children where respiratory causes are more common.
- Identification and treatment of reversible causes of CPAs (4 Hs and 4 Ts) during the arrest appears to improve survival.
- CPAs due to primary arrhythmias, especially in young adults or children, may represent a genetic/familial cause.
- Survivors of CPAs develop an inflammatory response that can result in adverse effects in many organ systems.

Introduction

Sudden cardiopulmonary arrest (CPA) is the commonest cause of death around the world. Sporadic attempts at resuscitation of sudden unexpected deaths have been reported for thousands of years, especially for neonates and victims of drowning. Initial attempts at resuscitation were limited to replacing or restoring breathing, as apnoea was the observed pathology, and it was assumed that restarting the heart was not possible. Establishing the aetiology of sudden death is usually difficult without an obvious cause (e.g. trauma, drowning, or electrocution). In the past, as now, the observed causes of CPA have driven the search for better treatment and prevention. The past 200 years has seen a shift in focus from trauma and drowning to deaths under anaesthesia, electrical injury, and most recently myocardial ischaemia.

Understanding the aetiology of cardiopulmonary arrests

Sudden CPA can occur anywhere, but the location of arrest is usually categorized as out-of-hospital or in-hospital, each of which have similarities and differences. The likelihood of CPA has driven a more targeted approach to training in basic life support and cardiopulmonary resuscitation (CPR). The CPA itself is due to rhythms that are either shockable (ventricular fibrillation (VF) or pulseless ventricular tachycardia), or not shockable (asystole and pulseless electrical activity (PEA); previously known as electro-mechanical dissociation or EMD). All of these rhythms require early basic life support followed by advanced life support. The requirement for early shocks in shockable rhythms has resulted in widespread distribution of automated external defibrillators (public access defibrillation). The majority of CPA in both out-of-hospital and in-hospital settings appear to be of cardiac origin, but the actual underlying causes, presenting rhythms and co-morbidities vary significantly among populations and between studies.

Out-of-hospital CPA

Approximately 75% of deaths from CPA occur in the prehospital setting. Cardiac arrests in the community occur at approximately 50–150/100,000 person years [1]. The incidence of CPA (and their outcomes) is significantly affected by the denominator used, e.g. including all cardiac arrests (89/100,000 person years) versus including only those with a presumed cardiac cause where resuscitation was attempted (31/100,000 person years) [2]. In addition to this, the incidence is variable depending on the reporting area of interest (e.g. between cities and between countries) [3]. In adults, the incidence of CPA increases with increasing age [1]. Perinatal asphyxia is obviously a unique situation, and will not be discussed here in any detail.

Apart from obvious causes (such as trauma or drowning), determining the actual aetiology of the out-of-hospital CPA can be very difficult.

Out-of-hospital CPA in children

Large registries are now providing insights into CPA in the out-of-hospital setting in children. The incidence of CPA is highest in infants (< 1 year; 73/100,000 person years); this is higher than for children (1–11 years; 4/100,000 person years), or adolescents (12–19 years; 6/100,000 person years) [4]. In this study, the overall rate of return of spontaneous circulation in the field was 10% and overall 6.4% survived to hospital discharge (3.3% for infants, 9.1% for children, and 8.9% for adolescents) [4]. The majority of paediatric CPAs are due to respiratory causes (including drowning). Other causes identified include cardiac (including congenital heart disease), trauma, neurological conditions, drug overdose/toxicity, and electrolyte disorders.

The majority of deaths in young adults are due to accidents and trauma, with only 15–20% due to cardiac causes [5].

Out-of-hospital CPA in adults

The incidence of out-of-hospital CPA in the published literature in adults has been quite variable (50–150/100,000 person years). The large Resuscitation Outcomes Consortium epistry reported

a range of incidences from 71.8–159.0 per 100,000 person years (median 96.8), with survival to hospital discharge ranging from 3.0–16.3% (median 8.4%) [6]. The incidence of CPA is reported to be higher in the poorer metropolitan neighbourhoods of the US and Canada. In addition, in the United States, Latinos and blacks are at higher risk for non-shockable rhythms, with their inherent worse prognosis.

A common way of reporting CPA outcomes is to use the Utstein benchmark (cases of attempted resuscitation following adult, witnessed CPA, with an initial rhythm of VF/pulseless ventricular tachycardia). Using this definition, survival to 28 days for out-of-hospital CPA has been reported to range from 4.5–37.7% [3].

Cardiac causes of out-of-hospital CPA in adults

The majority (60–80%) of adult out-of-hospital CPAs are due to cardiac disease [3,7]. Obviously the term 'cardiac causes' includes a large number of subcategories. The commonest cardiac cause in adults is ischaemic heart disease [1], where an identified coronary occlusion is detected in most patients with recent CPA (including at least 25% of those without ST-elevation) [7]. Other specific cardiac causes include cardiomyopathy, valvular abnormalities, and primary cardiac arrhythmias (both brady-arrhythmias and tachyarrhythmias) [1]. The group of primary arrhythmias is of special interest because of the implications for genetic counselling [1,5] and for the specific potential benefits of anti-arrhythmic drugs, electrophysiological ablation techniques, or implantable defibrillators.

Non-cardiac causes of out-of-hospital CPA in adults

There are a large number of conditions, involving a myriad of organ systems, which can result in CPA (see Box 61.1). The teaching surrounding cardiac arrest management has evolved to focus on the detection and correction of potential causes of cardiac arrests, and a number of educational approaches have been used to help rescuers consider these causes. These approaches include the commonly used 'Hs and Ts' [8] (see Box 61.2) advocated by many resuscitation councils, the simple zig-zag technique [9] and the use of ultrasound. The most important justification for identifying or excluding these causes is that the use of individualized specific treatment may be lifesaving [8].

In-hospital cardiopulmonary arrest

It is estimated that the total number of in-hospital CPA where resuscitation is attempted, is similar to the number seen in the out-of-hospital setting. Patients may be in-hospital for a number of reasons, including for minor procedures, but in general hospitalized patients have more comorbidities and are sicker than the general population.

In-hospital CPA in children

In-hospital CPA in children is very uncommon ranging from 0.11/1000 admissions [11], to approximately 3/1000 admissions [12]. The majority of these cases appear due to cardiac causes (including congenital heart disease). The survival rates are better with shockable rhythms, and appear to be improving over time with all rhythms [13]. These survival rates are higher than those seen in the out-of-hospital setting [13], despite the fact that the in-patients have more comorbidities.

In-hospital CPA in adults

The vast majority of in hospital deaths occur in settings where they are expected, and resuscitation attempts are not made [14,15]. The reported incidence of in-hospital CPA in adults where resuscitation is attempted ranges from 3.8–13.1 per 1000 admissions [12]. Outcomes again seem to be critically dependent on the underlying rhythm at the time of the arrest [10,12], with the best outcomes seen with shockable rhythms, and in hospitals with a higher cardiac arrest volume. Registry data have reported improvements in survival over the past decade [12]. In-hospital CPAs that are actively treated are associated with a higher survival than out-of-hospital CPA, especially for non-shockable rhythms. This is probably due to a combination of early recognition, early advanced life support, and the detection and treatment of reversible causes (given the access to a wider range of investigative and treatment options) [8]. Arrests in patients that are witnessed (or monitored) also appear to have better outcomes [12].

The majority of in-hospital CPA seem to be related to cardiac causes, but other causes include: respiratory (e.g. pulmonary emboli, hypoxia), vascular (e.g. aortic rupture), intoxications and adverse drug effects, blood loss, metabolic causes (e.g.

hyperkalaemia and hypokalaemia), and others (including neurological, sepsis, complications of interventions, and accidental hypothermia) [8,10].

Those patients with cardiac causes for CPA had better outcomes than those with non-cardiac causes. The best survival outcomes from any CPA (near 100%) occur in the electro-physiology laboratory, where VF is often deliberately induced.

A lot is known about the antecedents to in-hospital CPA [12,16], and rapid response systems have been developed to intervene well before CPA ensues.

In patients aged 65 years or older, factors associated with lower odds of survival included older age, male sex, chronic disease burden, and black or other non-white race [15]. Cardiac arrests were also more frequent for black and other non-white patients [15].

Specific situations

Anaesthesia

The incidence of anaesthesia-related CPA appears to be decreasing. In patients undergoing non-cardiac surgery the reported incidence ranges from 0.2–1.1 per 10,000 adults and from 1.4–2.9 per 10,000 children [17]. The overwhelming majority of patients are in non-shockable rhythms at the time of arrest, and the CPA appear to be related to pre-existing medical or surgical disease [17]. The other key aetiological factors can be grouped into the categories of anaesthetic technique (including drug-related) and those associated with the surgical procedure. Airway and ventilatory causes of arrest have decreased since the introduction of improved monitoring (e.g. pulse oximetry, capnography, ventilator alarms), and guidelines and training around management of the difficult airway [17].

Intensive care

A large, but variable proportion of reported in-hospital CPA occur in the intensive care setting, where significant monitoring and interventions are already in place. In one series the published survival to hospital discharge after nearly 50,000 cardiac arrests in critically patients was 15.9%, but this was much lower in patients receiving vasopressors at the time of arrest [18].

Pathophysiology of CPA

The actual CPAs are due to either shockable or non-shockable rhythms. Irrespective of the initiating rhythm, the end result of a CPA is inadequate delivery of oxygenated blood to the tissues. This process, combined with the underlying cause of the arrest, result in a large number of changes within the body. These include the activation of a number of mechanisms that result in a systemic inflammatory response, as well as irreversible damage to those organs at particular risk. A three-stage approach has been proposed to describe the sequential activation of various biochemical pathways: an electrical phase, a circulatory phase, and a metabolic phase. Tissue injury can occur from any of the compounding effects of local ischaemia, global ischaemia, and reperfusion. The changes in levels of oxygen free radicals, endotoxin, cytokines, interleukins, and tumour necrosis factor, as well as a number of other immunological effects, are similar to those seen with systemic sepsis. The resultant organ system damage (post-cardiac arrest syndrome) has been divided into, post-cardiac arrest brain injury, post-cardiac arrest myocardial dysfunction, and the systemic ischaemia/reperfusion response [12,19]. The occurrence of all of these phenomena has resulted in the tailoring of post-arrest therapy in a way to minimize the damage done, and speed recovery of function [12].

Ischaemic organ damage

Organs at particular risk of direct ischaemic damage include the brain, the heart, and the kidneys. The brain is at particular risk, because of its high oxygen consumption (and hence intolerance of ischaemia) and its response to reperfusion. Specific potential mechanisms for neuronal injury include excitotoxicity, disrupted calcium homeostasis, free radical formation, pathological protease cascades, and the activation of cell death signalling pathways [19]. Specific areas of the brain at risk include the hippocampus, the cortex, the cerebellum, the corpus striatum, and the thalamus [19].

Conclusion

The increasing understanding of the epidemiology and pathophysiology of cardiac arrests has resulted in improved outcomes over the last decade. Continued focus on prevention, early detection and individualized treatment will hopefully result in ongoing improvements.

CHAPTER 62

Cardiac massage and blood flow management during cardiac arrest

Gavin D. Perkins

Key points

- The quality of cardiopulmonary resuscitation (CPR) is critical to outcome from cardiac arrest.
- Optimal CPR quality is defined by compressions of adequate depth, rate, and avoidance of both leaning and interruptions to chest compressions.
- Compression only CPR is useful during dispatcher assisted CPR and if a CPR provider is unable or unwilling to perform ventilation.
- Mechanical chest compression devices can be helpful when it is difficult or unsafe to perform manual CPR.
- Vasoactive drugs improve haemodynamics and short term patient outcomes, but may worsen long term outcomes.

Introduction

When cardiac arrest occurs, meaningful blood flow ceases within seconds, leading to loss of consciousness and a decline in oxygen delivery to the vital organs. Without intervention, energy stores are depleted within minutes and a cascade of biochemical reactions occur, which culminate in death.

The birth of modern cardiopulmonary resuscitation (CPR) is widely attributed to a report in the *Journal of the American Medical Association* in 1960 [1]. External chest compressions were applied to a group of 20 patients in cardiac arrest—14 were successfully resuscitated and survived to hospital discharge. The authors concluded that 'Anyone, anywhere, can now initiate cardiac resuscitative procedures. All that is needed are two hands' [1].

At best, external chest compressions achieve approximately one-third of the normal cardiac output. Since the early descriptions of chest compressions, considerable information has emerged to define the optimal characteristics of chest compressions.

Optimal chest compression characteristics

Compression depth

Most animal models show a linear relationship between chest compression depth and cardiac output, coronary perfusion pressure and flow, although some suggest this effect plateaus at higher compression depths. In humans, increasing compression force raises aortic systolic pressure and end-tidal carbon dioxide, although there is no effect on aortic diastolic pressure [2]. Observational studies found deeper chest compressions are associated with defibrillation success, return of spontaneous circulation and survival to hospital admission [3]. In a cohort of 9136 adult patients receiving resuscitation from out of hospital cardiac arrest chest compression depth >38 mm was associated with better outcome [4]. For each 5 mm increment in compression depth the adjusted odds ratios were 1.06 (95% CI 1.04–1.08) for return of spontaneous circulation, 1.05 (95% CI 1.03–1.08) for 1-day survival and 1.04 (95% CI 1.00–1.08) for survival to discharge. Covariate-adjusted spline curves revealed that the maximum survival is at a depth of 45.6 mm (optimal range 40.3 and 55.3 mm) with no differences between men and women.

Chest compression rate

Higher compression rates are linked to better outcomes. The ILCOR review of science (2015) concluded that compression rates should be between 100–120/min [4]. Observational and experimental studies show that compression rates exceeding 120/min impact on other compression quality parameters (e.g. compression depth, leaning, decay) [5]. Data from recent human studies suggest a threshold effect with compression rates greater than 120/min are linked to worse outcomes [6].

Duty cycle

Duty cycle refers to the proportion of the chest compression cycle spent in the compression phase relative to the relaxation phase. Forward coronary blood flow occurs during the decompression phase of a chest compression cycle. Mathematical and animal models suggest a duty cycle of 50% is optimal.

Leaning

Failing to fully release pressure from the chest between sequential chest compressions is known as leaning. Observational studies indicate that leaning is relatively common during resuscitation. In animal models, even small amounts of leaning are associated with reduced mean arterial blood pressure, coronary perfusion pressure, cardiac output, and myocardial blood flow [7]. Guidelines recommend ensuring that pressure is fully released between sequential chest compressions.

Interruptions in chest compressions

Interruptions in chest compressions are common. Analysis of the reasons for interruptions identifies airway interventions, rhythm analysis, operating the defibrillator, switching chest compression provider, and poor team dynamics as causative factors. Interruptions in chest compressions are harmful, particularly around the time of attempted defibrillation. Interruptions just before a shock reduce the likelihood of shock success. In a series of 2006 cases, analyses adjusted for Utstein variables found that pre-shock pauses of < 10 sec and peri-shock pauses of < 20 sec improved survival to hospital discharge [8]. Pausing chest compressions briefly to check rhythm and then restarting chest compressions while the defibrillator is charged (Fig. 62.1) can minimize preshock pauses to less than 2 seconds [9].

Chest compression fraction

Compression fraction is the proportion of the resuscitation time during which compressions are performed; the higher the compression fraction, the better the outcome. In an observational study in 506 in-hospital cardiac arrests, the adjusted odds ratio for survival was 1.11 (95% CI, 1.01–1.21) for every 0.1 increase in compression fraction. Higher compression to ventilation ratios are linked to higher compression fractions; the current recommended ratio of compressions to ventilations of 30:2 is associated with higher chest compression fractions than previous ratios of 5:1 or 15:2. Asynchronous ventilation and continuous chest compressions minimize interruptions in CPR and are possible once the airway is secured with an endotracheal tube or supraglottic airway device.

Compression-only CPR

During the first few minutes after cardiac arrest due to a cardiac cause, there is likely to be sufficient oxygen within the lungs to maintain oxygenation during CPR. Randomized controlled trials provide convincing evidence that ambulance dispatcher telephone instructions should focus on compression only CPR [10]. Compression-only CPR is certainly better than no CPR in the event that a rescuer was unable or unwilling to do full CPR. However, there are certain specific situations where compressions-only CPR (without ventilation) is harmful; these include arrest secondary to asphyxia, cardiac arrest in children, and during prolonged resuscitation attempts.

Adjuncts and alternatives to CPR

Impedance threshold device

The impedance threshold device (ITD) [11] is a one-way valve that is placed at the airway to limit airflow into the lungs during chest recoil between compressions. This reduces intrathoracic pressure and increases venous return to the heart. Although most animal studies show improved haemodynamics during CPR with the ITD, clinical trials have produced conflicting results.

Active compression decompression

The active compression–decompression CPR (ACD-CPR) device is a hand-held manually-operated device that incorporates a suction cup to enable the chest to be lifted actively during decompression. Active decompression reduces intrathoracic pressure, which increases venous return to the heart and enabling increased cardiac output and increases coronary and cerebral perfusion pressures during the compression phase. However, a Cochrane review of ten trials found no evidence for improved patient-centred outcomes [12].

CPR feedback devices

CPR feedback and prompt devices allow real time feedback in training and clinical settings. Devices range from a simple metronome or flashing light that guide compression rate to more complex devices that monitor and provide feedback about actual CPR performance. The more complex devices allow data download at the end of the event for subsequent performance review, audit, and/or debriefing. The ILCOR systematic review of CPR feedback and prompt devices concluded that there is good evidence supporting the use of CPR feedback/prompt devices during CPR training to improve CPR skill acquisition and retention

[13]. Their use in clinical practice as part of an overall strategy to improve the quality of CPR may be beneficial.

Mechanical compression devices

Mechanical compression devices automate the process of manual chest compression. Most experimental studies show improved haemodynamics with mechanical CPR [14]. Additional advantages of mechanical compression devices are that they provide CPR of a consistent quality and can be deployed in situations where manual chest compressions are difficult (e.g. in an ambulance or during a percutaneous coronary intervention procedure) [14]. Despite theoretical advantages 3 large randomised trials have failed to show improved long-term outcomes [15–18]. ILCOR therefore recommends against the routine use of mechanical CPR devices. Mechanical CPR may be considered in situations where manual CPR is impractical or may compromise provider safety. Such situations may include ambulance transport, during cardiac catheterisation and prolonged resuscitation attempts.

Vasoactive drugs

Adrenaline (epinephrine) has been an integral component of advanced resuscitation algorithms since the early 1960s. Initial guidelines recommended intracardiac adrenaline (0.5 mg) or high dose intravenous adrenaline (10 mg). Adrenaline increases the rate of return of spontaneous circulation but impairs cerebral blood flow and increases cardiovascular instability [19]. This creates the paradox of an increase in initial survival, but worse survival and greater brain injury by the time of hospital discharge [20]. The need for randomized, placebo-controlled trials has been indentified by the International Liaison Committee for Resuscitation.

Extracorporeal Resuscitation

Extracorporeal membrane oxygenation (E-CPR) has been used as a rescue therapy in refractory cardiac arrest. A growing number of observational studies report survivors amongst patients who would otherwise have had resuscitation attempts terminated [20]. From the limited literature available, it is too early to draw definitive conclusions as to the effectiveness of this intervention for which patient selection is likely to be the key to the success. Identification of patients with limited co-morbidities, a reversible cause of cardiac arrest, and other good prognostic factors (e.g. witnessed arrest, early bystander CPR) and initating ECPR within 60 minutes of cardiac arrest is likely to be central to whether the treatment is found to clinically and cost effective [20].

CHAPTER 63

Defibrillation and pacing during cardiac arrest

Charles D. Deakin

Key points

- Defibrillation should not be allowed to interrupt external chest compressions for more than 5 seconds.
- Biphasic waveforms are more effective than the older monophasic waveform.
- In adults, biphasic shocks should commence at 150 J, with subsequent shocks being given at the same or greater energy levels.
- In children (<8 years), all shocks should be delivered at 4 J/kg.
- External pacing is ineffective for asystole, but should be considered for bradyarrhythmias refractory to pharmacological therapy.

Defibrillation

Defibrillation is the passage of an electrical current across the myocardium in order to change the electrical activity of the heart from a chaotic to organized rhythm. It is a term usually used in relation to the treatment of ventricular fibrillation (VF) or ventricular tachycardia (VT); when used for the treatment of atrial fibrillation (AF) or atrial flutter, it is usually termed 'cardioversion'.

History

Although the Danish physician Abildgaard described the use of electricity to stun and revive chickens in 1775, it was not until 1899 when Prevost and Batelli demonstrated that electric shocks could terminate VF in dogs that a more scientific understanding of defibrillation began. The first successful human defibrillation was performed in 1947 by Beck, using internal cardioversion, followed nine years later by Zoll using external defibrillation. Direct current defibrillation soon replaced alternating current as it was shown to result in less myocardial stunning and fewer post-shock arrhythmias.

Mechanisms of action

The precise mechanism of defibrillation remains unknown and the existence of several hypotheses suggests that a complex mechanism underlies the ability of electrical impulses to restore organized electrical activity in the heart [1].

Critical mass hypothesis

Proposes that only a critical mass of myocardium must be depolarized, rather than the entire myocardium. Activation fronts not terminated by the shock in the remaining myocardium are not sufficient to maintain fibrillation and soon extinguish. The critical mass has been estimated as 75–90% of myocardial mass.

Upper limit of vulnerability hypothesis

Proposes that to successfully defibrillate, a shock must:

- Halt the activation fronts of fibrillation by either directly activating the myocardium or by rendering it refractory to stimulation just ahead of these activation fronts.
- Prevent re-initiation of new activation fronts, which could propagate away from the border of the directly excited region and re-initiate fibrillation [2].

Refractory period extension hypothesis

Proposes that because successful defibrillation shock extends the refractory period of action potentials in excitable myocardium, VF wave fronts are terminated by blocking their propagation throughout the ventricles.

Synchronized repolarization hypothesis

Proposes that a defibrillation shock creates an additional phase of depolarization from just after completion of the upstroke (phase 0) to a nearly maximal repolarization time (late phase 3), of the fibrillating action potentials. As a result, the myocardium repolarizes at a constant time after the shock irrespective of its pre-shock fibrillating electrical activity. This creates an iso-electric window during which synchronized electrical activity can resume.

Virtual electrode polarization hypothesis

Defibrillation shocks can produce simultaneous areas of depolarization and hyperpolarization. Depolarization can result in prolongation of the action potential if the tissue is refractory, or activation if the tissue is excitable. Conversely, hyperpolarization can shorten the action potential and completely repolarize the tissue to restore excitability [3].

Technical aspects of defibrillation

Waveforms

Biphasic defibrillators have become established as the defibrillators of choice, and very few monophasic defibrillators remain in clinical use. Unfortunately, defibrillators are not marked as to their waveform and the highest possible energy levels should be used if the operator is unsure which type of waveform the defibrillator delivers.

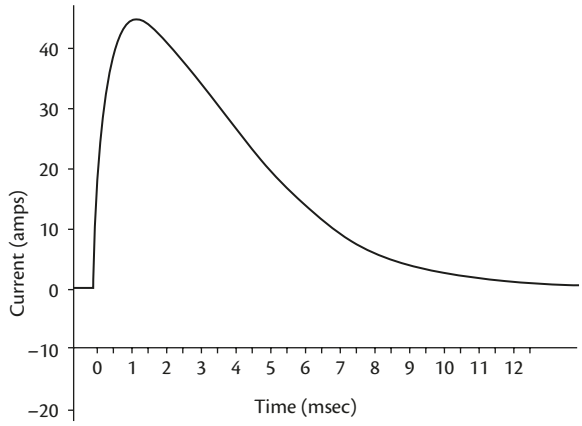

Fig. 63.1 Monophasic damped sinusoidal waveform.

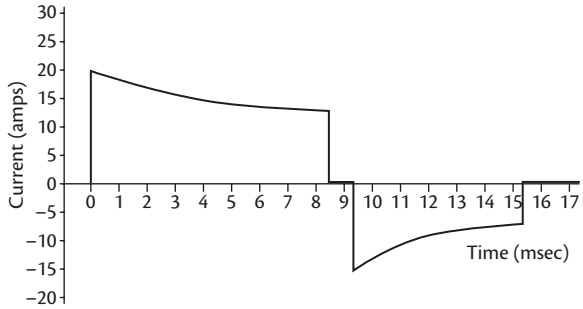

Fig. 63.2 Biphasic truncated exponential waveform.

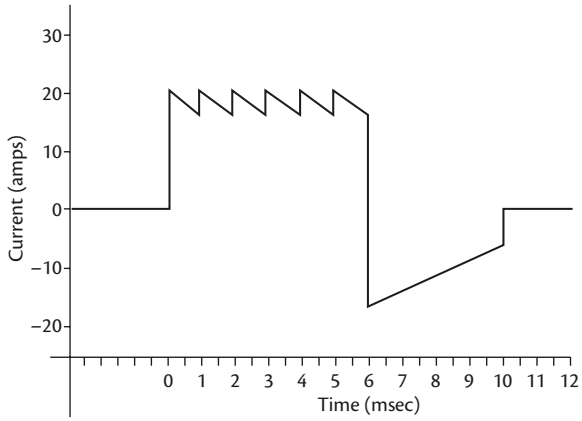

Fig. 63.3 Rectilinear biphasic waveform.

The commonest monophasic waveform is the damped sinusoidal (MDS) waveform, which gradually returns to zero current flow (Fig. 63.1). Monophasic waveforms are very susceptible to variation in transthoracic impedance (TTI); small patients with low TTI would receive an excessive transmyocardial current, and large patients with a high TTI risked receiving a broadened waveform that failed to reach sufficient peak current to achieve successful defibrillation. Monophasic waveforms are of limited efficacy, delivering first shock success rates of 50–70%.

There are two main types of biphasic waveform: the biphasic truncated exponential (BTE) (Fig. 63.2) and the rectilinear biphasic

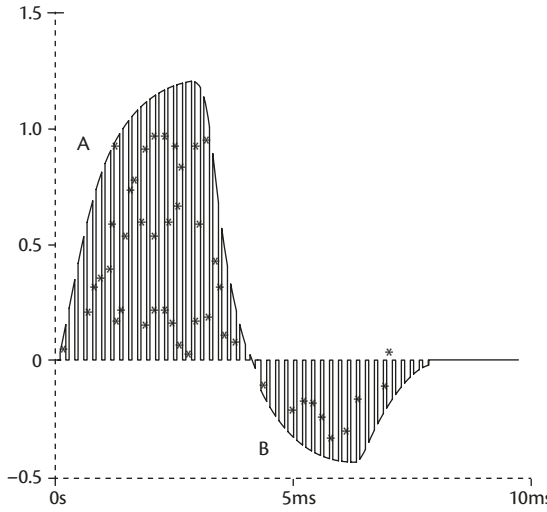

Fig. 63.4 Multiphase biphasic waveform.

(RLB) waveform (Fig. 63.3). Computer modelling suggests that the role of the first positive phase of a biphasic defibrillation waveform is to hyperpolarize the cardiac cell membrane from its most negative potential of approximately –65 mV during fibrillation back to its resting transmembrane voltage of –90mV. This decrease in transmembrane potential is hypothesized to allow Na^+ channels to recover, thus allowing easier tissue stimulation during the second negative phase of the biphasic waveform.

Biphasic defibrillators compensate for variations in transthoracic impedance by electronically adjusting the waveform to optimize its magnitude and duration. Biphasic waveforms typically deliver only half the current associated with monophasic waveforms, but achieve a greater first shock success rate of 90–95%. However, use of biphasic waveforms have not been shown to be associated with greater survival than monophasic waveforms. Because of the significantly lower current, biphasic waveforms are associated with reduced post-shock burns, fewer post-shock arrhythmias, and reduced electrocardiogram (ECG) injury potential.

The newest waveform in clinical use is the multiphasic waveform, in which a multiphase waveform is incorporated into a biphasic waveform. A recent study has demonstrated similar efficacy rates to those seen with biphasic waveforms (Fig. 63.4).

Triphasic, and quadriphasic waveforms are showing promise for delivering effective defibrillation at even lower currents and other novel waveforms such as those that form a spinning thoracic current are also under investigation as potentially effective waveforms.

Safety

Oxygen concentrations as high as 60% have been measured in enclosed environments using oxygen-powered medical devices [4], 24% oxygen doubles the rate of combustion and 30% oxygen increases combustion rate 10-fold. In an oxygen-enriched atmosphere, sparking from poorly applied defibrillator paddles in an oxygen-enriched environment can cause a catastrophic fire.

The risk of fire during attempted defibrillation can be minimized by taking the following precautions:

- Remove any oxygen mask or nasal cannulae and place ≥ 1 m away from the patient's chest.

- Leave any bag-valve device connected to a tracheal tube or other airway adjunct (e.g. laryngeal mask airway, Combitube, or laryngeal tube). Alternatively, disconnect any bag-valve device from the tracheal tube (or other airway adjunct), and remove it ≥ 1 m from the patient's chest during defibrillation.
- If the patient is connected to a ventilator, leave the ventilator tubing (breathing circuit) connected to the tracheal tube during defibrillation [5].

Application of defibrillation electrodes

Self-adhesive defibrillation pads are generally replacing defibrillation paddles. They improve safety by avoiding the need to lean over the patient during defibrillation and provide better electrical contact with the skin compared with the flat metal plates of defibrillation paddles, minimizing the risk of electrical arcing and fire.

Optimal electrode position is one that results in greatest current flow across the myocardium. The standard position to achieve this is the sternal electrode placed to the right of the sternum, immediately below the clavicle and the apical paddle placed in the mid-axillary line (Fig. 63.5), level with the V6 ECG electrode position. Acceptable alternative positions include:

- Bi-axillary.
- **Anterior (left sternal edge)**: posterior (between the left clavicle and spine).
- **Posterior (behind the right clavicle)**: apical [5].

Clinical aspects of defibrillation

Defibrillation is one of the few interventions that have been shown to improve survival from cardiac arrest and it is therefore a key link in the chain of survival (Fig. 63.6). The probability of successful defibrillation and neurologically-intact survival to hospital discharge is time critical, with every minute that passes between collapse and defibrillation resulting in an increase in mortality of 7–10%, this increase is slowed marginally in patients receiving bystander resuscitation.

In order to reduce delays in defibrillation, the introduction of public access defibrillators in areas of high population density (e.g. airports, shopping centres, railways stations, etc.) has resulted in significantly improved survival rates, particularly in some urban areas. In more rural areas rapid activation of trained community responders is also contributing to early defibrillation.

CPR versus defibrillation as the initial treatment

Although early studies suggested that a period of cardiopulmonary resuscitation (CPR) for 1–3 minutes prior to defibrillation increased the defibrillation success rate, subsequent larger studies failed to repeat these observations. It is now recommended that when treating both in- and out-of-hospital cardiac arrest, rescuers should provide good-quality CPR, while a defibrillator is quickly applied and charged, but routine preshock CPR (e.g. 2 or 3 minutes) is no longer recommended.

One shock versus three shock sequence

With first shock efficacy of biphasic waveforms exceeding 90%, failure to successfully defibrillate is more likely to suggest the need for a period of CPR, rather than a further shock. The previous recommendations for up to three shocks before resuming CPR have now been superseded by a single shock sequence.

Only on the rare occasion of a monitored VF/non-pulsatile VT arrest, it is acceptable to deliver three stacked shocks using a

Fig. 63.6 Chain of survival.
Reproduced with permission from Laerdal Medical.

manual defibrillator before commencing 2 minutes of external chest compression and ventilation if necessary. Automatic external defibrillators (AEDs) are all programmed to deliver a single shocks before recommencing the 2-minute CPR cycle [5].

Energy levels

First shock efficacy of the BTE waveform using 150–200 J has been reported as 86–98% and of the RLB waveform using 120 J as 85% [6]. The initial biphasic shock should be no lower than 120 J for RLB waveforms and 150 J for BTE waveforms. Ideally, the initial biphasic shock energy should be at least 150 J for all waveforms when defibrillating ventricular arrhythmias.

If the first shock is unsuccessful, there is no evidence to suggest that either a fixed or escalating energy protocol is more effective. However, although an escalating strategy reduces the number of shocks required to restore an organized rhythm compared with fixed-dose biphasic defibrillation, rates of return of spontaneous circulation or survival to hospital discharge are not significantly different between strategies. Both fixed or escalating strategies are acceptable, but when using a manual defibrillator, it is reasonable to increase the energy for subsequent shocks.

The lower efficacy of the monophasic waveform means the initial and all subsequent monophasic shocks should be delivered at 360 J [5].

Detrimental effects of defibrillation

Interruptions to chest compressions adversely affect the outcome of a resuscitation attempt. One of the commonest causes of these interruptions is defibrillation, due to pre-shock and post-pauses in chest compressions associated with ECG analysis, delivery of the shock and a pulse check.

In order to minimize interruptions to chest compressions associated with defibrillation, it is now recommended to continue chest compressions whilst the defibrillator is charged. Immediate resumption of chest compressions following defibrillation is also emphasised, without pausing for a pulse check, which should only then take place after 2 minutes of CPR [7]. Defibrillation should be achievable with an interruption in chest compressions of no more than 5 seconds [8].

Defibrillation in children

Shockable rhythms occur in only 7–15% of paediatric and adolescent arrests with a much lower percentage than in adult cardiac arrest. Common causes of VF in these children include trauma, congenital heart disease, drug overdose, and hypothermia.

Ideally, paediatric self-adhesive pads with electrical attenuators should be used for children aged less than 8 years, but when these are not available, adult pads are acceptable, as long as there is no direct contact between the two electrodes.

The recommended energy levels for both monophasic and biphasic defibrillation are 4 J/kg for the initial and all subsequent shocks [9].

Internal defibrillation

When using internal paddles during a cardiac arrest, a 10–20 J shock is considered optimal [10].

Pacing

In emergencies, pacing is usually limited to delivery through external pads (placed in similar position to that for defibrillation), unless an internal system (endocardial or epicardial) has been placed previously.

External pacing delivers a pulsed transmyocardial impulse that causes ventricular depolarization and myocardial contraction. It is usually delivered in a demand mode because a fixed mode does not sense the QRS complex and risks pacing on the T-wave, with the potential to induce VF. The relatively high current can cause chest muscle contractions and cutaneous pain under the electrode. Using the lowest output setting necessary to achieve capture will minimize this discomfort, but sedation and/or analgesia may be necessary.

Pacing is of no proven effectiveness for asystole unless P waves are present, but it should be considered for:

- Patients with symptomatic bradycardia refractory to anti-cholinergic drugs or other second line therapy.
- Conduction blocks at or below the His-Purkinje level.

If transthoracic pacing is ineffective, consider transvenous pacing which requires central venous access and pacing wire insertion under X-ray guidance or through an appropriate pulmonary artery catheter [5].

CHAPTER 64

Therapeutic strategies in managing cardiac arrest

John Field

Key points

- Updated resuscitation guidelines emphasize the need for minimally interrupted high quality chest compressions as a prerequisite for successful resuscitation outcome.
- Resuscitation involves the integration of complex systems and the interdisciplinary coordination of multispecialty emergency and critical care providers.
- The immediate period following return of spontaneous circulation (ROSC) is crucial and is dominated by the presence of two critical goals—identification of the pathophysiological cause, and the assessment and initiation of time-dependent interventions, directed at preventing recurrent arrest, and improving immediate and long-term outcome.
- There is no vasopressor or anti-arrhythmic agent whose use is associated with improved outcome at discharge. In-hospital resuscitation should focus on the provision of high quality chest compressions and the search for immediate treatable precipitants of the arrest in those patients who achieve ROSC.
- A systematic checklist may aid in the systematic evaluation of patients following ROSC.

Introduction

Traditional care of the cardiac arrest patient has emphasized two treatment components: basic life support (BLS) and advanced cardiac life support (ACLS). An algorithmic approach to resuscitation emphasizes the 'chain of survival'. However, successful resuscitation and optimal patient outcome require a broader interdisciplinary approach that includes immediate post-cardiac arrest care. This topic will focus on the important components and interventions of care to achieve return of spontaneous circulation (ROSC) and immediately stabilize a patient while positioning them for optimal long-term recovery. Important components of basic and advanced life support are summarized. Comprehensive details can be reviewed in recent 2010 updates of Guidelines for Cardiopulmonary Resuscitation (CPR) and Emergency Cardiovascular Care [1,2].

During resuscitation: optimizing success for return of spontaneous circulation

Basic life support

Immediate by-stander CPR predicts improved survival and outcome from cardiac arrest. However, the traditional focus on complex training and treatment sequences failed to emphasize simple skills and focus on major determinants of patient survival—high quality chest compressions and very early defibrillation. Failure to perform high quality minimally interrupted chest compressions is associated with decreased response to defibrillation attempts, decreased ROSC and, ultimately, decreased survival of patients with good neurological outcome. 'Push hard, push fast' is now the core skill in BLS and very early defibrillation is the major intervention emphasized. A new circular American Heart Association (AHA) algorithm highlights the importance of continuous uninterrupted chest compressions (Fig. 64.1).

Very early defibrillation

Early defibrillation in conjunction with high quality minimally interrupted chest compressions is critical to survival following sudden cardiac arrest. Survival rates decrease 7–10% with each minute that passes without defibrillation and an initial shockable rhythm of ventricular fibrillation (VF) will then deteriorate into pulseless electrical activity (PEA) and asystole.

It is important however, to realize that early defibrillation alone does not usually improve survival and that integration of high quality minimally interrupted chest compressions is essential for optimal outcome. For example, the National Registry of CPR (NRCPR) observed that the use of an automatic external defibrillator (AED) was not associated with improved survival for in-hospital cardiac arrest in patients presenting with VF as the initial rhythm [3].

Advanced life support

For patients in refractory VF, PEA, or asystole, advanced life support (ALS) measures are initiated and include intravenous access, pharmacological therapy, mechanical adjuncts for circulatory support together with airway support and intervention. However, no ALS technique has been demonstrated in randomized controlled trials to improve outcomes defined as discharged alive and neurologically intact. The European Resuscitation Council Advanced

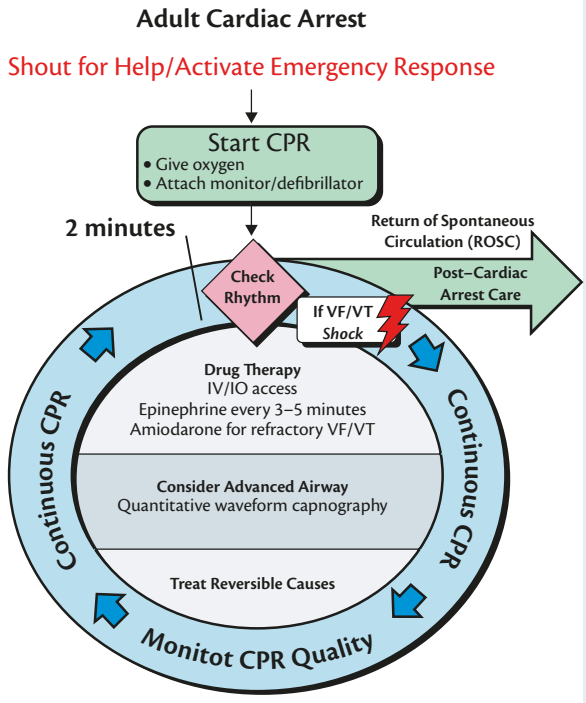
Life Support algorithm emphasizes the essential components of ALS including core high quality CPR and immediate post-cardiac arrest treatment (Fig. 64.2). Current guidelines have decreased the emphasis on advanced airway interventions and pharmacological therapy during adult sudden cardiac arrest. Airway management is discussed in Chapter 59, 'Airway Management in Cardiopulmonary Resuscitation'.

Pharmacological therapy

Historically, significant efforts and resuscitation goals focused on the administration of drugs during CPR largely based on animal data and non-randomized clinical trials. Pharmacological agents have proved disappointing and no specific drug has improved outcome following cardiac arrest. Vasopressors and anti-arrhythmic agents are included in current guidelines, but their administration should not delay or interrupt high quality chest compressions or attempts at defibrillation. However, possible confounding parameters for pharmacologic efficacy are time to administration and quality of chest compressions permitting delivery of drugs to the circulation.

Vasopressors

The vasopressors epinephrine and vasopressin have been studied in animal models and randomized clinical trials. To date, no placebo-controlled trials have shown that any vasopressor administered during management of VF/VT, asystole, or PEA improves survival to hospital discharge. Epinephrine was initially the preferred vasopressor largely based on animal experiments. Peripheral selective alpha-2 adrenergic stimulation and improvement in aortic diastolic pressure and coronary perfusion pressure improved



CPR Quality
- Push hard (≥2 inches [5 cm]) and fast (≥100/min) and allow complete chest recoil
- Minimize interruptions in compressions
- Avoid excessive ventilation
- Rotate compressor every 2 minutes
- If no advanced airway, 30:2 compression-ventilation ratio
- Quanititave waveform capnography
  – If P_{ETCO_2} <10 mm Hg, attempt to improve CPR quality
- Intra-arterial pressure
  – If relaxation phase (diastolic) pressure <20 mm Hg, attempt to imprve CPR quality

Return of Spontaneous Circulation (ROSC)
- Pulse and blood pressure
- Abrupt sustained increase in P_{ETCO_2} (typically ≥40 mm Hg)
- Spontaneous arterial pressure waves with intra-arterial monitoring

Shock Energy
- **Biphasic:** Manufacturer recommendation (120–200 J); if unknown, use maximum available. Second and subsequent doses should be equivalent, and higher doses may be considered.
- **Monophasic:** 360 J

Drug Therapy
- **Epinerphrine IV/IO Dose:** 1 mg every 3–5 minutes
- **Vasopressin IV/IO Dose:** 40 units can replace first or second dose of epinerphrine
- **Amiodarone IV/IO Dose:** First dose: 300 mg bolus. Second dose: 150 mg.

Advanced Airway
- Supraglottic advanced airway or endortracheal intubation
- Waveform capnograpghy to confirm and monitor ET tube placement
- 8–10 breaths per minute with continuous chest compressions

Reversible Causes
- **H**ypovolemia
- **H**ypoxia
- **H**ydrogen ion (acidosis)
- **H**ypo-/hyperkalemia
- **H**ypothermia
- **T**ension pnuemothorax
- **T**amponade, cardiac
- **T**oxins
- **T**hrombosis, pulmonary
- **T**hrombosis, coronary

Fig. 64.2 European Resuscitation Council Adult Advanced Cardiac Life Support.

ROSC, but associated alpha-1 and beta-2 adrenergic stimulation is potentially detrimental. However, pure alpha-vasoconstrictors failed to prove beneficial as compared to epinephrine [4]. Beta blockade during cardiac arrest was promising in animal models, but clinical trials in humans demonstrating efficacy remain to be performed [5].

Vasopressin was introduced as a non-adrenergic vasoconstrictor increasing both coronary and cerebral blood flow while avoiding the inotropic and chronotropic beta-2 adrenergic stimulation of epinephrine. However, randomized clinical trials have failed to show vasopressin to be superior to epinephrine [6].

Anti-arrhythmia agents

Although anti-arrhythmic agents are used routinely during refractory VT/VF cardiac arrest, lidocaine, and amiodarone have not been demonstrated to improve survival to discharge. Amiodarone improves admission to hospital when administered for refractory out-of-hospital VT/VF [7,8]. Available evidence suggests that the routine use of atropine for PEA/asystole is not associated with improved outcome and atropine has been eliminated from recent resuscitation algorithms for these rhythms.

Return of spontaneous circulation and differential diagnosis

Following sudden arrest, ROSC is defined as the presence of an organized rhythm and a palpable pulse. The immediate period following ROSC is crucial and is dominated by the presence of two critical goals. The first goal attempts to define the trigger or aetiology for the cardiac arrest (Fig. 64.2 and Table 64.1) and, concurrently, the second goal incorporates the assessment and initiation of time-dependent interventions directed at preventing recurrent arrest and improving immediate and long term outcome (Fig. 64.3). It is important in this context to realize that resuscitation continues following ROSC and is called post-cardiac arrest care.

Immediate decisions following ROSC

Both during refractory cardiac arrest and immediately following ROSC a quick check list helps to identify comorbidities that have contributed to the arrest and serve to position the patient for recurrent arrest, haemodynamic compromise and serious arrhythmias. Common pathophysiological conditions have been described as the H's and the T's and serve as a useful checklist during and immediately after ROSC (Table 64.1). Specific diagnostic and laboratory tests are prioritized to help establish a differential diagnosis in the minutes following ROSC. Most helpful are tests to assess the metabolic status of the patient, a 12-lead electrocardiogram, chest X-ray, and cardiac ultrasonography (Table 64.2).

Table 64.1 The Hs and the Ts (modified). Immediately following ROSC a checklist differential diagnosis using the pneumonic 'H's and T's' can guide post-cardiac arrest assessment. The checklist is prioritized as additional patient history is integrated into consideration. Indicated and expedited laboratory and diagnostic testing is ordered targeting correctable causes and comorbidities of cardiac arrest

Hs	Ts
☐ Hypoxia	☐ Thrombosis (coronary)
☐ Hypo/hypervolaemia (CHF)	☐ Thrombosis (PTE)
☐ Hydrogen ion (acidosis)	☐ Tear (aorta)
☐ Hypo/hyperkalaemia	☐ Tamponade (cardiac)
☐ Hypothermia	☐ Tension pneumothorax
☐ Head (stroke/haemorrhage)	☐ Toxins

Data from www.resus.org.au

Table 64.2 ROSC Laboratory and Diagnostic Checklist. A checklist can guide and prioritize laboratory and diagnostic testing following ROSC to identify the cause of the cardiac arrest or comorbidity compromising stability or impacting on optimal outcome

Lab/metabolic	Diagnostic
☐ Electrolytes	☐ Focused clinical exam
☐ Haemoglobin/haematocrit	☐ 12-lead electrocardiogram
☐ Arterial blood gas	☐ Chest X-ray
☐ Lactate	☐ Cardiac ultrasound
☐ Core temperature	☐ Indicated CT scans

Stabilization and immediate decisions post-cardiac arrest

Following ROSC important time-dependent decisions must be made (Fig. 64.3). Following initial haemodynamic and respiratory stabilization, consideration of targeted temperature management (TTM), triage for coronary angiography (if indicated), and transfer to an appropriate critical care unit with comprehensive post-cardiac arrest care protocols and resources are essential [9,10]. Bundled, goal directed therapy has been shown to reduce early haemodynamic instability and subsequent morbidity and mortality from cardiovascular, neurologic, metabolic, and other reversible pathology [11].

Initiation of targeted temperature nanagement (induced hypothermia)

Two small randomized trials [12,13] reported that induced hypothermia improved neurological outcome following resuscitation from cardiac arrest. These trials reported improved neurological outcome in comatose patients with out-of-hospital VF. More recently a much larger high quality trial led by the Scandinavian Critical Care Trials Group reported no difference in outcome when the target temperature was either 33°C or 36°C [14]. Following that trial the International Liason Committee on Resuscitation considers temperature management targeting either 33°C or 36°C to be appropriate treatment following ROSC. Although the efficacy and optimal time-to-target temperature is undefined, many systems initiate temperature management as early as possible during emergency medical services (EMS) transport and coronary angiography.

Triage for coronary angiography and percutaneous coronary intervention

The majority of adult out-of-hospitals cardiac arrests (OHCA) occur in the setting of an acute coronary syndrome and adult patients with no obvious cause for OHCA may be considered for triage to percutaneous coronary intervention (PCI) facilities. Despite the lack of randomized data the performance of PCI following ROSC has been associated with favourable outcomes [15–17] and survivors of cardiac arrest with ST-segment elevation myocardial infarction (STEMI) have a particularly good neurological outcome [18]. Importantly, comatose patients should not be excluded from consideration of angiography and therapeutic hypothermia can be successfully initiated or continued during PCI [19].

Patients with STEMI should be triaged to PCI capable facilities. The electrocardiogram (ECG) is specific for STEMI following cardiac arrest, but the recording may be insensitive and patients with other ECG patterns may also benefit [17]. If indicated induced hypothermia can be initiated successfully during transport to and within hospital and during cardiac catheterization.

Conclusion

Strategies for management of cardiac arrest are time-sensitive and immediate successful ROSC requires prompt recognition, high quality minimally interrupted chest compressions and, when indicated, early defibrillation. Airway interventions, drug administration, and other interventions during management of cardiac arrest should not delay defibrillation and avoid interrupting high quality chest compressions. Following ROSC, a critical period exists when appropriate triage and use of time-dependent treatments with coordinated interdisciplinary care can improve both short-term outcome and long-term functional recovery.

CHAPTER 65

Post-cardiac arrest arrhythmias

Marwan F. Jumean and Mark S. Link

Key points

- Global ischaemia and reperfusion injury are the hallmarks of post-arrest myocardial dysfunction.
- In patients with recurrent arrhythmias, every effort should be made to correct the underlying precipitating factors that led to the arrest.
- Early coronary revascularization should be considered in all patients with recurrent ventricular arrhythmias.
- Amiodarone is a relatively safe anti-arrhythmic agent and should be used in recurrent ventricular arrhythmia once underlying causes have been treated.
- ICD placement is recommended in all patients with ventricular arrhythmia with the exception of those within 48 hours of an ST elevation myocardial infarction.

Introduction

There has been increasing emphasis in recent years on understanding the pathophysiology and management of the post-cardiac arrest syndrome that follows the return of spontaneous circulation (ROSC) [1,2]. The importance of post-arrest care and its impact on survival has been highlighted by the addition of the 5th link in the chain of survival in the American Heart Association (AHA) resuscitation guidelines [2]. Following ROSC, a variety of measures should be undertaken in an attempt to halt or reverse pathologic processes that occur at the time of and following cardiac arrest. ROSC initiates a cascade of ischaemic reperfusion injury to the myocardium that is mediated in part by oxygen free radicals and high levels of circulating cytokines [3]. These processes create a state of electrical instability in the 24–72-hour period after ROSC, which may give rise to a wide spectrum of arrhythmias ranging from atrial fibrillation and premature ventricular complexes to intractable ventricular tachycardia (VT) or ventricular fibrillation (VF). The focus of this chapter is to explore the arrhythmias that can develop after cardiac arrest, and understand the pathophysiology, prevention, and management of such arrhythmias.

Post-arrest arrhythmias

Sustained ventricular tachycardia and ventricular fibrillation

VT (Fig. 65.1) is an organized monomorphic wide complex tachycardia, while VF (Fig. 65.2) is a disorganized polymorphic wide complex tachycardia. Some experts argue for dividing VF into subtypes of polymorphic VT, torsades (Fig. 65.3), or standard VF, but generally all subtypes appear to be of similar morphology when they initiate (course and undulating) and all will degenerate into more standard VF if they continue. Recurrent VT or VF following ROSC is most commonly due to an acute coronary syndrome, particularly ST segment elevation myocardial infarction (STEMI). In the fibrinolytic era, 10% of patients presenting with STEMI had ventricular arrhythmias and in the percutaneous coronary intervention (PCI) era 6% had VT or VF within the first 48 hours [4–5]. The development of VT usually correlates with a larger infarct size [7]. There may be a familial genetic component to the increased risk of VT and VF in patients presenting with acute coronary syndrome (ACS) [8]. Following out of hospital cardiac arrest, recurrent VF has been reported in as many as 61–79% of patients with ROSC [6].

The development of recurrent VT or VF within 48 hours of an acute coronary syndrome is associated with increased in-hospital mortality. However, the data on long-term mortality risk following early (less than 48 hours) VT is inconclusive, whereas for patients with VF, long-term mortality beyond 30 days does not appear to be significantly increased [4,7].

In addition to myocardial ischaemia, uncorrected electrolyte disturbances, particularly hypokalaemia and hypomagnesaemia, can predispose to VF by a decrease in current flow of the rapid component of the delayed rectifier potassium current (IKr) leading to prolonged QT interval. This effect may be potentiated by the use of drugs known to prolong QTc, including most anti-arrhythmic agents, certain antibiotics (azithromycin, erythromycin), anti-emetics (droperidol), and antipsychotic medications (chlorpromazine, haloperidol).

Accelerated Idioventricular rhythm

Accelerated idioventricular rhythm (AIVR) (Fig. 65.4), also known as slow VT, was first described in 1910, and is usually observed in patients with acute coronary syndromes. AIVR is defined as a wide complex arrhythmia originating in the ventricle at a rate less than 120 bpm. In the era of thrombolytic therapy, AIVR was felt to be a marker of successful reperfusion. However, this has not generally been observed in the PCI era [9]. AIVR results from increased automaticity or triggered activity. It is often facilitated by sinus bradycardia, and does not usually cause haemodynamic instability unless significant myocardial dysfunction exists. AIVR is not associated with increased short or long term mortality.

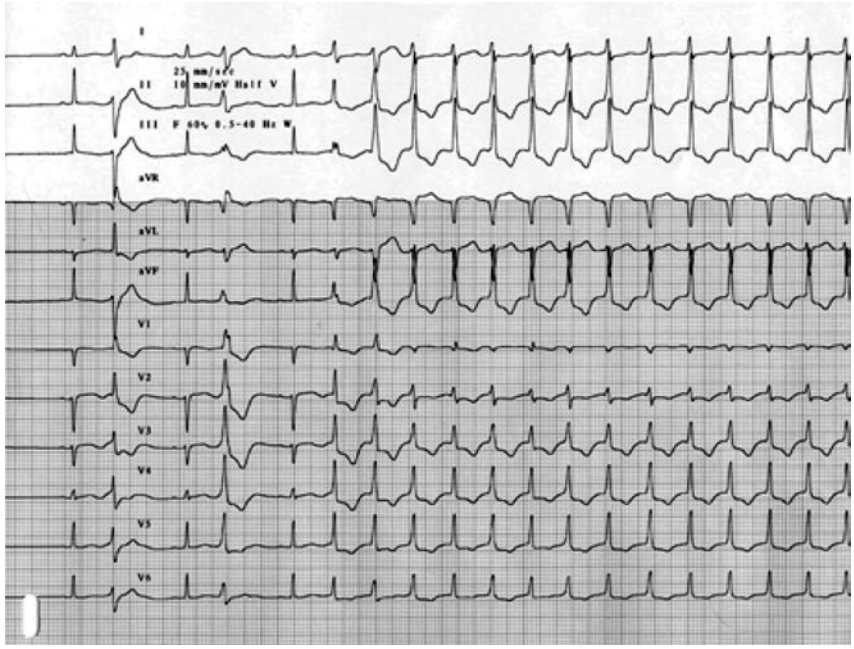

Fig. 65.1 Monomorphic ventricular tachycardia due to ischaemic cardiomyopathy

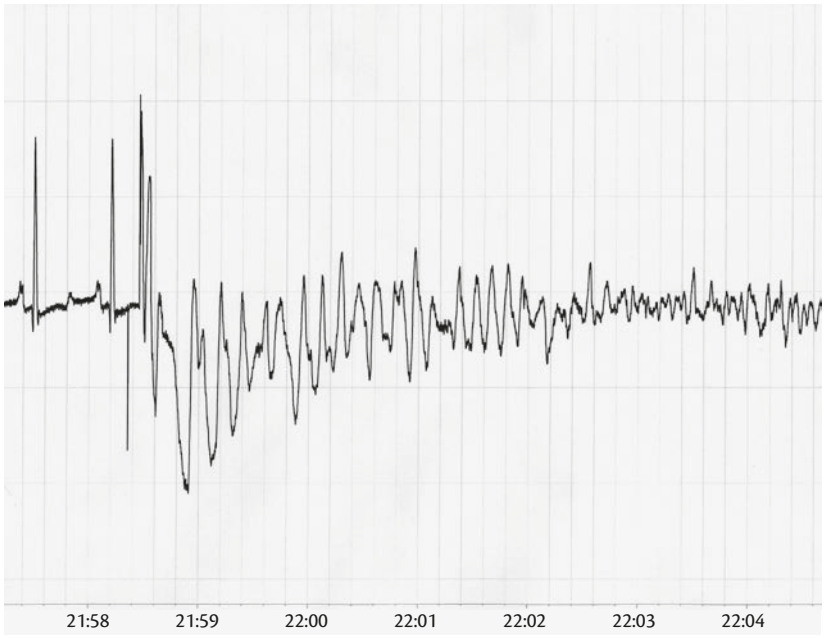

Fig. 65.2 Ventricular fibrillation in an animal model of commotio cordis. The initiation of ventricular fibrillation appears to be polymorphic ventricular tachycardia which quickly degenerates into ventricular fibrillation.

Atrial fibrillation

Atrial fibrillation (AF) is the most common cardiac arrhythmia in the general public, yet there are no published studies that assessed the prevalence or mechanisms of AF following ROSC. AF, even in the setting of haemodynamic instability, rarely leads to cardiac arrest with the exception of patients with Wolff–Parkinson–White syndrome (WPW). AF following ROSC is multifactorial, often triggered by the interplay between the neuro-hormonal milieu in the post-arrest period, increased catecholamine levels, frequent use of inotropes, vasopressors, the patient's underlying comorbid conditions, and the cause of the arrest. There are no published mortality data on patients with AF following ROSC.

Mechanism

There are several factors that place cardiac arrest patients at a higher risk of cardiac arrhythmia following ROSC, particularly in the first few days that follow the arrest. These factors include persistence of

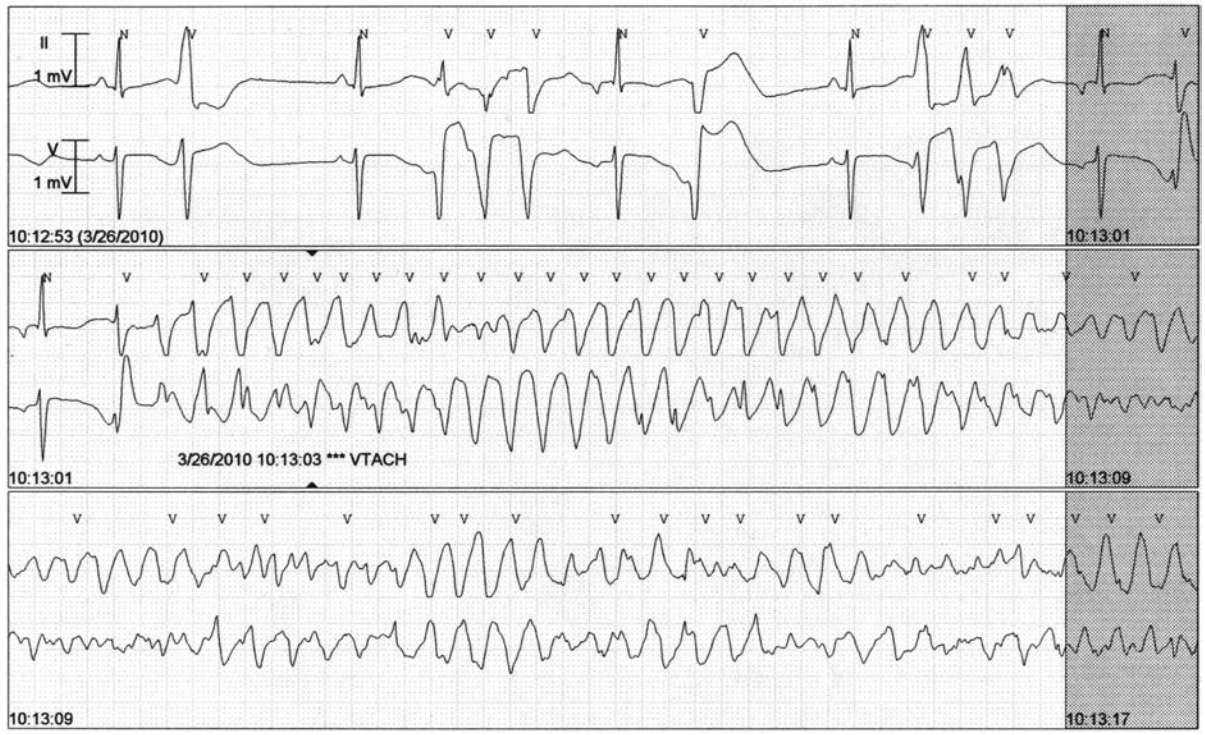

Fig. 65.3 Torsades de pointes or polymorphic ventricular tachycardia in a 28-year-old patient treated with fluconazole and nortryptiline. Note the prolonged QTc and the R on T beat in the upper panel. In the middle panel, torsades de pointes initiates and then degenerates into ventricular fibrillation.

Fig. 65.4 Accelerated idiopathic ventricular tachycardia. This wide complex ventricular rhythm is barely more rapid than the normal sinus rhythm.

uncorrected precipitating factor(s) that led to the arrest, changes in the neuro-hormonal milieu following the arrest, and the development of post-arrest myocardial dysfunction. Precipitating factors of persistent electrical instability post-arrest include persisting coronary artery lesions with unstable plaque or fresh thrombus in patients presenting with ACS; chronic ischaemic, dilated, restrictive, congenital, or hypertrophic cardiomyopathies, large pulmonary emboli, uncorrected severe electrolyte and acid-base disturbances, or toxins. During cardiopulmonary resuscitation, the delivery of electrical defibrillation may contribute to post-arrest myocardial dysfunction [10]. Following ROSC a number of factors contribute to a state of cardiac electrical instability, These include elevated endogenous catecholamine levels, the lingering effects of vasoactive agents such as vasopressin and epinephrine administered during the arrest, the subsequent use of inotropic agents and vasopressors. These factors increase left ventricular afterload, may induce coronary vasospasm, and an increase in myocardial oxygen demand all of which predispose to arrhythmias [1]. Furthermore, therapeutic hypothermia implemented to minimize hypoxic brain injury often leads to bradycardia and prolongs QTc which predisposes to polymorphic VT and VF [11]. Lastly, emerging evidence suggests that both acute systolic and diastolic left ventricular dysfunction due to myocardial stunning is common following cardiac arrest, this also predisposes to recurrent arrhythmias [12].

Management

With few exceptions, the management of post-arrest arrhythmias should not differ from the acute management of the initial arrhythmias that led to the arrest. Every effort should be made to correct and treat precipitating factors and reversible causes, with particular emphasis on coronary revascularization in those presenting with VF.

Ventricular fibrillation and tachycardia

The use of beta-blockers and anti-arrhythmic drugs is an effective approach for the treatment of recurrent ventricular arrhythmias following ROSC. VF, torsades de points, and polymorphic VT are not organized rhythms and never maintain haemodynamic stability. Thus VF should be treated immediately with early, high energy defibrillation following established ACLS protocols.

Since the most common cause of recurrent ventricular arrhythmias is ongoing myocardial ischaemia, reducing adrenergic drive and myocardial ischaemia by use of beta blockers, the use of intra-aortic balloon counter pulsation, and early coronary revascularization should be considered [13,14].

If VT or VF is persistent or recurrent, amiodarone may be used. Two randomized clinical trials initiated in the 1990s, the ARREST and ALIVE trials, demonstrated that following out-of-hospital cardiac arrest more patients survive to hospital admission with the use of amiodarone compared with lidocaine [15,16]. However neither trial demonstrated a survival advantage to hospital discharge.

Observational studies suggest that polymorphic ventricular tachycardia associated with a long QTc in normal sinus rhythm (sometimes subtyped as torsades de pointes) may be prevented with IV magnesium [17] and polymorphic ventricular tachycardia associated with bradycardia can be prevented by increasing heart rate with ventricular pacing and/or isoproterenol or epinephrine.

VT can be effectively treated with anti-arrhythmic agents. The lack of negative inotropic effect and the low rate of pro-arrhythmic effects makes the class III drug amiodarone an attractive agent in many cases of recurrent ventricular arrhythmias, particularly as new or pre-existing myocardial dysfunction is commonly present following ROSC, and the use of other anti-arrhythmic agents may be detrimental due to their negative inotropic effects. However, in head to head comparisons intravenous procainamide has a higher rate of conversion of VT compared with amiodarone [17]. Lidocaine and sotalol are alternative agents if amiodarone is unavailable or proves ineffective.

Atrial fibrillation

In the setting of haemodynamic instability, synchronized electrical cardioversion is the treatment of choice. In the setting of haemodynamic stability a rate control strategy to target a heart rate of less than 100 beats per minute with beta-blockers, non-dihydropyridine Ca channel blockers, or amiodarone may be acceptable. Procainamide should be utilized for patients with AF in the setting of WPW. Anti-coagulation should be considered in patient in whom AF persists [18].

Long term treatment of survivors of VT/VF cardiac arrest

With the exception of patients who have VF/VT within 48 hours of an acute ST elevation myocardial infarction, current European Society of Cardiology and AHA guidelines recommend the placement of implantable cardioverter-defibrillator (ICD) for secondary prevention in patients suffering a cardiac arrest [19]. A recent meta-analysis of three major trials: CASH, CIDS, and AVID demonstrated a 25% reduction in overall mortality in patients with an ICD compared with treatment with anti-arrhythmic drugs. The difference was driven largely by a reduction in sudden cardiac death [20]. The long-term adjunctive use of anti-arrhythmic drugs should be reserved to those patients with recurrent ventricular arrhythmias.

CHAPTER 66

Management after resuscitation from cardiac arrest

Jerry P. Nolan and Michael J. A. Parr

Key points

- Following return of spontaneous circulation, the quality of the treatment provided in the post-arrest period influences outcome.
- Most patients resuscitated after a prolonged period of cardiac arrest will develop the post-cardiac arrest syndrome.
- All survivors of out-of-hospital cardiac arrest should be considered for urgent coronary angiography unless the cause of cardiac arrest was clearly non-cardiac or continued treatment is considered futile.
- Several interventions may impact on neurological outcome; the most significant of these is targeted temperature management.
- In patients remaining comatose after resuscitation from cardiac arrest, prediction of the final outcome in the first few days may be unreliable. Prognostication should normally be delayed until at least 3 days after return to normothermia and should involve more than one mode (e.g. clinical examination combined with another investigation).

Introduction

Interventions applied after return of spontaneous circulation (ROSC) impact significantly on the quality of survival. There is considerable variation in post–cardiac arrest treatment and patient outcome between hospitals [1]. Based on updated data from the UK Intensive Care National Audit and Research Centre, approximately 35% of patients admitted to an intensive care unit (ICU) after out of hospital cardiac arrest will survive to be discharged from hospital [2] and most of these will have a good neurological outcome [3].

Post-cardiac arrest syndrome

Systemic ischaemia during cardiac arrest and the subsequent reperfusion response after ROSC causes the post-cardiac arrest syndrome (PCAS) [4]. The severity of this syndrome is determined by the cause and duration of cardiac arrest, and has four key clinical components (Box 66.1).

All components of the PCAS need to be addressed if outcome is to be optimized and post-cardiac arrest care should start immediately after ROSC has been achieved, irrespective of location. An 'ABCDE' (Airway, Breathing, Circulation, Disability, Exposure) systems approach is used to identify and treat physiological abnormalities and organ injury.

Airway and breathing with controlled re-oxygenation

After a brief period of cardiac arrest (e.g. single successful shock for witnessed ventricular fibrillation (VF) arrest) patients usually recover consciousness, maintain their airway safely, and breathe adequately without the need for tracheal intubation. Patients who remain comatose or agitated with a decreased conscious level, and those with breathing difficulties will require sedation, tracheal intubation, and mechanical ventilation. The duration of ventilation may be determined by the use of therapeutic hypothermia, and the extent of the neurological injury.

Increasing evidence suggests that hyperoxaemia after ROSC is harmful and worsens outcomes [5]. Current guidelines recommend that the inspired oxygen concentration immediately after ROSC should be adjusted to achieve a normal arterial oxygen saturation (94–98%) when measured by pulse oximetry or arterial blood gas analysis [6]. Adjust ventilation to achieve normocarbia and monitor using end-tidal CO_2 with waveform capnography, and arterial blood gases. Avoid hyperventilation, which will cause cerebral vasoconstriction and possible cerebral ischaemia.

Box 66.1 Key components of the post-cardiac arrest syndrome

- Post-cardiac arrest brain injury—this manifests as coma and seizures.
- Post-cardiac-arrest myocardial dysfunction—this can be severe and usually recovers after 48–72 hours.
- Systemic ischaemia/reperfusion response—tissue reperfusion can cause programmed cell death (apoptosis) effecting all organ systems.
- Persisting precipitating pathology—coronary artery disease is the commonest precipitating cause after OHCA.

Circulation

About 80% of sudden out-of-hospital cardiac arrests (OHCAs) are caused by coronary artery disease. Early reperfusion therapy is indicated for ST elevation myocardial infarction (STEMI) and this is achieved most effectively with primary percutaneous intervention (PCI) as long as a first medical contact-to-balloon time of less than 90 minutes can be achieved. If not, fibrinolysis (thrombolysis) may be preferable. In the past, patients in a coma after a cardiac arrest were often denied PCI in the expectation that few would make a good neurological recovery. There is now a trend towards considering immediate coronary artery angiography in all OHCA patients without an obvious non-cardiac cause of arrest regardless of ECG changes. This is because the early post-resuscitation 12-lead electrocardiogram (ECG) is less reliable for diagnosing acute coronary occlusion than it is in non-arrest patients. About 25% of patients without an obvious non-cardiac cause for their cardiac arrest and no evidence of STEMI on their initial 12-lead ECG will have a coronary lesion on angiography that is amenable to stenting [7].

After cardiac arrest, patients often develop reversible myocardial dysfunction ('myocardial stunning') causing haemodynamic instability and arrhythmias. The severity increases with the duration of the arrest and in those with pre-existing myocardial dysfunction. Echocardiography enables the extent of myocardial dysfunction to be quantified; it usually shows global impairment of both systolic and diastolic dysfunction. Although systemic vascular resistance (SVR) may be high initially, the release of inflammatory cytokines associated with the PCAS will then result in a low SVR [4]. Treatment with fluids, inotropes, and vasopressors is guided by blood pressure, heart rate, urine output, and rate of plasma lactate clearance, central venous oxygen saturations, and cardiac output monitoring. In patients with severe cardiogenic shock intra-aortic balloon counterpulsation may be used. There are no proven evidence-based targets for post-cardiac arrest patients, although the use of a goal directed protocol may improve outcomes.

Patients who survive a cardiac arrest caused by VF/pulseless ventricular tachycardia (pVT) and who have no evidence of a disease that can be effectively treated (e.g. coronary revascularization) should be considered for an implantable cardioverter-defibrillator before leaving hospital.

Brain (disabilty)

Neurological injury is the cause of death in about two-thirds of OHCAs and a quarter of in-hospital cardiac arrests (IHCAs) admitted to ICU [8]. Aneurysmal subarachnoid haemorrhage is a potential cause of OHCA and should be excluded in comatose victims with ROSC who do not have an obvious cardiac cause for their cardiac arrest, because the use of thrombolytics will be contraindicated [9]. Strategies to improve neurological outcome are described in the remainder of this section

Targeted temperature management

Pyrexia associated with a systemic inflammatory response is common in the first 72 hours after cardiac arrest, and is associated with worse outcome. Mild hypothermia (32–36°C) improves outcome after a period of global cerebral hypoxia-ischaemia. Cooling suppresses many of the pathways associated with ischaemia-reperfusion injury, including apoptosis (programmed cell death), and the harmful release of excitatory amino acids and free radicals. Hypothermia also decreases the cerebral oxygen requirements (6% for each 1°C reduction in temperature), although this is not thought to be a primary mechanism for its impact on outcome.

Indications for post-arrest cooling

Several animal studies have shown that mild hypothermia applied after ROSC improves neurological outcome. Two randomized studies showed improved neurological outcome at hospital discharge or at 6 months in comatose patients after out-of-hospital VF cardiac arrest [10,11]. Cooling was initiated within hours after ROSC and a target temperature of 32–34ºC was maintained for 12–24 hours. The use of hypothermia for non-shockable rhythms and after in-hospital cardiac arrest is supported mainly by observational data. Despite this, many centres use hypothermia irrespective of initial cardiac arrest rhythm or location. In the Targeted Temperature Management (TTM) trial, 950 all-rhythm OHCA patients were randomized to 24 hours of temperature control at either 33°C or 36°C [12]. Strict protocols were followed for assessing prognosis and for withdrawal of life-sustaining treatment (WLST). There was no difference in the primary outcome—all cause mortality, and neurological outcome at 180 days was also similar. Importantly, patients in both arms of this trial had their temperature well controlled so that fever was prevented even in the 36°C group. There is no international consensus on the optimal target temperature and clinicians will need to decide locally which target temperature to adopt in their post-resuscitation protocol. Clearly, if there are problems with attaining a target of 33°C it is rational to aim for 36°C instead. In any case, the TTM trial does not support abandoning temperature control.

Cooling techniques

Targeted temperature management comprises induction of hypothermia, maintenance at a constant temperature in the range 32–36°C, and rewarming while preventing hyperthermia. Infusion of 30 mL/kg of 4°C 0.9% sodium chloride or Hartmann's solution decreases core temperature by approximately 1.5°C. A recent study documented increased rates of re-arrest and pulmonary oedema with this technique when used in the prehospital setting, but use under close monitoring in-hospital is still considered safe.

Following induction with cold iv fluids, ice packs and/or wet towels can be used to maintain hypothermia, but fluctuations in temperature are common when using techniques that do not include temperature feedback control and automatic temperature regulation. Several surface cooling devices that include temperature feedback control are also available [13]. There are several intravascular cooling systems that provide tight temperature control via a cooling catheter in a large vein (usually femoral), but they produce no better neurological outcome than the external cooling systems. Initial cooling is facilitated by concomitant neuromuscular blockade with sedation to prevent shivering. Animal evidence indicates that outcomes are better the earlier cooling is started, but so far, this has not been proven conclusively in humans. By starting cooling in the prehospital phase, it is possible to achieve the target temperature more rapidly. Nasopharyngeal cooling, achieved by instilling perflurocarbon via nasal prongs (cooling is produced by evaporation), enables induction of hypothermia during cardiac arrest.

The optimal duration of induced hypothermia is unknown. Although current guidelines suggest 12–24 hours, some experts are using longer periods of hypothermia (at least 24 hours and sometimes up to 72 hours) especially when there has been a long

Box 66.2 Complications associated with therapeutic hypothermia

- **Shivering**: reduced with sedation, neuromuscular blockers and magnesium.
- **Dysrhythmias**: bradycardia is the most common.
- **Diuresis**: may cause hypovolaemia and electrolyte abnormalities.
- **Electrolyte abnormalities**:
  - Hypophosphataemia.
  - Hypokalaemia.
  - Hypomagnesaemia.
  - Hypocalcaemia.
- **Decreased insulin sensitivity and insulin secretion**: hyperglycaemia.
- Impaired coagulation and increased bleeding.
- **Impairment of the immune system**: increased infection rates, e.g. pneumonia.
- Increased plasma amylase concentration.
- **Reduced drug clearance**: clearance of sedative and neuromuscular blocking drugs is reduced by up to 30% at a temperature of 34ºC.

duration of cardiac arrest. Rewarming should be controlled at 0.25–0.5°C per hour and potentially harmful rebound hyperthermia avoided. The complications of therapeutic hypothermia are listed in Box 66.2 [14]. Many of these should be more accurately described as normal physiological response to mild hypothermia.

Sedation

Patients are sedated during treatment with therapeutic hypothermia, because this reduces oxygen consumption, prevents shivering, and facilitates cooling [14]. Short-acting sedatives and opioids (e.g. propofol, alfentanil, remifentanil) will enable earlier neurological assessment after rewarming. Clearance of many drugs is reduced by about one third at 34°C and this must be considered carefully before making decisions about prognosis.

Cerebral perfusion

Autoregulation of cerebral blood flow is impaired after cardiac arrest and cerebral perfusion is dependent on an adequate blood pressure. Brain oedema can occur transiently after ROSC following asphyxial cardiac arrest, but sustained intracranial hypertension is rare. Aim to maintain a normal mean arterial pressure for that particular patient.

Control of seizures

Seizures, myoclonus, or both occur in about 24% of those who remain comatose and are cooled after cardiac arrest [15]. Ideally, continuous electroencephalography (EEG) monitoring is used in patients receiving neuromuscular blocking drugs to ensure seizures are not missed. Seizures are associated with a fourfold increase in mortality, but good neurological recovery has been documented in 17% of those with seizures [15]. Seizures should be treated with benzodiazepines, phenytoin, sodium valproate, propofol, or a barbiturate. Clonazepam, sodium valproate, levetiracetam, and propofol may be used to treat myoclonus; phenytoin is often ineffective.

Glucose control

Both hyperglycaemia and hypoglycaemia after ROSC are associated with a poor neurological outcome [15]. Based on the available data and expert consensus, following ROSC, maintain blood glucose between 4–10 mmol/L.

Prognostication

Predicting outcome in patients remaining comatose after cardiac arrest is challenging. Previous guidelines on prognostication [16] were derived from data collected before the introduction of therapeutic hypothermia and are now known to be unreliable. This may reflect a direct effect of hypothermia on the progress of neurological recovery and/or the residual effects of sedatives and opioids, which tend to be used in larger doses and take longer to clear after hypothermia, confounding neurological assessment. Several studies have shown that a Glasgow Coma Scale (GCS) motor score of 1 or 2 on day 3 is highly unreliable as a predictor of poor outcome in patients who have been cooled. Furthermore, amongst these studies, there are several examples of good outcomes despite absent pupil or absent corneal reflexes on day 3, and in one series good outcomes were documented among 9% of patients with myoclonus [17]. The absence of EEG background reactivity to a stimulus (e.g. tracheal suction) is a strong predictor of a poor outcome, although most of the studies on this prognosticator have been undertaken by the same group. Serum neuron-specific enolase (NSE) values above 60 μg/L measured at 48–72 hours from ROSC are very rarely associated with a good outcome.

Two systematic reviews [18,19] summarize all the science supporting updated guidance on prognostication in comatose survivors of cardiac arrest, which has been published by the European Resuscitation Council and the European Society of Intensive Care Medicine (Fig. 66.1) [20].

The current consensus is that a multimodal approach should be used for prognostication in comatose patients after cardiac arrest. This generally means a combination of neurological examination and assessment using one or more of: electrophysiology, biomarkers, or imaging [20]. The ERC-ESICM prognostication algorithm is entered if the patient is unconscious with a motor score of 1 or 2 and after excluding residual sedation. This will be at least 72 hours after ROSC, but more usually 72 h after return to normothermia.

Organ donation

Up to 16% of patients who achieve sustained ROSC after cardiac arrest fulfil criteria for brain death and can be considered for organ donation. Transplant outcomes for organs from donors who have suffered a cardiac arrest are similar to those achieved with organs from other beating-heart donors.

Cardiac arrest centres

Post-cardiac arrest patients are likely to have improved outcomes if they are cared for in a hospital that offers a comprehensive package

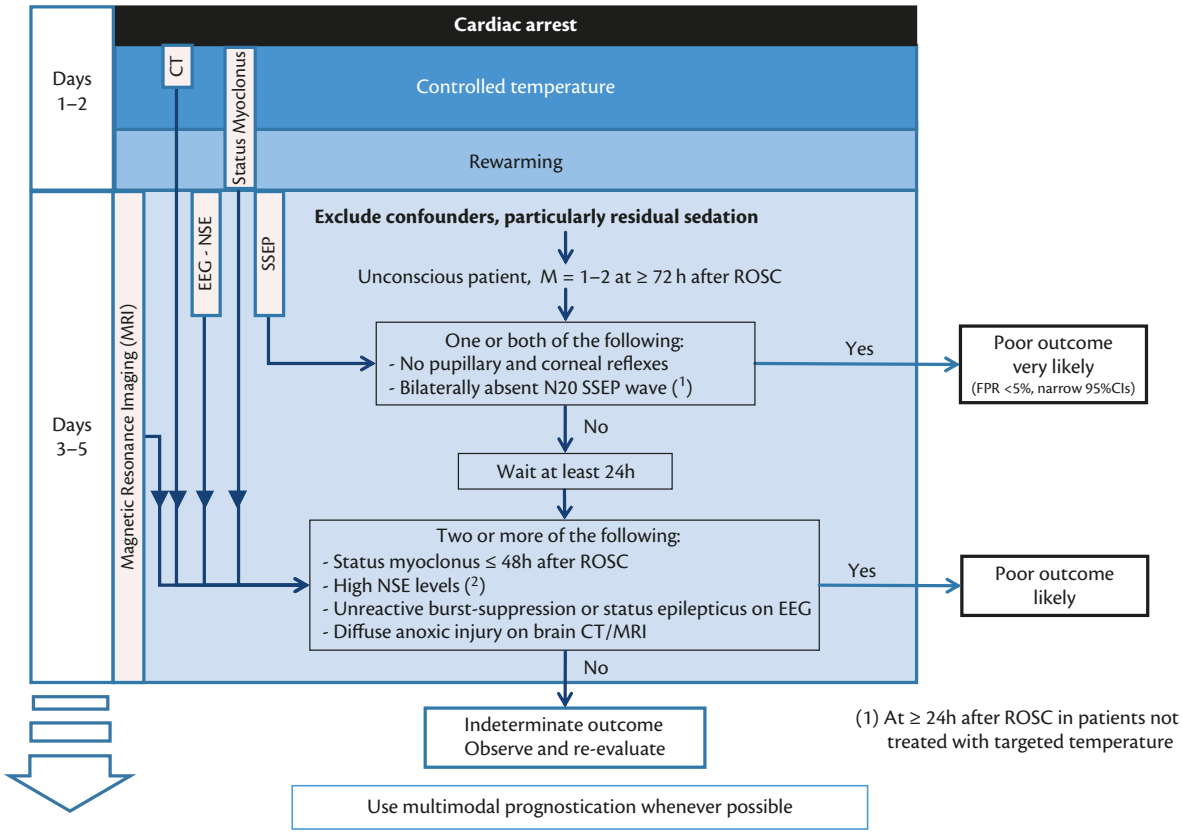

Fig. 66.1 European Resuscitation Council and European Society of Intensive Care Medicine algorithm for prognostication in comatose survivors of cardiac arrest.
ROSC, return of spontaneous circulation; SSEP, somatosensory evoked potential; NSE, neuron specific enolase.

of care that includes PCI and targeted temperature management. In some observational studies, hospitals that offer a post-cardiac arrest 'care bundle' have shown improved good quality survival. There may be a volume effect, whereby hospitals treating the most post-cardiac arrest patients achieve the best outcomes, but this has not been proven conclusively.

CHAPTER 67

Ethical and end-of-life issues after cardiac arrest

Carolyn Benson and G. Bryan Young

Key points

- Accurate prognostication following cardiac arrest requires the presence of two or more negative prognosticators, especially following treatment with therapeutic hypothermia.
- Poor prognosis is generally defined as severe disability with full dependency, vegetative state, or death.
- Negative prognosticators include:

  Day 1: presence of axial myoclonus, **Day 3**: absence of pupillary light reflex or corneal reflex, **Day 6**: extensor posturing or no motor response, **Days 1–3**: bilateral absent N20 response on somatosensory-evoked potentials (SSEPs), Diffusion restriction on MRI, EEG non-reactive, isoelectric, or status epilepticus.
- Early contact with family or surrogate decision makers, the involvement of medical experts, and clear explanation of both prognosis and the limitations of intensive care can help reduce the provision of medically futile care.
- In discussion with families about the level of care to be provided to the patient autonomy is often considered of the foremost importance.

Introduction

Out-of-hospital cardiac arrest represents a major cause of morbidity and mortality in developed countries. Despite advances in the management of these patients, overall mortality rates continue to exceed 90%. In survivors, anoxic-ischaemic brain injury is of particular concern and predicting neurological outcome at an early stage becomes important for directing medical care. Early discussions with families and surrogate decision makers may address further resuscitation and whether to continue with intensive care. Establishing the neurological prognosis is the first essential step in arriving at goals of care.

Prognostic determination

Studies evaluating predictors of neurological recovery following cardiac arrest aim to reliably predict Glasgow outcome scores (GOS) of three or less (vegetative state, defined as wakefulness with no conscious awareness, or severe disability with total dependency), at six months post-arrest. As prediction of this degree of disability often results in withdrawal of life-sustaining treatments, it is important that the combination of clinical, radiographic and electrophysiological tests used have a very low (close to zero) false positive rates for determining poor prognosis.

The clinical examination following cardiac arrest should ideally include assessment of pupillary reaction to light, corneal reflex and motor response to noxious stimuli. The presence of axial myoclonus, defined as bilateral synchronous jerks of the proximal limbs, trunk or face, should be noted. Axial myoclonus may be accompanied by status epilepticus on electroencephalogram (EEG) or originate from the brainstem and have no EEG correlation. It is important to distinguish axial myoclonus from tonic-clonic activity and multifocal, asynchronous myoclonus, both of which may occur during passive rewarming and have limited prognostic value. It is difficult to assess the function of the cerebral cortex in a comatose patient, but as the brainstem is more resilient to anoxic-ischaemic injury, dysfunction of the brainstem post-arrest suggests the cerebral cortex has suffered severe anoxic injury.

For many years, prediction of neurological outcome has been based on the work by Levy and colleagues [1]. In 2006, the American Academy of Neurology (AAN) published practice parameters based on a systematic review of the literature and provided clinicians with guidelines to identify patients who would have poor neurological outcomes following cardiac arrest [2]. Clinical features indicating poor outcome included presence of myoclonic status epilepticus on day one, and absence of either pupillary responses or corneal reflexes or extensor posturing as the best motor response on day 3. Bilateral absence of N20 response on somatosensory-evoked potentials (SSEPs) performed on day 1–3 and serum neuron-specific enolase (NSE) >33 μg/L also predicted negative outcome with an acceptable false positive rate (FPR). It is important to note that the guidelines identify patients who will have poor outcomes, but many patients will remain severely impaired from anoxic brain injury in the absence of unfavourable prognostic signs. A major issue with the AAN guidelines is that they were based on studies conducted prior to widespread use of therapeutic hypothermia which followed two landmark studies published in 2002 that reported therapeutic hypothermia (TH) could improve neurological outcome following cardiac arrest. Recent evidence suggests that different standards may be needed in patients who have been treated with hypothermia as established prognostic indicators are unreliable in patients who have been treated with hypothermia [3]. Rossetti and colleagues conducted a prospective study to validate the AAN guidelines in

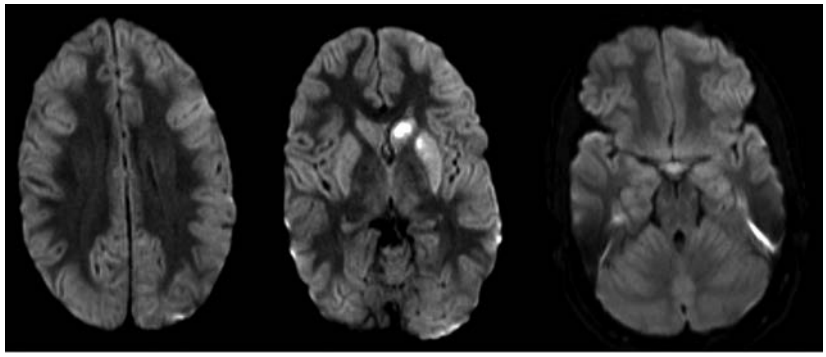

Fig. 67.1 MRI of a post-arrest patient demonstrating diffusion restriction in the cortex and basal ganglia.

patients treated with hypothermia. They found that when assessed within 72 hours of cardiac arrest the following variables had higher FPRs for mortality than reported in the AAN guidelines: absent brainstem reflexes (FPR 4%), myoclonus (FPR 3%), and absent motor response to pain (FPR 24%). The presence of at least two negative prognosticators (absent brain stem reflexes, myoclonus, unreactive EEG, and bilaterally absent N20 on SSEPs) had a positive predictive value of 100% for poor neurological outcome [4]. The presence of axial myoclonus was considered uniformally fatal prior to the use of hypothermia and continues to carry a negative prognosis. However, recent reports of good neurological recovery in patients with axial myoclonus following cardiac arrest due to cardiac pathology, emphasize the importance of having multiple negative prognosticators [5–7].

Longer anoxia time (time between collapse and initiation of cardiopulmonary resuscitation (CPR)) and longer duration of CPR intuitively lead to poorer outcomes. The Brain Resuscitation Clinical Trial and Study Group confirmed that anoxia time exceeding 5 minutes and CPR time exceeding 20 minutes were independent predictors of mortality. However, some patients with prolonged anoxia times and longer duration of CPR had good neurological outcome meaning that these factors alone are insufficient to predict unfavourable neurological outcome [8].

Electrophysiological tests, which include SSEPs and EEG, can help to assess cortical function post-arrest. Bilateral absence of the N20 response (the response from the primary somatosensory cortex that occurs 20 msec after electrical stimulation of the median nerve at the wrist) on SSEPs has a specificity as high as 100% for unfavourable outcome [9]. Electrodes placed over the brachial plexus and upper cervical cord result in responses at 9 and 13 msec, respectively, and confirm that that the sensory pathway is intact from the wrist to the brainstem, reducing FPR (Fig. 67.1).

EEG patterns associated with poor outcomes post-arrest include generalized suppression, burst suppression, and epileptic discharges, including status epilepticus and generalized periodic epileptiform discharges on a flat background [10]. The presence of reactivity, meaning a change in frequency and/or amplitude in response to an external stimulus, is a favourable sign. Lack of reactivity on EEG has been associated with poor neurological outcome, but with a FPR of 7% [4]. The EEG does not have a sufficient positive predictive value to be used alone for prognostication and is susceptible to many confounders including sedation, multi-organ failure, and hypothermia.

Early after cardiac arrest a cranial computed tomography (CT) scan is usually negative, but in the presence of severe anoxic injury may show loss of gray–white differentiation and cerebral oedema [11]. Diffusion-weighted magnetic resonance imaging (MRI) is sensitive for early ischaemic changes and may be useful for prognostication when the cranial CT is normal and clinical examination is equivocal (Fig. 67.2).

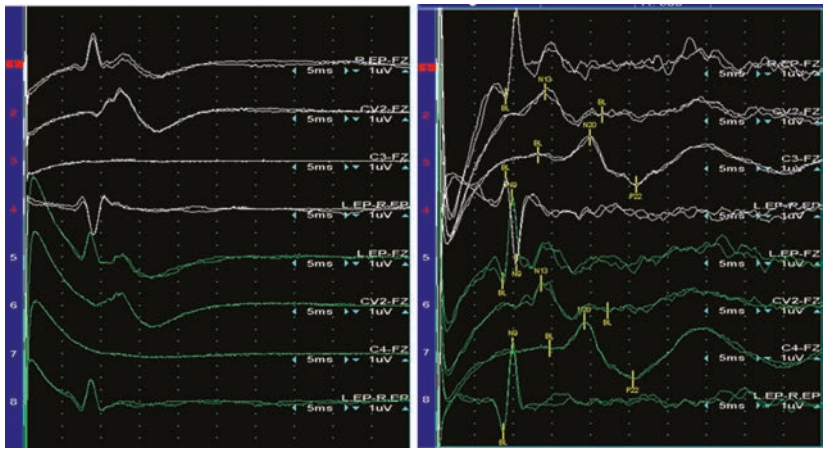

Fig. 67.2 SSEPs. The figure on the right demonstrates normal SSEPs with bilaterally present N20 responses. In contrast, the figure on the left demonstrates bilaterally absent N20 responses (channels 3 and 7).

Several biomarkers have shown potential to identify patients who will have poor neurological outcome. NSE is a cytoplasmic enzyme found in neurons and neuroectodermal cells. Neuronal damage results in NSE release into the cerebrospinal fluid and blood, with a half-life of 24 hours. Although the AAN guidelines found a NSE above 33 μg/L to be reliably predictive of poor outcome, these results do not seem to apply to patients treated with hypothermia in who NSE concentrations greater than 90 μg/L may be recorded in patients who subsequently regain consciousness [12,13].

S100B is a calcium-binding protein with a half-life of 2 hours found predominantly in astroglial cells. Depending on time of measurement, cut-off measurements from 0.7–5.2 μg/L have been shown to have 100% specificity for poor neurological outcome [13]. The measurement of such biomarkers is not available at many medical centres and more research is needed to determine a serum cut-off measurement with 100% specificity.

In addition to treatment with hypothermia, other confounders of the neurological examination include organ failure, specifically hepatic and renal dysfunction, cardiogenic shock, metabolic acidosis, other metabolic derangements, and treatment with sedatives and neuromuscular blocking agents. As many as 83% of patients are still treated with sedative agents on day 3 post-arrest, and the receipt of a sedating drug within 12 hours of the 72-hour neurological examination increases the risk of false-positive predictions [14]. Hypothermia can result in increased serum drug concentrations, increased duration of action, and decreased clearance. Relevant drugs commonly used in patients treated with hypothermia include fentanyl, midazolam, propofol, and neuromuscular blocking agents.

The use of at least two established predictors of poor outcome markedly improves the predictive value and allows the use of some predictors, e.g. EEG, MRI, and axial myoclonus, that by themselves have good, but not perfect predictive values. At the same time, it is useful to consider factors that indicate a favourable outcome. These include EEG reactivity, serum biomarkers, the presence of purposeful limb movements, e.g. localization, and imaging findings, such as minimal to no diffusion restriction on magnetic resonance imaging (MRI) and an intact default mode network on resting functional magnetic resonance imaging (fMRI). Further research is needed to improve parameters for poor prognostication in patients treated with hypothermia and also to discriminate patients who will have full recovery from those who will be left with moderate and severe disability.

Prognostication following cardiac arrest remains a medical, ethical, and socioeconomic challenge. A number of errors occur when doctors provide prognoses without sufficient evidence and it remains difficult to predict a patient's neurological prognosis with certainty. Published literature guides physicians by providing the FPR of physical signs and diagnostic tests. However, it also reports cases of miraculous recovery. The socioeconomic pressure to determine prognosis in the very early post-arrest period, in order to ensure appropriate use of scarce medical resources, may lead to false prediction of an unfavourable outcome and premature withdrawal of life-sustaining treatments. Perman and colleagues retrospectively reviewed the medical records of patients admitted following cardiac arrest and found 57% of patients had documentation of poor prognosis during hypothermia or within 15 hours of normothermia and some patients had withdrawal of life support prior to rewarming [15]. While other factors, for example, other terminal disease or pre-existing disability, may influence decision-making, accurate prognostication is not reliable during hypothermia, and is probably best delayed until 72 hours or longer after the arrest.

Ethic principles and end-of-life decision making

Discussions regarding prognosis and management of patients who remain unresponsive after resuscitation from cardiac arrest must be conducted in a professional manner and show respect for the individuals involved, their culture and religion. It is vital that the physician who is 'breaking bad news' explain the condition and prognosis in lay terms, be honest and open, show respect and acknowledge the emotional responses that follow. Often more than one meeting is necessary to allow friends and relatives to fully understand the situation, to communicate with each other and to consider the options for future treatment. The prognosis should be presented in an evidence-based manner, using statistical probabilities when feasible, and using terms that lay persons can understand.

The object of the discussion with substitute decision makers is to arrive at an informed decision about the level of care that is appropriate for the patient. Possible levels of care include:

- Full intensive care including ventilator support, treatment of infections, haemodynamic support and providing CPR if another cardiac arrest were to occur.
- Full intensive care, but without CPR.
- Limitations of support, which could include providing ventilator support, but restricting investigations and some treatments.
- Withdrawal of life-sustaining therapy with the object being to prevent distress or the appearance of distress. This usually includes withdrawal of ventilator support, but can also include withdrawal of hydration and nutrition.

The Beauchamp–Childress system of medical ethics recognizes four guiding principles:

- Respect for autonomy or self-determination.
- Non-maleficence or avoidance of harm.
- Beneficence or promoting what is good or beneficial.
- Distributive justice or respect for societal values and principles.

In discussion with families about the level of care to be provided to the patient autonomy is often considered of the foremost importance. When a patient is mentally competent, he or she can decide the level of care acceptable to them based on the expected outcome, which includes the withdrawal of life-sustaining treatments. Following cardiac arrest most patients will not be mentally competent, but some will have an advance directive giving written instructions directing treatment in the event of incapacity certain prognoses or written designation of proxy decision-makers in the event of incapacity. The advance directive is the most powerful assertion of the patient's wishes and should be respected. In the event that specific directives were not given, it is essential to emphasize to the surrogate decision maker(s) that they should act according to what they feel the patient would have wanted, based on previous conversations, values, and beliefs.

Medical futility

With increasing available technology to support critically-ill patients, a particularly difficult ethical dilemma arises when decision makers request the continuation or initiation of treatments that the health professional team believes to be futile. Defining medical futility is fraught with controversy. Schneiderman defines medical futility as the 'unacceptable likelihood of achieving an effect that the patient has the capacity to appreciate as a benefit' [16]. Medical futility can be divided into quantitative and qualitative components. Quantitative futility is the extreme unlikelihood of accomplishing a desired physiological effect and is linked to the basic ethical principle of beneficence. Qualitative futility is the unlikelihood of improving a patient's life in a meaningful way and must be assessed on an individual basis. There are several reasons families may insist on pursing treatment deemed medically futile by the treating team. Cultural and religious reasons can compel families and surrogate decision makers to continue intensive care, even against their own judgment of what the patient would want. Lack of understanding of the limitations and complications of intensive care has also been cited as a reason for continuing medically futile care. Early and open communication, being as definitive as possible with the prognosis, exploring patient values, and where necessary the involvement of medical ethicists may help families and health professional teams reach common ground and agree on appropriate levels of care. While reaching such an agreement is preferable it is not always possible and it may sometimes be necessary to resort to 'Consent and Capacity Boards' (or a similar independent body that is legally empowered to hold hearings) or courts of law to arrive at a decision regarding treatment to be provided or to withhold life-sustaining treatments.

PART 3.3

Fluid management

CHAPTER 68

Physiology of body fluids

Anthony Delaney

Key points

- In health, approximately 60% of body weight is water, 66% of this is intracellular fluid, 33% is extracellular fluid. The extracellular fluid is distributed approximately 20% in the intravascular or plasma space and 80% in the interstitial space.
- The endothelial glycocalyx layer appears to play an important role in determining the movement of fluid between the vascular compartment and the interstitial compartment.
- Intracellular fluid volume is largely determined by changes in osmolarity.
- Extracellular fluid volume is largely determined by total body sodium.
- Consideration of the physiological nature of fluid losses will allow appropriate fluid replacement.

Introduction

An understanding of the physiology of body fluids is essential in the consideration of appropriate fluid resuscitation and fluid replacement therapy in critically ill patients. This chapter will provide an overview of the body fluid compartments and forces that govern the distribution of fluids between compartments, and the regulation of body fluid status.

Body fluid compartments

The human body, in health, is composed of approximately 60% water. This proportion declines with age [1] and increasing obesity [2], and is lower in females compared to males [3]. The measurement of total body water can be performed via indicator dilution techniques using Deuterium oxide (^2H_2O), tritium oxide (^3H_2O), or ^{18}O-labelled water [4], or more recently via bioelectrical impedance analysis [2].

Total body water is classically described as being distributed between an intracellular fluid compartment, and extracellular fluid compartment. The extracellular fluid compartment can be further divided into an intravascular or plasma component, an interstitial component and a transcellular component [5], as shown in Fig. 68.1.

Intracellular fluid compartment

The intracellular component of total body water is generally estimated from the difference between total body water and extracellular fluid space [2]. Approximately 60% of total body water is in the intracellular fluid compartment and thus the intracellular fluid compartment makes up approximately 35% of total body weight. While the composition of intracellular fluid varies greatly between tissues and organs, the approximate electrolyte composition of the intracellular fluid is shown in Table 68.1.

Extracellular fluid compartment

The extracellular fluid compartment, composed of all the fluid external to cells, can be divided into an intravascular or plasma component, an interstitial component and a transcellular component. The extracellular fluid volume can be measured by indicator dilution using non-ionic substances such as inulin, mannitol, or sucrose, or ionic substances such as bromide, chloride, or sulphate. The extracellular fluid composes approximately 20% of total body weight. The approximate electrolyte composition of the extracellular fluid compartment is shown in Table 68.1.

Intravascular fluid compartment

The intravascular compartment is composed of a cellular component (largely filled by the red cell mass, but also the other cellular components of blood) and the plasma volume. The plasma volume can be estimated by an indicator dilution technique using Evans blue or radiolabelled albumin. The plasma contains a number of proteins: albumin, globulins and fibrinogen and clotting proteins. These proteins have specific physiologic roles, such as hormone transport, buffering, immune function, and in clotting, as well as maintaining the plasma colloid osmotic pressure.

Interstitial fluid compartment

The interstitial fluid compartment is difficult to measure and its volume is estimated by the difference between the extracellular fluid volume and the plasma volume. The interstitial fluid compartment has an electrolyte composition that is similar to that of plasma and the rest of the extracellular fluid compartment, as shown in Table 68.1. The protein content of the interstitial fluid is only approximately 40% of that of the plasma [7].

Transcellular fluid compartment

The transcellular fluid compartment consists of all fluid that is formed by the transport activity of cells. This includes the fluids found in the gastrointestinal tracts, biliary tree, salivary glands, the eye, and the cerebrospinal fluid. In health these volumes total approximately 1000 mL, although in disease states (such as bowel obstruction), the volume may be considerably more. The electrolyte composition of the transcellular fluid varies according to the tissue where it is produced.

Table 68.1 Average electrolyte composition of body fluid compartments

Electrolyte	ICF (mmol/L)	ECF (mmol/L)	Plasma interstitial
Sodium	10	140	145
Potassium	155	3.7	3.8
Chloride	3	102	115
Bicarbonate	10	28	30
Calcium (ionized)	<0.01	1.2	1.2
Magnesium	10	0.8	0.8
Phosphate	105	1.1	1.0

ICF, intracellular fluid compartment; ECF, extracellular fluid compartment.

This table was published in the *American Journal of Medicine*, **27**, Edelman IS, et al., 'Anatomy of body water and electrolytes', pp. 256–77, Copyright Elsevier and Alliance for Academic Internal Medicine 1959.

Forces governing movement of fluid between compartments

Forces governing the movement of fluid to and from the intravascular fluid compartment, and the interstitial fluid compartment

The movement of fluid between the plasma and the interstitial space is classically governed by Starling forces [8]. The Starling equation summarizes these forces:

$$J_v = K[(P_c - P_i) - \sigma(\pi_c - \pi_i)],$$

where J_v is the fluid flux across the capillary membranes, K = is the filtration coefficient, P_c is the capillary hydrostatic pressure, P_i is the interstitial hydrostatic pressure, σ is the reflection coefficient and π_c is the capillary osmotic pressure and π_i is the interstitial osmotic pressure [9].

The capillary hydrostatic pressure is determined by the pressure inside the capillaries and is higher at the arterial end of the capillary bed compared to the venous end, leading to a net movement of fluid out of the capillary at the arterial end and a net movement of fluid back into the capillary at the venous end. The interstitial hydrostatic pressure is maintained at a slightly negative value by the action of the lymphatics actively removing fluid from this space. The plasma osmotic pressure is due to the osmotic action of the plasma proteins, in particular albumin, but also due to the additional effect of the sodium, potassium, and other cations that are held with the plasma proteins, an effect known as the Donnan effect. The osmotic pressure in the interstitial space is due to proteins that have leaked through pores in the capillary membrane.

Under normal circumstances there is a small net force that leads to approximately 2 ml/min of fluid moving from the capillaries to the interstitium to be returned to the circulation via the lymphatics [7], as shown in Fig. 68.2.

In more recent times, the classic Starling hypothesis and equation have been questioned and the endothelial glycocalyx layer, a web of glycoproteins and proteoglycans that are bound on the luminal side of the vascular endothelial cells, has assumed increased importance in theories regarding the movement of fluid between the vascular and interstitial spaces. There is little evidence to support the hypothesis that fluid resorption occurs at the venous end of most capillary beds [10], rather most filtered fluid returns to the circulation via the lymphatic system. The endothelial glycocalyx covers the endothelial intercellular clefts, and as such separates the plasma from a region below the glycocalyx, the sub-glycocalyx space. This

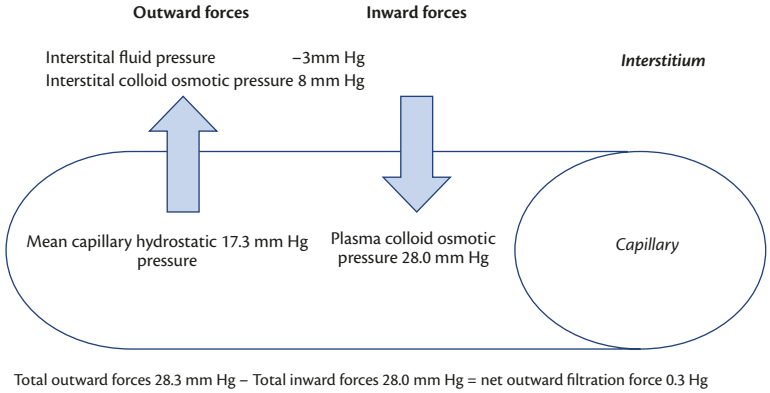

Fig. 68.2 Forces governing the movement of fluid across capillary membranes.

space, which is almost protein free, determines the flow of fluid across the capillary membrane from the plasma to the interstitial space [11].

This revised model provides an explanation of why isotonic saline solutions result in similar plasma volume expansion as colloids [12] when capillary pressure is low. Disruption of the endothelial glycocalyx layer, which can occur with rapid infusion of fluids, acute hyperglycaemia, surgery, and sepsis, can alter the functioning of this barrier [11], and in part explains why fluid distribution differs in various disease states.

Forces governing the movement of fluid to and from the interstitial fluid compartment, and the intracellular fluid compartment

As water is able to pass freely across cell membranes, the major determinant of fluid movement into or out of cells is the relative osmolarity of the intracellular and interstitial fluid compartments. The internal composition of cells is maintained via a number of active transport mechanisms [13] including volume sensitive chloride channels [14]. Thus changes in interstitial osmolarity are most responsible for changes in intracellular fluid volume.

The regulation of body fluid status

Body fluid status is governed by the difference between the intake and outputs. Fluid intake in health is regulated by thirst, which in turn determines the osmolarity of the internal environment, and plays a crucial role in regulating intracellular fluid status. Fluid output largely consists of losses from the gastrointestinal tract [15], and insensible losses [16], as shown in Table 68.2; the renal system regulates sodium and water balance, with an obligatory fluid loss to enable excretion of metabolic waste.

The regulation of intracellular fluid status

The major factor regulating the intracellular fluid volume is the relative osmolarity of the interstitial fluid which is determined by the balance between water intake and excretion. Osmoreceptors in the lamina terminalis in the posterior pituitary gland detect of systemic osmolarity and once plasma osmolarity is greater than 284 mOsm/L, there is a linear increase in the secretion of antidiuretic

Table 68.2 Approximate daily volume and electrolyte composition of body fluid losses

	Volume (ml/day)	Na^+ (mmol/L)	K^+ (mmol/L)	Cl^- (mmol/L)	$HCO3^-$ (mmol/L)
Gastrointestinal tract					
Saliva	500–1000	30	20	10–35	0–15
Stomach	1000–2500	60	10	100–120	0

hormone (ADH), accompanied by a corresponding increase in thirst [17]. Systemic hypotension and activation of baroreceptors may also trigger these responses. As well as increasing thirst, ADH causes water retention in distal tubule of the kidney via increased expression of aquasporins mediated by V_2 receptors.

The integration of thirst and ADH secretion maintain plasma osmolarity within the narrow range of 284–295 mOsm/L [17]. The maximal ADH response occurs at 295 mOsm/L, and as there is an obligatory urine volume required to excrete metabolic waste, further water conservation is not possible. Thus, unless water intake is increased, hyperosmolarity and intracellular volume depletion result. Conversely, at plasma osmolarity of below 284 mOsm/L ADH secretion is suppressed. Maximal renal water excretion is 15–20 L/day, and if water intake exceeds this, then hypo-osmolarity will follow with consequent increase in intracellular water, and cell swelling [17].

The regulation of extracellular volume status

The regulation of extracellular volume status is inextricably linked to the regulation of sodium, the predominant electrolyte in extracellular fluid. The human body has a number of well-described mechanisms to avoid hypovolaemia, and to deal with total body sodium overload or hypervolaemia.

In addition to the cardiovascular responses to hypovolaemia, neurohumoral responses include activation of baroreceptors with increase secretion of ADH, activation of the renin-angiotensin-aldosterone system, and the release of endogenous corticosteroids all of which promote the retention of sodium and water.

CHAPTER 69

Choice of resuscitation fluid

John Myburgh and Naomi E. Hammond

Key points

- On current evidence, isotonic crystalloids should be considered the first-choice resuscitation fluids for almost all patients.
- On the balance of evidence, that colloids do not confer any clinically meaningful advantage over crystalloids.
- Albumin is contraindicated for the resuscitation of patients with recent severe traumatic brain injury.
- Resuscitation with hydroxyethyl starch (HES) is associated with increased risk of death and use of renal replacement therapy in critically-ill patients, especially those with severe sepsis and septic shock.
- Current evidence does not support the use of other semi-synthetic colloids for resuscitation.

Introduction

Fluid resuscitation, the administration of fluid to increase or maintain intravascular volume, is a ubiquitous intervention in acute medicine, used in almost all patients undergoing anaesthesia, following severe trauma and burns. It is used extensively in the emergency department and the intensive care unit (ICU).

The first use of an intravenous alkalinized saline solution for resuscitation was described during the cholera pandemic in 1832. The use of asanguinous fluid resuscitation accelerated following the development of blood fractionation in the 1940s and has effectively replaced blood-based resuscitation, except in patients with active haemorrhage.

Despite the widespread use of resuscitation fluids, there is a wide variation in fluid resuscitation practice, with little consensus over the best fluid in many situations. Until recently there were very few high-quality trials to guide clinical practice.

The principal aim of administering fluid for resuscitation is to rapidly and effectively restore intravascular volume to restore vital organ perfusion and function.

The ideal resuscitation fluid should therefore be one that:

- Is retained within the intravascular space.
- Produces a predictable and sustained increase in intravascular volume.
- Is physiologically constituted as close as possible to extracellular fluid.
- Is metabolized and completely excreted without accumulation.
- Does not produce transient biochemical or metabolic adverse effects.
- May be used safely and effectively in all patient populations.

At present there is no such ideal fluid available for clinical use. Resuscitation fluids are broadly categorized into crystalloid and colloid solutions.

Crystalloids

Crystalloids are solutions of ions that are capable of passing through semi-permeable membranes. They are inexpensive, have a long shelf life and are usually supplied in plastic containers. The constituents and physicochemical properties of commonly used crystalloid solutions are shown in Table 69.1.

Commonly used crystalloid resuscitation solutions contain sodium and chloride that determines the tonicity of the fluid relative to extracellular fluid. Tonicity refers to the ability of the solution to exert osmotic pressure across the cellular membrane. These two physicochemical properties are important determinants of both the efficacy of volume expansion and potential for toxicity.

All crystalloids produce a transient increase in intravascular volume before equilibrating with the extracellular fluid, generally within 1 hour after administration. Compared to colloid solutions, greater volumes of crystalloids are required to achieve an equivalent increase in intravascular volume. As a consequence, crystalloid administration is more likely to be associated with the development of interstitial oedema that depends on the rate and volume of fluid administered and on endothelial permeability. A common clinical manifestation is acute pulmonary oedema, although interstitial oedema with resultant organ dysfunction may occur in the brain, myocardium, intestines, and kidney, particularly when endothelial permeability is altered. Excessive administration of crystalloids may also cause a dilutional coagulopathy.

Crystalloid solutions in common clinical use

'Normal' (0.9%) saline

Normal saline, which is isotonic due to its high sodium concentration, is the most common crystalloid solution prescribed for fluid resuscitation. It is recommended for fluid resuscitation of patients following trauma, particularly those with traumatic brain injury, in patients who are hypovolaemic due to upper gastrointestinal losses and in patients with diabetic ketoacidosis.

As sodium and chloride are present in the same concentrations, the strong ion difference in normal saline is zero. As a result the

Table 69.1 Crystalloid solutions (per litre)

Solution	Osmolarity (mOsmol/L)	pH	Na^+ (mmol/L)	K^+ (mmol/L)	Cl^- (mmol/L)	Ca^{2+} (mmol/L)	HCO_3^- (mmol/L)	Other (mmol/L)
Normal (0.9%) saline	308	5.0	154	—	154	—	—	—
Compounded sodium lactate (Hartmann's)	280.6	5.0–7.0	131	5.4	111	2.0	—	Lactate: 29
Ringer's lactate	273	6.5	130	4	109	2.7	—	Lactate: 28
Ringers acetate	304	4.6–5.4	140	4	127	2.5	—	Acetate: 24 Malate: 5.0 Magnesium: 1.0
Plasmalyte A	294	7.4	140	5	98	—	—	Acetate: 27 Gluconate: 23 Magnesium: 3.0
5% Glucose in water	277	3.5–6.5	—	—	—	—	—	—
4% Glucose in 0.18% saline	284	3.5–6.5	31	—	31	—	—	—

rapid administration of large volume results in the generation of a hyperchloraemic metabolic acidosis [1]. Adverse effects attributed to this metabolic acidosis include impaired renal and splanchnic function, hypotension, and coagulopathy, although whether the acidosis is clinically harmful or not is unclear. Normal saline is also the crystalloid vehicle for many colloid solutions, including some preparations of albumin and hydroxyethyl starch.

'Balanced' salt solutions

Crystalloids with a chemical composition that approximates to that of extracellular fluid have been termed 'balanced' or 'physiological' solutions. Of these, Hartmann's solution which was originally used in the 1940s for rehydration of children with severe gastro-enteritis, was the prototype. However, none of the proprietary solutions are either truly balanced or physiological. Balanced salt solutions are relatively hypotonic as they have a lower sodium concentration than extracellular fluid. The predominant anions in extracellular fluid are chloride and bicarbonate. However, due to the instability of bicarbonate-containing solutions in plastic containers, alternative anions such as lactate, acetate, gluconate, and malate have been used to substitute for bicarbonate.

Excessive administration of balanced salt solutions may result in hyperlactataemia, metabolic alkalosis, hypotonicity (compound sodium lactate), and cardiotoxicity (acetate). In addition, if solutions containing calcium are co-administered with citrated red blood cells microthrombi may form during administration. Hypotonic crystalloids are also relatively contraindicated in patients with traumatic brain injury, because of the potential to worsen cerebral oedema.

Balanced salt solutions are increasingly recommended as first line resuscitation fluids in surgical patients, trauma, and burns.

Despite increased use and recommendations, there have been no large scale trials to establish the safety and efficacy of 'balanced' salt solutions or to compare their safety and efficacy with that of normal saline. The evidence that balanced salt solutions confer any benefit over saline is limited to data from observational studies.

Hypertonic crystalloid solutions

The concern regarding sodium and water overload with crystalloid resuscitation has resulted in the concept of 'small volume' crystalloid resuscitation using hypertonic saline (3%, 5%, 7.5% sodium chloride) solutions. The early use of hypertonic saline, particularly in patients with traumatic brain injury, is theoretically attractive, but the most definitive trial to date did not demonstrate a significant advantage for hypertonic saline [2].

Consequently, hypertonic fluids are not recommended or established in current practice, although hypertonic saline may still be used as part of osmotherapy protocols for the control of intracranial hypertension in selected patients

Hypotonic crystalloids

With the exception of dehydrated patients with hypernatraemia hypotonic or 'salt free' crystalloids (for example, 5% glucose in water, 4% glucose in 0.18% saline) have no substantial role in fluid resuscitation. These solutions are commonly used as 'maintenance' fluids or for correction of insensible or 'third space' losses. This practice is increasingly questioned with the recognition that it contributes to water overload and pathological interstitial oedema [3].

Colloid solutions

Colloid solutions are suspensions of plasma-derived or semi-synthetic molecules that do not pass through semi-permeable membranes under normal physiological conditions. An international survey published in 2010 reported that colloid solutions were more commonly used for fluid resuscitation than crystalloids and that hydroxyethyl starch was the most common colloid solution used for fluid resuscitation [4]. The theoretical advantage of colloids is that they stay within the intravascular compartment longer due to their increased molecular weight, as a result less volume is needed

Table 69.2 Colloid solutions (per litre)

Solution	Osmolarity (mOsmol/L)	pH	Na^+ (mmol/L)	K^+ (mmol/L)	Cl^- (mmol/L)	Ca^{2+} (mmol/L)	Other
Albumin 4% (Albumex 4®)	250	7.0	140	—	128	—	Octanoate 6.4 mmol/L
Albumin 20% (Albumex 20®)	130	7.0	48–100	—	—	—	Octanoate 32 mmol/L
6% Hydroxyethyl starch (130/0.4) in saline (Voluven®)	308	4.0–5.5	154	—	154	—	—
6% Hydroxyethyl starch (130/0.4) in balanced salt solution (Volulyte®)	286	5.7–5.5	137	4	110	—	Acetate 34 Magnesium 1.5
6% Hydroxyethyl starch (130/0.42) in balanced salt solution (Tetraspan®)	296	5.6–6.4	140	4.0	118	2.5	Acetate 24 Malate 5 Magnesium 1.0
Succinylated gelatin (Gelofusin 4%®)	274	7.4	154	—	120	—	—

Albumex is a trademark of CSL Bioplasma, Broadmedows, Victoria, Australia. Other preparations of albumin may contain different constituents and preservatives.

for the same effect and there is therefore less potential to produce interstitial oedema. However, the duration of intravascular effect is variable and dependent on the rate of metabolism and clearance of the different solutions. Generally, plasma derivatives have a longer duration of effect (4–6 hours) than synthetic colloids (1–4 hours), although this may vary substantially within and between patients.

Traditional teaching is that 3 L of isotonic crystalloid is needed to expand plasma volume by the same amount as 1 L of colloid. However, recent blinded trials suggest that only 1.4 L of isotonic crystalloid is needed for the same effect as 1.0 L of colloid; this reduces considerably the theoretical advantage of colloid solutions [5,6].

A recent open-label randomized-controlled trial compared resuscitation with crystalloids to colloids in severely hypovolaemic critically-ill patients and demonstrated no difference in the a priori primary outcome of 28-day mortality [7].

Off set against the potential volume sparing effect of colloids is their greater potential for toxicity.

The constituents and concentrations of some commonly used colloid preparations are shown in Table 69.2.

Plasma derivatives

Human albumin

Under normal conditions albumin is the predominant plasma protein and the predominant determinant of plasma colloid osmotic pressure. Its normal biological half-life is 15 days. Solutions for therapeutic use are produced by fractionation of blood and heat treated to prevent transmission of pathogenic viruses. 4–5% albumin is considered to be the reference colloid solution. More concentrated solutions (20 or 25%) are sometimes referred to as 'salt-poor' as they contain less sodium per gram of albumin. The more concentrated solutions are available as hypertonic preparations.

Albumin is used widely as a resuscitation fluid. Although a Cochrane Injuries Group meta-analysis suggested that administration of albumin was harmful [8], a large randomized trial found that overall it had equivalent effects to normal saline in adult ICU patients [6] and subsequent meta-analyses have concluded that its use is safe. The exception to this is in patients with severe traumatic brain injury where resuscitation with albumin soon after injury is associated with a significant increase in mortality, primarily due to the development of increased intracranial pressure [9,10].

Albumin may have a beneficial role in reducing mortality in patients with severe sepsis/septic shock, both as a resuscitation fluid [11] and as an infusion to maintain a serum albumin of 30 g/L [12], although this has not been conclusively demonstrated in specific randomized controlled trials.

Potential limitations of albumin are that most commercial preparations are supplied in glass bottles and compared to other fluids it is expensive. This is of particular concern in low income countries. The role of albumin (and saline) for bolus resuscitation of febrile children with impaired perfusion has been questioned following a large randomized trial conducted in Africa that showed increased mortality with bolus resuscitation with both albumin and saline compared to avoiding boluses of fluid [13]. The applicability of these results to other health care settings is not currently known. While hypoalbuminaemia is associated with increased mortality in critically-ill patients, there is no convincing evidence that routine albumin supplementation to correct hypoalbuminaemia reduces mortality [14].

Given these limitations, the role of albumin for resuscitation remains uncertain and there is currently no definitive evidence of benefit of albumin over crystalloid resuscitation [15,16].

Semi-synthetic colloids

Given the relative expense and limited availability of albumin, a number of semi-synthetic colloids have been developed as alternative colloid solutions.

Hydroxyethyl starches

HES are the most commonly used semi-synthetic colloids and are produced by hydroxyethyl substitution of amylopectin obtained from sorghum, maize, or potatoes. HES solutions are supplied in normal saline or 'balanced' salt solutions, in plastic containers.

The pattern of hydroxyethyl substitution of glucose influences the susceptibility of the HES molecules to hydrolysis by non-specific amylases in the blood. A high degree of substitution protects against enzymatic breakdown thereby prolonging plasma volume expansion and also the potential for HES to accumulate in the reticulo-endothelial system.

Older HES preparations, specifically pentastarch (10%) have a high molecular weight (>200 kD) and high degree of substitution (>0.6). Their use has been linked with an increased risk of acute renal injury and failure [17] pruritis and prolongation of clotting times. In general they have been superseded by newer less concentrated and less substituted preparations. Hydroxyethyl starch (6%) with a molecular weight of 130 kD and molar substitution of around 0.4 is currently extensively used as a resuscitation fluid, particularly in anaesthetic practice and in patients with trauma and sepsis. Its use is more widespread and more common in Europe than in other parts of the world.

Recent high quality randomized trials have demonstrated increased risk of death and increased use of renal replacement therapy in patients resuscitated with 6% HES (130/0.42) in Ringer's acetate in patients with severe sepsis and septic shock [5], and an increase in the use of renal replacement therapy in ICU patients in general with the use of 6% HES (130/0.4) in saline [18].

Given these findings and the relative expense compared to crystalloids, the use of HES as a resuscitation fluid in critically-ill patients is now being questioned [19].

Gelatins

Gelatins are prepared by hydrolysis of bovine or porcine collagen. The commonly available preparations are succinylated gelatin and urea-linked gelatin-polygeline. They are supplied in saline in plastic containers.

Gelatin has a relatively low molecular weight (30–35 kD) and expands plasma volume for only 1–2 hours. It is then metabolized and excreted via the kidney. Gelatins have a long shelf life, but a recognized incidence of anaphylaxis and their use may increase the risk of acute renal injury [20]. There have been no large scale trials comparing efficacy and safety of gelatins with other resuscitation fluids and therefore their role as resuscitation fluids has not been clearly defined.

Dextrans

Dextrans are polysaccharides, enzymatically synthesized from sucrose by bacteria that produce lactic acid as the major end-product of carbohydrate fermentation. Resuscitation fluids containing dextrans are typically described by the average molecular weight of the dextran molecules they contain, although the molecular weights of the dextran molecules in the solution are highly variable with 80% of the molecules having a molecular weight ranging from 10–90 kD. A number of dextran preparations are available and are supplied in glucose or saline in plastic containers.

High molecular weight dextrans (average molecular weight >60 kD) are slowly excreted. They expand plasma volume for 6–8 hours, but remain in the circulation for weeks following administration. Lower molecular weight dextrans (average molecular weight <40 kD) are primarily used as antithrombotic agents, but their use may be associated with acute renal injury. The use of dextrans for resuscitation has been superseded by other fluids and there is no robust evidence to support their ongoing use as resuscitation fluids.

Clinical applications of resuscitation fluids

General principles to consider when selecting a resuscitation fluid

The volume (i.e. dose) and rate of administration of the fluid bolus needs to be carefully considered, particularly once recognizable fluid deficits have been corrected. No single clinical index reliably represents the degree of volume deficit. Clinical and biochemical signs of hypovolaemia vary widely in different disease states and within patients over the course of the critical illness.

Specific indications

In patients who are actively bleeding, blood and blood component transfusion should be commenced as soon as practical.

Hypovolaemia should be corrected using the most pragmatic fluid available usually a crystalloid such as a balanced salt solution or normal saline.

While the selection of resuscitation fluids is influenced by clinician preference, institution protocol and fluid availability, other important considerations include serum sodium (or osmolality), pH, renal function, and coagulation status.

There are few evidence-based indications for specific resuscitation fluids in specific settings and little evidence that colloids confer any advantage over crystalloids. Rather, certain resuscitation fluids may be considered relatively or absolutely contra-indicated in certain patient populations, for example:

- Albumin in patients with recent severe traumatic brain injury.
- HES in patients with severe sepsis or septic shock.
- HES in patients at risk of acute kidney injury.
- Bolus resuscitation with albumin or saline in children with compensated shock in Africa and other resource-poor settings.

CHAPTER 70

Therapeutic goals of fluid resuscitation

Bashar S. Staitieh and Greg S. Martin

Key points

- Central venous pressure and pulmonary capillary wedge pressure are poor predictors of fluid responsiveness.
- Downstream markers of tissue perfusion (lactic acid, base deficit, and central venous oxygen saturations) are helpful but relatively late and non-specific.
- A conservative fluid strategy is recommended in ARDS.
- Early fluid resuscitation followed by a conservative fluid strategy is recommended in septic shock.
- Arterial waveform analysis is a useful method of predicting fluid responsiveness.

Introduction

By far the most common goal of fluid resuscitation is to optimize tissue perfusion, generally through improved stroke volume and cardiac output. Knowing how well patients have responded to intravenous (iv) fluid administration has, however, become one of the more vexing problems in critical care medicine. Because traditional variables such as blood pressure, heart rate, capillary refill, and urine output are poor markers of perfusion and the adequacy of resuscitation, clinicians are increasingly turning to surrogate markers of adequate tissue perfusion. These measures can be divided into upstream, which assess the macrocirculation, and downstream, which assess the microcirculation (Table 70.1 shows the therapeutic targets for haemodynamic monitoring). Here, we review these markers, offer an overview of the available methods to assess response to fluid administration, and present guidance on the endpoints of resuscitation.

Upstream markers

Central venous pressure

Central venous pressure (CVP), transduced from a vascular catheter in the great vessels of the chest, has the advantage of being relatively simple to obtain. Owing largely to the advent of early goal-directed therapy for septic shock, CVP has become a common surrogate for preload and volume status in the critically ill. Despite that, abundant historical data are reinforced in a recent systematic review [1] confirming an exceedingly poor relationship between CVP and blood volume and showing that changes in CVP are unhelpful in predicting a patient's response to a fluid challenge. Its dependence on a wide range of factors, (including patient position, intrathoracic pressures, and venous compliance), makes it difficult to interpret, but the fact remains that CVP, particularly at extreme values, is still frequently used as a metric in critically-ill patients to indicate hypo- or hypervolaemia.

Pulmonary capillary wedge pressure

Pulmonary capillary wedge pressure (PCWP), which requires a pulmonary artery catheter (PAC) to obtain, provides an indirect measurement of left atrial pressure, which is a common surrogate for preload or intravascular volume. The catheter can also provide additional physiological information including cardiac output and mixed venous oxygen saturation. It is frequently cited as the gold standard for haemodynamic monitoring. However, two landmark studies [2,3] published in the last several years found that PAC-guided therapy did not improve outcomes in critically-ill patients. Despite their different approaches, the data from those two studies and several others have led to a drastic reduction in the use of PACs in the critical care setting.

Cardiac output

There are several different methods available at the bedside to assess cardiac output (CO). Traditional PAC-based thermodilution has given way to thermodilution-calibrated systems that use continuous arterial blood pressure waveforms to derive CO. Furthermore, non-calibrated systems using arterial waveform analysis have shown increasing accuracy in the past decade. Bioimpedance systems have given way to more accurate bioreactance systems, although both have limitations in critically-ill patients. Echocardiography also offers a bedside assessment of cardiac function and can estimate pulmonary artery pressures through the study of valvular flow. Less invasive and increasingly portable transthoracic echocardiography equipment permits dynamic assessment of cardiac output in response to fluid or inotrope administration. However, comprehensive training is required to use echocardiography for such discrete monitoring and many critical care providers lack that training [4].

Predictors of fluid responsiveness

Conceptually, stroke volume variation (SVV) and pulse pressure variation (PPV) rely on the basic physiology of patient-ventilator interactions [5]. A breath delivered via mechanical ventilation decreases the preload of the right ventricle (RV) by decreasing

venous return and increases the afterload of the RV by increasing transpulmonary pressure. These two factors combine to decrease RV stroke volume at the end of inspiration. 2–3 cardiac cycles later, this reduction in RV stroke volume results in a decrease in LV filling and a decrease in LV stroke volume (which is at its lowest during expiration). The magnitude of that decrease provides an indication of biventricular preload dependence. A recent systematic review found that measurements of SVV and PPV are highly sensitive and specific in predicting which mechanically-ventilated patients would respond to a fluid challenge with an increase in stroke volume. Measurement of PPV and SVV generally involve arterial catheters and can be accomplished with several commercially-available systems.

Systolic pressure variation (SPV) relies on similar physiologic concepts to the SVV and PPV. The SPV is the difference between the maximum and minimum systolic blood pressure over a single respiratory cycle. As with SVV and PPV, several studies have shown that increased SPV correlates with hypovolaemia.

Fluid challenge

The traditional method of assessing preload responsiveness with a fluid challenge has come under scrutiny for two main reasons [6]. First, many haemodynamically unstable patients will not respond to a fluid bolus, and the time spent waiting for a response may delay other necessary therapies. Second, and more importantly, excess volume may cause direct injury to patients. The risks involved in excessive fluid administration have popularized the passive leg raise (PLR) as an alternative to the traditional fluid challenge for assessing actual response to additional volume. PLR involves a passive transfer of blood from the lower extremities to the central circulation to determine whether increased preload will increase cardiac output [7]. When the legs are returned to the horizontal position, the autotransfusion returns to the lower extremities. Several clinical trials have confirmed its utility in the critical care setting.

Downstream markers

Base deficit

Base deficit (BD) is derived from the values obtained in an arterial blood gas analysis. It is typically thought to represent the presence of unmeasured anions and viewed as a surrogate for lactic acidosis. It has been studied in surgical populations as an independent marker for mortality. But other metabolic derangements leading to acidosis can influence the BD and not be specifically related to tissue ischaemia, and thus not related to mortality risk [8]. Trends of the BD may be useful in demonstrating the effects of resuscitation, but it is not a particularly specific marker.

Central venous and mixed venous oxygenation ($ScvO_2$ and SvO_2)

Practically, the measurement of mixed venous oxygen saturation (SvO_2) has been hampered by declining PAC use. As a surrogate, a thoracic central venous catheter can permit measurement of central venous oxygen saturation ($ScvO_2$), which generally correlates well with SvO_2 [9]. The $ScvO_2$ and SvO_2 are essentially measures of the amount of oxygen left over after the body has extracted oxygen from the systemic circulation. They are thus related to both oxygen delivery and oxygen consumption. As a target for fluid resuscitation, they have been used most often in the management of septic shock and its utility is currently being investigated in 3 large multicenter trials. Ensuring a $ScvO_2$ of at least 70% or a SvO_2 of at least 65% guarantees an appropriate amount of oxygen is being delivered to the tissues. However, whether the tissues are able to make use of that delivered oxygen relates more to the severity and type of the disease process.

Lactate

Lactic acid, an end-product of anaerobic metabolism, has been found to be a useful, albeit insensitive, marker of tissue dysoxia. Elevation of serum lactate during critical illness has prognostic implications, and a decreasing level is an appropriate target for resuscitation in critical illness. That said, as a result of the imbalance between lactate production and utilization, lactate levels can also be elevated outside critical illness, particularly after a seizure or strenuous exercise. In such settings, lactate levels do not carry a specific mortality risk, which can confound its use in the critical care setting [10].

Safety endpoints

Traditionally, knowing went to stop fluid administration in the critically ill involved recognition of the side effects of excess fluids. Pulmonary oedema can result from over-aggressive fluid resuscitation, particularly in the setting of left ventricular dysfunction or kidney injury. In addition, changes in pulmonary capillary permeability in conditions such as acute respiratory distress syndrome (ARDS), can result in pulmonary oedema even in the absence of LV failure. Other side effects of excessive fluid administration include acid-base disturbances, particularly hyperchloraemic acidosis from normal saline administration and hypotonicity from Lactated Ringer's administration.

Extravascular lung water

Extravascular lung water (EVLW) is an emerging safety endpoint that has been shown to aid in the resuscitation of the critically ill. The measurement of EVLW allows the characterization of patients with increased pulmonary oedema and in turn allows the determination of appropriate end-points of resuscitation (i.e., the point at which additional fluid increases pulmonary oedema without a concomitant benefit in blood pressure or stroke volume) [11]. Results of several key studies have demonstrated an increase in ventilator-free days and a reduction in mortality when using EVLW to guide fluid therapy in pulmonary oedema, but larger trials and wider access are both necessary before it achieves more general use.

Therapeutic goals in specific cases

Table 70.2 shows the therapeutic targets for specific disease states.

Post-cardiac arrest syndrome

As discussed in recent consensus guidelines [12], post-arrest myocardial dysfunction and consequent hypotension are well-described and frequently reversible. Preload should be optimized, although limited data exists to help direct management. In one study, 3.5–6.5 L of iv crystalloid was required to maintain right atrial pressures between 8 and 13 mmHg. If iv fluids are insufficient to support haemodynamic stability, vasopressors should be

Table 70.1 Therapeutic targets for haemodynamic monitoring

Upstream markers	Advantages	Disadvantages
CO	Most direct measurement of volume responsiveness	Difficult to determine optimal cardiac output in individual patients. Accuracy varies by measurement technique
CVP	Easily obtainable through central venous line	Not predictive of intravascular volume, fluid responsiveness, or cardiac output
PCWP	Familiarity, and historically considered the gold standard of volume assessment	Not predictive of intravascular volume, fluid responsiveness, or cardiac output; increased complications compared with CVP
Arterial blood pressure waveform analysis	Accurate assessment of volume responsiveness	Limited availability, requires arterial catheter placement
Fluid challenge	Rapid assessment of volume responsiveness	Fluid administration carries inherent risks
Passive leg raise	Rapid assessment of volume responsiveness without disadvantages of inappropriate fluid administration	Requires personnel to stand at the bedside for several minutes each time
Downstream markers		
Base deficit	Data support usage in surgical populations	Non-specific marker. Abnormal in scenarios other than hypoperfusion
$ScvO_2$	Easily obtainable through central venous line. Data supports use in septic shock resuscitation	Non-specific marker of oxygen delivery and consumption. Does not ensure adequate tissue perfusion
SvO_2	More accurate than $ScvO_2$ for measuring the balance between oxygen delivery and consumption	Requires pulmonary artery catheterization. Non-specific marker of oxygen delivery and consumption. Does not ensure adequate tissue perfusion
Lactic acid	Data support usage in septic shock. Easily obtainable	Non-specific marker of end-organ perfusion

initiated. Downstream measures of perfusion such as lactate clearance and mixed venous oxygen saturation can be used to guide therapy, as can other non-invasive cardiac monitors (Table 70.2). In addition, although elevations of intracranial pressure in the post-arrest period are uncommon, if present, mean arterial pressure should be increased (potentially with vasopressor therapy) to ensure a cerebral perfusion pressure of at least 60 mm Hg.

ARDS

Understanding and manipulating the Starling forces present at the alveolar-capillary membrane have been the primary goals in determining an optimal fluid strategy in ARDS. Although pulmonary oedema accumulates due to capillary injury and not to an increase in hydrostatic pressure per se, an impaired alveolar-capillary barrier mitigates oncotic pressure as an oedema-protective mechanism and thus small alterations in hydrostatic pressure have larger effects on oedema production [13]. Restricting the amount of fluid given to these patients should therefore aid in lung function recovery. Balanced against that fact is the reality that many patients with ARDS have concomitant critical issues that necessitate fluid resuscitation to ensure adequate organ perfusion. A few trials have compared fluid management strategies in patients with ARDS. The largest study to date found that a conservative fluid strategy resulted in more ventilator and intensive care unit (ICU)-free days than a liberal fluid strategy with no increase in shock or in renal dysfunction [14]. In that study, the conservative fluid management group was around 150 mL net negative, while the liberal fluid management group was around 6 L net positive. Although that study used CVP and PCWP to target management, they were often unable to meet their set goals. More importantly, based on the available data on filling pressures and their relationship to fluid responsiveness, CVP or PCWP-driven protocols are now inadvisable. That said, management in ARDS should involve minimizing fluid administration while using other available haemodynamic monitoring tools to ensure adequate organ perfusion.

Severe sepsis and septic shock

Historically, determining appropriate endpoints for fluid resuscitation in severe sepsis and septic shock has been challenging, but efforts were aided by the advent of early goal-directed therapy. Data from a landmark trial in critical care suggest that targeting a CVP of 8–12 (10–14 if the patient is intubated) and a SvO_2 of 70% resulted in an absolute reduction in hospital mortality of 16% for patients who present in septic shock or severe sepsis with an elevated lactate (>4 mEq/L) [15]. The study has come under scrutiny for several reasons, and several recent multi-centre trials have called into question the importance of protocolized sepsis care versus a focus on early identification and antibiotic administration. In addition, other recent data suggest that a significantly positive fluid balance at three-days is harmful, particularly with regard to lung function [16]. Overall, a strategy of rapid volume expansion at diagnosis followed by consideration of diuresis once haemodynamic stability

Table 70.2 Therapeutic targets for specific disease states

Disease state	Target
Post-cardiac arrest syndrome	Data limited. Attempt to optimize preload and maintain RAP 8–13 mmHg if able. May require inotropic or vasopressor support.
ARDS	Minimize fluid administration, while using haemodynamic monitoring tools to ensure adequate organ perfusion.
Sepsis	Early targeted fluid resuscitation. May follow EGTD protocol using CVP or $ScvO_2$, but focus primarily on early identification and antibiotics. Target negative fluid balance at 72 hours as able.
Burns	Data limited. Target urine output 0.5 mL/kg, 1 mL/kg if rhabdomyolysis or electrical injury present. Caveat that excessive fluid administration carries risks.
Trauma	Data limited. Emphasis on permissive hypotension prior to control of bleeding. Favour use of blood products for resuscitation over iv fluids. APP may be a useful metric in patients with IAH.

has been achieved appears to be a sound strategy in the management of septic shock in the ICU.

Burns

The historical dogma that fluid resuscitation in burns should be targeted to urine output has given way to more invasive monitoring techniques and a balance to avoid 'fluid creep,' the concept that over-resuscitation carries significant risks, including pulmonary oedema, increased likelihood of tracheostomy, and compartment syndromes. The traditional concept of intravenous fluid resuscitation involves the Parkland formula: volume of Lactated Ringer's solution given in the first 24 hours after injury = 3–4 mL/kg/% total body surface area. Half of the volume should be given in the first 8 hours, the second half in the following 16 hours. Urine output should be targeted at 0.5 mL/kg/hour under normal circumstances, and at 1 mL/kg/hour in cases of crush injuries with rhabdomyolysis and high voltage electrical burns. The recognition that urine output is not representative of adequate intravascular volume has led to a greater emphasis on more invasive monitoring [17].

Trauma

In cases with uncontrolled traumatic bleeding, the emphasis in fluid management should be to avoid over-resuscitating patients until the bleeding is under control. In trauma, this concept is known as 'permissive hypotension,' and rests on the premise that bleeding will worsen if blood pressure is elevated prior to control of the bleeding source. A trial comparing delayed intraoperative fluid resuscitation to early prehospital intervention in hypotensive patients with uncontrolled bleeding due to thoraco-abdominal stab or gunshot wounds found that prehospital resuscitation resulted in both a higher mortality rate and a higher rate of post-operative complications compared with patients in the delayed resuscitation group. This concept does not apply to patients whose bleeding can be brought under control prior to definitive surgical intervention. In those cases, the use of iv fluid to restore a normal blood pressure is still recommended, with the caveat that relying more heavily on blood products is advisable in an effort to break the cycle of acidosis, coagulopathy, and hypothermia that iv fluid itself may exacerbate [18].

Another metric that may prove useful is the abdominal perfusion pressure (APP), which is calculated by subtracting the intra-abdominal pressure (IAP, obtained at the bedside from bladder pressure) from the mean arterial pressure. A study of surgical patients with intra-abdominal hypertension (defined as IAP > 15 mmHg) found that an APP > 50 mmHg was more predictive of survival than other traditional markers of resuscitation [19]. More data are needed to determine whether using the APP as a resuscitation goal offers a survival advantage.

Patients with traumatic brain injury present a special case, as they are exquisitely sensitive to episodes of hypotension. As a result, most advocate a more aggressive fluid resuscitation strategy in these cases. This strategy must be balanced against the risks of increasing intracranial pressure (ICP). Striking this balance has led some to advocate the use of hypertonic saline as a resuscitation fluid, since it has been shown to lower ICP significantly when compared to isotonic resuscitation fluids, while still increasing systemic blood pressure. The ICP and mean arterial blood pressure are generally targeted to a cerebral perfusion pressure of approximately 60 mmHg.

SECTION 4

The respiratory system

PART 4.1

Physiology

CHAPTER 71

Normal physiology of the respiratory system

Göran Hedenstierna and João Batista Borges

Key points

- Functional residual capacity (FRC) is lowered in supine position and reduced further by anaesthesia. Acute lung injury (ALI)/acute respiratory distress syndrome (ARDS) goes with very low lung volume, frequently below 1 L.
- Compliance of the lung is increased in emphysema, but reduced in lung fibrosis and during anaesthesia, the latter because of reduced ventilated lung volume. ALI/ARDS are found with very low lung compliance and frequently with low chest wall compliance.
- Airway resistance is increased in obstructive lung disease, but also during anaesthesia and in ALI/ARDS because of reduced lung volume with decreased airway dimensions.
- Inspired air goes mainly to lower, dependent lung regions, but a shift to upper lung can be seen during anaesthesia and in ALI/ARDS, because of low lung volume promoting airway closure in dependent regions.
- Lung blood flow goes mainly to dependent lung regions and more so with increase in alveolar gas pressure. Besides a gravitational perfusion distribution there is also a non-gravitational perfusion inhomogeneity that may possibly exceed gravitational inhomogeneity.

Lung volumes and ventilation

The lungs contain 2–300 million alveoli with a total surface area, for gas exchange, of approximately 140 m^2. The alveoli are reached via 23 generations of airways with a rapidly increasing total surface area from 2.5 cm^2 at the trachea to 70 cm^2 in the 14th generation that enters the acinus, to 0.8 m^2 (8000 cm^2) in the 23rd generation [1]. Gas flow velocity decreases as the area increases. For an ordinary breath, the average velocity of gas in the trachea is around 0.7 m/sec, but at the alveolar surface it is no higher than 0.001 mm/sec (Fig. 71.1, left part). This is much slower than the diffusion rate of O_2 and CO_2. Transport of O_2 and CO_2 is therefore accomplished by diffusion in the peripheral airways and in the alveoli, not by convective flow.

The gas volume in the lung after a maximum inspiration is called **total lung capacity** (TLC) and is typically 6–8 L [2]. TLC can increase in patients with chronic obstructive pulmonary disease (COPD), and decrease in fibrosis and other restrictive disorders.

Even after a maximum expiratory effort, some air is left in the lung, preventing collapse. This remaining gas volume is called **residual volume** (RV) and amounts to 2–2.5 L. The maximum volume that can be inspired and expired is called **vital capacity** (VC), and is around 4–6 L. It is reduced in restrictive lung diseases, frequently before a decrease in RV. What may not be equally clear is that VC is also reduced in obstructive lung disease. This is an effect of the chronic 'air trapping' that increases RV, mainly at the expense of VC [2].

The volume in the lungs after an ordinary expiration is called functional residual capacity (FRC) and is approximately 3–4 L [2]. It is increased in obstructive lung disease and reduced in restrictive disorders. It is reduced by 0.7–0.8 L when supine compared with an upright position and by another 0.4–0.5 L by anaesthetics, muscle relaxants, and possibly sedatives (lowered muscle tone) [3].

All inspired air does not reach the alveoli. Approximately 100–150 mL will be confined in the airways and does not participate in gas exchange. This 'anatomical deadspace' is approximately 30% of tidal volume; that is, the V_D/V_T ratio is 0.3 [4]. The remaining part of ventilation reaches the alveoli and respiratory bronchioles (with some alveoli tapered on the airway wall). Thus, 'alveolar ventilation' is around 5 L/min, similar to cardiac output, which is also approximately 5 L/min. Accordingly, the overall alveolar ventilation-perfusion ratio is 1.

Ventilation through a mouthpiece, facemask, or tubings adds an apparatus deadspace of 25 to a few hundred millilitres. Intubation of the trachea reduces anatomic dead space almost to half, 70–80 mL. Pulmonary emboli and obstructive lung disease increase deadspace by ventilation of alveoli that are not perfused or ventilated in excess of perfusion ('alveolar dead space'). The sum of the anatomic and alveolar dead spaces is called 'physiological dead space'.

Compliance of the respiratory system

The lung recoils like an elastic rubber balloon. The pressure needed to keep the lung inflated at a certain volume is pleural minus alveolar pressure, or 'transpulmonary pressure' (Ptp) [5]. Oesophageal pressure (Pes) is for technical and safety reasons substituted for pleural pressure. A change in lung volume (ΔV) divided by the concomitant change in Ptp gives lung compliance. Normally, it is around 0.2–0.3 L/cmH_2O (2–3 L/kPa). It is increased in emphysema, but reduced in fibrotic lung disease and during anaesthesia, the latter being a consequence of reduced ventilated lung volume [6]. It can be markedly reduced in acute lung injury (ALI, ARDS) [7]. If a lung is resected, the measured compliance is reduced, despite the fact that the remaining lung tissue is unaltered (a compensatory expansion may occur).

The chest wall also exerts elastic impedance to breathing that goes undetected during spontaneous breathing because the chest wall is part of the pump itself. During muscle relaxation, on the other hand, the separate compliances of the lung and the chest wall can be measured by dividing ΔV with ΔPtp (lung) and ΔV with ΔPes (chest wall). Compliance of the chest wall is approximately the same magnitude as compliance of the lungs, around 0.2 L/cmH_2O. It may go down in obesity and in ALI/ARDS, especially in so called 'extra-pulmonary ARDS' [7].

Resistance of the respiratory system

Pressure is required to force gas flow (V') through the airways during respiration. In addition, movement of lung tissue and chest wall during inspiration and expiration exerts resistance (R) [8]. In the mechanically-ventilated subject airway, lung tissue, and chest wall resistances are mostly measured together as R_{tot} = (peak airway–end-inspirtory airway pressure):V', but techniques are available for recording of the individual components.

In larger airways, gas flow is turbulent and proportional to the square of the pressure. In smaller airways, flow is laminar and is linearly related to pressure. Thus, most of the energy or pressure involved in creating flow of gas is expended on overcoming resistance in the larger airways [8]. Only about 20% of the measured airway resistance, in a normal subject, is located in the small bronchi [9].

Airflow resistance is normally around 1 cmH_2O/L/sec. Since airway dimensions vary with lung volume, resistance goes up with decrease in volume. At RV resistance may be 4–6 cmH_2O/L/sec, similar to that in moderate asthma [10]. Breathing through a size 8 endotracheal tube causes a resistance of 5 cmH_2O/L/sec at a flow of 1 L/sec and size 7 tube increases resistance to 8 cmH_2O/L/sec [11].

The resistance of lung tissue and the chest wall has been studied to a lesser extent. Lung tissue resistance amounts to around 1 cmH_2O/L/sec in normal cases, but can be increased three- to four-fold in chronic lung disease. Even less has been studied regarding chest wall resistance. However, the sum of lung tissue and chest wall resistance is markedly increased in acute respiratory failure, demanding mechanical ventilation [12].

Distribution of inspired gas

During quiet breathing, inspired air goes mainly to the lower, dependent regions—basal, diaphragmatic areas in the upright or sitting position, dorsal units in the supine position, and left lung in left lateral position [9]. The reason for this seemingly gravitational orientation of something as light as gas is the combined effect of the curved pressure–volume relationship of the lung tissue and the increasing pleural pressure down the lung (Fig. 71.1, upper right).

With increasing flow rate, more inspired air goes to the upper, non-dependent lung regions [13]. This is because the airways are more expanded in the upper than in the lower regions and resistance becomes increasingly important with increasing gas flow.

Airway closure

Airways become narrower during expiration, as can be inferred from the previous discussion. If the expiration is deep enough, airways in dependent regions will eventually close. The volume above RV at which airways begin to close during expiration is called the **closing volume** (CV), and the sum of RV and CV is called **closing capacity** (CC) [14]. Airway closure is a normal physiological phenomenon and is caused by increasing pleural pressure during

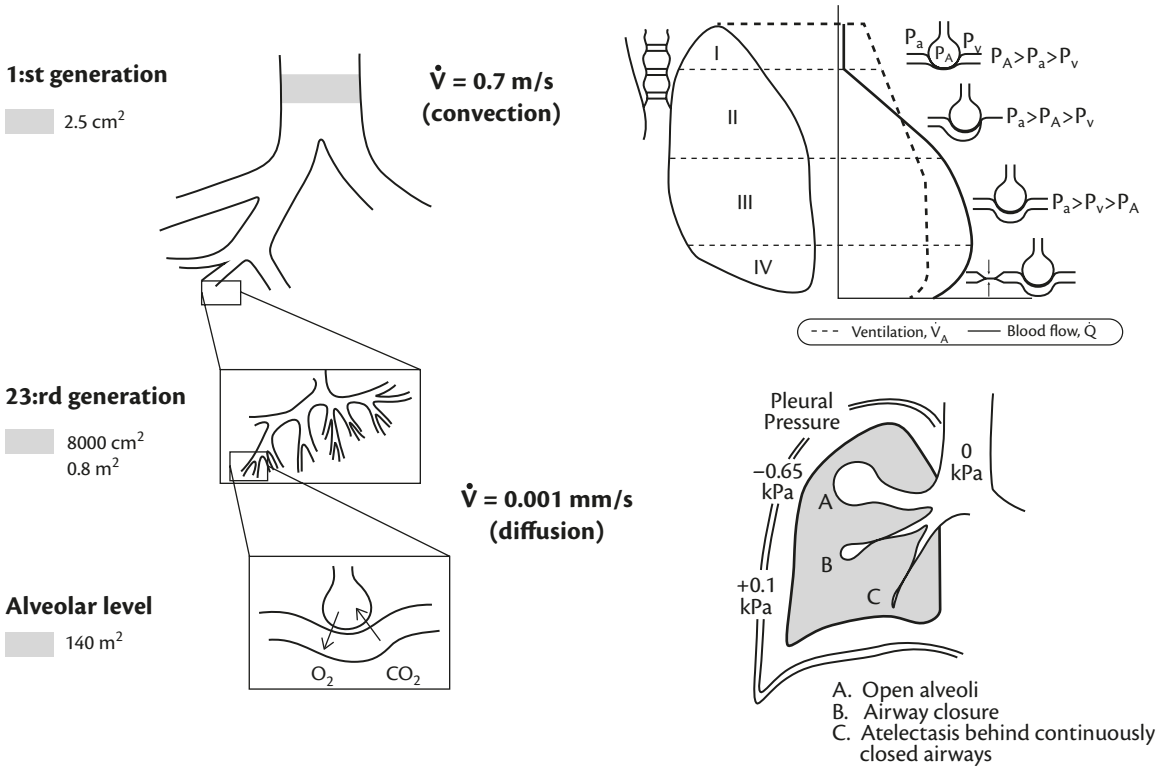

Fig. 71.1 The airway tree from generation 1 (trachea) to generation 23 (terminal bronchioli) (left panel), the vertical distributions of ventilation and blood flow (upper right) and airway closure and alveolar collapse (lower right).

expiration. When pleural pressure exceeds atmospheric pressure it will compress the airway and close it. Because pleural pressure is higher in dependent regions than higher up, closure of airways begins in the bottom of the lung. With increasing age, pleural pressure is 'positive' at higher lung volume, and at an age of 65–70 years, airway closure may occur above FRC [14].

Airway closure plays an even greater role in the supine position, because FRC is reduced, whereas CC is not. Closure of airways may occur above FRC, even at an age of 45–50 years. Airway closure is more common during anaesthesia because of the decrease in FRC, whereas CC seems to be unaltered [6]. If the anaesthetized patient is ventilated with a high concentration of O_2, the alveoli will collapse behind continuously closed airways, thus producing atelectasis (see Fig. 71.1, lower right) [6]. Airway closure is also more common in obstructive lung disease [14].

Diffusion of gas

Oxygen diffuses passively from the alveolar gas phase into plasma and red cells, where it binds to haemoglobin. Carbon dioxide diffuses in the opposite direction, from plasma to the alveoli. The amount that can diffuse over the membranes for a given period is determined by:

- The surface area available for diffusion.
- The thickness of the membranes.
- The pressure difference of the gas across the barrier.
- The molecular weight of the gas.
- The solubility of the gas in the tissues that it has to traverse.

Diffusion limitation is of importance in lung fibrosis and in emphysema, but seems not to be an important issue in anaesthesia and intensive care. For further details, see ref. [15].

Pulmonary perfusion: pressure–flow relationship

The pulmonary circulation is a low-pressure system with a pulmonary artery pressure of approximately 20/8 mmHg. The lower pressure is an effect of larger vascular diameter and shorter distance of the pulmonary vessels than the systemic ones. As a consequence of the lower resistance, pulmonary capillary blood flow is pulsatile, contrary to the steady flow in systemic capillaries [16]. Another consequence of the low pressure is that the capillary and alveolar walls can be made very thin without causing any leakage of plasma, and this facilitates diffusion of O_2 and CO_2, but also of oedema formation if the vascular pressure goes up.

Distribution of lung blood flow

The 'classical' model of lung blood flow distribution is related to gravity [17]. Pulmonary artery pressure (PAP) increases down the lung by 1 cmH_2O/cm distance. This causes a PAP difference between the upper and lower regions of 11–15 mmHg, depending on the height of the lung. There is thus less driving pressure to the top of the lung. If alveolar pressure is increased, as during positive-pressure ventilation, it may exceed PAP and compress the pulmonary capillaries and prevent blood flow (so called zone I). Further down, arterial pressure exceeds alveolar pressure and blood flow will be established. The increasing PAP down the lung and the constant alveolar pressure increase blood flow down this 'zone II'. Further down the lung, both arterial and venous pressures exceed that in the alveoli (zone III). Despite similar increase in arterial and venous pressure, perfusion increases down this zone, by increasing dilation of vessels. In the bottom of the lung perfusion decreases, presumably because of increasing interstitial pressure (zone IV; Fig. 71.1, upper right).

There is also accumulating evidence that there are morphological or functional differences (or both) between lung vessels that—and perhaps more importantly than gravity—determine blood flow distribution with more inhomogeneity in a horizontal than vertical plane ('fractal distribution') [18].

Hypoxic pulmonary vasoconstriction

Hypoxic pulmonary vasoconstriction (HPV) reduces blood flow in hypoxic lung regions. A major stimulus for HPV is low alveolar oxygen tension, whether caused by hypoventilation or by breathing gas with a low PO_2. The stimulus of mixed venous PO_2 is much weaker [19]. The strength of the constriction is also dependent on the size of the lung segment exposed to the hypoxia, being stronger the smaller the region is.

Chronic lung disease with hypoxaemia also causes HPV, but the slow progress of the disease allows time for remodelling of the pulmonary vascular wall, with thickening of the wall preventing oedema formation [19].

PART 4.2

Respiratory monitoring

CHAPTER 72

Blood gas analysis in the critically ill

Gavin M. Joynt and Gordon Y. S. Choi

Key points

- Oxygenation is assessed by measuring PaO_2 and SaO_2 in the context of the inspired oxygen concentration, haemoglobin concentration, and the oxyhaemoglobin dissociation curve.
- Ventilation is assessed by measuring the $PaCO_2$ in the context of systemic acid-base balance.
- Acid base assessment requires the integration of clinical findings and a systematic interpretation of arterial blood gas parameters.
- For clinical use, traditional acid base interpretation rules based on the bicarbonate buffer system or standard base excess estimations, and the interpretation of the anion gap, are substantially equivalent to the physicochemical method of Stewart.
- The presence of a metabolic acidosis or alkalosis, and its influence on compensatory respiratory responses is important to recognize.

Introduction

Arterial blood gases provide information that allows the assessment of patient oxygenation, ventilation and acid-base status. Usually, modern blood gas machines directly measure pH, and the partial pressures of carbon dioxide ($PaCO_2$) and oxygen (PaO_2) dissolved in arterial blood. These values are then used to calculate the arterial oxygen saturation (SaO_2), bicarbonate (HCO_3^-) concentration and base excess (BE). The addition of a co-oximeter allows the direct estimation of haemoglobin content, haemoglobin oxygen saturation (SaO_2), and carbon monoxide (COHb) and methaemoglobin (MetHb) saturation. More sophisticated and expensive machines can measure electrolyte concentrations including sodium, potassium, chloride, magnesium, and calcium. Commonly measured parameters and their significance are listed in Table 72.1.

Assessment of oxygenation

The PaO_2 and SaO_2 are used to assess oxygenation. These values should be interpreted in conjunction with the fractional inspired oxygen concentration (FIO_2). Hypoxaemic respiratory failure is characterized by PaO_2 lower than 60 mmHg (8.0 kPa) when breathing room air at sea level. In critically-ill patients, it is usually not necessary or desirable to remove oxygen supplementation to interpret blood gases with the patient breathing room air. Hypoxaemic respiratory failure in the critically ill can be most simply expressed in terms of the PaO_2/FIO_2 or PF ratio. With the PaO_2 measured in mmHg (kPa), the normal PF ratio is approximately 450 (60) and a PF ratio < 200 (25) indicates severe hypoxaemic respiratory failure.

Major pathophysiological mechanisms leading to hypoxaemia include a reduction of inspired oxygen tension, hypoventilation, ventilation–perfusion mismatch, right-to-left shunting, and diffusion impairment. Causes may be elucidated by determining the alveolar–arterial oxygen gradient (A–a PO_2) where:

$$PaO_2 = (P_B - P_{H_2O}) \times FIO_2 - (PaCO_2 / R) \quad \text{[eqn 1]}$$

where P_B = barometric pressure, 760 mmHg (101kPa) at sea level, P_{H_2O} = partial pressure of fully saturated water vapour, 47 mmHg (6.3 kPa) at 37°C, $PaCO_2$ = partial pressure of alveolar carbon dioxide ~ $PaCO_2$ because of the ease of exchange of carbon dioxide, R = respiratory quotient (R = 0.8 for a 'normal' diet).

The normal (A–a PO_2) gradient varies with age and ranges from 7 to 14 mmHg (0.9–1.9 kPa) when breathing room air, but increases with age [1], where:

$$(A - a\ PO_2) = 2.5 + 0.21 \times \text{age (in years), in mmHg} \quad \text{[eqn 2]}$$

$$(A - a\ PO_2) = 0.3 + 0.03 \times \text{age, in kPa} \quad \text{[eqn 3]}$$

Solving the alveolar gas equation helps distinguish whether hypoxaemia is caused by hypoventilation, or is the result of ventilation perfusion mismatch, and/or diffusion abnormalities. In hypoventilation, there will be a normal gradient between alveolar and arterial blood, while other abnormalities result in an increased A–a PO_2. Mixed abnormalities often occur, such as in a patient with chronic obstructive airways disease (causing alveolar hypoventilation) and lobar collapse (causing a decreased ventilation perfusion ratio or shunt).

The following formula illustrates that the amount of dissolved oxygen in the blood, measured by PaO_2, is relatively small, and the oxygen content of blood is primarily determined by the haemoglobin concentration and the haemoglobin-bound O_2 (HbO_2), expressed as a saturation.

$$\text{Blood } O_2\text{content (mL/100 mL)} = Hb(g/dL) \times SaO_2 \times 1.306 + PaO_2(mmHg) \times 0.003 \quad \text{[eqn 4]}$$

Table 72.1 Common parameters reported on an arterial blood gas

Parameter	Normal values	Significance
pH (m)	7.35–7.45	**Measurement of hydrogen ion [H^+]:** *Acidaemia*: arterial pH < 7.35 *Alkalaemia*: arterial pH > 7.45 *Acidosis*: an abnormal process or condition that would lower arterial pH *Alkalosis*: an abnormal process or condition that would raise arterial pH (if there were no secondary changes in response to the primary aetiological factor)
$PaCO_2$ (m)	35–45 mmHg (4.7–6 kPa)	**Partial pressure of CO_2 in arterial blood**: $PaCO_2$ > 45 mmHg (6 kPa) indicates respiratory acidosis $PaCO_2$ < 35 mmHg (4.7 kPa) indicates respiratory alkalosis
HCO_3^- (c)	22–26 mmol/L	**The amount of buffer base in arterial blood**: <22 mmol/L indicates metabolic acidosis >26 mmol/L indicates metabolic alkalosis
Standard base excess (c)	−2 to +2 mmol/L	The amount of acid (in mmol/L) required to restore 1 L of tested blood to a pH of 7.4
SaO_2 (m or c)	93–98%	The percentage of oxygen bound to haemoglobin
PaO_2 (m)	80–100 mmHg (10.7–13.3 kPa)	**Partial pressure of oxygen in arterial blood**: Hypoxaemia is defined as PaO_2 < 60 mmHg (8 kPa)

Measured parameters are designated (m) and calculated parameters designated (c).

The PaO_2 should thus always be interpreted in the context of the relationship between PaO_2 and HbO_2. The oxyhaemoglobin dissociation curve describes this relationship (Fig. 72.1). If the measured saturation is not what you would expect from the PaO_2 it may indicate a shift in the oxyhaemoglobin dissociation curve. The PaO_2 at which saturation is 50% (P_{50}) is usually used as a reference point. If P_{50} is increased, it indicates a shift to the right and vice versa. Possible causes of shift are shown in Fig. 72.1. Note that in clinical practice, saturations of <88–90% are considered risky, because below this saturation the content of oxygen carried by arterial blood decreases substantially with relatively small decreases in PaO_2, risking tissue hypoxia. When SaO_2 is not measured by co-oximetry, but calculated by the blood gas machine on the basis of the oxyhaemoglobin dissociation curve, inaccuracies in SaO_2 estimations are likely, especially when PaO_2 is relatively low (as occurs in venous samples). Also related to the shape of the curve, saturations greater than 90–92% will increase oxygen content by relatively small amounts. Co-oximetry also allows the quantitative measurement of abnormal haemoglobin complexes, such as COHb and MetHb, both of which can substantially reduce blood oxygen content when present in high concentrations.

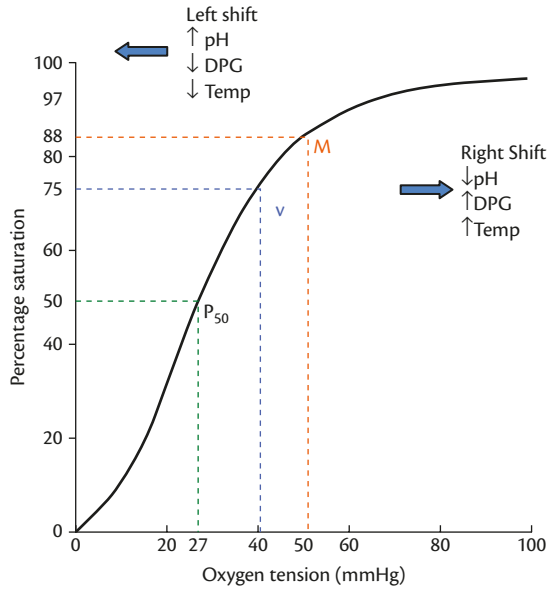

Fig. 72.1 The normal oxyhaemoglobin dissociation curve with causes of left and right shift. Relationships at key points are shown; the partial pressure at which saturation is 50% (P_{50}), mixed venous oxygen tension (v), and the inflection point of the oxyhaemoglobin dissociation curve known as the minimum saturation point (M). Below M a small reduction in PaO_2 will result in a large decrease in oxygen saturation and oxygen content. To convert to kPa, divide by 7.5 DPG, 2,3-diphosphoglycerate.

Assessment of ventilation and acid-base disturbances

Ventilation should always be assessed in combination with acid-base status, as ventilation forms an integral part of acid-base homeostasis. A rise in $PaCO_2$ indicates alveolar hypoventilation, while a decrease indicates alveolar hyperventilation. Given the requirement to maintain a normal pH, functioning homeostatic mechanisms result in metabolic acidosis triggering a compensatory hyperventilation, and metabolic alkalosis a compensatory reduction in ventilation. Similarly, when primary alveolar hypoventilation generates a respiratory acidosis, it results in a compensatory increase in serum bicarbonate that is achieved, in part, by kidney bicarbonate retention. In the same way, respiratory alkalosis induces kidney bicarbonate loss.

It may happen that more than one 'primary' abnormality exists, for example, respiratory alkalosis and metabolic acidosis can be

Box 72.1 Systematic Interpretation Rules for the Arterial Blood Gas

- **Step 1: assess the pH**. Acidosis or alkalosis is present if the pH value indicates acidaemia or alkalaemia, respectively. If pH is normal then *either* there is no acid-base disorder *or* a compensating disorder is present (e.g. a disorder with alkalosis compensating for the acidosis).
- **Step 2: determine whether the primary disturbance is metabolic or respiratory**. Clinical assessment, and/or the relationship between the direction of changes in the pH, bicarbonate (HCO_3^-) and $PaCO_2$ may indicate the origin of the disorder. In primary metabolic disorders the pH and $PaCO_2$ change in the same direction, but in primary respiratory disorders, the pH and $PaCO_2$ change in **opposite** directions.

Metabolic acidosis	pH ↓	HCO_3^- ↓	$PaCO_2$ ↓
Metabolic alkalosis	pH ↑	HCO_3^- ↑	$PaCO_2$ ↑
Respiratory acidosis	pH ↓	HCO_3^- ↑	$PaCO_2$ ↑
Respiratory alkalosis	pH ↑	HCO_3^- ↓	$PaCO_2$ ↓

Note: Respiratory compensation for primary metabolic acidosis does not restore the pH to normal and the presence of a normal pH in a patient with a perceived primary metabolic acidosis should raise suspicion of a concomitant primary alkalosis (e.g. severe sepsis presenting with hypoperfusion and a primary respiratory alkalosis). A mixed disorder cannot be completely excluded when both the HCO_3^- and $PaCO_2$ changes in the same direction, but a mixed disorder must be present if the HCO_3^- and $PaCO_2$ move in an opposite direction.

- **Step 3: use either the Boston or Copenhagen bedside rules to assess the appropriateness of the compensatory response**. If the observed compensation is not in the range of the expected normal compensation, it is likely that more than one primary acid-base disorder is present (e.g. if an acidaemic patient with a low [HCO_3^-] has a $PaCO_2$ higher than the expected compensatory range, a coexisting primary respiratory acidosis should be suspected, such as might occur in a patient with diabetic ketoacidosis and chronic obstructive pulmonary disease). Note the greater allowance for the compensatory response in chronic disorders, as renal buffering and some transcellular responses are time dependent.

Boston rules

Disorder	Primary change	Compensatory change
Metabolic acidosis	[HCO_3^-] < 22 mmol/L	$PaCO_2$ (mmHg) = 1.5 × (HCO_3^-) + 8 $PaCO_2$ (kPa) = [(HCO_3^-)/5] + 1
Metabolic alkalosis	[HCO_3^-] > 26 mmol/L	$PaCO_2$ (mmHg) = 0.7 × (HCO_3^-) + 21 $PaCO_2$ (kPa) = [(HCO_3^-)/10] + 2.6
Respiratory acidosis (acute)	$PaCO_2$ > 45 mmHg (6.0 kPa)	HCO_3^- (mmHg) = [($PaCO_2$ – 40)/10] ×1 +24 HCO_3^- (kPa) = [($PaCO_2$ – 5.3)/4] ×3 +24
Respiratory acidosis (chronic)	$PaCO_2$ > 45 mmHg (6.0 kPa)	HCO_3^- (mmHg) = [($PaCO_2$ – 40)/10] ×4 +24 HCO_3^- (kPa) = ($PaCO_2$ – 5.3) ×3 +24
Respiratory alkalosis (acute)	$PaCO_2$ < 35 mmHg (4.7 kPa)	HCO_3^- (mmHg) = 24 – [(40 – $PaCO_2$)/10] × 2 HCO_3^- (kPa) = 24 – 1.5 × (5.3 –$PaCO_2$)
Respiratory alkalosis (chronic)	$PaCO_2$ < 35 mmHg (4.7 kPa)	HCO_3^- (mmHg) = 24 – [(40 – $PaCO_2$)/10] × 5 HCO_3^- (kPa) = 24 – 4 × (5.3 –$PaCO_2$)

Copenhagen rules

Disorder	Primary change	Compensatory change
Metabolic acidosis	SBE < −5 mmol/l	$PaCO_{2\,(mmHg)} = 40 + SBE$ $PaCO_{2\,(kPa)} = 5.3 + 0.13 \times SBE$
Metabolic alkalosis	SBE > +5 mmol/l	$PaCO_{2\,(mmHg)} = 40 + 0.6 \times SBE$ $PaCO_{2\,(kPa)} = 5.3 + 0.08 \times SBE$
Respiratory acidosis (acute)	$PaCO_2$ > 45 mmHg (6.0 kPa)	SBE = 0 $PCO_2 = 40 + 0.6 \times SBE$ $PCO_2 = 5.3 + 0.08 \times SBE$
Respiratory acidosis (chronic)	$PaCO_2$ > 45 mmHg (6.0 kPa)	SBE (mmHg) = 0.4 × ($PaCO_2$ − 40) SBE (kPa) = 3 × ($PaCO_2$ − 5.3)
Respiratory alkalosis (acute)	$PaCO_2$ < 35 mmHg (4.7 kPa)	SBE = 0
Respiratory alkalosis (chronic)	$PaCO_2$ < 35 mmHg (4.7 kPa)	SBE (mmHg) = 0.4 × ($PaCO_2$ − 40) SBE (kPa) = 3 × ($PaCO_2$ − 5.3)

- **Step 4: if metabolic acidosis exists, calculate the anion gap (AG):**

$$AG = [Na^+] + [K^+] - \left([Cl^-] + [HCO_3^-]\right)$$

Because of electrochemical neutrality requirements, total [cations] must equal total [anions]. The difference must indicate the presence of unmeasured anions and a 'normal' anion gap is approximately 12 ± 4 mmol/L. Albumin (a weak acid) accounts for the major part of unmeasured anions and therefore the anion gap and the following correction is required. AG_{corr} = AG + (40 – measured albumin/4).

If an increased anion gap is present, it is strongly supportive of the presence of a primary metabolic acidosis and is often a useful pointer to the cause of metabolic acidosis, e.g. the presence of lactate or keto-acids.

- **Step 5: re-consider all the evidence** from the history, examination, additional investigations, and systematic blood gas analysis to formulate a complete acid-base diagnosis.

caused simultaneously by salicylate poisoning, and diagnosis of combined disorders like this can be challenging. Therefore to assess acid-base and ventilatory disturbances it is necessary to have at least a basic understanding of acid-base physiology, and a systematic approach to the interpretation of the arterial blood gas.

Systematic blood gas interpretation methods

Three commonly used systematic approaches exist to this end [2]. The two traditional, established methods use the arterial blood value of pH as a measure of the degree of acidity or alkalinity, $PaCO_2$ as a marker of the respiratory component and bicarbonate concentration (HCO_3^-) or BE as a marker of the non-respiratory or metabolic component of acid-base balance.

The first approach is based mainly on the interpretation of the Henderson–Hasselbach equation:

$$CO_2 + H_2O <> H_2CO_3 <> H^+ + HCO_3^- \quad \text{[eqn 5]}$$

Rearranged this gives:

$$pH = pK + \log\left\{\left[HCO_3^-\right]/\left[H_2CO_3\right]\right\} \quad \text{[eqn 6]}$$

where pK is the dissociation constant for carbonic acid.

This can further be expressed as:

$$pH = pK + \log\left\{[HCO_3^-]/[0.03 \times pCO_2]\right\} \quad \text{[eqn 7]}$$

According to this construct, changes in arterial pH occur as a result of changes in either $[HCO_3^-]$ or $PaCO_2$. Primary disorders occur with initial changes in either of the two parameters. Metabolic acidosis occurs with a reduction in $[HCO_3^-]$, whereas an increase in $[HCO_3^-]$ occurs with metabolic alkalosis. An increase in $PaCO_2$ is indicative of respiratory acidosis, while a reduction in $PaCO_2$ indicates respiratory alkalosis.

Homeostasis, however, demands a normal, or near normal, pH and in this system the bicarbonate buffering system accomplishes this goal. The most immediate response is simply that as $PaCO_2$ increases, the law of mass action will result in more $[HCO_3^-]$ production. However, this response by itself may be insufficient so there are additional responses in the kidney that increase $[HCO_3^-]$ production. It is, however, well known that 'hidden' buffers like haemoglobin, albumin, and phosphates also buffer excess protons and minimize alterations in pH. One way of addressing this complexity has been to observe normal compensatory changes in humans and animals exposed to acid base disorders, and quantify them in terms of changes in pH, $PaCO_2$ and $[HCO_3^-]$. This data has provided empirical limits for normal compensation and observed aberrations outside these compensatory limits are assumed to be the result of the presence of other primary abnormalities. Much of this work was completed in Boston, hence, the term 'Boston Rules' when this approach is used [3]. Box 72.1 provides a guide for using this approach in the clinical setting.

Despite widespread use of the 'Boston' method, theoretical limitations are the assumption that $PaCO_2$ and $[HCO_3^-]$ are independent of one another, and that all buffering of metabolic acids is by HCO_3^-. An alternative method of interpretation deals with these theoretical limitations. The 'standard bicarbonate' is a CO_2-independent index of the HCO_3^- concentration of a sample when the partial pressure CO_2 has been adjusted to 40 mmHg (5.3 kPa) at a temperature of 37°C. Buffer base was introduced as a measure of the concentration of all the buffers present in either plasma or blood, and BE as a measure of how far buffer base has changed from its normal value. BE is defined as the amount of strong acid or base required to return the pH of 1 L of whole blood to 7.4, assuming $PaCO_2$ of 40 mmHg (5.3 kPa), a temperature of 37°C. BE is routinely reported by most blood gas analysing machines. Thus, BE is proposed as a measure of the magnitude of the metabolic disorder, because it assesses all the extracellular buffers (in the blood sample) and is independent of $PaCO_2$. As haemoglobin is a buffer, but is not distributed throughout the extracellular fluid (ECF), BE is calculated for a haemoglobin concentration of 30 or 50 g/L, instead of the actual haemoglobin, allowing the whole ECF buffering capacity (and not just whole blood) to be estimated. With this adjustment, known as standard BE, the differences between in vitro and in vivo behaviour are largely eliminated [4]. It is BE variation from normal that forms the basis of the second traditional method of systematic arterial blood gas analysis. The 'Copenhagen' rules are usually used in a similar context to the Boston rules (Box 72.1).

More recently, an alternative method developed by Stewart used the physical-chemical principles of electrical neutrality, conservation of mass, and laws of dissociation of electrolytes to explain hydrogen ion disturbances [5]. In this model $[H^+]$ and $[HCO_3^-]$ are dependent variables and within the system, the concentration of $[H^+]$ changes only as a result of the degree of dissociation of water. The degree of dissociation is significantly influenced by three independent factors:

- **The strong ion difference (SID)**: the difference between strong (always dissociated) cations and strong anions.
- **The total non-volatile weak acids (A_{TOT})**: mainly albumin and phosphate (existing in dissociated (A^-) and non-dissociated (AH) forms).
- The $PaCO_2$.

Thus, it is the electrochemical forces produced by changes in SID, A_{TOT} and $PaCO_2$ that alter the $[H^+]$. Stewart solved a series of simultaneous mathematical equations describing the relationship between the factors listed above and $[H^+]$. Although more complex, this method produces an accurate description of acid-base abnormalities, and often provides clearer pathophysiological explanations of clinically observed acid-base phenomena than traditional methods [6].

Bedside blood gas interpretation

Attempts to compare the different methods of systematic interpretation of arterial blood gases have failed to demonstrate the clear superiority of any one system. The Boston rules approach (including the use of the anion gap) has been shown to be mathematically similar to the BE method and the Stewart physicochemical method [7,8]. When applied in experimental and clinical settings, the ability of traditional and the Stewart systems to predict the outcome of acid-base alterations is also similar [9]. Although the Stewart remains attractive because it provides explanatory information that appears to more precisely explain observed pathophysiological changes, it is currently infrequently used at the bedside. Whether it apparently superior explanatory value will

Box 72.2 Common Causes of Primary Respiratory Acid-base Disorders—Acidosis

Decreased elimination of carbon dioxide

Central respiratory depression

- **Drug**: sedatives, opioids.
- Obesity hypoventilation syndrome.
- **Intracerebral lesions**: infarct, haemorrhage, tumour.

Neuromuscular diseases

- High spinal cord lesions.
- Guillain–Barré syndrome, myasthenia gravis.
- **Neuromuscular toxins**: organophosphates, snake venom.

Lung or chest wall defects

- Obstructive and restrictive lung diseases.
- **Dead space ventilation**: pulmonary embolism, lung hypoperfusion.
- Acute respiratory distress syndrome, pulmonary oedema.
- Pneumothorax, haemothorax.
- **Chest trauma**: flail chest, contusion, haemothorax.

Airway disorders

- Obstructive sleep apnoea.
- **Upper airway obstruction**: laryngospasm, angioedema.

Over-production of carbon dioxide

- Excessive bicarbonate infusion.
- Hypermetabolism (malignant hyperthermia, thyroid storm, seizure).

Increased inspired carbon dioxide

Anaesthetic circuit malfunction/↑ deadspace with rebreathing of CO_2.

Box 72.3 Causes of Primary Respiratory Acid-base Disorders—Alkalosis

Central respiratory centre stimulation

- Head injury.
- Cerebral vascular accident.
- Anxiety-hyperventilation syndrome.
- Pain, fear, stress.
- Pregnancy.
- Sepsis.
- **Drugs**: medroxyprogesterone, catacholaemines, salicylate intoxication.

Hypoxaemia-induced hyperventilation

- Low inspired partial pressure of oxygen.
- Impairment of diffusion across blood-gas membrane.
- Ventilation perfusion inequality.
- Intracardiac shunt.
- Low mixed venous oxygen saturation.

Iatrogenic hyperventilation

Excessive controlled mechanical ventilation.

ultimately translate into superior clinical bedside utility remains to be seen [10].

To summarize, all systematic approaches to the diagnosis of acid-base disorders involve three critical steps. The first is a thorough clinical assessment based on history, examination and initial investigations. This should lead to a clinical decision as to what is the most likely acid-base disorder, and what the possible differential diagnoses are. Mixed disorders are often difficult to recognize, and history and examination alone are usually insufficient to make a firm diagnosis. The second step is to perform a systematic evaluation of the arterial blood gas (Box 72.1), including an analysis of the anion gap, and the last is to synthesize all available information and finalize the diagnosis. For the purposes of respiratory monitoring, a diagnosis of respiratory acidosis or alkalosis should lead to the search for associated clinical causes and the implementation of appropriate interventions (Boxes 72.2 and 72.3). Although the detailed diagnosis of metabolic disorders is beyond the scope of this chapter, recognition of the presence of a metabolic acidosis or alkalosis, and its influence on compensatory respiratory responses is important to recognize.

CHAPTER 73

Pulse oximetry and capnography in the ICU

Richard Lee

Key points

- Both pulse oximetry and capnography are essential monitors in the intensive care unit (ICU), particularly during intubation, ventilation, and transport.
- Equivalent continuous information is not otherwise available.
- It is important to understand the principles of measurement and limitations, for safe use and error detection.
- End tidal carbon dioxide ($P_{ET}CO_{2)}$ and oxygen saturation should be regularly checked against $PaCO_2$ and co-oximeter SO_2 obtained from the blood gas machine.
- The P_ECO_2 trace informs endotracheal tube placement, ventilation, and blood flow to the lungs.

Introduction

Pulse oximetry and capnography provide continuous, rapidly obtained, non-invasive, reasonably accurate information. In 1991 the Society of Critical Care Medicine listed both as necessary monitoring for patients on respiratory support [1].

Pulse oximetry

Pulse oximeters are used ubiquitously, in emergency departments, intensive care units (ICUs), operating rooms, during patient transport, in outpatient departments, and in increasingly in general practice. As for many monitors there is no evidence of patient outcome benefit from their use [2], but there is for detecting hypoxaemia and influencing management.

General principles

Oximetry has been performed in vitro since the 1930s by spectrophotometry. The absorption of known wavelengths of light, based on Beer's Law (absorbance is proportional to the chromophore concentration), and Lambert's Law (absorbance is proportional to the thickness of the absorbing layer), and the differing absorption of light by the Hb species are used to measure their concentrations.

Co-Oximetry in modern blood gas machines uses multiple wavelengths of light, passed through a transparent cuvette containing the blood specimen, haemolysed by ultrasound to make a suspension. The light path distances and cuvette wall thickness are known. Non-invasive clinical oximetry had been inhibited by quantifying the variable light absorption and thickness of skin, subcutaneous tissue and venous blood until the 1970s when an eight-wavelength ear oximeter for clinical use was available, but it was expensive, bulky, and required heating of the skin. In 1974, Aoyagi described the principle of pulse oximetry [3]. He noticed a pulsatile variation in the tissue optical density caused by arterial pulsation and realized that if the optical density of the pulsatile component was measured at two appropriate wavelengths a ratio could be obtained, which related closely to arterial SaO_2.The development of compact light emitting diodes (LEDs) and microprocessors led to easy application, and rapid machine response. The first commercial pulse oximeter was marketed in 1983.

The pulse oximeter probe is applied to a part of the body, where pulsatile arterial blood flow is sensed. Probes may be disposable or reusable, and are designed to be applied to finger, forehead, nose, ear, or toe. They are calibrated for transmitted or reflected light, and should not be dismantled or used other than in accordance with the manufacturer's instructions.

The probe consists of two LEDs—one emits 660nm (red, R) and the other 940 nm (infrared, IR) light, chosen for maximum separation in absorbance characteristics of deoxyhaemoglobin (deoxyHb) and oxyhaemoglobin (oxyHb)—and a photodiode, which detects the intensity of the light—reflected or transmitted. The LEDs strobe at 720 Hz, sequentially (R, IR, and both OFF to provide a reference), cycling at 30 cycles/sec. The transmitted or reflected signal is digitalized, the difference between systolic and diastolic measured to give a pulsatile component (ac) and non-pulsatile component (dc), therefore allowing for quantification of absorption due to tissue, venous blood, nail, and polish. A ratio of ratios, *R*, is then obtained [(ac R/ac IR)/(dc IR/dc R)], simplified to *R* = ac 660.dc 660/ac 940. dc 940. *R* is empirically calibrated against look up tables of *R* versus known SaO_2 [4]. The tables are obtained using co-oximetry and having normal young volunteers breathe hypoxic mixtures to produce saturations in the range 70–100% SaO_2.

Pulse oximeters usually also calculate heart rate and provide visual measures of signal quality.

The monitor may calculate SpO_2 25–30 times per second, but averages SpO_2 over 3–12 seconds to allow artefact rejection, and update the screen every 1–2 seconds, depending on fast or slow mode, and the manufacturer.

A delay of around 1–2 minutes occurs after application of a finger probe before achieving a measurement, and a sudden reduction in FIO_2 produces a fall in SpO_2 with a lag of 10 seconds for ear probes and 50 seconds for finger probes [4].

Terminology

Oximetry is the measurement of oxyHb in blood as a percentage of Hb species. Because of the use of only two wavelengths of light the only species of Hb targeted in pulse oximetry are oxyHb and deoxyHb. Co-oximeters using multiple wavelengths of light (commonly 128) may report functional saturation (SO_2, the ratio: oxyHb/(oxyHb + deoxyHb)) and fractional saturation (FO_2Hb, the ratio oxyHb/tHb including dyshaemoglobins) and report methaemoglobin (MetHb) and carboxyhaemoglobin (COHb)). The terminology is often misused and misunderstood [5].

Accuracy

The pulse oximeter reading generally achieves a mean bias of ±2% in normal volunteers in the SO_2 range of 80–100%, although the International Standard requires ±4%. There are large variations in bias and error between machines, manufacturers, clinical situations, sexes, and saturation levels [6] and it is suggested that a pulse oximeter SO_2 of 94% is necessary to ensure a co-oximeter SO_2 of 90% from a simultaneous arterial blood gas [7]. Bias increases as Hb and SO_2 fall.

Errors

There are many potential sources of error [8]. Pulse oximeters require a detectable pulse and perform poorly in poor perfusion states. They are insensitive to large changes in PaO_2 in the high PaO_2 range and increasing bias occurs at low PaO_2. They are calibrated using co-oximetry, which is also prone to errors [9].

Errors can be described as 'safe' (under-read or fail to read, leading to false alarms) or 'unsafe' errors (over-read, leading to false security) due to the following factors.

Patient factors

- **Abnormal Hb** [10]:
  - Pulse oximeters read HbCO as mostly HbO_2, over-read SO_2 1% for every 1% of COHb in blood.
  - MetHb absorbs both wavelengths tending to an R of 1, forces SpO_2 towards 85% as MetHb rises.
  - Fetal Hb absorbs similarly to adult Hb, produces no clinically significant error.
- **Dyes**: methylene blue and indocyanine green absorb red light, artificially lower SpO_2.
- **Other light absorbents**: bilirubin does not interfere with oximetry.
- **Nail varnish**: blue, black, green, beige, purple, and white polish artificially lower SpO_2. Racial pigment does not significantly affect the measurement; difficulty with signal may be overcome by using the nail bed, less pigmented.
- **Pulsatile veins** (tricuspid regurgitation, venous congestion) lower SpO_2.
- **Non-pulsatile flow** on cardiopulmonary bypass decreases signal to noise ratio, measurement difficult.
- Anaemia increases bias at low SO_2.

Equipment factors

- Delay due to averaging and blood flow to peripheral tissues.
- Flooding of external light may force a value of 85% or trigger alarm.
- Penumbra or optical shunting around the tissue will produce false readings, countered by the 'LED OFF' period as a reference in the machine algorithm.
- Movement artefact may trigger an alarm or variable errors. Seizures and helicopter vibration are reported to not interfere.
- Fluorescent light falsely lowers SpO_2, but is countered by the LED OFF period as reference in the machine algorithm.
- **Radio-frequency interference**:
  - MRI use requires a link to the patient with fibre optic cables, may produce a falsely low SpO_2.
  - Cautery artificially decreases SpO_2 with older machines, interferes with heart rate estimation.

Advances have occurred in new software and hardware for movement artefact rejection, e.g. signal extraction technology (SET), Fourier artefact suppression (FAST) and Oxismart technology [11]. Multiple wavelength pulse oximeters are available to measure other haemoglobin species, but inherent limitations of the techniques confound the accuracy [12].

Capnography and end-tidal CO_2 monitoring

Most national intensive care organizations recommend that capnography be used for all sedated or intubated patients, and failure to use or misinterpret the readings is regarded as a gap in care [13].

Technology

Methods available to measure CO_2 in the gas phase include IR absorption, mass spectrometry, Raman scattering, and photo-acoustic spectroscopy. IR absorption is the commonly used technique in ICU because of cost and rapid response. The Beer and Lambert Laws are applied to measurement in a calibrated cuvette either positioned within the ventilator circuit with an adaptor (mainstream) or remote from the circuit with gas aspirated via a thin tube to the analyser (sidestream). As absorption is dependent on the number of particles of targeted substance in the gas mixture, it is a partial pressure detector. End tidal carbon dioxide partial pressure ($PETCO_2$) measurement requires rapid response for clinically useful breath-by-breath analysis.

IR gas analysers use the principle that all gases with two or more dissimilar atoms in the molecule absorb IR radiation. CO_2 is absorbed in the band 4.3 μm, oxygen does not absorb IR, but anaesthetic gases (e.g. nitrous oxide in the 4.5 μm band) and water will.

Collision broadening is the phenomenon where the presence of a second gas (e.g. N_2, N_2O, C_3H_6) widens the absorption spectrum of the other gas so that absorption is increased. This is usually countered by a standard offset.

Features of mainstream sensors

- Better capnograph.
- More rapid response.
- No gas aspirated from the airway.
- Heavier, bulkier, and more cumbersome in the circuit.
- Expensive electronic consumables, which are prone to damage.
- Measuring window heated to 40°C and needs to be kept clean.
- Periodic calibration.

Features of sidestream systems

- Cheaper consumables.
- Practical in non-intubated patients.
- Prone to distorted capnogram.
- Sampling rates 50–500 mL/min may interfere with ventilation in small patients.
- Slow response distorts capnogram.
- Fast aspiration falsely lowers $P_{ET}CO_2$.
- Sampling tube occlusion may occur due to airway secretions or water.
- Need fluid trap and filter.

Information revealed

The presence of a continued CO_2 trace indicates the intra-airway position of the endotracheal tube (ETT) following intubation. The trace acts as a disconnection alarm and apnoea detector, and may detect respiratory change (V/Q mismatch, bronchospasm, etc.), effectiveness and prognosis of cardiopulmonary resuscitation (CPR), and air embolism [14]. This continuous non-invasive information decreases need for arterial blood gas estimation (ABGE) as $P_{ET}CO_2$ provides a useful surrogate of $PaCO_2$ in patients with normal lung function and trend in patients with COPD.

Four phases are visible on the P_ECO_2 time trace (Fig. 73.1):

- **I** represents the expiration of carbon dioxide free gas from anatomical dead space, upper airway to bronchi.
- **II** represents mixed gas from airways and alveoli.
- **III** represents the alveolar plateau of gas from alveoli, rising slightly due to variable mixing and time constants. The peak value represents $P_{ET}CO_2$
- 0 sharp descent is due to the absence of carbon dioxide in inspired gas.
- Two angles are observed (A and B), which may be increased by lung pathology (V/Q mismatch, asthma) and rebreathing (from incompetent valves, low fresh gas flow), respectively.

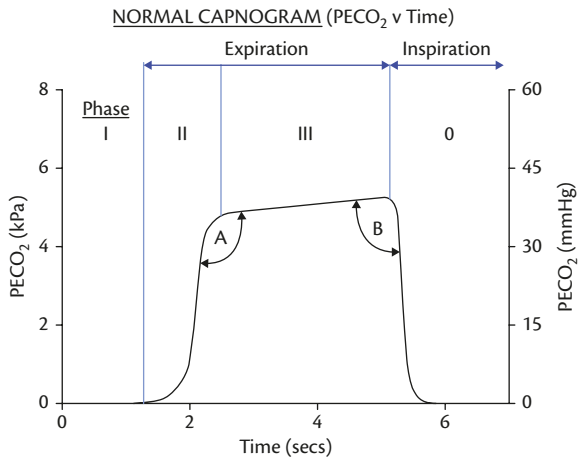

Fig. 73.1 Normal capnogram. Partial pressure of expired carbon dioxide (P_ECO_2) graphed against time in seconds, from time 0 at the start of expiration (for phases and angles, see in Information Revealed).

$P_{ET}CO_2$ approximates P_ACO_2 and, hence, $PaCO_2$.

$$PaCO_2 = k.\,VCO_2/AV, \qquad \text{[eqn 1]}$$

where AV or alveolar ventilation = (TV – VD) × RR, k is a constant, VCO_2 is CO_2 production, AV is alveolar ventilation, TV is tidal volume, VD is dead space volume, and RR is respiratory rate.

Therefore, a change in an accurately recorded $P_{ET}CO_2$ suggests a change in CO_2 production, minute ventilation, or dead space ventilation.

CO_2 production

- Increased by fever, parenteral nutrition, malignant hyperthermia, thyrotoxicosis, tourniquet release, bicarbonate infusion.
- Decreased by hypothermia, sedation.

Minute ventilation

- Increased by hyperventilation.
- Decreased by hypoventilation.

Dead space ventilation

- Increased by shock, cardiac arrest, air embolism, pulmonary embolism, V/Q mismatch.
- Decreased by effective CPR.
- The gap between $P_{ET}CO_2$ and $PaCO_2$ is usually < 5 mmHg (0.67 kPa), but may be >15 mmHg (1.99 kPa) in ARDS and is dependent on ventilation mode, dead space, and cardiac output. **Alveolar dead space can be estimated as 1– ($P_{ET}CO_2$: $PaCO_2$).**

Errors

Most errors relate to technical problems of calibration, blocked sensor window or blocked sampling tube, or delay in achieving a trace. High sampling flow rate with a sidestream sensor will produce a falsely low $P_{ET}CO_2$. Capnography provides information, which requires pattern recognition, interpretation, comparison with normal, and clinical decision-making, which are all major clinical sources of error. An absent trace after intubation in cardiac arrest may be falsely attributed to ineffective CPR and low cardiac output, but a flattened trace should at least be seen. In event of oesophageal intubation after ingestion of carbonated drinks may give an initial CO_2 trace, falling after several breaths.

Common abnormal patterns

- **Absent PCO_2 trace**: oesophageal intubation, disconnection, apnoea, total airway obstruction, cardiac arrest without CPR.
- **Elevated Phase 1**: rebreathing, incompetent circuit valves, exhausted CO_2 absorber during anaesthesia, low fresh gas flow, slow sidestream sampling rate.
- **Decreased Phase II slope**: slow sidestream sampling rate, kinked or blocked ETT, expiratory obstruction (e.g. asthma or chronic obstructive pulmonary disease (COPD)).
- **Absent Phase III plateau:** in COPD, bronchospasm, acute respiratory distress syndrome (ARDS).
- **Elevated $P_{ET}CO_2$**: hypoventilation, malignant hyperthermia (MH), CO_2 insufflated at laparoscopy, bicarbonate administration, release tourniquet.
- **Decreased $P_{ET}CO_2$**: hyperventilation, hypothermia, low cardiac output (CO), pulmonary embolus (PE) [15].

CHAPTER 74

Respiratory system compliance and resistance in the critically ill

Ricardo Luiz Cordioli and Laurent Brochard

Key points

- Correct understanding of the relationship between pressure, volume, and flow is a basic requirement for correctly setting a ventilator.
- The lungs and chest wall both participate to global respiratory mechanics. In some situations, such as obesity or ARDS, the chest wall could explain a large part of the low compliance of the respiratory system.
- Resistance represents the ratio between the pressure dissipated by the friction of gas and the mean gas flow.
- Compliance denotes the capacity of the pulmonary system to expand and is calculated as ratio between volume and pressure.
- Intrinsic positive end expiratory pressure (PEEP) can be present with short expiratory time, high respiratory rate, or expiratory flow limitation in airway obstructive disease.

Introduction

Acute respiratory failure is a common situation in patients admitted to intensive care units (ICU) and, in the most severe forms, mechanical ventilation (MV) is a life-saving support. MV can also be harmful and lead to ventilation-associated lung injury (VALI) [1]. VALI occurs mainly when pressures (**barotrauma**) and volumes (**volutrauma**) are not adapted to the specific respiratory conditions of the patient, which can be assessed by measurement of respiratory mechanics.

Impairment in pulmonary function is, in general, accompanied by changes in respiratory mechanics, especially during acute exacerbations of chronic obstructive pulmonary disease (COPD), asthma, or the acute respiratory distress syndrome (ARDS), situations that are associated with large changes in resistance (R) and compliance (C) of the respiratory system. An assessment of the respiratory mechanics is therefore necessary for correctly adapting the ventilatory settings. Monitoring the magnitude of these changes with time is also important because of their direct relationship with severity of disease. It can help defining prognosis and response to treatment [2,3].

In order to ventilate the patient appropriately, clinicians need to understand the relationship between pressure (P), volume (V), and flow ($\dot{V}$). To appreciate the risks associated with MV, one also needs to understand the partition between lungs and chest wall in terms of respiratory mechanics.

Equation of motion of the respiratory system

To move air in and out the thorax, energy must be dissipated mostly against elastic (F_{EL}) and resistive (F_R) forces. A simple equation of motion describes the forces in the respiratory system (F_{RS}):

$$F_{RS} = F_{EL} + F_R \qquad \text{[eqn 1]}$$

Any pressure applied is either stored as elastic pressure (P_{EL}) or dissipated as resistive pressure (P_{RES}). In some circumstances, another force can participate, the inertial force (F_{IN}). Inertia can usually be neglected in the respiratory system, with rare exceptions such as coughing or high-frequency ventilation.

Elastance (E) relates P to V, and resistance relates P to ($\dot{V}$), so the equation of motion can be modified to explain how the pressure at the airway opening (P_{AW}) can be partitioned into a resistive and an elastic pressure component:

$$P_{AW(t)} = P_0 + E\left(V\right)_{(t)} + R(\dot{V})_{(t)} \qquad \text{[eqn 2]}$$

where $_{(t)}$ is a given time, P_0 is the starting pressure in the respiratory system, and P_0 represents the total positive end expiratory pressure ($PEEP_T$).

Methods of measurement

In passively mechanically-ventilated patients, it is easier to measure pulmonary mechanics during constant flow, volume-controlled ventilation (VCV) than during pressure-controlled ventilation (PCV). In an actively-breathing patient under MV, the total pressure is the sum of P_{AW} and of the muscular pressure. Because the patient's spontaneous breathing activity is usually not directly monitored, this greatly limits the ability to make these measurements at the bedside.

One simple, but essential manoeuvre involves stopping flow by occlusion at the end of the insufflation phase, allowing measurement of the plateau pressure (P_{PLAT}), which represents the alveolar pressure at end-inspiration (P_{ALV}), as shown on Fig. 74.1.

Usually, P, V and $\dot{V}$ are directly measured by the ventilator; V is calculated as the integral of inspiratory flow tracing over time. There are several technological limitations with the calculation of V [4].

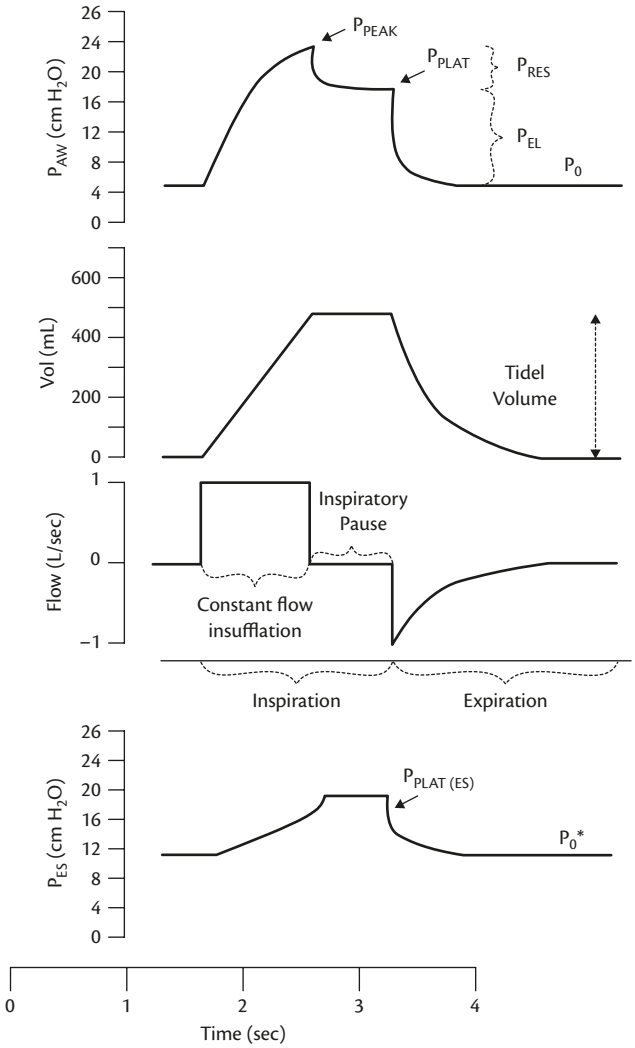

Fig. 74.1 Ventilator screen image representing changes in airway pressure (P_{AW}), flow, volume, and oesophageal pressure (P_{ES}) versus time; P_{PEAK} inspiratory peak pressure, P_{PLAT} plateau airway pressure, $P_{PLAT(ES)}$ plateau oesophageal pressure, P_0 total PEEP at the airway pressure waveform, P_{0*} total PEEP at the oesophageal pressure waveform, V_T tidal volume.

Resistance and flow

Definition

Resistance (R) represents the ratio between the pressure dissipated and the mean gas flow ($\dot{V}$). The resistance of the respiratory system (R_{RS}) is a purely dynamic force caused by the movement of molecules and the friction between them, and against the tracheobronchial tree and the endotracheal tube (ETT), and, to a smaller extent, to the resistance to parenchyma deformation.

Measurement

In a situation of constant flow, R_{RS} can be calculated as:

$$R_{RS} = \frac{P_{PEAK} - P_{PLAT}}{\dot{V}} \rightarrow P_{PEAK} - P_{PLAT} = P_{RES} = R_{RS} \times \dot{V} \quad \text{[eqn 3]}$$

Because flow is constant, one can approximate that this value of R_{RS} is constant during the whole insufflation. Such an assumption cannot be made if ($\dot{V}$) is not constant during insufflation, such as during PCV. The resistive pressure (P_{RES}) reflects the energy lost to overcome F_R, which is usually mainly situated in the upper or proximal airways, including the ETT. As a consequence, P_{RES} disappears before reaching the deep lung and is not present in alveoli.

P_{RES} gives insight about the conducting airways and tells the clinician which part of P_{AW} is not transmitted to the alveoli and does not contribute to a risk of VALI. P_{RES} is, by definition, dependent on flow. R_{RS} can also increase with flow when it changes from laminar to partially or fully turbulent. The pressure and flow relationship is curvilinear as it is the case in endotracheal tubes [5]. In other words, small changes in flow can induce large changes in P_{RES}.

There are many other methods to calculate resistance, but the end-inspiratory occlusion method described here is the simplest.

Flow

In the lung, flow can change from purely laminar with little friction, to fully turbulent with instabilities, large frictional forces and high pressure dissipation. In ETT and in upper airways flow is mostly turbulent, whereas laminar flow predominates in the more distant and small airways.

According to Hagen–Poiseuille's Law during laminar flow, R is directly related to airway length (L), gas viscosity (η) and inversely proportional to tube radius to the fourth power:

$$R_{RS} = \frac{8\eta L}{\prod r^4} \quad \text{[eqn 4]}$$

where Π is a mathematical constant.

Clinical implications

To avoid excessive F_R and, subsequently energy loss, an adequately-sized ETT is important. In severe obstructive lung disease a mixture of helium and oxygen has a decreased density, reducing the resistance of the airway [6]. In a healthy individual adult under MV using a square flow set at 60 L/min (or 1 L/sec), R_{RS} is usually less than 10 cmH_2O/L/sec and rarely exceeds 15 cmH_2O/L/sec. During acute exacerbation of COPD or asthma, R_{RS} can increase up to 20 cmH_2O/L/sec or 40 cmH_2O/L/sec in the most severe forms of bronchospasm. During MV, a sudden augmentation in P_{PEAK} without an increase in P_{PLAT} indicates an abrupt increase in P_{RES} and in R_{RS}; the most common reasons like tube kinking, mucus clotting in the airway or bronchospasm can be readily identified and treated after visualizing the increase of P_{RES} on the P_{AW} curve.

Resistance is a dynamic force, acting only when flow is present. During constant flow VCV the same amount of P_{RES} is present during the whole insufflation. During PCV, the major part of P_{RES} is dissipated at the beginning of the breath due to the decelerating flow pattern. Because flow is decelerating, P_{RES} progressively decreases along insufflation and P_{PEAK} becomes close to P_{PLAT}. P_{PEAK} equals P_{PLAT} only when flow has reached zero at the end of insufflation. So in many instances, P_{PEAK} during PCV remains higher than the true P_{PLAT}.

Flow–volume curves

The effects of airway resistance can be visualized on dynamic flow–volume curves (during inspiration and expiration). Analysis of this curve may be useful for identifying different clinical situations (Fig. 74.2) [7].

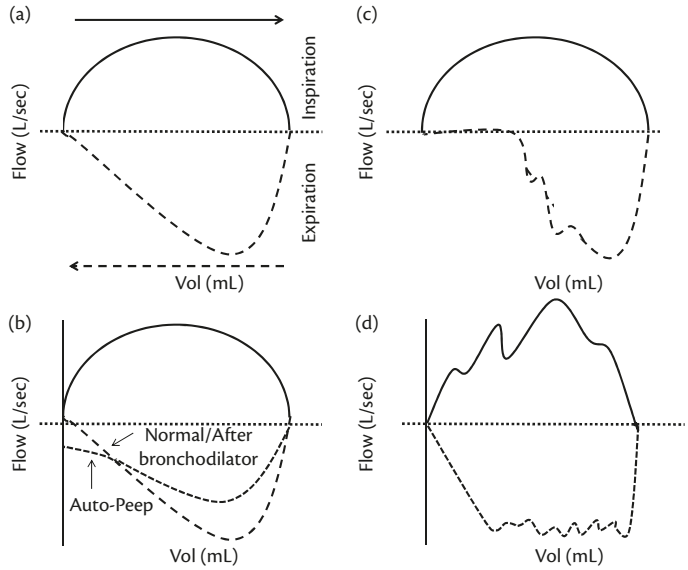

Fig. 74.2 Flow volume curves in different situations. (a) Normal patient; (b) COPD patient with dynamic hyperinflation and auto-PEEP, and after bronchodilator treatment; (c) sudden interruption of exhalation flow representing an important gas leak from the patient (bronchopleural fistulae) or from the ventilator circuit; (d) a saw-tooth pattern is observed in both inspiratory and expiratory limbs and indicate presence of secretions in the airways.

Elastance (E) and compliance (C)

Definition

The elastance of the respiratory system (E_{RS}) reflects the capacity of the pulmonary system to return to its resting position and measure the recoil pressure over a given volume. Since E = 1/C, the compliance of the respiratory system (C_{RS}) denotes the capacity of the pulmonary system to expand. Traditionally, C_{RS} has been used to assess the severity of ARDS [8,9].

Measurement

Compliance (C) can be defined as the change in volume (ΔV) per unit of change in applied pressure (ΔP):

$$C = \Delta V / \Delta P \qquad \text{[eqn 5]}$$

When applying an end-inspiratory occlusion or pause, there is no movement of gas (i.e. no resistive pressure) and the elastic properties can be calculated by these static (or quasi-static) measurements. The static compliance of the respiratory system ($C_{STAT(RS)}$) can be calculated as:

$$C_{STAT(RS)} = \frac{V_T}{P_{PLAT} - P_0} \qquad \text{[eqn 6]}$$

During MV, P_0 is the total PEEP, which is the sum of extrinsic positive end expiratory pressure ($PEEP_E$) set on the ventilator and intrinsic PEEP above it ($PEEP_I$ or auto-PEEP). The latter can be present during short expiratory times (e.g., inverted I/E ratio ventilation), high respiratory rate with fixed inspiratory time, or in expiratory flow limitation (COPD, asthma, cardiogenic pulmonary oedema, ARDS) where alveoli have prolonged and delayed emptying due to their mechanical characteristics or collapse of the small airways, trapping residual gas inside the alveoli. It can be measured with an occlusion manoeuvre at the end of the expiratory phase under controlled MV (Fig. 74.3). $PEEP_I$ and $PEEP_E$ must be taken into account when measuring P_0 with eqn 2. C_{RS} and the equation of motion should be written as:

$$C_{(RS)} = \frac{V_T}{P_{PLAT} - \left(PEEP_E + PEEP_I\right)} \qquad \text{[eqn 7]}$$

$$P_{RS(t)} = \frac{1}{C}\left(V\right)_{(t)} + R(\dot{V})_{(t)} + PEEP_E + PEEP_I \qquad \text{[eqn 8]}$$

Pressure–volume curve

C_{RS} can vary with lung volume. It is analysed over the whole lung volume by plotting static pressure values over a large volume ranges, e.g. from functional residual capacity (FRC) to total lung capacity (TLC), with construction of a pressure–volume (P/V) curve [10–12] (Fig. 74.4). The slope of this curve represents the C_{RS} and is not constant over lung volume. The patient must be passive for accurate results, though paralysis is not always mandatory [13].

The P/V curve of the respiratory system depends on both compliance of the chest wall (C_{CW}) and the lung (C_L). The latter depends primarily on the aerated lung volume available to ventilation.

Information from the shape and the different values of the P/V curve can be extrapolated to the clinical condition of a mechanically ventilated patient [11]. The first part of the P/V curve (starting from FRC) in patients with ARDS often has a relatively flat shape with a low C_{RS} due to a collapsed lung. In this phase, a larger change in P_{AW} is necessary to produce a small change in volume. In the second part, part of the lung has been reopened and/or is reopening, and C_{RS} becomes higher with a more linear curve. It indicates a region where the work of breathing is lower. Finally, the upper section of the P/V curve shows a lower C_{RS} reflecting that the lung has been reopened and possibly overdistended [14].

The lower inflection point (LIP) and upper inflection point (UIP) represent a separation of the different parts. Schematically in ARDS, the LIP represents the beginning of substantial recruitment,

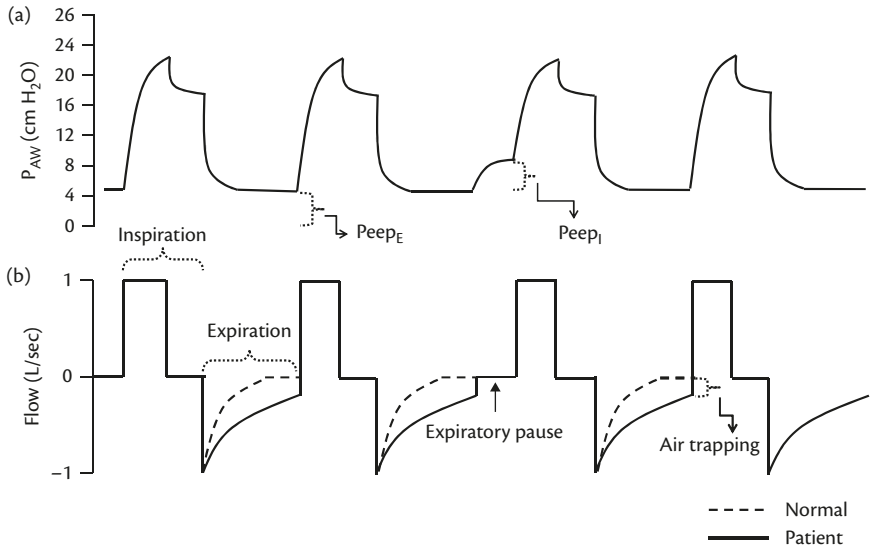

Fig. 74.3 The occurrence of intrinsic PEEP can be observed on the screen of the ventilator from a patient with obstructive lung disease. (a) Airway pressure waveform with an expiratory pause showing the existence of $PEEP_I$ (or auto-PEEP). (b) Flow curve demonstrating the failure to exhale all gas during the expiratory time and, consequently, formation of gas trapping.

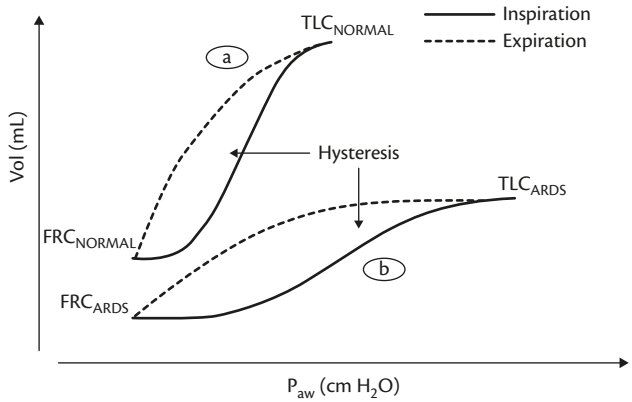

Fig. 74.4 Pressure–volume curves (P/V) and its hysteresis. (a) P/V curve from a normal patient. (b) P/V curve from an ARDS patient.
FRC, functional residual capacity; TLC, total lung capacity.

while the majority of recruitment has already occurred at the UIP. In reality, alveolar recruitment occurs all over the curve [15].

The P/V curve can also be drawn during the expiratory phase of ventilation, better reflecting the closing pressures and more useful when setting PEEP, but being more complex to analyse.

The different slopes of the P/V curve between inspiration and expiration generate an area called hysteresis. P/V curve with a large hysteresis could represent a potential for alveolar recruitment, especially at the early stage of ARDS [11].

Partition of the respiratory system elastance/compliance

The E_{RS} represents the sum of the effects of the lung (E_L) and of the chest wall elastance (E_{CW}):

$$E_{RS} = E_L + E_{CW} \quad \text{[eqn 9]}$$

Usually, the chest wall has a modest influence and more than 80% of the pressure is generated by the lungs. In several situations (e.g. obesity, highly oedematous patients, large pleural effusions, increased intra-abdominal pressure, ARDS) the differentiation of the sources of elastance is important. If E_{CW} is high compared with E_L, then a large part of the elastic pressure will be used to distend the chest wall and much less than the total P_{AW} to expand and distend the lung. Interpretation of the P_{AW} in terms of risk of VALI then differs.

The pleural pressure (P_{PL}) has to be estimated to calculate C_{CW}, and in critical practice this is done using oesophageal catheters with a balloon that measure oesophageal pressure (P_{ES}) (Figs 74.1 and 74.5) [16]. P_{ES} is a very useful substitute in determining P_{PL}, although there are some controversies about its absolute value. The C_{CW} can be calculated with the following equation:

$$C_{STAT(CW)} = \frac{V_T}{P_{PLAT(ES)} - P_0} \quad \text{[eqn 10]}$$

$P_{PLAT(ES)}$ is the end-inspiratory plateau pressure and P_0 the starting pressure both measured on the oesophageal pressure.

Transpulmonary pressure is the difference between P_{AW} and $P_{ES} = P_L$. It represents the force really distending the lung parenchyma. Elastance or compliance of the lung can then be easily obtained as:

$$C_{STAT(L)} = \frac{V_T}{P_{PLAT(L)} - P_{0(L)}} \quad \text{[eqn 11]}$$

Clinical implications

The normal $C_{STAT(RS)}$ in a patient depends first on the size of the lung and, therefore, of the height of the patient (and age for children). Volumes are preferentially expressed in mL/kg of predicted body weight reflecting the height rather than the current weight of the patient [17].

Because compliance has a direct relationship with the lung volume available for ventilation, loss of lung volume (e.g. during atelectasis, pneumonia or pulmonary oedema) will cause a proportional drop in compliance. The concept of 'baby lung', introduced in

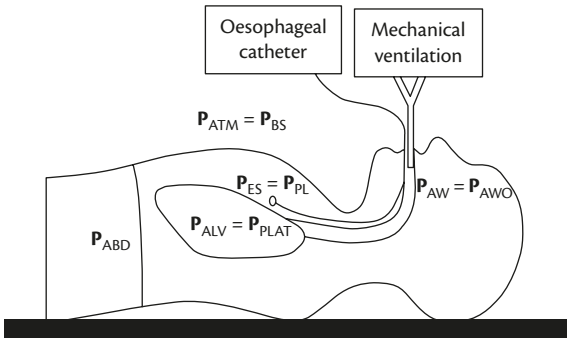

Fig. 74.5 The main different pressures involved in pulmonary mechanics. P_{ABD}, intra-abdominal pressure; P_{ATM}, atmospheric pressure; P_{ALV}, alveolar pressure; P_{AW}, airway pressure; P_{AWO}, opening airway pressure; P_{BS}, body surface pressure; P_{ES}, oesophageal pressure; P_{PL}, pleural pressure; P_{PLAT}, plateau pressure. Transpulmonary pressure (P_L) is the difference between P_{AW} and P_{ES}.

the middle of 1980s showed that, in most ARDS patients, the normally aerated tissue represents only a small proportion of the whole lung, explaining why $C_{STAT(RS)}$ is low, and C_{RS} is proportional to the size of the 'baby lung' (amount of normally aerated tissue) [18]. FRC, representing the amount of lung aerated at end expiration, is much smaller in ARDS patients than in patients with normal lungs [19]. In other words, C and E changes do reflect the amount of aerated lung volume available, which indirectly reflects the severity of the ARDS process in the whole lung. It is an important indication of the volume that can be safely delivered to the remaining lung and the risks of ventilation in terms of VALI.

In mechanically-ventilated adults in the supine position, $C_{STAT(RS)}$ is frequently lower than in erect healthy subjects, often in a range of 40–70 mL/cmH_2O. When it becomes lower than 25 mL/cmH_2O, like in severe ARDS patients, the work of breathing can be 4–6-fold increased, and the total energy dissipated becomes much greater.

The specific elastance is the ratio of elastance to FRC. The concept of specific lung elastance reflects the ratio between the transpulmonary pressure (stress) and the change in lung volume relative to its resting volume during respiration (strain). Specific lung elastance was shown to be constant among patients with ARDS and healthy subjects [20], suggesting that the measurement of FRC could be used to evaluate the change in transpulmonary pressure induced by tidal volume. Therefore, monitoring these parameters could potentially be used to better set MV and avoid VALI [3].

Conclusion

Understanding the relationship between P, V, and $\dot{V}$ as well as the concepts of R and C makes understanding of ventilation much easier, as well as the interpretation of the changes of pressure and flow traces on the ventilator screen. This knowledge helps the clinician to decide for the best treatment option.

CHAPTER 75

Gas exchange principles in the critically ill

Peter D. Wagner

Key points

- Gas exchange is a process of molecular movement governed by the unifying principle of mass conservation applied equally to both gas uptake and elimination.
- Pulmonary gas exchange in the critically-ill patient is almost always impaired with multiple causes both internal and external to the lung.
- In a normal subject breathing sea level air at rest, the $\dot{V}A / \dot{Q}$ ratio of the lung as a whole is around 1 because total alveolar ventilation and pulmonary blood flow are about the same. In the critically ill, inequality can be very severe.
- The $\dot{V}A / \dot{Q}$ ratio uniquely determines PaO_2 and $PaCO_2$ in a given lung region, since all lung regions are subject to the same boundary conditions and O_2-Hb and CO_2 dissociation curves.
- Hypoxaemia and hypercapnia are caused by $\dot{V}A / \dot{Q}$ inequality, inspiratory hypoxia, hypoventilation, diffusion limitation, shunt, or extrapulmonary factors.

Introduction

This chapter discusses the several reasons for, and mechanisms of, abnormal gas exchange in critically-ill patients in intensive care units (ICUs). The principles underlying gas exchange have been well known since the 1950s when Rahn and Fenn [1], and Riley [2–4] and colleagues developed quantitative approaches to its understanding. While these principles apply equally to normal subjects and patients with lung disease, nowhere is their application and understanding both more difficult and also more important than in the ICU. It is well known that patients in the ICU usually endure severe lung disease, no matter what the cause of their illness, and that supportive interventions to improve gas exchange carry their own, sometimes severe, risks of further lung damage.

What follows applies only under steady-state conditions—that is, conditions in which concentrations of gases (such as O_2 and CO_2) are constant in time for at least several minutes. Rapid changes in cardiopulmonary structure or function frequently occur in the ICU, and then the steady state is disturbed, with O_2 and CO_2 concentrations rapidly changing, and the use of steady-state concepts will be in error.

Basic principle: mass conservation

Gas exchange is a process of molecular movement governed by the unifying principle of mass conservation, both when movement is by convection (ventilation and blood flow) and by diffusion (gas transfer across the alveolar-capillary blood gas barrier). It applies equally to gas uptake (e.g. O_2) and elimination (e.g. CO_2).

To best understand this, one applies conservation of mass equations, similar for O_2 and CO_2, so that illustrating the case using O_2 is here sufficient. Conservation of mass decrees that all the inhaled O_2 not exhaled on the next breath (eqn 1) is transferred into the pulmonary capillary blood (eqn 2). This transfer rate is the O_2 uptake, $\dot{V}O_2$:

$$\dot{V}O_2 = \dot{V}A[FIO_2 - FAO_2] \quad \text{[eqn 1]}$$

$$\dot{V}O_2 = \dot{Q}[CaO_2 - CvO_2] \quad \text{[eqn 2]}$$

Taking eqns 1 and 2, and rearranging gives:

$$\dot{V}A / \dot{Q} = [CaO_2 - CvO_2] / [FIO_2 - FAO_2] \quad \text{[eqn 3]}$$

$\dot{V}A$ is alveolar ventilation and $\dot{Q}$ total pulmonary blood flow; CaO_2 and CvO_2 are systemic and pulmonary arterial O_2 concentrations, respectively; FIO_2 and FAO_2 are inspired and alveolar O_2 concentrations respectively. A minor approximation appears above—inspired and expired gas volumes are taken to be the same, which is true to within about 1%.

This equation is written for the whole lung, so that CaO_2 is mixed arterial blood $[O_2]$, while FAO_2 is mixed alveolar gas O_2 fractional concentration. It applies equally to small homogeneous regions in the lung (i.e. approximately, the acinus [5], but the terminology differs:

$$\dot{V}A / \dot{Q} = [Cc'O_2 - CvO_2] / [FIO_2 - FAO_2] \quad \text{[eqn 4]}$$

where 'c', or 'end-capillary', represents $[O_2]$ in the pulmonary venule draining the homogeneous region, and FAO_2 is now the alveolar $[O_2]$ in the same region.

Eqn (4) shows that three factors determine gas exchange:

- The region's $\dot{V}A / \dot{Q}$ ratio.
- The 'boundary conditions', i.e. O_2 composition of inspired gas (FIO_2) and pulmonary arterial blood (CvO_2).
- The characteristics of the O_2-Hb dissociation curve.

The latter is involved because $Cc'O_2$ and FAO_2 are directly linked through that curve. Since by Dalton's law of partial pressures $PO_2 = FO_2 * [PB - PH_2O]$, the alveolar PO_2 (PaO_2) is also defined. Thus, there is only a single value of PaO_2 that satisfies eqn 4 for

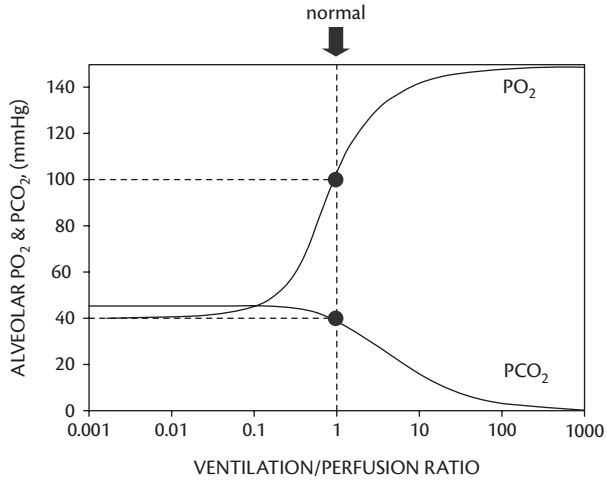

Fig. 75.1 Semi-logarithmic plot of alveolar gas PO_2 and PCO_2 as a function of the ventilation/perfusion ratio.

any set of the three groups of variables listed immediately previously. This is shown in Fig. 75.1, where the boundary conditions and O_2Hb dissociation curve are held constant (using normal values), while the $\dot{V}A / \dot{Q}$ ratio is systematically varied from zero to infinity. Fig. 75.1 also shows the results for CO_2, based on identical considerations and normal values. Eqn 4 is called the ventilation/perfusion ($\dot{V}A / \dot{Q}$) eqn for O_2. For CO_2, it is in essence identical, but because CO_2 is eliminated while O_2 is taken up, the quantities appear in reverse order to avoid negative signs:

$$\dot{V}A/\dot{Q} = [CvCO_2 - Cc'CO_2] / [FACO_2 - FICO_2] \quad \text{[eqn 5]}$$

It is also useful to write the analog of eqn 1 for CO_2, giving:

$$\dot{V}CO_2 = \dot{V}A * FACO_2 - \dot{V}I * FICO_2 \quad \text{[eqn 6]}$$

This is useful, because, disregarding inspired [CO_2] as negligible, the ratio of eqn 6 to eqn 1, gives:

$$\dot{V}CO_2 / \dot{V}O_2 = (\dot{V}A * [FACO_2]) / (\dot{V}A * [FIO_2 - FAO_2]) \quad \text{[eqn 7]}$$

or,

$$\dot{V}CO_2 / \dot{V}O_2 = R = (PACO_2) / [PIO_2 - PAO_2] \quad \text{[eqn 8]}$$

because F (fractional alveolar gas concentration) and P (alveolar partial pressure) are proportional. $\dot{V}A$ cancels out of the equation; R is the respiratory exchange ratio (the ratio of CO_2 produced to O_2 consumed). Re-arranging gives:

$$PAO_2 = PIO_2 - PACO_2 / R \quad \text{[eqn 9]}$$

This is the simple form of the alveolar gas equation. It suffices for clinical use, but if one wishes to account for $\dot{V}I$ and $\dot{V}A$ being slightly different, it becomes:

$$PAO_2 = PIO_2 - (PACO_2/R) + (PACO_2 * FIO_2 * (1-R)/R) \quad \text{[eqn 10]}$$

The alveolar gas equation defines the PaO_2 if we know $PaCO_2$, PIO_2, and R. It applies to the lung as a whole or to a small homogenous region, just like the ventilation/perfusion equation.

The most important outcome is understanding that the $\dot{V}A / \dot{Q}$ ratio uniquely determines PaO_2 and $PaCO_2$ in a given lung region (since all lung regions are subject to the same boundary conditions and O_2-Hb and CO_2 dissociation curves); see Fig. 75.1.

Ventilation/perfusion matching and gas exchange

If all lung regions had the same $\dot{V}A / \dot{Q}$ ratio, they would all have the same PaO_2 and $PaCO_2$. In a normal subject breathing sea level air at rest, the $\dot{V}A / \dot{Q}$ ratio of the lung as a whole is around 1 because total alveolar ventilation and pulmonary blood flow are about the same at 5–6 L/min. PaO_2 is ~100 mmHg, while $PaCO_2$ is ~40 mmHg (Fig. 75.1). Because all regions reach diffusion equilibrium of O_2 exchange across the blood–gas barrier at rest in health [6], end capillary PO_2 and PCO_2 would equal their alveolar counterparts in each region, and thus the systemic arterial blood would also have a PO_2 of 100 mmHg and PCO_2 of 40 mmHg. However, if regional $\dot{V}A / \dot{Q}$ ratio was lower than average. Fig. 75.1 shows PaO_2 is reduced and $PaCO_2$ increased in that region. Symmetrically, in a high $\dot{V}A / \dot{Q}$ region, PaO_2 will rise, and $PACO_2$ fall.

Using Fig. 75.1, we may consider what we call $\dot{V}A / \dot{Q}$ inequality, when not all regions have the same values of $\dot{V}A / \dot{Q}$. In the critically ill, inequality can be very severe. A simple 'two-compartment' model suffices to illustrate the principles, lung is usually far more complex. The top panel (Fig. 75.2A) shows the two-compartment model in the homogeneous state, with both ventilation ($\dot{V}A$) and blood flow ($\dot{Q}$) equally distributed. With total ventilation and perfusion each set to 6 L/min, the $\dot{V}A / \dot{Q}$ ratio is 1.0 in each compartment. From Fig. 75.1, PaO_2 is 104 mmHg and $PACO_2$ 39 mmHg in each compartment. Mixed exhaled gas will also have these partial pressures, as will the mixed pulmonary venous blood returning to the left heart, and then systemic arterial PO_2.

If the left airway is now largely partially obstructed (by mucus, bronchoconstriction, airway wall thickening, aspirated foreign object, tumour, etc.) as in the lower panel, Fig. 75.2B, $\dot{V}A$ of the obstructed compartment will be reduced (here by 90%) to 0.3 L/min. Because we wish to model only the effects of $\dot{V}A / \dot{Q}$ inequality, total ventilation, and blood flow are unchanged. Thus, the right-hand compartment now receives more ventilation than normal, here 5.7 L/min. There is, thus, one compartment with low $\dot{V}A / \dot{Q}$ ratio (0.1) and one with high $\dot{V}A / \dot{Q}$ ratio (1.9), but the total ventilation and blood flow remain normal. From Fig. 75.1, the alveolar (and end capillary) PO_2 are 45 (low $\dot{V}A / \dot{Q}$ unit) and 122 mmHg (high $\dot{V}A / \dot{Q}$ unit). PO_2 in mixed exhaled gas (PE) is the ventilation-weighted average of the two PaO_2 values. Ventilation weighting is required to ensure conservation of mass.

$$PE = [(0.3 * 45) + (5.7 * 122)] / 6.0 = 118\,\text{mmHg} \quad \text{[eqn 11]}$$

This calculation should strictly use concentration, rather than partial pressure. However, partial pressure can be used because Dalton's Law states that partial pressure and concentration are proportional.

This is 14 mmHg higher than in the homogeneous lung (Fig. 75.2A). Inspired PO_2 is about 150 mmHg and thus the inspired-exhaled PO_2 difference in the homogeneous state is 150 – 104 = 46 mmHg and after airway obstruction is 150 – 118 = 32 mmHg. If mixed exhaled gas has a higher PO_2, more O_2 is

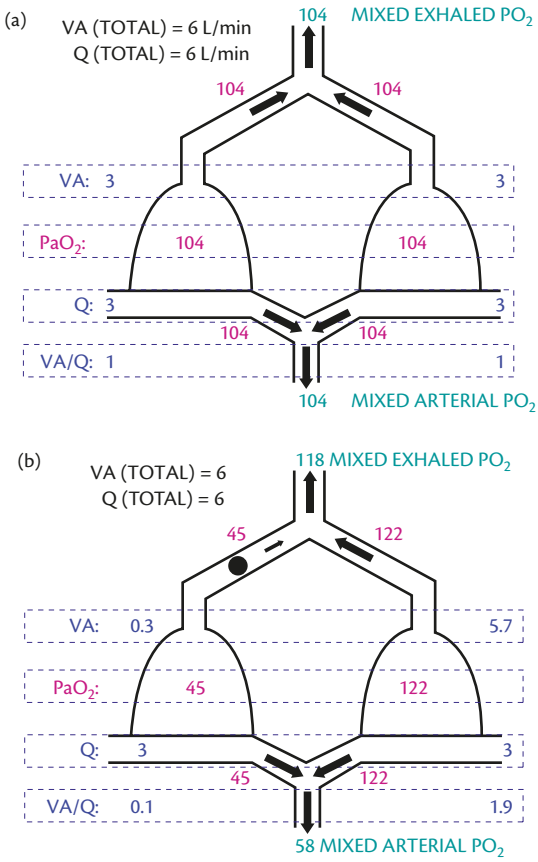

Fig. 75.2 (a) A two-compartment model of the lungs, with equally distributed ventilation and blood flow, resulting in a homogeneous lung. (b) A two-compartment model of the lungs with ventilation reduced by 90% on the left side (see text for description).

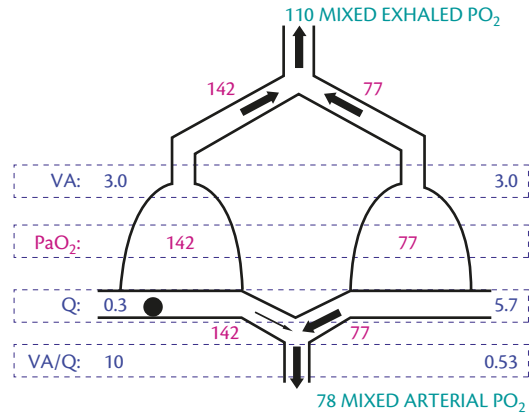

Fig. 75.3 A two-compartment model of the lungs with blood flow reduced by 90% on the left side (see text for description).

exhaled and therefore less is transferred into the blood: $\dot{V}O_2$ has fallen to 32/46 (i.e. ~70%) of that in the homogeneous lung.

PO_2 in the mixed pulmonary venous blood is calculated from the perfusion-weighted average of the two O_2 concentration values, using the O_2-Hb dissociation curve to compute the corresponding PO_2. This PO_2 is only 58 mmHg.

For CO_2, the numbers are quite different, but the outcome is qualitatively identical, but opposite: CO_2 elimination is reduced, but only by ~13%, and arterial PCO_2 rises, but by less than 1 mmHg. Indeed, the exchange of all gases is impaired by $\dot{V}A / \dot{Q}$ inequality and is manifest by a fall in arterial blood values for all gases taken up (e.g. O_2) and a rise in arterial blood values for all gases being eliminated (e.g. CO_2).

In this example, the effects are greater for O_2 than for CO_2. The same analysis obstructing the pulmonary artery of the left compartment (and restoring equal ventilation distribution) is shown in Fig. 75.3. Here, everything else is identical to that in Fig. 75.2B. The resulting compartmental ratios of $\dot{V}A / \dot{Q}$ are 10.0 and 0.53. As in the airway obstruction model, the two compartments have a below-average (right) and above-average (left) $\dot{V}A / \dot{Q}$ ratio. Reading off Fig. 75.1, PaO_2 are 142 and 77 mmHg, respectively. Mixed exhaled PO_2 is 110 mmHg (weighted mean of 142 and 77), while arterial PO_2 is 78 mmHg. $\dot{V}o_2$ is reduced, to (150–110)/(150–104), or 87% of control, while $\dot{V}co_2$ falls to 75% of control and arterial PCO_2 increases by 2 mmHg.

Thus, the two models—airway and vascular obstruction—both show impaired overall gas transfer, hypoxaemia, and hypercapnia, but airway obstruction affects O_2 transfer more than it affects CO_2, while with vascular obstruction, CO_2 transfer is more affected.

The causes of hypoxaemia and hypercapnia

There are six possible physiological causes of hypoxaemia and hypercapnia:

- $\dot{V}A / \dot{Q}$ inequality.
- Inspiratory hypoxia.
- Hypoventilation.
- Diffusion limitation.
- Shunt.
- Extra-pulmonary factors related to metabolic rate and cardiac output.

$\dot{V}/\dot{Q}$ inequality

Very important in critically-ill patients, inequality is defined as a range of $\dot{V}A / \dot{Q}$ ratios throughout the lung. In some regions, the $\dot{V}A / \dot{Q}$ ratio is low, in others normal, and in others high. This impairs overall O_2 uptake and CO_2 elimination (until compensated by increased O_2 extraction, ventilation, or cardiac output), and causes hypoxaemia and hypercapnia.

There are many reasons for $\dot{V}A / \dot{Q}$ inequality in ICU patients. They result from the pathological processes in the lung—infection, inflammation, fluid accumulation, vascular obstruction, tissue breakdown, and effects of ventilator management and other therapies. Importantly, these processes are never uniformly distributed throughout the lung. They are conveniently discussed by site of origin—airways, alveoli, blood vessels, and pleura. What follows is not exhaustive, but addresses the majority of mechanisms of inequality.

In the airways, bronchial wall thickening, mucus secretions, alveolar debris (cells, bacteria, inhaled particles, fluid) moved up the airways by ciliary function, bronchial smooth muscle contraction, and diminished parenchymal radial traction on the airway wall (the latter especially with pre-existing COPD) will each act to

reduce airway lumen size, (partially) obstructing the airway, and increasing airflow resistance. Because some regions will be more obstructed than others, more affected regions become underventilated, and a low regional $\dot{V}_A / \dot{Q}$ ratio will usually develop. With overall lung ventilation maintained, less affected regions (taking the air originally designated for the obstructed regions) are over-ventilated, raising the $\dot{V}_A / \dot{Q}$ ratio above normal, and causing hyperinflation and risk of barotrauma.

In affected alveoli, cellular debris, oedema fluid, and bacterial fragments will (partly) displace the air, diminishing their ventilation (even if the airways are normal). Alveoli completely filled with such material will not be ventilated at all, resulting in shunt. Collapsed alveoli will not receive ventilation, also resulting in shunt. Impaired surfactant activity often occurs, reducing compliance and promoting atelectasis. Interstitial oedema will also reduce compliance, and, with airways factors mentioned in the preceding paragraph, reduce regional ventilation.

Thus, a large number of specific processes all acting to impair regional ventilation may be present in the lungs of critically-ill patients, creating regions of low $\dot{V}_A / \dot{Q}$ ratio, $\dot{V}_A / \dot{Q}$ inequality and hypoxaemia. At the same time, over-ventilation of less affected regions occurs. As pathological processes continue, partial airway obstruction may become complete, converting what was $\dot{V}_A / \dot{Q}$ inequality into shunt.

Pulmonary vascular pathology may also cause $\dot{V}_A / \dot{Q}$ inequality and hypoxaemia. In the ICU, one cause is pulmonary thromboembolism. It may be classical emboli from thrombosed veins in extra-pulmonary regions of the body or local thrombosis in damaged pulmonary vessels. The resulting (partial) vascular obstruction diverts blood flow to less affected lung regions. In this manner, the affected regions develop high $\dot{V}_A / \dot{Q}$ ratios due to loss of perfusion, while the unaffected regions become over-perfused, so their $\dot{V}_A / \dot{Q}$ ratio falls.

High $\dot{V}_A / \dot{Q}$ regions may develop from mechanical ventilation with high airway pressures. This may overventilate and hyperinflate the most normal, compliant alveoli, stretching alveolar walls, compressing alveolar capillaries [7], increasing vascular resistance, reducing their perfusion and increasing the $\dot{V}_A / \dot{Q}$ ratio. At first sight, this may not seem problematic (a high $\dot{V}_A / \dot{Q}$ ratio corresponds to a high PO_2 and low PCO_2, Fig. 75.1). However, there are three major concerns:

- Risk of barotrauma from the hyperinflation.
- Poorly perfused alveoli are not effective for gas exchange, because little O_2 can be added to the blood or CO_2 removed.
- The ventilation delivered to these alveoli causes the perfused alveoli that undertake most of the gas exchange to become under-ventilated and CO_2 retention may develop.

Pleural processes that may affect gas exchange include pneumothorax and effusion, both of which promote atelectasis (and thus shunt), or pleural thickening that restricts lung inflation.

To summarize, many mechanisms may co-exist in ICU patients to produce $\dot{V}_A / \dot{Q}$ inequality. Those that primarily affect the airways, alveoli, and pleura lead mostly to regions of reduced $\dot{V}_A / \dot{Q}$ ratio, while those that primarily affect the vasculature result in regions of high $\dot{V}_A / \dot{Q}$ ratio. These different locations of effect may then result in different arterial PO_2/PCO_2 pictures, as expressed in Figs 75.2 and 75.3, gas exchange is always impaired.

Inspiratory hypoxia

Reduced inspired PO_2 (e.g. ascent to altitude, plane flight) causes arterial hypoxaemia, but in the ICU, this should not occur and will not be discussed.

Hypoventilation

Insufficient ventilation to the lungs as a whole will cause arterial PO_2 to fall and PCO_2 to rise. Fig. 75.4 (representing eqns 1 and 6) shows how sensitive PO_2 and PCO_2 are to changes in ventilation, especially when reduced. Unless by therapeutic design, overall hypoventilation is not commonly seen in ICU patients.

Diffusion limitation

An assumption of the preceding analysis has been that diffusion of O_2 and CO_2 between alveolar gas and capillary blood is complete within the transit time of a red cell through the lung capillaries, such that alveolar and end-capillary PO_2 are equal (and similarly for PCO_2). In critically-ill patients in the ICU, this assumption is known to be reasonable.

Shunt

Shunt is defined as blood flowing from the right side to the left side of the heart without any alveolar gas contact, thus affording no O_2 uptake or CO_2 elimination. Shunt pathways include direct communications between the ventricles or atria of the heart, and blood passing through completely unventilated lung regions. Common causes include atelectasis, alveolar filling with fluid or exudate, and pneumothorax. Shunting is common and often substantial in the ICU. Uncommonly, dilated pulmonary vessels may carry blood that fails to (fully) oxygenate, even when adjacent alveoli are ventilated. This may happen in chronic liver disease [8], and in infants/children suffering bronchopulmonary dysplasia.

Extrapulmonary factors

For a given metabolic rate ($\dot{V}o_2$), reduction in cardiac output will necessitate greater tissue O_2 extraction to maintain adequate O_2 supply. If cardiac output falls (in relation to $\dot{V}o_2$), PO_2 of the venous blood returning to the lungs also falls. Similarly, high cardiac output (in relation to $\dot{V}o_2$) will result in an elevated venous PO_2. As

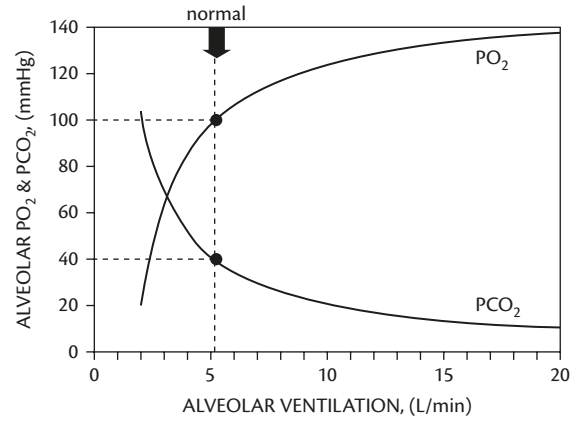

Fig. 75.4 Alveolar PO_2 and PCO_2 as a function of alveolar ventilation in a homogeneous lung. Vertical dashed line represent a normal ventilation, black dots represent the interception with PO_2 and PCO_2 curves, and vertical dashed lines indicates the corresponding pressure values on the ordinate axis.

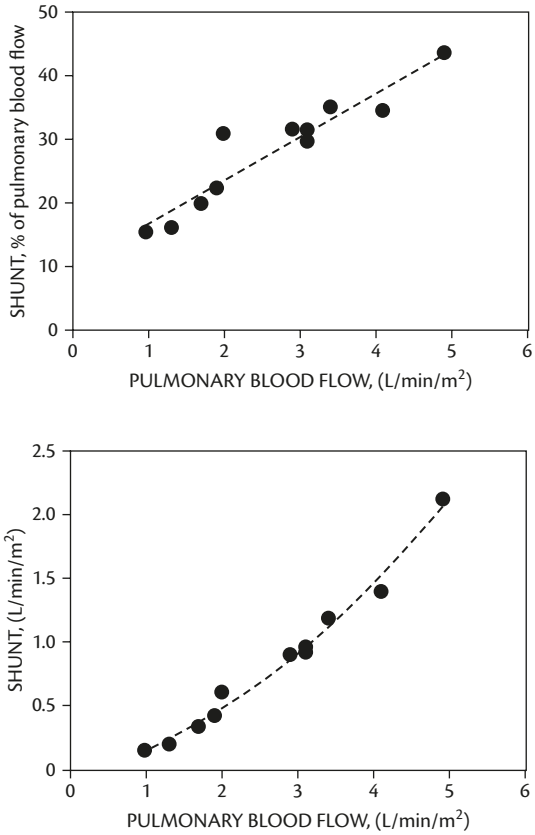

Fig. 75.5 Change in shunt fraction and flow in one ICU patient [9]. Reproduced with permission of the authors. Lemaire F, Harf A, Teisseire BP, 'Oxygen exchange across the acutely injured lung'. In: Zapol WM, Falke KJ (eds), *Acute Respiratory Failure*, New York: Dekker; 1985, p. 521–52.

the ventilation/perfusion equation shows (eqn. 4), the boundary conditions (composition of pulmonary arterial blood and inspired gas) affect the values of PO_2 and PCO_2 independently of the $\dot{V}_A / \dot{Q}$ ratio. As venous PO_2 falls, alveolar, and end-capillary PO_2 will fall at a given $\dot{V}_A / \dot{Q}$ ratio, and vice versa. In this way, extrapulmonary factors (cardiac output and $\dot{V}o_2$ especially) will affect arterial PO_2, in addition to all the preceding potential causes of hypoxaemia. Reduction in blood [Hb] has the same effect as reduction in cardiac output—greater fractional extraction of O_2 and lower venous PO_2.

The message is that when changes in metabolism, cardiac function, and/or [Hb] occur, changes in arterial oxygenation are expected that have nothing to do with lung health. Recognizing this is paramount in providing the best therapeutic response. For example, thinking a sudden fall in arterial PO_2 is due to new alveolar oedema or collapse when it is due to cardiac dysfunction may lead to poor clinical decisions.

In closing, two special cases of the role of extrapulmonary factors deserve mention—the first is dependence of shunt on total pulmonary blood flow. In patients with shunt, a change in cardiac output changes not just venous PO_2 as discussed, but also the volumetric flow distribution between the shunt channels and the rest of the lung. The reason remains unclear, but may have to do with differing degrees of hypoxic pulmonary vasoconstriction in the shunt vessels compared to the rest of the lungs. Fig. 75.5 shows an extraordinary example of this effect [9]. The implication is clear—increasing blood flow through a damaged lung has the potential of worsening the shunt, which will oppose any beneficial effect of higher blood flow on the venous PO_2.

The second example occurs when high positive airway pressure are used. This impedes venous return to the heart and cardiac output falls. As a result, even if higher airway pressure successfully re-inflates collapsed alveoli and reduces shunt, the expected benefit in arterial PO_2 may not occur, or may be lessened, because the reduced cardiac output lowers venous PO_2.

CHAPTER 76

Gas exchange assessment in the critically ill

Peter D. Wagner

Key points

- The cornerstone of insightful monitoring is directly sampled systemic arterial blood, but there are both more and less complex and invasive methods.
- Pulse oximetry is the least invasive measure, but limitations include poor signal and inability to track substantial change in PO_2 at higher SaO_2 (flat O_2-Hb curve).
- The PaO_2/FIO_2 ratio is used in the ICU so measurements at different FIO_2 can be compared, although it is not completely independent of FIO_2 in the critically ill.
- The alveolar-arterial PO_2 difference corrects the alveolar PO_2 for values of $PaCO_2$ different than 40 mmHg. It becomes less useful as FIO_2 is increased if $\dot{V}A/\dot{Q}$ inequality is the main problem.
- Using oximeter-tipped catheters placed in the pulmonary artery, mixed venous saturation is continuously available. A high arteriovenous difference implies high O_2 demand in relation to supply, and vice versa but correct interpretation depends on $\dot{V}o_2$ and cardiac output.

Introduction

Since most patients admitted to the intensive care unit (ICU) have damaged lungs, monitoring of gas exchange is critical to informed management. Monitoring can be descriptive (how abnormal is gas exchange?) and mechanistic (how may gas exchange reveal pathophysiological insights?)

The cornerstone of insightful monitoring is directly sampled systemic arterial blood, but there are both more and less complex and invasive methods. Usually, the more complex and invasive, the greater will be the insights gained, and vice versa. The key is to balance the complexities against the information content to select an approach that is sufficiently useful yet not overly complex.

Pulse oximetry

The simplest, least invasive approach is pulse oximetry, which measures arterial O_2 saturation (SaO_2). With immediate, continuous, low cost, non-invasive response requiring no specialty training, it is widely used to good advantage. The clinical range of use is mostly 85–100%. If SaO_2 is <85–90%, direct arterial blood sampling and urgent therapeutic responses are usually required.

Oximetry does not measure arterial PCO_2/pH and usually does not reveal mechanistic information. Moreover, as the O_2-Hb dissociation curve shifts when pH, temperature, and PCO_2 change, a given saturation may correspond to different PO_2 values.

Two major limits to pulse oximetry are:

Inadequate signal: most oximeters are lightly clamped on a finger. They are easily dislodged and require adequate digital perfusion.

The shape of the O_2-Hb dissociation curve: when arterial PO_2 lies on the flat part of the O_2-Hb curve (SaO_2 > ~95%), large changes in PO_2 may occur from significant changes in lung function without measureable differences in SaO_2.

Since the standard deviation of SaO_2 is ~2%, a true SaO_2 of 97% (normal) may read 95%, while a true value of 93% (abnormal) may also read 95%. It is thus problematic to know whether such a value represents poor lung function or random variation from normal.

Additionally, when saturation falls below ~70%, many oximeters will indicate an even lower (i.e. erroneous) value. This should not happen in the ICU, because saturations this low imply life-threateningly poor lung function, requiring placement of an arterial catheter to directly sample arterial blood.

Arterial blood gas sampling

Arterial blood sampling, via in-dwelling catheter or needle puncture, is the current backbone of ICU gas exchange assessment. Unlike oximetry, sampling is discrete, not continuous (continuously recording in-dwelling electrodes are under development). Sample volume can be less than 200 μL, enabling paediatric use. Analysis (blood gas analyser) takes only 1–2 minutes, and yields PO_2, pH, PCO_2, SaO_2 [Hb], lactate, bicarbonate, and base excess, thus evaluating acid–base state and gas exchange.

Precautions in arterial blood sampling

Several important precautions are necessary to avoid errors:

- The sample must be taken and kept without exposure to air until measured.
- The sample syringe must be free of air (bubbles). These distort the results and should be immediately expelled from the syringe.
- The syringe must be pre-heparinized to prevent clotting, which obstructs analysers and causes malfunction. Use just enough heparin to prevent coagulation without diluting the sample.
- The sample should be analysed immediately. If delay is unavoidable, keep it iced to reduce white blood cell metabolism, which will

reduce PO_2 and raise PCO_2. This is especially important when PO_2 is high, since PO_2 may otherwise fall 10–20 mmHg/min.

- Aggressively rotate the sample until the moment of analysis to avoid red cell settling causing errors in [Hb] and haematocrit.
- Document patient temperature, to understand temperature-induced shifts in the O_2-Hb dissociation curve, and to correct of PO_2, PCO_2 and pH back to body temperature (clinical analysers usually run at 37°C). Suppose a patient's temperature is 39°C. As the sample cools to 37°C in the analyser, the number of O_2 molecules per unit volume cannot change (no air contact). Thus, SaO_2 is not affected by cooling. However, the O_2-Hb curve shifts leftward, and so PO_2 falls. We usually need PO_2 at body temperature, and so temperature-correct the value accordingly, about 6% per degree Centigrade. Thus, a PO_2 of 80 mmHg would become ~90 mmHg expressed when the patient's temperature was 39°C. Directional changes are similar for PCO_2 and blood [H^+], yielding a higher PCO_2 and lower pH than indicated by the analyser. The opposite is true when the patient is below 37°C. Most analysers temperature-correct automatically.
- Document inspired [O_2] at sampling. A PO_2 of 90 mmHg, breathing room air, is interpreted very differently from the same PO_2 measured during 100% O_2 breathing.

Interpretation of blood gas variables

First, ask only how different PO_2, PCO_2, pH, SaO_2, and [Hb]/haematocrit are from normal. Two things are required—expected normal values, and analyser measurement error, to establish the 95% confidence limits (roughly, mean ± 2 SD). If the values lie outside those limits, there is at least a 95% chance that the data are abnormal. When FIO_2 is elevated, (common in the ICU), normal alveolar PO_2 expected at any FIO_2 can be estimated from the alveolar gas equation:

$$\text{Expected alveolar } PO_2 = FIO_2 * (PB - PH_2o) - PACO_2/R \quad \text{[eqn 1]}$$

FIO_2 is inspired O_2 fraction, PB is barometric pressure; PH_2O is saturated water vapour pressure (47 mmHg at 37°C); $PaCO_2$ is arterial PCO_2 and R is respiratory exchange ratio, usually assumed to be 0.8.

In sea level room air, normal alveolar PO_2 is about 100 mmHg. On 100% O_2, it rises to ~660 mmHg. The relationship is essentially linear in between. Normal arterial PO_2 should be a few mmHg lower than alveolar.

Clinical analysers commonly have a coefficient of variation for PO_2 of ~5% (thus if PO_2 = 100 mmHg, 95% confidence limits are 90–110 mmHg). If PO_2 is 500 mmHg, 95% confidence range is ~450–550 mmHg.

PCO_2 usually shows less variance; if PCO_2 = 40 mmHg, 95% confidence limits should be 38–42 mmHg, while when pH = 7.40, 95% confidence limits should be 7.38–7.42. However, ignoring the above sampling precautions will increase uncertainty.

Arterial blood gas variables can answer more than whether the results are normal or not. Well-established equations and relationships exist for quantifying gas exchange disturbances to estimate the extent of lung damage, and responses to interventions and therapies.

PaO_2/FIO_2 ratio

This simple and popular ratio [1] is used in the ICU so measurements at different FIO_2 can be compared. Since arterial PO_2 in health rises linearly with FIO_2, PaO_2/FIO_2 is somewhat constant as FIO_2 changes. This attractive concept has limitations: Fig. 76.1 shows the PaO_2 (upper panel) and PaO_2/FIO_2 ratio (lower panel) over the FIO_2 range from room air to 100% O_2 in several computational models [2] of varying gas exchange abnormality, labelled A through G.

Curve A (open squares) represents the normal lung. PaO_2 rises linearly (upper panel) and PaO_2/FIO_2 is very high and is essentially constant. However, even here, PaO_2/FIO_2 is not totally independent of FIO_2—small changes must not be over-interpreted.

Curves B, C, and D represent lungs with increasing heterogeneity of ventilation with respect to blood flow ($\dot{V}A/\dot{Q}$ inequality), quantified by the term SDQ (in effect, the standard deviation of the $\dot{V}A/\dot{Q}$ distribution). The normal range is 0.3–0.6 [3]. SDQ = 1.0 represents moderate inequality as in stable chronic lung disease; SDQ = 2.0 corresponds to a very ill ICU patient. In B, C, and D, there is zero shunt. PaO_2/FIO_2 increases considerably and non-linearly with increasing FIO_2 despite a constant amount of $\dot{V}A/\dot{Q}$ inequality. Both PaO_2/FIO_2 itself and its change with FIO_2 depend on the amount of $\dot{V}A/\dot{Q}$ inequality and the FIO_2, making PaO_2/FIO_2 somewhat difficult to interpret.

Curves E, F, and G represent lungs without $\dot{V}A/\dot{Q}$ inequality, but with shunting of 10, 20, and 30%, respectively. The behaviour

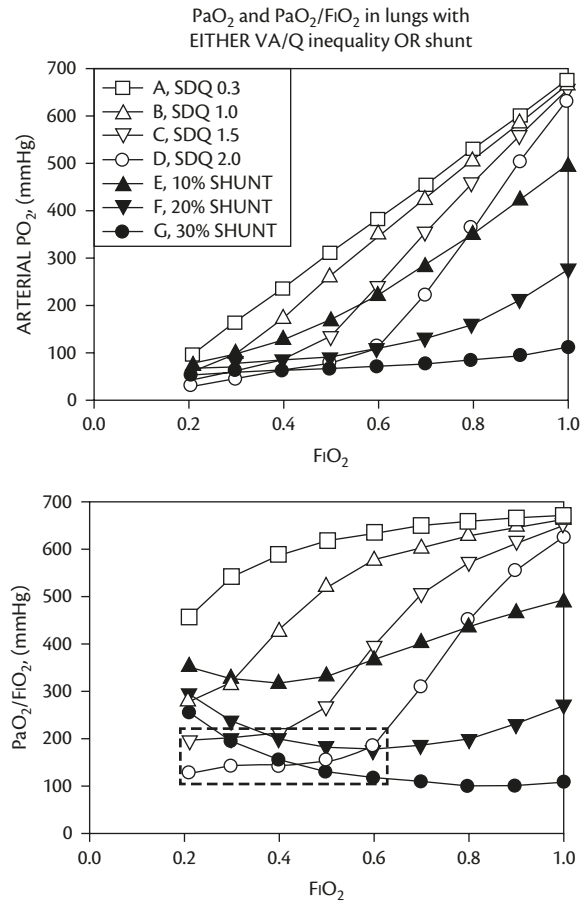

Fig. 76.1 PaO_2 and PaO_2/FIO_2 ratio change with inspired O_2 concentration between room air and 100% O_2 in normal lungs (A), in lungs with moderate to severe $\dot{V}A/\dot{Q}$ inequality (B–D) and in lungs with varying amounts of shunt (E–G) (see text for description).

of PaO_2/FIO_2 as FIO_2 is different again—the ratio first falls as FIO_2 increases, before modestly rising as FIO_2 approaches 1. Especially important is the region encompassed by the dashed-line box: over a wide FIO_2 range (room air to 0.6), PaO_2/FIO_2 is largely independent of FIO_2, but lungs with moderate to severe $\dot{V}A/\dot{Q}$ inequality and lungs with 20–30% shunt are, in practice, unable to be distinguished.

When $FIO_2 = 1$, no matter the severity of $\dot{V}A/\dot{Q}$ inequality, PaO_2/FIO_2 is very high while with shunt, the ratio falls progressively as shunt increases. Fig. 76.1 also suggests that it may be useful to assess PaO_2/FIO_2 at two different values of FIO_2. Its behaviour as FIO_2 changes allows more insight into the gas exchange defect.

The alveolar-arterial PO_2 difference: A-aPO_2

The alveolar gas equation allows calculation of alveolar PO_2, and subtracting arterial PO_2 from this yields the A-aPO_2. The advantage of A-aPO_2 is that it corrects the alveolar PO_2 for values of $PaCO_2$ different than 40 mmHg. Thus, if a patient with normal lungs, breathing room air, hypoventilates and $PaCO_2$ rises to 80 mmHg, alveolar PO_2 is 50 mmHg ($PaO_2 = 150 - 80/0.8 = 50$). If arterial PO_2 were 48 mmHg, A-a$PO_2 = 50 - 48 = 2$ (normal). This shows that the hypoxaemia is fully explained by hypoventilation, which is not evident from looking at PaO_2 alone. Had arterial PO_2 been 40 mmHg, A-aPO_2 would have been 10 mmHg, and this would have suggested the presence of significant additional gas exchange defect from shunt or $\dot{V}A/\dot{Q}$ inequality (or both).

While very useful in patients breathing room air, A-aPO_2 becomes less useful as FIO_2 is increased if $\dot{V}A/\dot{Q}$ inequality is the main problem. This is because at high FIO_2, A-aPO_2 falls, approaching zero on 100% O_2, no matter how severe the $\dot{V}A/\dot{Q}$ mismatch is. However, if A-aPO_2 on 100% O_2 is elevated, the reason has to be a shunt, and A-aPO_2 is very useful.

In between room air and 100% O_2, A-aPO_2 will change with FIO_2 in a manner specific to the nature and extent of the gas exchange disturbance, as shown in Fig. 76.2, which uses the same data as Fig. 76.1. With $\dot{V}A/\dot{Q}$ inequality (open symbols), A-aPO_2 first rises as FIO_2 is increased, and then falls, to nearly zero when 100% O_2 is breathed. The maximal A-aPO_2 and the FIO_2 at which it occurs depends on the severity of the inequality as shown. This behaviour is explained by the shape of the O_2-Hb dissociation curve.

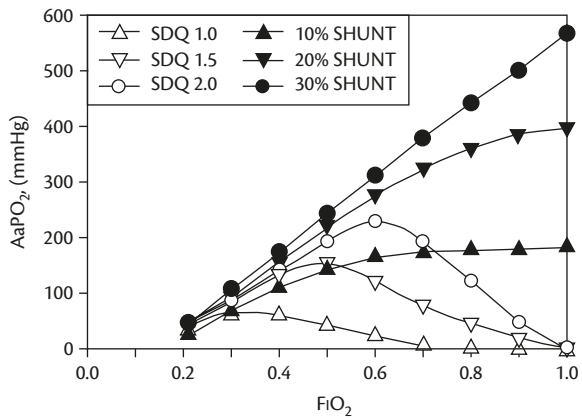

Fig. 76.2 Alveolar-arterial PO_2 difference in the same six lung models of $\dot{V}_A/\dot{Q}$ inequality and shunt as shown in Fig. 76.1.

However, when the problem is shunt, A-aPO_2 rises steadily with FIO_2 as shown.

There is an important cautionary note—Figs 76.1 and 76.2 reflect constancy of the main determining variables as FIO_2 is altered. Thus, the extent of $\dot{V}A/\dot{Q}$ heterogeneity and/or shunt, together with tidal volume and respiratory frequency, cardiac output, metabolic rate, [Hb], acid–base state, and temperature are all presumed to remain fixed. If any of these change over time, or from changing FIO_2, the data shown in these figures must change. Absorption atelectasis, release of hypoxic pulmonary vasoconstriction, and changes in cardiac output may all occur as FIO_2 is raised. Any of these may change shunt and $\dot{V}A/\dot{Q}$ inequality.

Physiological shunt: $\dot{Q}s/\dot{Q}T$

Since the 1950s [4–6], a further, simple, analysis of blood gas data has proven useful. The calculation of physiological shunt, or '$\dot{Q}s/\dot{Q}T$'. $\dot{Q}$ denotes blood flow, s denotes shunt and T denotes total. It reflects the shunt equation, based on mass conservation, applied to a lung imagined as two compartments, one having zero ventilation. The second compartment performs all gas exchange. The shunt equation is:

$$\dot{Q}T \times CaO_2 = \dot{Q}S \times CvO_2 + (\dot{Q}T - \dot{Q}S) \times Cc'O_2 \qquad \text{[eqn 2]}$$

$\dot{Q}T$ is total pulmonary blood flow and $\dot{Q}S$ is blood flow through the shunt compartment, which transmits blood unchanged (with mixed venous O_2 concentration) to the pulmonary veins. CaO_2 is systemic arterial O_2 concentration, CvO_2 is O_2 concentration in mixed venous (pulmonary arterial) blood, and $Cc'O_2$ is end-capillary O_2 concentration of the second, ventilated compartment. $Cc'O_2$ is computed from the O_2-Hb dissociation curve based on the alveolar PO_2 from the alveolar gas equation. The equation states that arterial O_2 concentration is the perfusion-weighted average of O_2 concentrations in the two compartments. After rearrangement:

$$\dot{Q}s/\dot{Q}T = [Cc'O_2 - CaO_2]/[Cc'O_2 - CvO_2] \qquad \text{[eqn 3]}$$

The equation can be used at any FIO_2. However at $FIO_2 < 1.0$, $\dot{Q}s/\dot{Q}T$ is termed 'venous admixture' or 'physiological shunt', while when $FIO_2 = 1.0$, it is regarded as 'true shunt'. This is because at $FIO_2 < 1.0$, $\dot{V}A/\dot{Q}$ inequality will contribute to $\dot{Q}s/\dot{Q}T$, while at $FIO_2 = 1.0$, $\dot{V}A/\dot{Q}$ inequality ceases to contribute and $\dot{Q}s/\dot{Q}T$ does, in fact, represent only shunt (see Figs 76.1 and 76.2).

Fig. 76.3 shows $\dot{Q}s/\dot{Q}T$ for the same data as in Figs 76.1 and 76.2. When the lung really does consist of two functional compartments—normal and shunt, as may happen in localized consolidation or atelectasis—the $\dot{Q}S/\dot{Q}T$ model accurately depicts the extent of shunt across the whole FIO_2 range. However, when there is $\dot{V}A/\dot{Q}$ inequality, rather than shunt, $\dot{Q}s/\dot{Q}T$ can be very high at low FIO_2, but eventually falls to zero on 100% O_2. Thus, the shunt equation will underestimate the true extent of $\dot{V}A/\dot{Q}$ inequality at FIO_2 above room air and may over-estimate true shunt at $FIO_2 < 1.0$.

To use the equation, CaO_2 is calculated from arterial PO_2, saturation, and [Hb], and $Cc'O_2$ is correspondingly computed from alveolar PO_2. The weakness is in CvO_2. To measure this directly requires a pulmonary artery catheter, which is often unavailable.

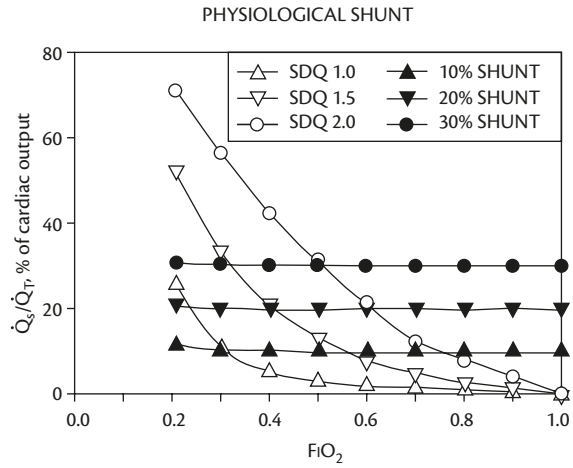

Fig. 76.3 Physiological shunt ($\dot{Q}s/\dot{Q}T$) in the same six disease models as shown in Figs 76.1 and 76.2.

Alternatively, CvO_2 can be calculated from metabolic rate ($\dot{V}o_2$) and cardiac output ($\dot{Q}T$) using the Fick principle:

$$\dot{V}O_2 = \dot{Q}T \times [CaO_2 - CvO_2] \quad \text{[eqn 4]}$$

Rearranging,

$$CvO_2 = CaO_2 - \dot{V}O_2 / \dot{Q}T, \quad \text{[eqn 5]}$$

which can be combined with eqn 3 to yield:

$$\dot{Q}s / \dot{Q}T = [Cc'O_2 - CaO_2] / [Cc'O_2 - CaO_2 + \dot{V}O_2 / \dot{Q}T] \quad \text{[eqn 6]}$$

However, if $\dot{Q}T$ and / or $\dot{V}o_2$ are not known, and must be assumed, application of the shunt equation can be considerably in error as Fig. 76.4 shows. The top panel shows how arterial PO_2 would actually vary as cardiac output (and thus CvO_2) varies for a lung with a fixed shunt that was 20% of the cardiac output, the patient always breathing 100% O_2. The fall in PaO_2 when cardiac output is low is due to the associated fall in mixed venous PO_2 required to meet the unchanged metabolic needs of the tissues, and vice versa when cardiac output is elevated. The lower panel shows the shunt calculated from the arterial PO_2 values in the upper panel if the venous O_2 concentration was assumed constant at the value actually seen when cardiac output was 6 L/min. Only at that cardiac output will the correct shunt value (20%) be obtained (dashed lines). As cardiac output drops, the calculated shunt is erroneously high; when cardiac output is elevated, the shunt is underestimated. The errors may be considerable.

Mixed venous O_2 saturation/PO_2

The preceding illustrates the risk of assuming mixed venous oxygenation when computing the shunt and a rationale for knowing the correct value. Another reason for estimating mixed venous PO_2 and/or saturation is to better understand the relationship between O_2 supply and demand. Using oximeter-tipped catheters placed in the pulmonary artery, mixed venous saturation is continuously available, and arterial saturation is also usually available. Thus, with [Hb], the arteriovenous O_2 concentration difference, CaO_2—CvO_2, becomes available. From the Fick principle in eqn 5, the arteriovenous difference is numerically equal to the ratio $\dot{V}o_2 / \dot{Q}T$, which is the ratio of whole-body O_2 demand ($\dot{V}o_2$) to supply ($\dot{Q}T$). A high arteriovenous difference implies high O_2 demand in relation to supply, and vice versa, which may be clinically useful information. This concept is, however, complicated by a major uncertainty. Suppose $\dot{V}o_2 / \dot{Q}T$ is high. Does that mean that demand is elevated or that supply is reduced? Measuring only the ratio cannot tell. We need the absolute value of either $\dot{V}o_2$ or $\dot{Q}T$ to resolve this. This is important because inappropriate therapy might otherwise be applied.

Physiological dead space, VD/VT

Just as for shunt, a two-compartment approach can estimate how much 'dead space' would have to exist to explain the mixed expired PCO_2 value. The concept is again to imagine the lungs as one normal compartment performing all gas exchange, and a second that is ventilated, but completely unperfused, and not participating in gas exchange (hence, the name 'dead space' for the ventilation associated with it). Again, we use mass conservation, applied to CO_2, as follows:

$$\dot{V}E \times PECO_2 = \dot{V}A \times PACO_2 + VD \times PICO_2 \quad \text{[eqn 7]}$$

Where $\dot{V}E$ is total minute ventilation (tidal volume ($\dot{V}T$) times breathing frequency), $\dot{V}A$ is ventilation of the normal compartment and VD is ventilation of the unperfused compartment. Note that $\dot{V}E = \dot{V}A + VD$. $PECO_2$ is the PCO_2 in the mixed exhaled gas. $PaCO_2$ is the alveolar PCO_2 of the normal compartment, and $PICO_2$ is the inspired PCO_2, since that must be the alveolar PCO_2 of the unperfused compartment. Replacing $\dot{V}A$ by $\dot{V}A - VD$, and rearranging eqn 7 yields:

$$VD / VT = [PACO_2 - PECO_2] / PACO_2 \quad \text{[eqn 8]}$$

If, as is commonly done, we substitute $PaCO_2$ (arterial PCO_2) for $PACO_2$, because the latter is actually very difficult to measure, we end up with:

$$VD / VT = [PACO_2 - PECO_2] / PACO_2 \quad \text{[eqn 9]}$$

VD/VT is the fraction of the total ventilation passing to the unperfused compartment (without gas exchange), and thus 'wasted'. It is a composite of three kinds of dead space: one is normal, and is the contribution from the conducting airway volume (from mouth to the last terminal bronchiole), called the anatomic dead space. The second is the tubing volume, if any, between a ventilated patient and the valve of the ventilator or fork in the ventilator tubing that separates inspired from expired gas. This includes the endotracheal or tracheostomy tube volume. The third is the 'alveolar dead space', which is a virtual volume of gas ventilating hypothetical alveoli that are completely unperfused. It is normally zero. Application of eqn 9 captures all three kinds inseparably as a single value, and what then has to be done is to subtract the first two kinds of dead space to arrive at the alveolar dead space, which is usually the number of interest. Tubing volume is calculated from its length and diameter. Anatomic dead space, rarely measured, is often taken as 1ml per pound (2 mL/kg), of lean body weight. It will be a little less if the pharynx is bypassed by an endotracheal or tracheostomy tube.

It is important to distinguish absolute dead space from percentage dead space. The latter is most frequently reported and, while useful, is affected directly by the tidal volume. A dead space of 200 mL with

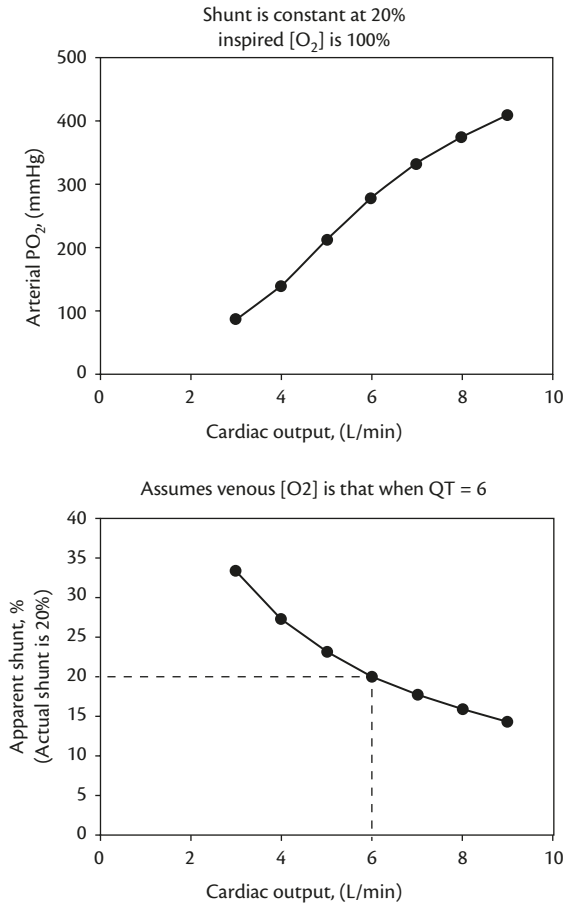

Fig. 76.4 (Upper panel) Arterial PO_2 (PaO_2) change with a fixed shunt (using an example of 20%) as cardiac output varies between 3 and 9 L/min, all other factors constant. As cardiac output falls, so too does mixed venous [O_2], which in turn explains why PaO_2 is lower. PaO_2 may be as low as 100 mmHg or as high as 400 mmHg, depending on cardiac output. (Lower panel) Figure shows how assuming a standard arteriovenous [O_2] difference (equal to that when cardiac output is 6 L/min using the same example) can cause large errors in shunt computed from the shunt equation. Only when cardiac output is 6 L/min will the equation return the correct value. There is two-fold range in apparent shunt.

500 mL tidal volume, yields 40% V_D/V_T, while the same dead space in a 1-L tidal volume reduces V_D/V_T to 20%. Therefore, reporting of alveolar dead space should also use absolute volume. In a normal lung, alveolar dead space (i.e. total, less anatomic, ventilator tubing volume) is essentially zero, but in lung disease with $\dot{V}_A / \dot{Q}$ inequality it can be substantial. In the cases presented in Figs 76.1–76.3, alveolar dead space is 17% when SDQ = 1.0, 35% when SDQ = 1.5, and 52% when SDQ = 2.0.

The popular perception is that only areas of above-normal $\dot{V}_A / \dot{Q}$ ratio contribute to alveolar dead space. However, areas of low $\dot{V}_A / \dot{Q}$ ratio and even shunt contribute to V_D/V_T when arterial PCO_2 is used as in eqn 9 because such areas not only depress arterial PO_2, they elevate arterial PCO_2.

Conclusion

In conclusion, several longstanding approaches to gas exchange allow quantification of gas exchange disturbances in the ICU. Perhaps the key point is that, for all, assumptions are made that may critically affect their interpretation and lead to erroneous therapeutic decisions. This discussion is intended to illustrate those important assumptions and thereby mitigate their consequences.

CHAPTER 77

Respiratory muscle function in the critically ill

Theodoros Vassilakopoulos and Charis Roussos

Key points

- The main inspiratory muscle is the diaphragm.
- Hyperinflation places the diaphragm at a great mechanical disadvantage, decreasing its force generating capacity.
- The ability to take one breath depends on the balance between the load faced by the inspiratory muscles and their neuromuscular competence, whereas the ability to breathe over time (endurance) depends on the balance between energy supplies to the inspiratory muscles and their energy demands.
- In response to acute increases in load, the inspiratory muscles develop fatigue, inflammation, and injury. In response to unloading by the use of mechanical ventilation they develop atrophy and dysfunction.
- Respiratory muscle function can be tested using the maximum static inspiratory and expiratory mouth pressures, and sniff pressure. Diaphragm function can be tested by measuring the transdiaphragmatic pressures, and the twitch pressures developed upon electrical or magnetic stimulation of the phrenic nerve.

Functional anatomy

The intercostal muscles

The intercostal muscles are two thin layers of muscle fibres occupying each of the intercostal spaces, the external being superficial to the internal [1]. The muscle fibres of the two layers run approximately at right angles to each other: The **external intercostals** extend from the tubercles of the ribs dorsally to the costochondral junctions ventrally, and their fibres are orientated obliquely, downward and forward, from the rib above to the rib below [1]. The **internal intercostals** begin posteriorly, as the posterior intercostal membrane on the inner aspect of the external intercostal muscles. From approximately the angle of the rib, the internal intercostal muscles run obliquely, upward and forward from the superior border of the rib and costal cartilage below to the floor of the subcostal groove of the rib and the edge of the costal cartilage above, ending at the sternocostal junctions [1]. All the intercostal muscles are innervated by the intercostal nerve [1].

The external intercostal muscles have an inspiratory action on the rib cage, whereas the internal intercostal muscles are expiratory, with the exemption of the parasternal intercostals, which are inspiratory [1].

The diaphragm

The floor of the thoracic cavity is closed by a thin musculotendinous sheet, the diaphragm, the most important inspiratory muscle, accounting for approximately 70% of minute ventilation in normal subjects [1]. The diaphragmatic fibres radiate from the central tendon to insert peripherally into skeletal structures. The diaphragm has two main components based on its point of origin—the crural (vertebral) part and the costal (sternocostal) part. The crural part arises from the crura (strong, tapering tendons attached vertically to the anterolateral aspects of the bodies, and intervertebral disks of the first three lumbar vertebrae on the right and two on the left) and the three aponeurotic arcuate ligaments. The costal part of the diaphragm arises from the xiphoid process, and the lower end of the sternum and the costal cartilages of the lower six ribs. These costal fibres run cranially so that they are directly apposed to the inner aspect of lower rib cage, creating a **zone of apposition** [1].

The shape of the relaxed diaphragm at the end of a normal expiration is that of two domes joined by a saddle that runs from the sternum to the anterior surface of the spinal column. The motor and proprioceptive innervation of the diaphragm is from the phrenic nerves. When tension develops within the diaphragmatic muscle fibres, a caudally-orientated force is applied on the central tendon and the dome of the diaphragm descends; this descent has two effects. First, it expands the thoracic cavity along its craniocaudal axis and, consequently, the pleural pressure falls. Secondly, it produces a caudal displacement of the abdominal visceral contents and an increase in the abdominal pressure that in turn results in an outward motion of the ventral abdominal wall. Moreover, when the diaphragm contracts, a cranially-orientated force is applied by the costal diaphragmatic fibres to the upper margins of the lower six ribs that has the effect of lifting and rotating them outward (insertional force) [1]. The actions mediated by the changes in pleural and abdominal pressures are more complex. If the diaphragm was the only muscle acting on the rib cage, it would have two opposing effects when it contracts [1]. On the upper rib cage, it causes a decrease in the anteroposterior diameter, and this expiratory action is primarily because of the fall in pleural pressure. On the lower rib cage, it causes an expansion. This inspiratory action on the lower rib cage is caused by the concomitant action of two different forces, the 'insertional' force already described and the 'appositional' force, whereby the increase in abdominal pressure expands the lower rib cage at the zone of apposition.

The abdominal muscles

The abdominal expiratory muscles constitute the ventrolateral wall of the abdomen (i.e. the rectus abdominis ventrally, and the external oblique, internal oblique, and transverses abdominis laterally). They are innervated by the lower six thoracic nerves and the first lumbar nerve [1]. As they contract, they pull the abdominal wall inward, thus increasing the intra-abdominal pressure. This causes the relaxed diaphragm to move cranially into the thoracic cavity, increasing the pleural pressure and decreasing lung volume. Expiration is usually passive, but can become active when minute ventilation has to be increased (e.g. during exercise) or during respiratory distress. Expiratory muscle action is also essential during cough.

Physiology: the ability to breathe—the load/capacity balance

For a human to take a spontaneous breath, the inspiratory muscles must generate sufficient force to overcome the elastance of the lungs and chest wall (lung and chest wall elastic loads), as well as the airway and tissue resistance (resistive load). This requires an adequate output of the centres controlling the muscles, anatomic and functional nerve integrity, unimpaired neuromuscular transmission, an intact chest wall, and adequate muscle strength [2,3]. This can be schematically represented by considering the ability to take a breath as a balance between inspiratory load and neuromuscular competence (Fig. 77.1a). Under normal conditions, this system is polarized in favour of neuromuscular competence (i.e. there are reserves that permit considerable increases in load). However, for a human to breathe spontaneously, the inspiratory muscles should be able to sustain the aforementioned load over time, as well as adjust the minute ventilation in such a way that there is adequate gas exchange. The ability of the respiratory muscles to sustain this load without the appearance of fatigue is called endurance, and is determined by the balance between energy supplies and energy demands (Fig. 77.1b).

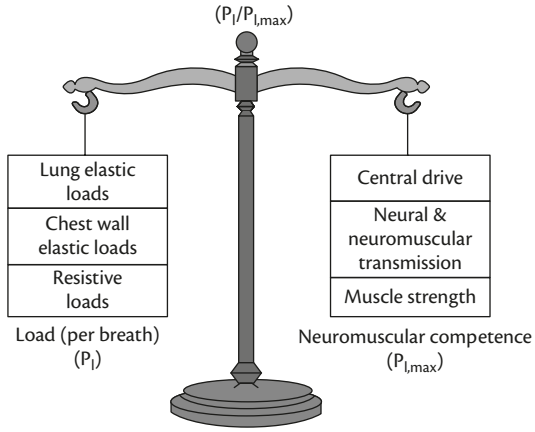

Fig. 77.1a Balance between inspiratory load and neuromuscular competence. The ability to take a spontaneous breath is determined by the balance between the load imposed on the respiratory system (pressure developed by the inspiratory muscles; P_I) and the neuromuscular competence of the ventilatory pump (maximum inspiratory pressure; $P_{I,max}$). Normally, this balance weighs in favour of competence, permitting significant increases in load. However, if the competence is, for whatever reason, reduced below a critical point (e.g. drug overdose, myasthenia gravis), the balance may then weigh in favour of load, rendering the ventilatory pump insufficient to inflate the lungs and chest wall.

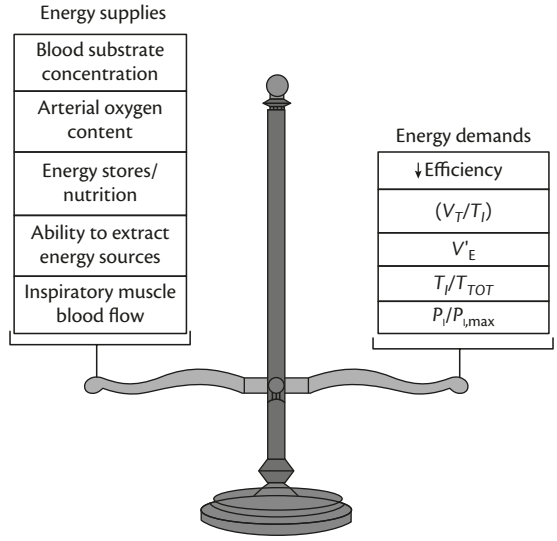

Fig. 77.1b Balance between energy supplies and energy demands. Respiratory muscle endurance is determined by the balance between energy supplies and demands. Normally, the supplies meet the demands, and a large reserve exists. Whenever this balance weighs in favour of demands, the respiratory muscles ultimately become fatigued, leading to inability to sustain spontaneous breathing. V_T/T_I, Mean inspiratory flow (tidal volume/inspiratory time); T_I/T_{TOT}, duty cycle (fraction of inspiration to total breathing cycle duration); $P_I/P_{I,max}$, inspiratory pressure/maximum inspiratory pressure ratio; V'_E, minute ventilation.
Reproduced with permission of the European Respiratory Society ©. *Eur Respir J* November 1, 1996 **9**, 2383–400; doi: 10.1183/09031936.96.09112383.

Energy supplies depend on the inspiratory muscle blood flow, the blood substrate (fuel) concentration, and arterial oxygen content, the muscle's ability to extract and use energy sources, and the muscle's energy stores [2,3]. Under normal circumstances, energy supplies are adequate to meet the demand, and a large recruitable reserve exists (see Fig. 77.1b). Energy demands increase proportionally with the mean pressure developed by the inspiratory muscles per breath (P_I) expressed as a fraction of maximum pressure that the respiratory muscles can voluntarily develop ($P_I/P_{I,max}$), the minute ventilation (V_E), the inspiratory duty cycle (T_I/T_{TOT}), and the mean inspiratory flow rate (V_T/T_I) and are inversely related to the efficiency of the muscles [2,3]. Fatigue develops when the mean rate of energy demands exceeds the mean rate of energy supply (i.e. when the balance is polarized in favour of demands) [2,3].

The product of T_I/T_{TOT} and the mean transdiaphragmatic pressure expressed as a fraction of maximal ($P_{di}/P_{di,max}$) defines a useful 'tension-time index' (TTI_{di}) that is related to the endurance time (i.e. the time that the diaphragm can sustain the load imposed on it). Whenever TTI_{di} is smaller than the critical value of 0.15, the load can be sustained indefinitely; but when TTI_{di} exceeds the critical zone of 0.15–0.18, the load can be sustained only for a limited time period—in other words, the endurance time. This was found to be inversely related to TTI_{di} [2,3]. The TTI concept is assumed to be applicable not only to the diaphragm, but also to the respiratory muscles as a whole:

$$TTI = P_I / P_{I,max} \times T_I / T_{TOT} \qquad \text{[eqn 1]}$$

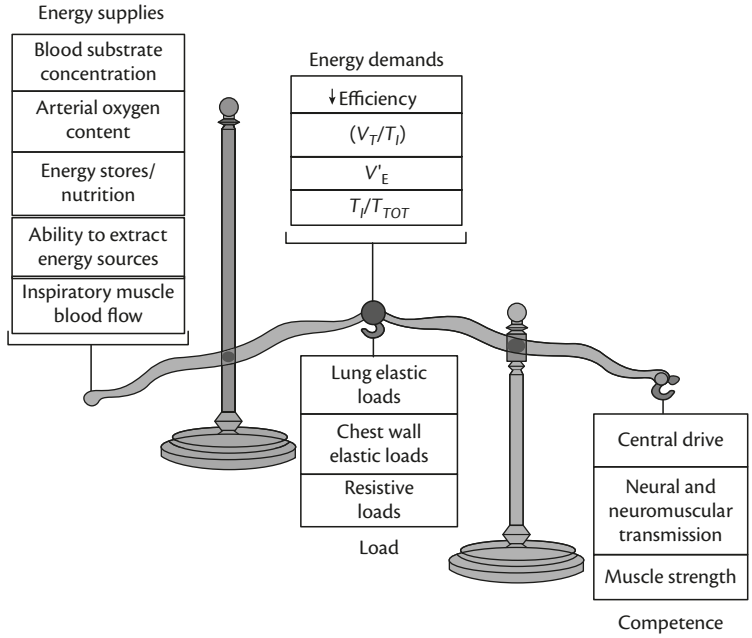

Fig. 77.1c System of two balances—load and competence, energy supplies and demands. The system of two balances, incorporating the various determinants of load, competence, energy supplies, and demands is represented schematically. The $P_I/P_{I,max}$, one of the determinants of energy demands (see Fig. 77.1a) is replaced by its equivalent—the balance between load and neuromuscular competence (see Fig. 77.1b). In fact, this is the reason the two balances are linked. When the central hinge of the system moves upward or is at least at the horizontal level, a balance exists between ventilatory needs and neurorespiratory capacity, and spontaneous ventilation can be sustained. In healthy persons, the hinge moves far upward, creating a large reserve.

Reproduced with permission of the European Respiratory Society ©. *Eur Respir J* November 1, 1996 **9**, 2383–400; doi: 10.1183/09031936.96.09112383.

Because endurance is determined by the balance between energy supply and demand, TTI of the inspiratory muscles has to be in accordance with the energy balance view [2,3]. In fact, as Fig. 77.1b demonstrates, $P_I/P_{I,max}$ and T_I/T_{TOT}, which constitute the TTI, are among the determinants of energy demands. An increase in either that will increase the TTI value, will also increase the demands, but what determines the ratio $P_I/P_{I,max}$? The numerator, the mean inspiratory pressure developed per breath, is determined by the elastic and resistive loads imposed on the inspiratory muscles. The denominator, the maximum inspiratory pressure, is determined by the neuromuscular competence (i.e. the maximum inspiratory muscle activation that can be voluntarily achieved). It follows, then, that the value of $P_I/P_{I,max}$ is determined by the balance between load and competence (see Fig. 77.1a). However, $P_I/P_{I,max}$ is also one of the determinants of energy demands (see Fig. 77.1b; therefore, the two balances (i.e. between load and competence, and energy supply and demand) are in essence linked, creating a system (Fig. 77.1c). Schematically, when the central hinge of the system moves upward, or is at least at the horizontal level, spontaneous ventilation can be sustained indefinitely. The ability of a subject to breathe spontaneously depends on the fine interplay of many different factors. Normally, this interplay moves the central hinge far upward and creates a great ventilatory reserve for the healthy individual. When the central hinge of the system, for whatever reason, moves downward, spontaneous ventilation cannot be sustained, and ventilatory failure ensues [2,3].

Hyperinflation

Hyperinflation (frequently observed in obstructive airway diseases) compromises the force-generating capacity of the diaphragm for a variety of reasons [2]: First, the respiratory muscles, like other skeletal muscles, obey the length–tension relationship. At any given level of activation, changes in muscle fibre length alter tension development. This is because the force-tension developed by a muscle depends on the interaction between actin and myosin fibrils (i.e. the number of myosin heads attaching and thus pulling the actin fibrils closer within each sarcomere). The optimal fibre length (Lo) where tension is maximal, is the length at which all myosin heads attach and pull the actin fibrils. Below this length (as with hyperinflation, which shortens the diaphragm), actin-myosin interaction becomes suboptimal, and tension development declines. Second, as lung volume increases, the zone of apposition of the diaphragm decreases in size, and a larger fraction of the rib cage becomes exposed to pleural pressure. Hence, the diaphragm's inspiratory action on the rib cage diminishes. Third, the resultant flattening of the diaphragm increases its radius of curvature (R_{di}) and, according to Laplace's law, $P_{di} = 2T_{di}/R_{di}$, diminishes its pressure-generating capacity (P_{di}) for the same tension development (T_{di}).

Respiratory muscle responses to changes in load

Acute responses to increased load

Respiratory muscle fatigue

Fatigue is defined as the loss of capacity to develop force and/or velocity in response to a load that is reversible by rest [4,5]. Fatigue should be distinguished from weakness, in which reduced force generation is fixed and not reversed by rest. Theoretically, the site of fatigue may be located anywhere in the long chain of events involved

in voluntary muscle contraction leading from the brain to the contractile machinery. A widely-used convention is to classify fatigue as central, peripheral high-frequency, or peripheral low-frequency.

Central fatigue is present when a maximal voluntary contraction generates less force than does maximal electrical stimulation [4,5].

Peripheral fatigue refers to failure at the neuromuscular junction or distal to this structure and is present when muscle force output falls in response to direct electrical stimulation [4,5]. This type of fatigue may occur because of failure of impulse propagation across the neuromuscular junction, the sarcolemma, or the T-tubules (transmission fatigue), impaired excitation–contraction coupling, or failure of the contractile apparatus of the muscle fibres. Peripheral fatigue can be further classified into **high-frequency** and **low-frequency**, on the basis of the shape of the muscle force-frequency curve. High-frequency fatigue results in depression of the forces generated by a muscle in response to high-frequency electrical stimulation (50–100 Hz), whereas low-frequency fatigue results in depression of force generation in response to low-frequency stimuli (1–20 Hz) [4,5]. **High-frequency fatigue** is attributed to transmission fatigue. Normal subjects breathing against high-intensity inspiratory resistive loads develop high-frequency fatigue, which resolves very quickly after cessation of the strenuous diaphragmatic contractions.

When the loss of force is not accompanied by a parallel decline in the electrical activity impaired excitation-contraction coupling is thought to be responsible. This type of fatigue is characterized by a selective loss of force at low frequencies of stimulation (low-frequency fatigue) and is long-lasting, taking several hours to recover [4,5].

Inflammation and injury

Strenuous diaphragmatic contractions (induced by resistive breathing, which accompanies many disease states such as chronic obstructive pulmonary disease (COPD) and asthma) initiate an up-regulation of cytokines within the diaphragm [6]. Prolonged, strenuous resistive breathing results in diaphragmatic ultrastructural injury (such as sarcomere disruption, necrotic fibres, flocculent degeneration, and influx of inflammatory cells) in both animals and humans. The mechanisms involved are not definitely established, but may involve intradiaphragmatic cytokine induction, adhesion molecule up-regulation, calpain activation, and reactive oxygen species formation [6].

Respiratory muscle response to inactivity and unloading

Respiratory muscles also adapt when they become inactive, as happens during denervation or when a mechanical ventilator undertakes their role as force generator to create the driving pressure permitting airflow into the lungs. Inactivity and unloading of the diaphragm caused by mechanical ventilation is harmful, resulting in decreased diaphragmatic force-generating capacity, diaphragmatic atrophy, and diaphragmatic injury, which are described by the term **ventilator-induced diaphragmatic dysfunction (VIDD)** [7]. The mechanisms are not fully explained, but muscle atrophy, oxidative stress, and structural injury contribute to various extents in the development of VIDD [7].

Testing respiratory muscle function

Maximal static mouth pressures

Measurement of the maximum static inspiratory ($P_{I,max}$) or expiratory ($P_{E,max}$) pressure that a subject can generate at the mouth is a simple way to estimate inspiratory and expiratory muscle strength [3,5]. These are measured at the side port of a mouthpiece that is occluded at the distal end. A small leak is incorporated to prevent glottic closure and buccal muscle use during inspiratory or expiratory manoeuvres [5]. The pressure must be maintained for at least 1.5 seconds, so that the maximum pressure sustained for 1 second can be recorded [5]. The pressure measured during these manoeuvres (P_{mo}) reflects the pressure developed by the respiratory muscles (P_{mus}), plus the passive elastic recoil pressure of the respiratory system including the lung and chest wall (P_{rs}). At functional residual capacity, P_{rs} is 0 so that P_{mo} represents P_{mus}. Normal values are available for adults, children, and the elderly. The tests are easy to perform, yet exhibit significant between- and within-subject variability, as well as learning effect. Nevertheless, a $P_{I,max}$ of –80 cmH_2O usually excludes clinically important inspiratory muscle weakness. In critically ill patients who cannot cooperate $P_{I,max}$ can be measured as the airway pressure developed after a prolonged (20 seconds) occlusion of the airway

Transdiaphragmatic pressure

When inspiratory muscle weakness is confirmed, the next diagnostic step is to unravel whether this is due to diaphragmatic weakness. This is accomplished by the measurement of maximum transdiaphragmatic pressure ($P_{di,max}$) [3,5]. $P_{di,max}$ is the difference between gastric pressure (reflecting abdominal pressure) and oesophageal pressure (reflecting intrapleural pressure) on a maximum inspiratory effort after the insertion of appropriate balloon catheters in the oesophagus and the stomach, respectively.

Sniff pressure

A sniff is a short, sharp voluntary inspiratory manoeuvre performed through one or both unoccluded nostrils [5]. It achieves rapid, fully coordinated recruitment of the diaphragm and other inspiratory muscles. The nose acts as a Starling resistor, so that nasal flow is low and largely independent of the driving pressure that is the oesophageal pressure. P_{di} measured during a sniff ($P_{di,sn,max}$) reflects diaphragm strength, and P_{es} reflects the integrated pressure of the inspiratory muscles on the lungs. Pressures measured in the mouth, nasopharynx, or one nostril give a clinically useful approximation to oesophageal pressure during sniffs without the need to insert oesophageal balloons, especially in the absence of significant obstructive airway disease. There is a wide range of normal values, reflecting the wide range of normal muscle strength in different individuals. In clinical practice, $P_{di,sn,max}$ values greater than 100 cmH_2O in males and 80 cmH_2O in females are unlikely to be associated with clinically significant diaphragm weakness. Values of maximal sniff oesophageal or nasal pressure numerically greater than 70 cmH_2O (males) or 60 cmH_2O (females) are also unlikely to be associated with significant inspiratory muscle weakness.

Electrophysiological testing

Electrophysiological testing helps determining whether weakness is due to muscle, nerve, or neuromuscular transmission impairment. This requires the measurement of P_{di} in response to bilateral supramaximal phrenic nerve electrical or magnetic stimulation, with concurrent recording of the elicited electromyogram of the diaphragm with either surface or oesophageal electrodes [3,5].

CHAPTER 78

Imaging the respiratory system in the critically ill

Lawrence R. Goodman

Key points

- Routine radiographs are not cost effective in the ICU setting.
- Most published guidelines agree that radiographs are worthwhile after insertion of tubes or catheters, and in patients receiving mechanical ventilation. Otherwise, they are required only for change in the patient's clinical status.
- Picture archiving and communication systems utilize digital imaging technology. They provide superior quality images, rapid image availability at multiple sites, and fewer repeat examinations, reducing both cost and patient radiation.
- Disadvantages of picture archiving and communication systems include expensive equipment and personnel required to keep them functioning.
- The majority of chest X-ray abnormalities in the ICU are best understood by paying careful attention to the initial appearance of the X-ray in relation to the patient's onset of symptoms and the progression of abnormalities over the next few days.

Introduction

In the 1960s and 1970s when intensive care units (ICUs) were novel, both clinicians and radiologists relied on the routine daily portable radiograph for patient care. As both groups gained sophistication in dealing with these critically-ill patients, and their various tubes and monitoring apparatus, many began to question the need for daily radiographs. Yet daily radiographs persist in many hospitals today despite rising concerns about radiation exposure (especially in patients under 40) and the rising costs of health care. There have been numerous studies looking at differences in outcome between daily and on-demand radiographs. Despite the wide differences in study design, patient mixes, and countries of origin, the results all point in the same direction [1–9]. Changing to on-demand radiographs decreases utilization by approximately 25–35% without measurable difference in outcome parameters (ICU or hospital mortality, length of stay, duration of mechanical ventilation, delay in addressing major unsuspected problems, etc.). Two recent meta-analyses [10,11] have confirmed these findings.

Although routine radiographs may not be rewarding, there are many scenarios where daily images are beneficial. The American College of Radiology has recently revised their guidelines for portable radiographs. Many of the recommendations are based on the articles discussed [1–11] with the ACR citing additional references where appropriate. Specifically, the ACR guidelines discuss four broad categories of clinical scenarios and present justification for their recommendations. Numerical ratings were also applied (less than 3 usually not appropriate, 4–6 may be appropriate, greater than 7 usually appropriate). These recommendations are for portable radiographs only, which produce a relatively low level of radiation (less than 0.1 mSv) [12].

- Admission or transfer to the ICU—recommendation: new patients should have an admission radiograph (rating = 7).
- Stable patients with no change in their clinical status. There is little justification in routine daily radiographs. Recommendation: radiographs should be ordered for change in clinical status only (rating = 3).
- Insertion or tube or catheter
  - Endotracheal tube—between 12–15% tubes are misplaced and malpositioning is seldom detected clinically. Recommendation: chest x-ray should be obtained immediately after intubation (rating = 9).
  - Following intravenous catheter insertion—the overall pneumothorax rate is approximately 10%. In addition, chest x-rays frequently show malpositioned catheters with subclavian vein catheters twice as likely to be malpositioned compared with jugular venous catheters. Recommendation: radiograph after central venous catheter insertion (rating = 9). Follow-up only for suspected complications only.
  - Swan-Ganz catheters—malpositioned catheters are frequent (greater than 20%) while pneumothorax is unusual (2%). Recommendation: radiograph after insertion. Once pneumothorax is excluded and proper position demonstrated, repeat for clinical indications only (rating = 9).
  - Nasogastric tube—significant malposition is uncommon (less than 1%). Recommendation: chest x-ray after initial insertion and before first feeding (rating = 9). Follow-up not required for stable position.
- Chest tube
  - At the time of initial insertion approximately 10% of chest tubes are not in "ideal" position. Many of these "malpositions" are clinically unimportant. Recommendation: chest x-ray on insertion to evaluate position, success of treatment, and complications related to intubation (rating = 9). Routine follow-up not required.

- Chest tube removal—pneumothorax complicates a small percentage of extubations and they are usually clinically apparent. There is seldom need for reinsertion of the tube. Recommendation: repeat chest x-ray for clinical indications only (rating = 5).

Another approach can be found in a survey of 190 intensivists from 34 ICUs (using the Delphi method) on the value of routine radiographs in 29 ICU scenarios (10 new medical devices, 10 existing medical devices and nine clinical situations) [13,14]. The clinicians' recommendations were similar to the radiologists' recommendations. A routine radiograph was considered appropriate after any tube insertion, except a nasogastric (NG) tube for reasons other than nutrition. There was strong, but not universal support for daily X-rays for patients with ARDS or oedema receiving mechanical ventilation, chest tubes, and for patients receiving non-invasive ventilation with a PaO_2/FiO_2 ratio <200 mmHg (Table 78.1).

In four clinical scenarios, there was support for daily radiographs in patients with haemodynamic instability and ventilated, invasive ventilation for status asthmaticus, mechanical ventilation for respiratory failure in the immunocompromised, and non-invasive ventilation for respiratory failure in the immunocompromised (Table 78.2).

In an accompanying editorial, Lessnau [15] correctly pointed out that within each group of catheter insertions and monitoring, there are subgroups where commonly requested radiographs may not be necessary (e.g. following uncomplicated bronchoscopically-guided percutaneous tracheostomy, etc.). He also pointed out that, in some countries such as the USA, there are conflicting financial incentives. If the hospital bills for the radiograph, demand-only X-rays will decrease revenues. If the radiograph is part of a global fee, then there is an incentive to decrease daily films. In 1998, Graham et al. [5] estimated that radiology expenses were 3.5% of overall inpatient costs. At their 1000 bed hospital in 1 year, over 69,000 portable films were obtained at a mean charge of $114.00 per examination; the portable radiograph bill was $8,000,000. In 100 patients after thoracic surgery, they estimated that over 80% of radiographs could have been eliminated, saving $286,000 ($725/patient).

Do on-demand radiographs impact ordering of higher level imaging, such as computed tomography (CT) and ultrasound (US)? Kröner et al. [16] demonstrated in two consecutive five-month periods that the number of X-rays per patient per day dropped from 1.1 to 0.6 with the elimination of routine radiographs. Length of stay and mortality rates were unchanged. During the on-demand period, the number of CTs ordered did not increase, although there

0, negative.

Data from Hejblum G, et al., 'A web-based Delphi study on the indications of chest radiographs for patients in ICUs', *Chest*, 2008, **133**(5), pp. 1107–12.

was a slight increase in the number of USs. In both periods, 38% of CTs or USs resulted in a change of therapy.

Digital imaging, picture archiving, and communication systems

At major hospitals centres, digital receptors of various kinds have replaced the traditional film screen cassette, and picture archiving, and communication systems (PACS) have replaced the traditional view box. Although the initial investment is steep (but decreasing) the advantages appear overwhelming [17,18].

- Digital images are available within minutes for evaluation in radiology and the ICU. Monitors on newer portable equipment provide almost instantaneous bedside viewing for image quality and for STAT diagnosis.
- Manipulation of the digital image contrast, magnification, and varied processing algorithms enhance diagnosis (e.g. pneumothorax, catheter placement, retro cardiac disease, etc.) and diminish the number of repeats, saving money and patient radiation.
- Serial digital portable radiographs and other studies (CT, US) are easier to compare on monitors. This is critical in understanding short- and long-term trends of disease. Images can be viewed in multiple locations simultaneously.
- Digital storage eliminates lost films, and images are easily transportable (disc or electronically) to other facilities.

There are, of course, disadvantages:

- The initial cost is expensive, sophisticated IT support is required, and robust back-up systems are required.
- If not properly monitored, patient radiation can increase using digital receptors.
- Communication between radiology and the ICU often decreases.

Hains et al. [18] reviewed the 1990s literature and argued that digital imaging was a qualified success. Over the last two decades, digital imaging plates and monitors have improved, and PACS functionality, reliability, and storage capacity have improved dramatically as prices drop [17,18].

Typical ICU imaging cases

A complete review of diagnostic imaging in the ICU is beyond the scope of this chapter. Eight imaging problems frequently seen in the ICU follow. Many believe 'all portables look alike'. Although this is true to some extent, there are many clues to arriving at a more specific diagnosis or a limited list of possibilities. Perhaps the most helpful approach is by considering the time of onset of the imaging findings relative to the patient's disease or status, and the speed of progression. For example, lung contusion is usually worse within the first day, but fades within a day or two. Aspiration of acid contents is usually visible within a few hours, gets worse for a day or two, and then subsides. Heart failure can appear rapidly and disappear just as rapidly with treatment, while ARDS usually appears 1–3 days after a major insult, worsens over a few days, then plateaus, often for prolonged periods of time. Atelectasis, which is the most frequent chest X-ray abnormality in the ICU, is almost universal after surgery, whereas similar appearing consolidation from hospital acquired pneumonia usually do not appear until many days after admission [3,19].

Case 1

A patient presents with shortness of breath and dry cough over a few hours. The focal density in the right costophrenic angle (Fig. 78.1a) is non-specific, but does suggest a pulmonary infarction (Hampton's hump). CT verifies infarction due to acute pulmonary embolism (PE) in the anterior basal segment (Fig. 78.1b—arrow). Although a Hampton's Hump or wedge-shaped pleural densities are highly suggestive of a PE, they are only seen in a minority of PE patients.

Case 2

A patient presents with dyspnoea after cervical spine fracture repair. A chest X-ray (Fig. 78.2a) shows patchy extensive bibasilar infiltrates, cardiomegaly, normal vessels and endotracheal tube within 2 cm of the carina. CT shows patchy infiltrates confined to the lower lobes, worse medially than laterally (Fig. 78.2b). This is the typical X-ray appearance of aspiration pneumonitis in a post-operative patient. The posterior basal segments of the lower lobe are most frequently involved. The only likely differential diagnosis would be extensive post-operative atelectasis.

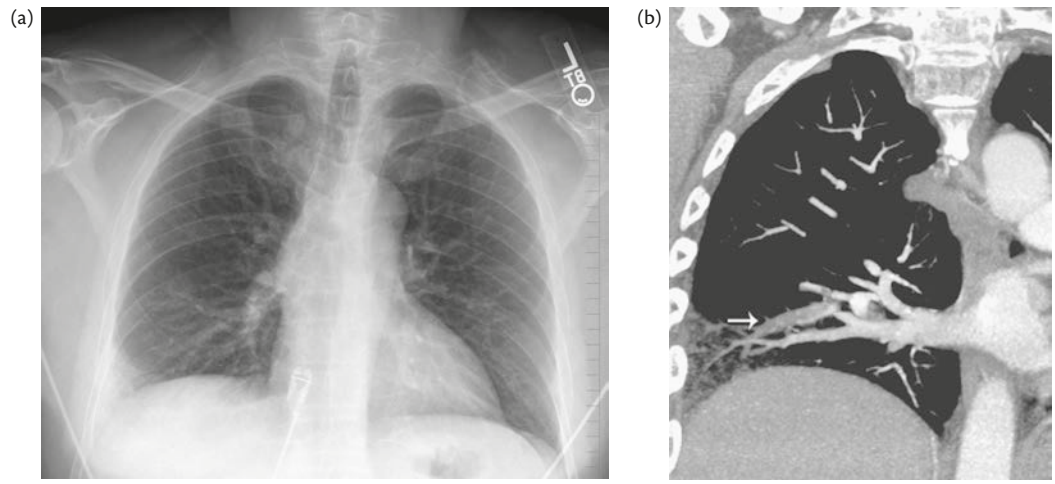

Fig. 78.1 Case 1. (a) X-ray; (b) CT scan.

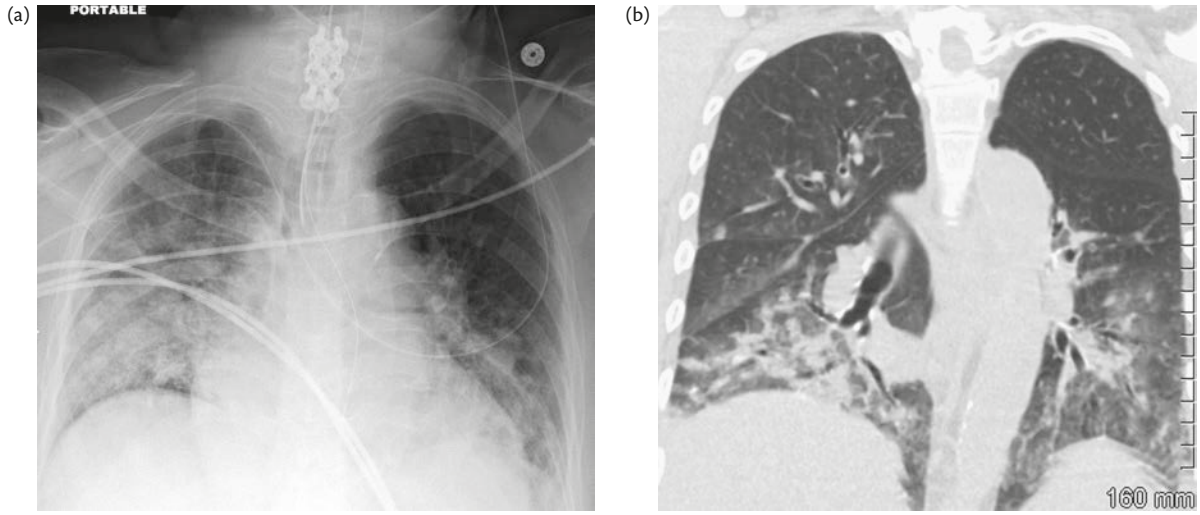

Fig. 78.2 Case 2. (a) X-ray; (b) CT scan.

Case 3

An elderly ICU patient with mild respiratory distress has a chest X-ray to rule out pulmonary embolism (Fig. 78.3a). The X-ray shows borderline enlarged heart, with large indistinct pulmonary arteries, mild peribronchial cuffing, and Kerley lines. CT shows Kerley lines laterally(arrows). The pulmonary artery is bigger than the adjacent bronchus and there is perivascular oedema (Fig. 78.3b circled). The radiographic findings of congestive heart failure (CHF) are well known. One would not order CT to diagnose CHF, but not infrequently, CT done for other reasons (e.g. PE or ARDS) reveals subtle CHF.

Case 4

A middle-aged male has a chest X-ray one day after cervical spine surgery for trauma (Fig. 78.4a). The trachea (ETT) and oesophagus (NG tube) are deviated to the left (arrow) of the spine rods. CT (Fig. 78.4b) shows seroma/haematoma deviating the trachea, the oesophagus, and the jugular vein to the left and the carotid artery to the right (surgically confirmed haematoma).

Case 5

A patient has respiratory distress one day after pancreatic surgery. A chest X-ray (Fig. 78.5a) shows total collapse of the right middle, right lower, and left lower lobes—the superior margin of the density on the right is the minor fissure. Both the right heart border and the right diaphragm are not visible (silhouette sign). Likewise, the left diaphragm is not visible. There are air bronchograms indicating patent airway (arrows). Absent air bronchograms indicate mucus plugging (Fig. 78.5b).

Case 6

A patient has fever of unknown origin several days after abdominal surgery. A chest X-ray shows vague focal densities throughout both lungs (Fig. 78.6a). CT Shows focal areas of consolidation varying from nodules to nodular cavities to focal parenchymal infiltrates (Fig. 78.6b). With septic emboli, the initial chest X-rays are often negative or vaguely positive. CT is virtually diagnostic early on with nodules, cavities and infiltrates in different stages of development.

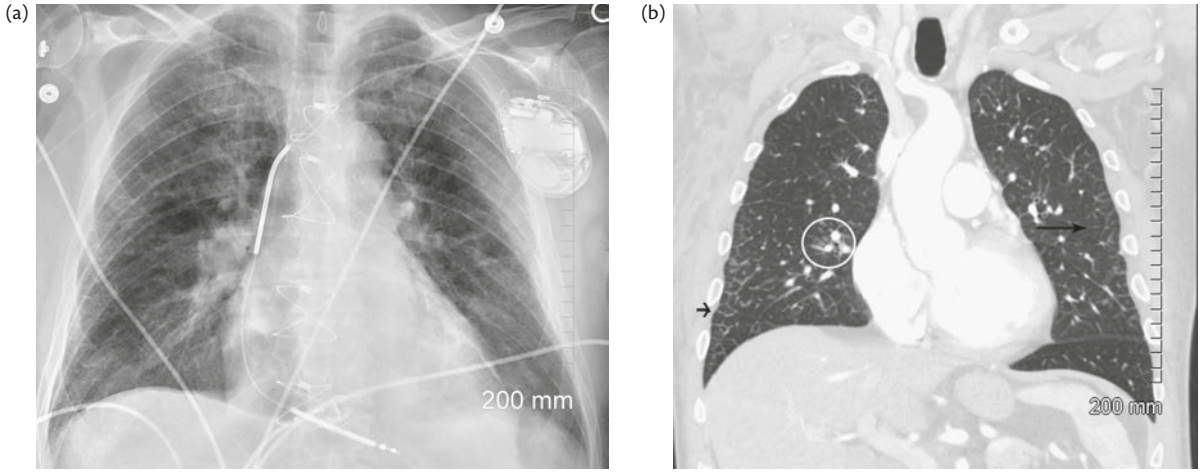

Fig. 78.3 Case 3. (a) X-ray; (b) CT scan.

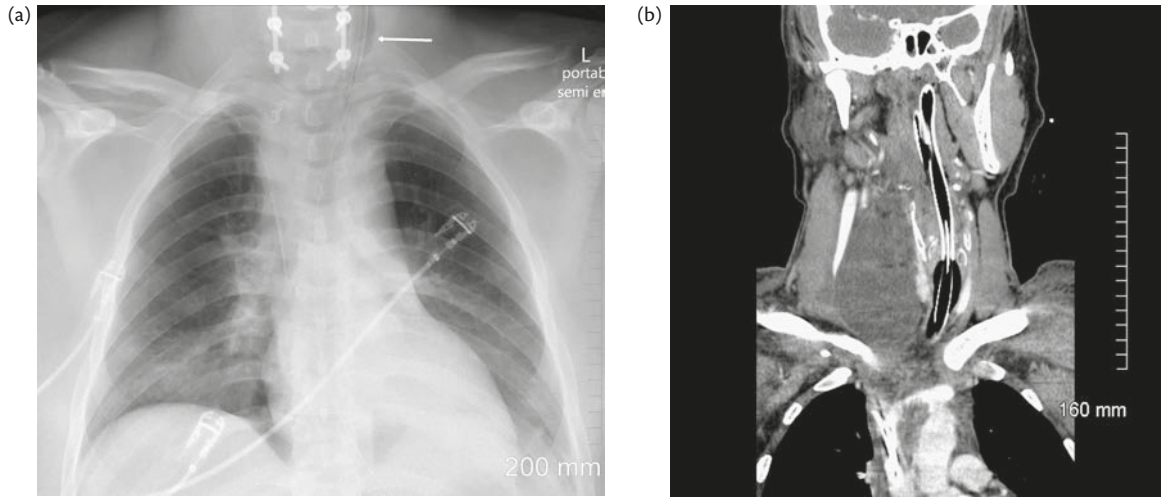

Fig. 78.4 Case 4. (a) X-ray; (b) CT scan.

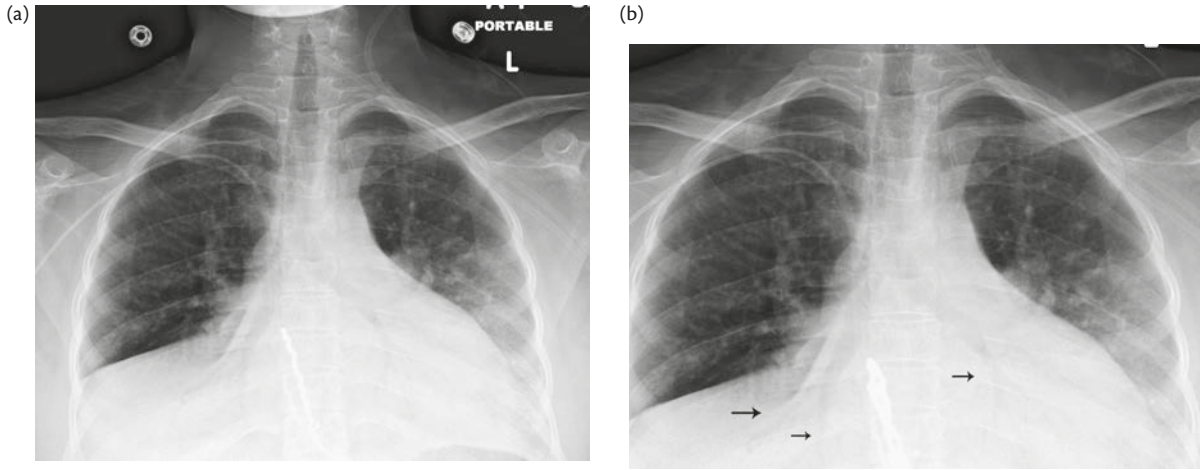

Fig. 78.5 Case 5. (a) X-ray; (b) X-ray (arrows show air bronchograms indicating patent airways).

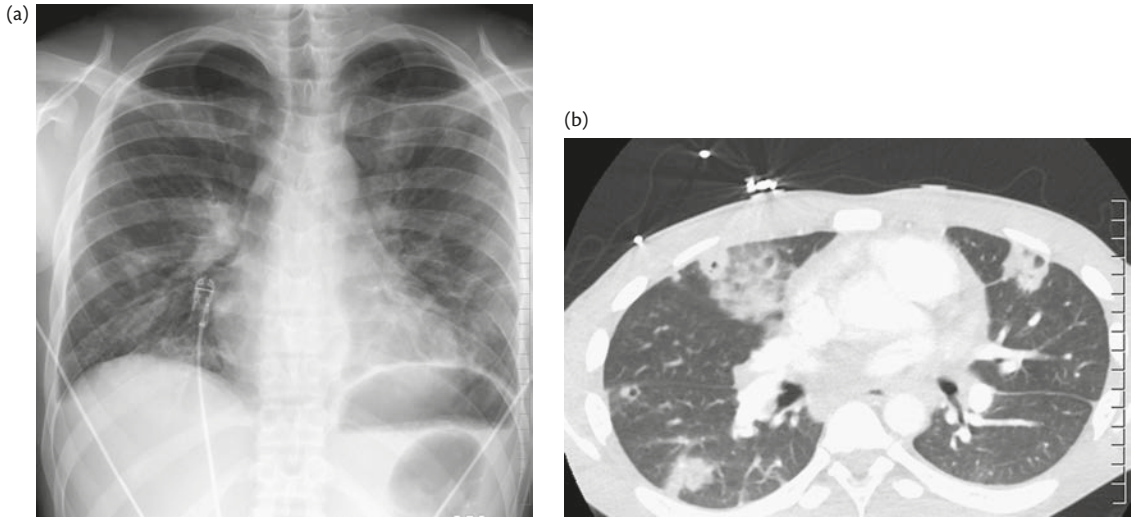

Fig. 78.6 Case 6. (a) X-ray; (b) CT scan.

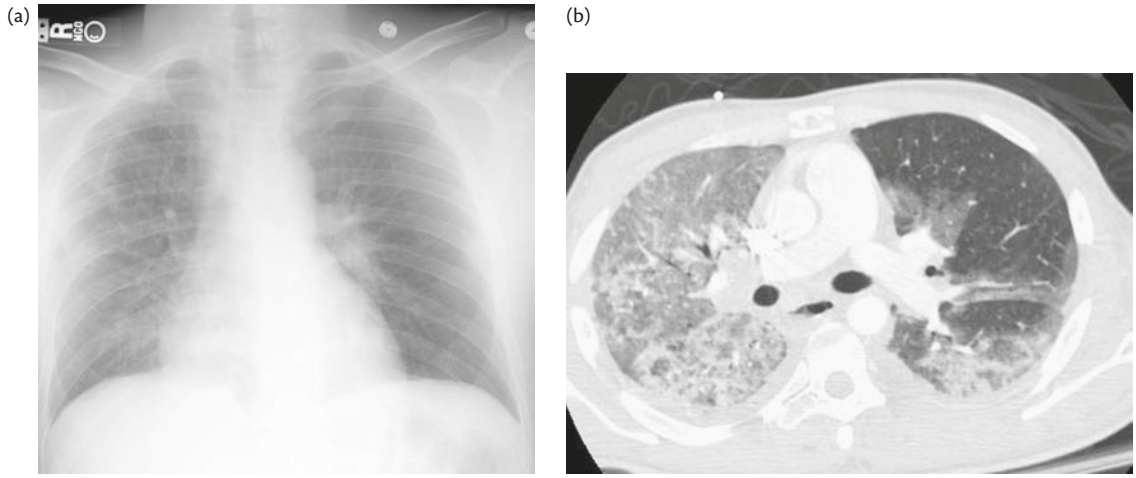

Fig. 78.7 Case 7. (a) X-ray; (b) CT scan.

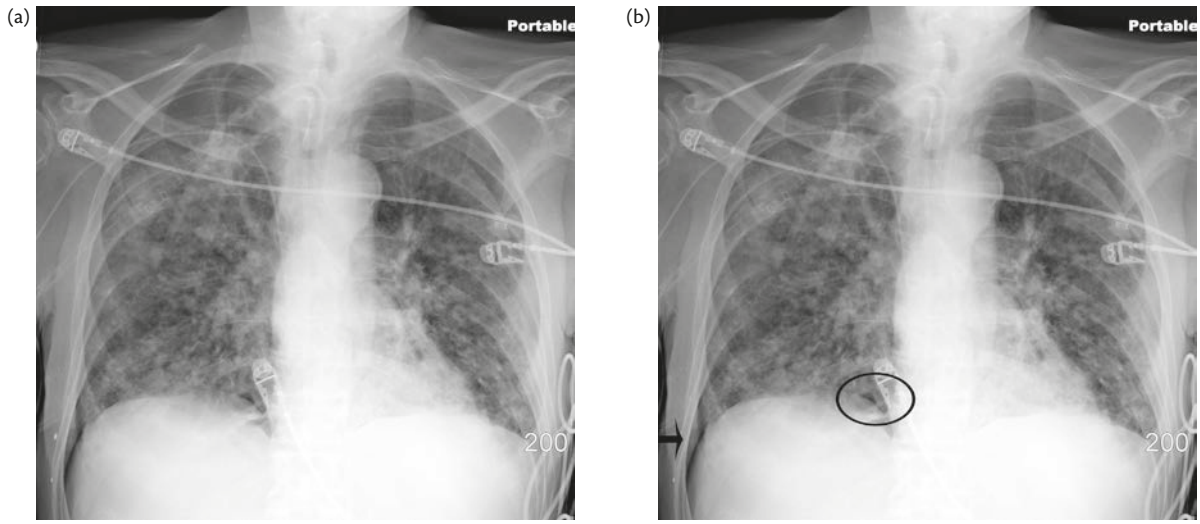

Fig. 78.8 Case 8. (a) X-ray; (b) X-ray (circle shows small amount of air medially along the diaphragm).

Case 7

A patient has shortness of breath several days after caecal perforation. A chest X-ray shows vague interstitial thickening, right greater than left (Fig. 78.7a). The pulmonary vessels and heart are not enlarged. A CT, done for possible PE, shows bilateral asymmetrical ground glass opacification, not gravity dependent (Fig. 78.7b). The pulmonary vessels are not distended and there are no Kerley lines. In this case, the oedema became symmetrical within 24 hours. Otherwise, this is the typical X-ray and CT appearance of ARDS as opposed to CHF.

Case 8

An elderly man in the ICU for 2 weeks with respiratory distress after a perforated appendix has a chest X-ray (Fig. 78.8a). This is a case of established ARDS with diffuse symmetrical patchy infiltrates changing little from day-to-day. The heart and vessels are normal. There is a lucency in the right costophrenic angle (deep sulcus sign). This indicates air in the pleural space collecting anteriorly and laterally (arrow). The deep sulcus sign is not infallible and a confirmatory upright or decubitus film is required for confirmation. A small amount of air is also seen medially along the diaphragm (Fig. 78.8b circle).

PART 4.3

Upper airway obstruction

CHAPTER 79

Upper airway obstruction in the critically ill

Edmond Cohen

Key points

- Partial upper airway obstruction (UAO) may progress to complete obstruction.
- UAO should be managed by personnel trained to manage airway crises using a supraglottic device, by performing tracheal intubation and, if necessary, by establishing a surgical airway.
- Do not burn any bridges! Sedatives, neuromuscular blocking drugs or airway manipulation may precipitate complete airway obstruction.
- Airway management devices must be immediately available **before attempting** any airway manipulation.
- UAO that develops gradually may not be obvious in a patient at rest. Sudden clinical deterioration is unpredictable. Noisy breathing is better than silence and no breathing.

Presentation

In a conscious patient, upper airway obstruction (UAO) may present as respiratory distress, stridor, dyspnoea, altered voice, cyanosis, cough, decreased or absent breath sounds, wheezing, the hand-to-the-throat choking sign in the case of a foreign body, facial swelling, and distended neck veins. Respiratory depression must be avoided to prevent cardiac arrest and anoxic brain injury. Partial airway obstruction may be mild, as in snoring or nasal congestion, or may be more severe, perhaps requiring the use of airway adjuncts. Complete UAO is usually managed by prompt intubation, but in some situations a surgical airway is life-saving [1].

Causes of upper airway obstruction

Although obstruction can occur at any level of the upper respiratory tract, laryngeal obstruction is especially important because the glottis is the narrowest portion of the upper airway (UA) [2]. UAO may be anatomical or functional, and may develop acutely or subacutely (Box 79.1).

The presence of stridor is ominous. Stridor is a noisy inspiration caused by turbulent gas flow in the UA and is common during airway obstruction [3]. Stridor indicates a serious airway emergency because it can progress rapidly to complete UAO. It is important to establish the aetiology of stridor and determine whether the obstruction can be safely treated by positive pressure mask ventilation or requires tracheal intubation.

Upper airway obstruction during anaesthesia

The induction of general anaesthesia is accompanied by a decrease in UA muscle tone and possibly even airway collapse. UAO may occur depending on the airway's calibre and shape, extraluminal tissue pressure and airway wall compliance [4]. Light sedation offers some protection against obstruction by maintaining muscle tone, whereas deep sedation is associated with muscle relaxation and lack of arousability, which may result in UAO. During anaesthesia, airway maintenance requires active intervention either by mask ventilation or tracheal intubation until the patient regains the ability to spontaneously maintain a patent airway.

Common causes of UAO during anaesthesia include:

- **Laryngospasm** following tracheal extubation due to an irritable airway (common among smokers). Initial treatment is positive pressure ventilation, but sometimes a small dose of succinylcholine (~20 mg iv) may be necessary to break the laryngospasm.
- **Residual neuromuscular block** despite the administration of reversal agents. Patients with impaired renal function require special attention because of their decreased ability to clear drugs.
- **Residual opioid medications** can cause respiratory depression and UAO in the post-anaesthesia care unit (PACU).

Obstructive sleep apnoea

Obstructive sleep apnoea (OSA) patients are at increased risk of developing UAO. Factors that act to narrow the airway and predispose to OSA are similar to those that predispose to UAO under anaesthesia [5]. These include increasing age, male gender distribution of body fat, obesity, increased neck circumference (>17 inches), macroglossia, retrognathia, and maxillary constriction [6]. Loud snoring suggests the presence of a narrow floppy airway that causes recurrent episodes of partial or complete UAO, apnoea, and hypoxaemic episodes during sleep [7].

With sleep, sedation or anaesthesia, upper airway collapsibility increases as a result of a reduction in pharyngeal dilator muscle activation, loss of the stimulatory effect of wakefulness, reduction in respiratory drive, and depression of negative pressure reflexes. In normal individuals without anatomic compromise, the upper airway is robust and patency is not significantly compromised. However, in individuals with anatomically vulnerable airways, these changes can precipitate partial or complete upper airway obstruction [8].

Box 79.1 Common causes of UAO in adult patients

Tumour

- Vocal cord tumours.
- Vocal cord paralysis.
- Laryngeal or pharyngeal tumours.
- Tracheal stenosis from intratracheal tumours.
- Tracheal stenosis from compression by extrinsic tumours.

Iatrogenic causes

- Tracheal stenosis following prolonged intubation.
- Tracheal stenosis post-tracheostomy or cricothyrotomy.
- Obstructive sleep apnoea.
- Foreign bodies.
- Tracheomalacia (functional).

Traumatic causes

- Airway burn.
- Acute laryngeal injury (post-thyroidectomy).
- Head and neck trauma.
- Haemorrhage (post-thyroidectomy)

Infections

- Retropharyngeal abscess.
- Tonsillar hypertrophy.
- Ludwig's angina.
- Epiglottitis.

Many OSA patients use a continuous positive airway pressure (CPAP) machine to maintain airway patency during sleep. CPAP titrated to the patient's need should be readily available for use in the peri-operative period. The American Society of Anesthesiologists (ASA) has published guidelines for the identification and management of patients with OSA [8].

Obesity

Obese patients often have a 'bull neck', macroglossia, and/or redundant folds of pharyngeal tissue, rendering them difficult-to-intubate and at increased risk of developing UAO. Mask ventilation may be challenging because of difficulty in maintaining a patent airway, decreased chest wall compliance, decreased FRC, and a high risk of aspiration. If tracheal intubation is not planned, a supraglottic airway device can be effective. If tracheal intubation is planned, adequate pre-oxygenation, and rapid sequence induction with cricoid pressure is recommended. If there is any concern about securing the airway safely, an awake fibre optic intubation is recommended.

Airway polyps

Polyps may occur anywhere in the upper airway and lead to partial or complete UAO. Vocal cord granulomas and polyps may result from traumatic intubation, vocal cord irritation from tracheal tube movement, or from lubricants. Patients with laryngeal papillomatosis may require frequent laser treatments to eradicate the papillomas.

Thyroid goitre

A large thyroid goitre can compress the trachea and, over time, cause tracheomalacia. A retrosternal goitre may exert pressure on the trachea causing partial airway obstruction. The CT scan should be reviewed preoperatively to assess the extent of any tracheal obstruction. If compression is severe, mask ventilation is challenging in these patients, who may progress to complete UAO. If the lesion is anterior to the trachea, the airway obstruction can worsen when the patient is placed supine for induction of general anaesthesia. In such cases, an awake fibre optic intubation would probably be best for the patient's safety. A potential complication of thyroidectomy is uni- or bi-lateral recurrent laryngeal nerve injury, which can result in uni- or bi-lateral vocal cord paralysis. Careful evaluation of the airway (vocal cord movement) following tracheal extubation is therefore crucial [9]. Finally, UAO may result from post-thyroidectomy bleeding in the PACU. If this is suspected, immediate re-opening of the surgical incision to relieve the extrinsic tracheal pressure can be life-saving.

Mediastinal masses

When a patient presents with an anterior mediastinal mass, careful evaluation of the degree of tracheal compression is critical. Some cases are associated with superior vena cava obstruction syndrome. Difficulty breathing when supine or pulmonary function tests showing an obstructive pattern, is cause for concern. Close interaction with the surgeon and review of the CT scan are essential when planning management. Anaesthesia is needed primarily for diagnostic biopsies, staging of neoplasms, and (occasionally) for relief of acute airway obstruction [10]. Use of short-acting agents, small doses of opioids, and adequate post-operative pain management should allow the patient to be tracheally extubated when fully awake. Maintaining spontaneous ventilation is preferable. A rigid bronchoscope should be immediately available in case complete airway obstruction develops. Turning the patient to the lateral position decreases pressure on the airway. If the tracheal obstruction is severe, a tracheal stent placed under sedation can provide some protection prior to the induction of general anaesthesia.

Epiglottitis

Epiglottitis can occur in adults, but is less symptomatic than in children because the adult airway is larger [11]. Management is challenging because the swollen epiglottis can act as a valve mechanism and obstruct the airway. For any surgical intervention, awake fibre optic intubation is the safest approach. These patients should not be paralysed prior to securing the airway because that would only exacerbate the degree of UAO.

Damage from endotracheal intubation

Acquired subglottic stenosis is a complication of long-term tracheal intubation. Tracheal tube complications are usually due to incorrect size, over-inflated cuff, traumatic or multiple intubations,

and movement of the tube due to inadequate analgesia and sedation. Cooper and Grillo [12] studied tracheal stenosis at the cuff site and found that the main cause was the pressure exerted by the cuff. Cuff pressures >30 mmHg (> 4 kPa) cause mucosal ischaemia by exceeding mucosal capillary perfusion pressure. The ischaemic area can develop chondritis and granulation tissue, then heal by fibrosis, leading to progressive tracheal stenosis. Most cases of post-extubation stridor resolve with appropriate medical interventions, such as racemic epinephrine or corticosteroids. Fibre optic bronchoscopy may reveal the formation of soft granulation tissue that can often be treated by the use of the CO_2 laser. In clinical practice, if a patient fails extubation for 2 weeks, an elective tracheostomy should be performed to avoid the development of tracheal stenosis.

Acquired vocal-cord paralysis or dysfunction

Vocal cord paralysis may be uni- or bi-lateral. The most common cause is damage to the recurrent laryngeal nerve (RLN) leading to transient or permanent cord paralysis. Damage to the RLN can result from a laryngeal, thyroid, or Pancoast tumour and from neck or mediastinal surgery. On spontaneous inspiration, the flaccid vocal cord becomes adducted across the midline, creating inspiratory airflow obstruction. UAO may result from vocal cord adduction during inspiration. It presents as acute attacks of dyspnoea, stridor or wheeze, and complaints about tightness at the neck. Tracheomalacia, in contrast, presents as airway obstruction during exhalation because of lack of support from the tracheal rings. Tracheomalacia is a condition in which there has been a weakening of the cartilaginous structures of the trachea [13]. Typical causes are rheumatic (polychondritis), infectious, secondary to external beam radiation, and secondary to trauma or surgery. In all these cases of UAO, the best treatment is to apply gentle positive pressure ventilation with a face mask. This may temporarily overcome the obstruction until a more definitive solution can be established.

Clinical evaluation of UAO

Airway resistance varies inversely with the fourth power of the radius at the point of UAO, and small changes in the underlying pathology may dramatically worsen respiratory airflow. Based on the patient's history and physical examination, it is useful to separate patients with potential UAO into those with severe symptoms and impending respiratory failure who require immediate intervention, from those with a more gradual course and less severe symptoms.

Plain X-ray and CT scan

Plain neck and chest films are useful screening tests that identify tracheal deviation, extrinsic compression, or presence of a foreign body. Computed tomography (CT) can be important in investigating UAO in a patient who is haemodynamically stable or in one who is unstable, but whose airway has already been secured. A CT scan focused on the airway evaluates the entire airway with thinner 'cuts'. If thicker cuts are used, one can underestimate, or miss the site of stenosis or obstruction. High-resolution CT of the neck and chest helps identify intrinsic and extrinsic tumours, vascular structures, and foreign bodies, as well as provides information on the degree and extent of airway compromise in UAO [14]. The risks and benefits of transporting such a patient to the radiology suite for examination must be carefully considered and a person qualified in airway management should accompany the patient.

Pulmonary function testing

Spirometry is useful in patients with gradual onset and mild symptoms of UAO. Flow-volume loops may identify the location and functional severity of the obstruction. Spirometry has no role in the management of a patient with acute respiratory distress [15]. The flow-volume loop shows an obstructive pattern. The flow-volume loop in a patient with fixed UAO shows flattening of the inspiratory and the expiratory phases. The test is performed with the patient upright and is repeated in the supine position to assess the degree of tracheal compression from an intrathoracic mass. The main purpose is to evaluate is the degree of airflow obstruction. It is an effort-dependent test and, therefore, requires the patient's cooperation.

Rigid and flexible bronchoscopy with direct visualization

Bronchoscopy is the primary procedure in the diagnostic work-up of tracheal stenosis and is key in defining the characteristic features, extent, and location of the stenosis. Bronchoscopy is performed with the patient awake and breathing spontaneously following adequate airway topicalization. A rigid bronchoscope should be available for emergency use to secure the airway by carefully passing it through the stenotic segment. Flexible bronchoscopy is useful to establish the diagnosis and deliver treatments including laser therapy, electrocautery, electrosurgery, balloon dilatation, and metal stenting once the airway has been secured and the patient stabilized [16]. Light sedation may be used. Dexmedetomidine infusion is useful because respiratory drive is maintained. Performing a fibre optic bronchoscopy in a conscious patient enables examination of vocal cord function and determination if RLN damage is present. It also permits the evaluation of dynamic airway collapse with respiration.

Management

In all cases of UAO, a rapid evaluation considering age group, history, physical examination, and clinical circumstances helps determine the site, cause, and the severity of the obstruction, and the urgency for establishing an airway. An actual or potential obstruction that impairs ventilation must be immediately addressed. If obstruction is near-complete, mask ventilation or a supraglottic airway device (e.g. laryngeal mask airway (LMA)) may alleviate the obstruction, otherwise prompt tracheal intubation may be life-saving. Management of UAO can be pharmacological or interventional (i.e. supraglottic device, tracheal tube, or a surgical airway).

Pharmacological management

Racemic epinephrine

Racemic epinephrine is used in patients with partial UAO who are conscious and breathe spontaneously. Racemic epinephrine administered by nebulizer is effective by inducing vasoconstriction, which

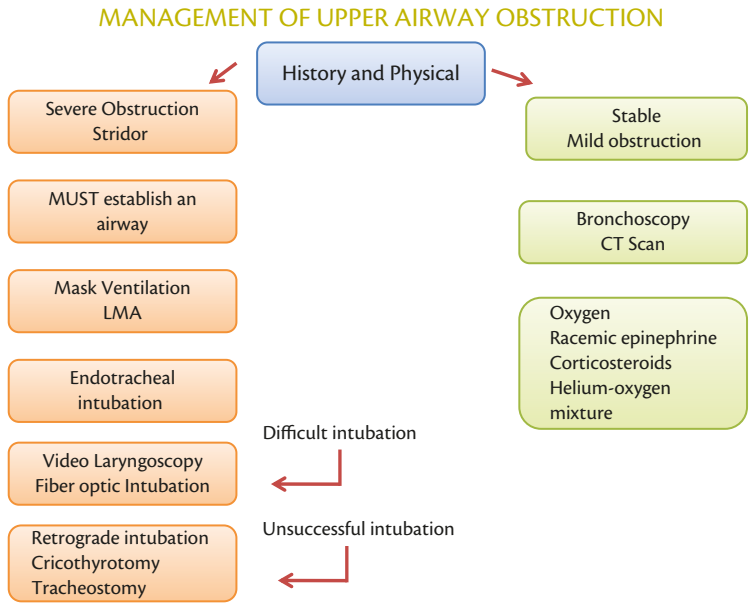

Fig. 79.1 Clinical approach to upper airway obstruction.

decreases mucosal oedema. Racemic epinephrine is also used to treat laryngeal oedema following extubation. The typical case is a patient, breathing easily for the first 2–3 hours, followed by the gradual progression of dyspnoea, inspiratory stridor, and increased respiratory effort. In this situation, racemic epinephrine can be used as a temporizing measure until the acute swelling and inflammation subside. These patients should be carefully monitored in the ICU until there is confirmation that the UAO has resolved, or at least greatly improved.

Corticosteroids

Corticosteroids, such as dexamethasone are used to treat UAO because of their effect in reducing airway oedema. Corticosteroids given at the time of tracheal extubation decrease capillary dilatation and permeability, oedema formation, and inflammatory cell infiltration. Randomized trials have confirmed the efficacy of corticosteroids in the treatment of croup, decreasing the need for intubation and hospital stay. Although the prophylactic use of steroids for post-extubation laryngeal oedema is widely accepted, one placebo-controlled, double-blind, multicentre study reported that dexamethasone does not prevent laryngeal oedema after tracheal extubation, regardless of duration of intubation [17].

Heliox

The low density of a helium–oxygen (heliox) gas mixture decreases the work of breathing by decreasing airway resistance to turbulent gas flow across the obstruction. Heliox has been useful in the treatment of post-extubation laryngeal oedema, tracheal stenosis or extrinsic compression, status asthmaticus, and angioedema [18]. Benefit is temporary because the obstruction remains until relieved. To be effective, the helium–oxygen ratio must be at least 70:30%, which limits its use in patients who cannot tolerate a low FIO_2.

Tracheal intubation and tracheostomy

In most cases of UAO, the airway can be established with tracheal intubation. If the airway is difficult, many video laryngoscopes are commercially available to facilitate the intubation, otherwise fibrescopic intubation may be necessary. If an airway cannot be established, a surgical airway via cricothyrotomy, tracheostomy, or retrograde intubation should be performed. The method of intervention should be individualized for each patient. The intervention chosen will depend on the aetiology of UAO and the urgency with which the airway must be secured.

The surgical airway-securing procedures require special expertise. Comparison of emergent versus elective tracheostomy reveals a two-fold complication rate in the former due to time spent isolating the trachea as a result of bleeding.

Laser therapy

Carbon dioxide or neodymium-doped yttrium-aluminium-garnet (Nd:YAG) laser therapy is used to treat intraluminal tracheobronchial lesions once the UAO has been stabilized and an airway secured. Although the onset of airway compromise is usually gradual, some patients remain asymptomatic despite airways that are only 2–3 mm in diameter. These patients only develop dyspnoea on exercise or when complete obstruction results from mucus, bleeding, inflammation, or swelling. It is easy to underestimate the risk of progression to a complete UAO. Laser therapy can be used to excise tracheal webs, treat benign obstructive lesions, or as palliative therapy for malignant tracheobronchial lesions [19].

Tracheal dilatation and stenting

Stents are usually placed following dilatation and maintain airway patency in patients with tracheal obstruction from benign or malignant conditions. A stent supports the airway wall against collapse or external compression, and impedes extension of tumour into the airway lumen. Rigid bronchoscopy is used to place a silicone stent or a flexible bronchoscope to deploy a metal stent. They are used either in the preparation for a more definitive resection procedure or palliative to alleviate the tracheal compression. If an intraluminal tumour is significant enough to cause UAO, it can be managed with laser therapy, photodynamic therapy, brachytherapy, or electrocautery.

The management of UAO is summarized in Fig. 79.1. Whatever the aetiology, a patient with UAO must be carefully monitored in an intensive care unit for impending respiratory failure [20].

PART 4.4

Airway access

CHAPTER 80

Standard intubation in the ICU

Sebastian G. Russo and Michael Quintel

Key points

- Preparation and planning are essential for tracheal intubation in the intensive care unit (ICU).
- During standard intubation in the ICU administration of neuromuscular blocking agents should be part of the routine.
- In case of an unexpected difficult airway, the number of intubation attempts should be limited to two and an alternative approach to maintain oxygenation and ventilation, such as extraglottic airway (EGA) devices, needs to be chosen.
- Whenever ventilator support is required, the use of capnography is mandatory to evaluate ventilation and to confirm clear airways.
- The intubating laryngeal mask airway (ILMA) is a useful back-up tool for both ventilation and intubation if tracheal tube placement fails.

Introduction

Airway access or control of the airways to maintain vital oxygenation and ventilation can be assured by different measures—face mask ventilation (FMV), extraglottic airway devices (EGA), endotracheal (ET) tubes, as well as tracheal access via a cricothyrotomy or tracheostomy. This chapter argues with the standard ET placement.

Tracheal intubation in the ICU

Wherever patients require some kind of oxygen administration, the establishment and maintenance of clear airways is the most important task for the caregiver, as without sufficient oxygen supply all other measures remain useless.

For elective conditions direct laryngoscopy is associated with a reassuring high percentage of good views on the laryngeal structures (Cormack & Lehane Score of 1 and 2), as well high success rate for tracheal intubation [1]. However, for the intensive care unit (ICU), several authors have indicated that airway management and tracheal tube placement while in the ICU is remarkably more challenging compared with the operating theatre [2,3]. Heuer et al. reported an incidence of difficult intubation of up to 25%, even if performed by anaesthesiologist [4].

Additionally, intensive care patients are critical ill, have reduced respiratory and haemodynamic capacities, and the circumstances and motives for tracheal intubation are awkward (Box 80.1). Thus, the time until desaturation is significantly shorter and the effects of insufficient oxygenation are more damaging. This is also mirrored by the results presented in the fourth National Audit Project in UK [5]. The outcome of failures during airway management in the ICU were particular adverse, with a high percentage of death or brain damage. Therefore, similar to the prehospital setting, even standard ET placement in the ICU should always considered to be significantly more difficult compared with elective airway management in the operation theatre (see Table 80.1).

Cook et al. have identified several factors contributing to unsuccessful airway management—poor identification of patients at risk, incomplete planning, inadequate provision of skilled staff and equipment, delayed recognition of events, and failed rescue due to lack of or failure of interpretation of capnography. Remarkable, even experienced anaesthetists tend to underestimate the level of complexity, while overestimating their own skills [4]. Therefore, it seems to be useful to define a standard procedure for tracheal intubation in the intensive care unit.

Standard intubation

Preparation

Prior to commencement, it is the health care provider's responsibility to check for the completeness and functionality of the equipment (see Box 80.2). It is essential that the entire equipment is **on scene** and not just **somewhere** in the ICU. Perfect access to the patient is crucial before attempting tracheal intubation. Therefore, whenever possible the strategic and logistical conditions should be optimized.

Whenever possible pre-oxygenation should be performed prior to the induction of anaesthesia. As shown by McGowan and Skinner a tight facemask seal is essential to apply high inspiratory oxygen concentrations [6]. In obese patients or in patients with decreased functional residual capacity, pre-oxygenation in the semi-recumbent position, as well as application of a positive end-expiratory pressure (PEEP) increases the interval to desaturation during apnoea significantly. Furthermore, non-invasive ventilation has been shown to be helpful in increasing the efficiency

Box 80.1 Circumstances for oro-tracheal tube placement in the intensive care unit

- Usually emergency indication to intubate.
- Keeping the patient on spontaneous breathing is usually not an option.
- Extraglottic airway devices as a long-term option most likely not appropriate.

Table 80.1 Reasons why to consider standard oro-tracheal tube placement in the intensive care unit to be difficult

Patient	Logistic
Secretions, blood, oedema	Difficult access to the head
Lung injury with reduced pulmonary reserves	Limited airway management devices
Concomitant haemodynamic instability	Potentially absent of capnography
	Limited access to further expertise

of pre-oxygenation and represents an elegant method of increasing patient safety in the ICU setting [7].

Induction of anaesthesia

In contrast to the most prevalent opinion that length of ICU stay or the fluid balance might influence the occurrence of a difficult intubation, Heuer et al. have shown that some of the main factors contributing to poor intubation conditions are an insufficient depth of anaesthesia and the lack of administration of neuromuscular blocking agents (NMBA) [4]. These observations mirror various publications regarding prehospital trauma care indicating that administration of neuromuscular blocking agents significantly increases the likelihood of successful tracheal intubation [8]. Therefore, if the indication for ET placement is given and the decision is made, adequate depth of anaesthesia and full neuromuscular blockade should be ensured.

As depolarizing NMBA are usually not indicated in the ICU setting, because of its fast onset, rocuronium seems to be the most appropriate NMBA. With sugammadex the effect of rocuronium can be reversed. However, the disposal of sugammadex should not lead to a false sense of security. Several authors have questioned whether the administration of sugammadex can save patients' lives in the case of an unexpected 'cannot ventilation–cannot intubate' scenario [9]. The time from decision making, to finding and preparation of the adequate dosage until full reversal of the neuromuscular block will probably be longer than the apnoeic tolerance of a critical-ill patient. Additionally, return of spontaneous ventilation will be impaired because of the previous administration of narcotics and, furthermore, will usually not resolve a 'cannot ventilation–cannot intubation' scenario [10,11].

Having said that, induction of anaesthesia for the standard intubation—considering no expected difficulties due to patient's anatomy of the upper airways—in the ICU should, nevertheless, always be performed as a rapid sequence induction. In detail, NMBA should be administered without checking the possibility of ventilation by face mask. There are several reasons for this recommendation:

- Once narcotics and anaesthetics have been administered recovery from anaesthesia to re-establish sufficient spontaneous ventilation is usually not an option if tracheal tube placement unexpectedly fails in a 'cannot ventilate–cannot intubation' situation.
- NMBA facilitate face mask ventilation and laryngoscopy, as well as placement of an EGA; especially if anaesthesia is light.
- Finally, the decision for a more defensive pathway needs to be made **prior** to induction **not during**.

As shown by Mort, more than two repeated attempts to intubate the patients tracheally are associated with significant-worth outcomes, such as hypoxaemia, regurgitation, aspiration, oesophageal intubation, and cardiac depression [12]. Therefore, it is crucial to limit the number of intubation attempts and consider alternative strategies for oxygenation and ventilation, e.g. EGA or face mask ventilation. While face mask ventilation will most likely serve only as a short time-bridge until other measures have been taken or prepared (such as videolaryngoscopy (VL), intubating laryngeal mask airway (LMA), or flexible fibre optic), an EGA may help also for a several hours to ventilate and oxygenate the patient.

Independently, whether ventilation is maintained by FMV, use of an EGA, or by tracheal tube placement, capnography is mandatory in all circumstances to confirm ventilation and correct placement of any airway device.

Box 80.2 Standard equipment for tracheal tube placement on the ICU

- Face mask and bag.
- Oropharyngeal tube.
- Functional suction.
- Functional laryngoscope (check light **prior** to induce anaesthesia).
- Adequately-sized tracheal tube (with a stylet if needed) + an additional tracheal tube one size smaller.
- Syringe to inflate the cuff.
- Capnography.
- Fixation.
- EGA device as back-up.

Strategies to increase time to desaturation

Apnoic oxygenation is usually known as a minimal oxygenation by placing the facemask tightly on the patients face with simultaneous application of a high oxygen flow. However, an open airway is a conceptual requirement of apnoeic oxygenation.

Ramachandran et al. [13] have performed a study in the operating theatre, including obese patients in the semi-recumbent position increasing significantly the time to desaturation simply by applying 5 L of oxygen via nasal probe during laryngoscopy (Table 80.2). Despite the lack of similar studies in the ICU setting, this concept seems to be very useful due to its simplicity, as well as because nasal probes are widely available. Therefore, it might by sensible to apply oxygen via nasal probes during laryngoscopy in order to prolong the time to desaturation or reduce the degree of desaturation, especially in patients with severe respiratory dysfunction.

Extraglottic airway devices

Since the first description of the classic LMA in 1983 [14], many other types of EGA became available. While EGA have their

Table 80.2 Effect of apnoeic oxygenation with 5 L of oxygen via a nasal probe during direct laryngoscopy

	Control group without O_2	Study group with O_2
Time to SpO_2 < 95%, min	3.5 (1.3)	5.3 (1.0)
Lowest SpO_2	88 (9)	94 (4)
Time to resaturate, min	1.6 (1.5)	0.7 (0.4)

Data from Ramachandran SK et al., 'Apneic oxygenation during prolonged laryngoscopy in obese patients: a randomized, controlled trial of nasal oxygen administration', *Journal of Clinical Anesthesia*, 2002, **22**(3), pp. 164–8. PubMed PMID: 20400000.

undisputed value during routine as well as emergency care, the use and distribution of EGA one the ICU seems to be limited.

Difficult laryngoscopy does usually not impair the insertion of an EGA. Therefore, EGA, as extensively shown for the OR and prehospital emergency medicine, are very valuable tools to secure patients' airways in case of an unexpected failure to intubate in the ICU. As the learning curves to gain adequate competency are steeper for EGA compared with intubation via direct laryngoscopy, they may be especially useful if expertise in advanced airway management is limited.

Available data for the use of EGA in the ICU refer mainly to LMA. Several case reports describe the use of LMAs in the ICU in cases of failed intubations [15]. Furthermore, so called 'second generation' devices contain an integrated drainage channel to passively or actively drain fluids from the gastrointestinal tract. Despite the lack of scientific evidence, it can be assumed that these features further reduce the risk of regurgitation. Additionally, as ventilation via a correctly-placed EGA reduces the risk of gastric air insufflation compared with FMV, EGA may serve to provisionally establish clear airways for oxygenation and ventilation.

Blind intubation via EGA is usually not associated with promising success rates. However, intubation via an EGA can be aided fibre optically, possibly with the help of an purpose-designed exchange catheter (Aintree Catheter, Cook Critical Care, Bloomington, IN, USA) [16].

One exception is the intubating laryngeal mask airway (ILMA, Teleflex Medical Europe Ltd, Ireland). It allows ventilation of the patients' lungs, as well as blind intubation with a very high success rate [17]. Furthermore, for novice users, both ventilation and intubation have proven to be more successful with the ILMA compared with FMV and intubation via direct laryngoscopy [18]. In case of failed blind intubation attempts, tracheal tube placement can easily be performed using a flexible fibre optic. As the airway tube of the ILMA is large, a tracheal tube can be advanced via a fibre optic once the trachea has been identified. Therefore, the ILMA might be a valuable back-up tool when planning tracheal intubation in the ICU.

Videolaryngoscopy

Currently, standard ET placement usually means the use of direct laryngoscopy. In 1998, the logical combination with a Macintosh blade, the video intubation laryngoscope, was introduced as a new concept for dealing with routine cases, as well as difficult intubations and was the subject of extensive scientific studies. The rapid spread of video laryngoscopy began at the latest with the introduction of the GlideScope® videolaryngoscope (GS-VL, Verthon Medical, Canada) in 2003.

The uncontested preserves of video laryngoscopy are:

- Training and supervising intubation by laryngoscopy.
- Laryngoscopic intubation in cases of an unexpectedly difficult airway in adults and children.
- Assessment and documentation of special constellations and pathological conditions of supraglottic airways and documentation of the tube position in the glottis.

VL systems have shown to improve the view of the laryngeal structures. The view of the glottis is consistently better using a VL system than with direct laryngoscopy. A study by Nouruzi-Sedeh et al., with providers not experienced in airway management, showed that patients were successfully intubated more often and faster with the GS-VL than by direct laryngoscopy [19]. Furthermore, the learning curve for VL seems to be steeper than for direct laryngoscopy, although the data obtained in model-based studies should be regarded with some reservations [20].

Granted, VL is not the Holy Grail for ET placement that will resolve all difficult airway scenarios, and it is self-evident that training and expertise are warranted with the use of VL. However, VL seems to be effective as a back-up device in the case of failed direct laryngoscopy, as well as the first choice tool for health care providers with less skilled in direct laryngoscopy. Furthermore, it can be speculated whether, parallel to the evolution in the OR and the pre-hospital setting, VL will replace direct laryngoscopy in the ICU in the future.

Without going into too much detail about different VL systems and concepts, at this stage it is difficult to predict whether strongly angulated VLs with a mandatory **indirect** view on the glottis (e.g. GlideScope) or VLs with Macintosh-like blades (e.g. CMac®, K. Storz GmbH, Tuttlingen, Germany), including the option of both indirect and direct laryngoscopy, will be the advantageous in the ICU setting.

Conclusion

Standard tracheal intubation in the ICU is more challenging compared with standard intubation in the OR. Therefore, planning and preparation are crucial. In order to facilitate laryngoscopy and tracheal tube placement, adequate anaesthesia, including full neuromuscular blockade should be part of the routine. EGA devices represent useful options in cases of unexpected failed intubation. However, wherever and whenever airway management is attempted, the use of capnography to confirm ventilation is mandatory. In the future, VL might become the standard procedure for tracheal intubation in the ICU.

CHAPTER 81

The difficult intubation in the ICU

Michael Frass

Key points

- Endotracheal intubation may sometimes be problematic in ICU (unprepared patients, emergency situations) and non-invasive alternative airway management may be necessary.
- In case of difficult mask ventilation (inability to maintain pulse oximetry oxygen saturation > 50% at FiO_2 = 100%) proper action must be planned.
- The oesophageal tracheal Combitube® and EasyTube™ may be valid alternatives.
- Laryngeal mask has proved of value in cardiopulmonary resuscitation.
- Modification of a laryngeal mask such as Fastrach® has been recommended as a rescue device for emergency airway management.

Airway access

Airway management in the ICU differs from conventional controlled setting, such as general anaesthesia in the operating room (OR). Due to adequate patient preparation and positioning in the OR, endotracheal intubation is mostly easy to perform. However, in the intensive care setting, endotracheal intubation is often difficult or impossible because patients are not prepared and intubation is immediately necessary without sufficient time for putting together technical and pharmaceutical equipment.

In the following, non-invasive alternate airway management with special respect on the recommendations of the 'Task Force on Managing the Difficult Airway' of the American Society of Anesthesiologists (i.e. ASA algorithm) is described [1].

Non-invasive airway management

Non-invasive ventilation (NIV) allows patients to speak and cough [2] and may reduce complications related to intubation. Indications for use of NIV are patients with diagnosis of chronic obstructive lung disease or cardiac failure, since weaning from respirator and cannula in these patients is often very difficult.

NIV can be performed via face mask covering mouth and nose, where a mask is pressed against the patient's face with the help of an elastic band. Ventilation is provided by either continuous positive airway pressure (CPAP, i.e. continuous flow), pressure support ventilation (PSV) or volume—or pressure-cycled systems (e.g. bi-level positive airway pressure (BiPAP). New devices include eyes into the mask and are better tolerated since pressure on the root of the nose can be circumvented.

NIV can also be performed via a helmet consisting of a cylindrical transparent part surrounding the patient's head sealed by an elastic ring around the patient's neck. The advantages of the helmet are that the patient enjoys a free view through the transparent helmet and may use glasses. Furthermore, additional openings allow nursing of the patient's face. Special designs of the helmet provide field of view and minimum level of noise.

In the intensive care unit (ICU), patients with hypoxia and deteriorated cardiopulmonary function may experience adverse events after shorter periods of lack of response to ventilation or intubation. Therefore, emergency tracheal intubation in critically-ill patients may be associated with a significant frequency of major complications. Opposite to routine intubation in the operating room, airway management in intensive care patients may be extremely difficult. Immediate need for intubation and ventilation in situations, such as acute respiratory failure, shock, or cardiopulmonary arrest could make securing of airways and adequate ventilation difficult.

In this situation, the intensivist should consider mask ventilation, when general anaesthesia is induced before securing the airway and whether there are any inadvertent obstacles making awake conventional endotracheal or fibre optic intubation difficult. Furthermore, to prevent adverse effects of unsuccessful intubation, a plan B should be ready.

Difficult mask ventilation (DMV) is defined as the inability of a trained anaesthetist to maintain the arterial oxygen saturation beyond 90% by help of a face mask and use of 100% inspired oxygen, when the preventilation oxygen saturation level was within the normal range [3].

Opposite to previous assumptions, difficulties in laryngoscopy and/or intubation may occur in routine patients in the OR. While minor complications making a second intubation attempt necessary occur in up to 8% of patients, grade 3 laryngoscopy requiring multiple attempts at conventional intubation occurs in 1–4% among all patients. In 0.05–0.35% of routine anaesthesia cases intubate may fail due to grade 3 or 4 laryngoscopic views. A cannot ventilate–cannot intubate situation may occur in approximately 2 out of 10,000 cases.

Alternative airways

Oesophageal-tracheal double lumen airways: combitube® and easytube™

The oesophageal tracheal combitube (ETC) has designed as a double-lumen airway with a 'pharyngeal' and an 'endotracheal' lumen where the lumens are separated by a partition. At the proximal end, the ETC is surrounded by a large oropharyngeal balloon, at the distal end by a conventional cuff (Covidien, Mansfield, MA,

USA). As an advantage, the ETC can be inserted blindly without help of a laryngoscope and works equally well in oesophageal or tracheal position. The ETC is inserted as deeply until the printed ring marks are positioned at the level of the upper teeth. Then, the oropharyngeal balloon is inflated with 85 (37F) or 100 mL (41F) of air sealing the oral and nasal cavities, while the distal cuff is inflated with 5 to 12 (37F) or 15 mL of air (41F) sealing either oesophagus or trachea. In about 97% the ETC enters the oesophagus after blind insertion. Therefore, test ventilation is recommended via the longer 'pharyngeal' blue lumen No. 1 (i.e. supraglottic ventilation). Confirmation of the tube's position may be done by auscultation of breath sounds in the absence of gastric inflation, and by capnography and/or oesophageal detection method. If the ETC has blindly entered the trachea (3% of blind insertions), ventilation is performed via the shorter transparent lumen No. 2, and ventilation is done like via a conventional endotracheal tube (ETT). Two different sizes of the ETC are available: a small adult model (37 Fr, Combitube® SA) for use in patients with a height ranging from 120 to 200 cm and a 41 Fr model for use in taller patients.

The ETC has been studied and used under emergency conditions, as well as during routine anaesthesia. To become familiar with the ETC, it is recommended to train during elective surgery before using the airway in emergency situations. When used routinely, the ETC could be inserted using a (video-) laryngoscope to minimize the risk of pharyngeal injury. Contraindications for use of the ETC are oesophageal pathologies, ingestion of caustic substances and central airway pathologies.

A major advantage of the Combitube® is its unequalled safety to prevent aspiration of gastric contents and the applicability of high airway pressures. The ETC can be left in place for up to 8 hours; replacement by an ETT can be performed either by tracheostomy or by cricothyrotomy with the ETC in place (since the trachea is not occupied in most cases), by direct laryngoscopy after deflation of the oropharyngeal balloon, or by fibre optics.

Recently, the EasyTube™ has been designed (Well Lead, Guangzhou, China). Its appearance is similar to the Combitube®, however, provides several advantages.

The 'pharyngeal' lumen of the EasyTube™ ends just below the oropharyngeal balloon. Therefore, the 'tracheo-oesophageal' lumen is thinner than that of the Combitube®, which carries the two lumens down to the end. Since the distal single lumen of the EasyTube™ is significantly thinner, the potential danger of mucosal damage is minimized. Another advantage is that the oropharyngeal balloon is latex free. The device comes in two sizes: the 28 F EasyTube™ ('paediatric size') is available for patients with a height ranging from 90 to 130 cm; the 41 F EasyTube™ is designed for patients taller than 130 cm. A small fibrescope may be passed via the so-called 'pharyngeal' lumen, since it is open at the distal end. This feature allows inspection of the trachea and possible replacement of the EasyTube™ using a guide wire. Furthermore, a larger suction catheter can be passed via both lumens (14 F suction catheter in the 41 F EasyTube™).

Laryngeal mask airway

The laryngeal mask airway (LMA) (LMA North America, San Diego, CA, USA) has been developed in parallel to the Combitube®. It was accepted rapidly and is used extensively during general anaesthesia. The LMA is used for different reasons—as a routine ventilatory airway as an alternative to conventional endotracheal airway or as help for tracheal intubation. The initial intention for use of the LMA was to replace the conventional face mask in the operating room in Great Britain. Tidal volumes were higher and problems associated with airway management (difficulties in maintaining the airway or maintaining SpO_2 > 95%) less frequently encountered during LMA use when compared with conventional regular face mask.

The use of the LMA as the immediate airway in cardiopulmonary resuscitation has been discussed controversially. Murray et al. performed a two-phase observational study of the effect of paramedic training for LMA insertion using a mannequin and the success rate in the prehospital setting. All paramedics successfully completed classroom mannequin training. Two-hundred-and-eight paramedics (100%) successfully completed training. The mean number of attempts was 1, and only four (2.1%) paramedics required a second attempt with a mannequin. The paramedics' perception of ease of use comparing the LMA with a bag valve mask (BVM) was evenly distributed across the three descriptors: 70 (39%) scored the LMA as easier to use, 57 (31%) as more difficult, and 54 (30%) stated there would be no difference. Of the 291 arrests during the study period, insertion of the LMA was attempted in 283 (97.3%) and was successful in 199 (70%) patients. The LMA became dislodged in 5 (2.5%) cases and was removed in 12 (6%) to clear vomit from the airway. The overall success rate was 182 (64%). The incidence of regurgitation prior to attempted insertion of the LMA was 28% (79 patients). Success rates did not vary significantly with the incidence of vomiting prior to insertion ($p = 0.11$). The majority of the paramedics evaluated LMA insertion as 'Very easy' 49/220 (22.3%) or 'Easy' 87/220 (39.6%). Paramedic evaluation of ease of use varied with success ($p = 0.001$). This study reports a 100% training success rate with a mannequin, and a 64% success with LMA insertion and ventilation in the field by paramedics among adult out-of-hospital non-traumatic cardiac arrest patients.

The potential value of the LMA was assessed in a multicentre study when the LMA inserted by ward nurses during cardiopulmonary resuscitation as a method of airway management before of the advanced life support team with tracheal intubation capability arrived. One-hundred-and-thirty nurses were trained, and 164 cases of cardiac arrest were studied. The LMA was inserted at the first attempt in 71% and at the second attempt in 26% of cases. Satisfactory chest expansion occurred in 86% of cases. The mean interval between cardiac arrest and LMA insertion was 2.4 min. Regurgitation of gastric contents occurred before airway insertion in 20 cases (12%), and during insertion in three cases (2%).

Early LMA insertion should be considered in patients suffering from supraglottic pathologies and unfavourable anatomy for face mask ventilation and/or tracheal intubation. Drawbacks of the LMA include the lack of access to the patient's central airways, risk of aspiration, limited applicability of positive airway pressures due to the often inadequate seal, and the need for training. Moreover, the LMA is a supraglottic ventilatory device and is thereby unable to establish adequate gas exchange in patients with central airway obstruction.

Several modifications of the LMA have been designed, e.g. the intubating LMA (Fastrach™, the Laryngeal Mask Company, Ltd.). The so-called Fastrach differs from conventional LMAs by having a wider, shorter stainless steel tube, a handle to steady the device, and an epiglottic elevating bar (a moveable flap fixed

to the upper rim of the mask). The Fastrach™ allows passage of endotracheal tubes up to an inner diameter (ID) of 8.5 mm providing blind or fibre optic intubation using the correctly placed Fastrach as a conduit. Success rates for blind Fastrach™ intubation in the 75 to >90% range have been shown by several investigators.

The Fastrach™

This has been recommended as a rescue device for emergency airway management. Ferson et al. used the Fastrach™ in 254 patients with different types of difficult airways. Insertions of the LMA-Fastrach™ were accomplished in three attempts or fewer in all patients. The overall success rates for blind and fibre optically-guided intubations through the LMA-Fastrach™ were 96.5 and 100.0%, respectively. Oesophageal perforation has occurred after repeated 'blind' intubation attempts with the LMA-Fastrach™ in an elderly patient. Therefore, the specially designed silicone-tube with rounded bevel should be used for blind Fastrach™ intubation, because success rates exceed those encountered with standard reinforced tubes. Muscle relaxation may help to increase success rates for blind Fastrach™ intubation.

LMA and LMA-Fastrach™ versus Combitube®

Sealing capacities and protection against regurgitation of gastric contents of LMA/Fastrach™ are inferior to those of the ETC, e.g. average leak fractions of the LMA are in the range 20–25% during positive pressure ventilation with airway pressures ranging from 20 to 30 cmH_2O. The special design of the ETC allows the use of high peak airway pressures and permits PEEP ventilation, thereby enabling higher tidal ventilation and maintenance of adequate gas exchange, even in patients suffering from severe underlying pulmonary pathology (e.g. aspiration of gastric contents). In contrast to the ETC, blind, or fibre optic intubation is possible through the LMA lumen (using conventional ETTs up to an ID of 6.5 mm) and especially through the Fastrach™ (up to 8.5 mm). With the currently available ETC model, no blind or fibre optic access to the patient airway is necessary. Krafft et al. modified the standard ETC model and created a larger ventilation hole, which can be used for fibre optic intubation or tracheal toilette. However, the redesigned model is currently not available and it is uncertain whether it will be produced in the near future.

CHAPTER 82

The surgical airway in the ICU

Danja S. Groves and Charles G. Durbin Jr

Key points

- Cricothyrotomy is an emergency surgical airway used to save a life when all attempts at securing a patent airway fail and arrest is eminent.
- Compared with translaryngeal intubation, tracheostomy improves patient comfort, and leads to shorter length of intensive care unit (ICU) and hospital stay.
- Tracheostomy relieves upper airway obstruction, protects the larynx and upper airway from damage, allows access to the lower airway for secretion removal, and provides a stable airway for patients requiring prolonged mechanical ventilation or oxygenation support.
- Timing of tracheostomy remains controversial and should be individualized; however, early tracheostomy (within 7 days) seems to be beneficial in certain patient populations (head injury, medically critically ill).
- Bedside techniques are safe and efficient, allowing timely tracheostomy with low morbidity.

Introduction

Surgical airways are discussed in this section, and include emergency cricothyroidotomy and elective tracheostomy. Emergency cricothyroidotomy is reserved for that urgent situation when spontaneous ventilation is inadequate, manual ventilation unsuccessful, and translaryngeal intubation fails. It is a life-saving intervention, which can be rapidly performed with acceptable risk, using few surgical tools or a special device. While a 'slash' cricothyroidotomy may be performed with only a scalpel and tube, a specially-designed kit with a tube, dilator, and guide wire is more efficient and safer in inexperienced hands. Another approach to a lost airway is transtracheal needle ventilation, which will help to prevent lethal hypoxaemia, while achieving a secure airway by other means. The remainder of this chapter will discuss elective tracheostomy in intensive care unit (ICU) patients. Unlike the emergency surgical airway, this is a carefully considered, surgical approach to prolonged airway management. Some authors suggest a tracheostomy may be performed through the less vascular cricothyroid membrane, but most recommend placement at lower tracheal rings to reduce the chance of permanent laryngeal damage that can result from loss of the cricoid cartilage.

Of the purported advantages of tracheostomy, only improved patient comfort, early discharge from an ICU, and shorter length of ICU and hospital stay have any supporting data. There is a belief that patients are safer following tracheostomy, but even this basic assumption is unsupported by science. Evolution of percutaneous techniques are rapidly reducing the need for surgical tracheostomy. Timing of tracheostomy remains controversial.

Elective tracheostomy

Elective tracheostomy is performed in as many as 10% of patients requiring more than 7 days of mechanical ventilation. Prolonged respiratory failure is the most frequent indication for tracheostomy followed by decreased level of consciousness, poor airway protective reflexes, and severe alterations in physiology. The safety of tracheostomy techniques has improved and most are now performed at the patient's bedside. There are two basic ways to perform tracheostomy—'open' or 'surgical' tracheostomy in which a formal neck incision is made, tissue planes are identified and incised, blood vessels ligated or cauterized, and a tracheal stoma surgically created and stabilized, or by percutaneous dilation, where the trachea is entered with a needle, and then a guide wire used to direct stoma creation and tube placement using tapered dilating devices.

Elective tracheostomy is used to relieve upper airway obstruction due to:

- Tumour, surgery, trauma, foreign body, or infection.
- Protect the larynx and upper airway from damage.
- Allow access to the lower airway for suctioning and secretion removal.
- Provide a stable airway for patients requiring prolonged mechanical ventilation or oxygenation support.

Although there are anecdotal reports using tracheostomy for emergency relief of airway obstruction, cricothyroidotomy remains the recommended approach when manual ventilation and intubation attempts have failed, and complete cessation of gas exchange occurs [1].

Benefits of early elective tracheostomy?

Protection of the larynx and the upper airway from prolonged intubation is an important reason to perform a tracheostomy, and to consider early provision of this airway. Many anatomical structures are at risk from translaryngeal intubation. Vocal cord oedema and damage, laryngeal mucosal erosions, laryngeal scaring and stenosis, and recurrent laryngeal nerve damage can lead to permanent disability. The potential for recovery or successful surgical repair of many of these injuries is less with continued, prolonged intubation. Direct laryngeal examination demonstrates marked airway changes within several days of translaryngeal intubation. Usually, these early changes are reversible and there is gradual improvement in

airway examination after the tube is removed from the larynx [2]. Prediction of progression with continued translaryngeal intubation is poor, but the consequences of injury are severe.

Improved patient comfort

Patients experience discomfort with persistent translaryngeal intubation and are more comfortable following tracheostomy [3]. Improved patient comfort and less requirements for sedation have been reported in several studies following placement of a tracheostomy. In a follow-up study of patients who were randomized to remain intubated translaryngeally for a prolonged period or receive an early tracheostomy, Blot et al. reported that oral comfort scores, mouth cleanliness, perception of change in body image, feelings of safety, and overall comfort were lower in the prolonged translaryngeal intubation group compared with those who were randomized to early tracheostomy [4]. Thirteen patients in this study who survived to hospital discharge, and had undergone both translaryngeal intubation and tracheostomy reported tracheostomy as the most comfortable airway of the two. Patient comfort alone may be enough to justify tracheostomy, rather than continuing with prolonged translaryngeal intubation if the risks of the two approaches are comparable. Other suggested advantages of elective tracheostomy and their strength of evidence are listed in Table 81.1.

Facilitated ventilator weaning and shorter length of stay

Elective tracheostomy may shorten duration of mechanical ventilation due to reduced work of breathing, the need for less sedation and analgesia, or because once a secure airway is in place clinician weaning behaviour changes [5]. A single prospective trial in surgical/trauma patients who were unable to pass a spontaneous breathing trial after 72 hours of mechanical ventilation, were randomly divided to continue translaryngeal intubation or proceed with immediate tracheostomy, demonstrated more rapid weaning following tracheostomy [6]. Several meta-analyses of randomized trials comparing earlier versus later tracheostomy confirmed that weaning is more rapid with early tracheostomy [7]. Earlier transition of a patient from the ICU remains a major demonstrable effect of tracheostomy, thus accruing fewer ICU and hospital days. However, this transition to a lower level care area may not be without risk.

Elective tracheostomy and patient safety

The presumed safety of having a tracheostomy in a patient managed outside an ICU or special care unit has come under scrutiny. In a prospective observational cohort study, Martinez et al. reported that patients discharged to the ward with a tracheostomy in place experienced three times the mortality of those who had received a tracheostomy, but who were decannulated prior to discharge to the ward [8]. Multivariate analysis identified three highly significant factors associated with increased ward mortality:

- Lack of decannulation at ICU discharge.
- Body mass index > 30kg/m^2
- Tenacious sputum at ICU discharge.

The last two would appear to be easier to manage with a tracheostomy, but most of the deaths on the ward were due to unexpected cardiorespiratory arrests, usually in the early morning hours when staffing may be compromised. Failure of monitoring of patients and of early treatment of airway problems may have played a part in the increased mortality in this group. Other groups have reported similar findings in less well-designed trials, while some have not identified having a tracheostomy at ward discharge a risk for increased mortality when corrected for other risk factors.

Others have noticed the additional risks of having a tracheostomy compared with standard translaryngeal intubation even when residing in an ICU environment. In 2000, Kapadia et al. reported airway accidents in 5046 patients intubated for 9289 days during a 4-year period. Of the 36 airway accidents, 26 occurred in the 5043 endotracheally-intubated patients—none were severe and no deaths occurred. Ten tracheostomy-related accidents occurred in 79 patients; six were severe and one resulted in death. Thus, even when monitored in an ICU, airway accidents associated with

Table 81.1 Suggested benefits of performing a tracheostomy in patients requiring prolonged intubation

Benefit	Quality of literature showing benefit
Improved patient comfort	Uncontrolled reports, clinical opinion
Less need for sedation	Several RCTs
Lower work of breathing	Theoretical analysis, one small study
Improved patient safety	Clinical belief, but minimal data, some contradictory (see text for details)
Improved oral hygiene	Clinical observation
Oral intake more likely	Opinion only
Earlier ability to speak	Uncontrolled reports
Better long-term laryngeal function	Large uncontrolled reports
Faster weaning from mechanical ventilation	One RCT
Lower risk of ventilator associated pneumonia	Controversial, data support for both sides
Lower mortality	One RCT supports, many do not; however, large RCT supports mortality not higher with tracheostomy
Shorter ICU and hospital stay	Several meta-analyses

RCT, randomized controlled trial.

tracheostomy tubes occurred more frequently and resulted in higher mortality (10%) than in patients with conventional endotracheal tubes [10].

No fewer lung infections with elective tracheostomy

Since micro-aspiration of oral secretions through the stented larynx, past the endotracheal tube cuff is believed to contribute to development of infection; it was hoped that incidence of ventilator-associated pneumonia (VAP) would decrease with early tracheostomy. If there is an influence on the incidence or course of VAP from tracheostomy, it is small. In addition to the meta-analysis by Griffiths et al. mentioned previously, a recent review and meta-analysis of early versus later tracheostomy by Durbin et al. confirmed the observation of minimal effect on the incidence of VAP [9]. The fact that most patients are intubated through the larynx prior to tracheostomy will contaminate any study attempting evaluate elective tracheostomy and VAP association.

Timing of elective tracheostomy

Tracheostomy is indicated when the need for endotracheal intubation is or is projected to be prolonged. In older guidelines, tracheostomy was recommended after 21 days; more recently, it has been suggested that tracheostomy be considered within 2–10 days of intubation and a projected need for 14 days of intubation. In patients with severe multi-trauma and/or head injury with low Glasgow Coma Scores, elective tracheostomy at the earliest convenient time, often within 3–4 days of intubation, appears to afford some benefits [10]. An argument against early tracheostomy in patients with neurological abnormalities has been advanced by King et al. [11]. In their review, it appears that poor mental status alone is insufficient to require prolonged intubation and thus tracheostomy. They noted cough effectiveness, secretion quantity, and secretion viscosity all impact on the success of extubation in this group (and other patients) as well.

While it is clear that delaying extubation is associated with increased morbidity, and length of stay, the medical literature also demonstrates harm from extubation failure. Over 55 studies, involving more than 30,000 patients, suggest that the overall rate of extubation failure is approximately 12% (range 2–25%) [12]. One study from a medical ICU found that re-intubation resulted in an average 12 additional days of mechanical ventilation, 21 ICU days, 30 hospital days, and an increased need for tracheostomy and post-acute care hospitalization [13]. While patients requiring re-intubation tend to be sicker, multivariate analyses have shown that premorbid health status, severity of illness, and complications directly associated with re-intubation do not explain the increased mortality associated with extubation failure [14]. A direct correlation between increasing time to re-intubation and mortality has led some authors to suggest that clinical deterioration prior to reinstitution of mechanical ventilatory support is responsible for the increased mortality associated with extubation failure [15]. It has been suggested that careful monitoring and rapid intervention for respiratory failure developing following extubation may prevent this excessive mortality. However, this hypothesis has not yet been tested.

Unlike other reports, a study by Rumbak et al. demonstrated a remarkable mortality benefit of early tracheostomy in medical patients, with 32% mortality with early tracheostomy group and over 61% in the late group [16]. This trial was performed in three institutions and included severely-ill patients (APACHE score > 25) randomized to a percutaneous tracheostomy at 48 hours, or at 14 days or later. Low tidal volume ventilation, a ventilator-weaning protocol, and daily spontaneous breathing trials were used in all patients. In addition to mortality benefit of early tracheostomy, infections, and other complications were more common in the late tracheostomy group.

A recent large trial (909 patients) of early (<4 days) versus late tracheotomy (>10 days) demonstrated no survival benefit in the early group, but 44% of the late group either died or were weaned before receiving a tracheostomy [17].

Techniques of elective tracheostomy

Since Ciaglia first described his use of a guide wire and serial dilation technique for percutaneous tracheostomy in 1985, the popularity of this technique over the open technique has grown dramatically. Comparisons between surgical and percutaneous tracheostomy suggest more (but generally less severe) early complications during percutaneous placement, but fewer late problems. These are summarized in several papers by Durbin [18,19]. Initially, percutaneous dilatory tracheostomy was reserved for patients with few risk factors and favourable neck anatomy. With growing experience, the indications for percutaneous dilatory tracheostomy have been expanded and the patient exceptions that mandate a surgical tracheostomy have decreased. In the case of morbid obesity and moderate coagulopathy, percutaneous dilatory tracheostomy may afford better survival with fewer complications [20].

There are several variants on the percutaneous dilatory tracheostomy. A wire-guided sharp, cutting forceps developed by Griggs et al. gained early popularity, but is reported to have more acute problems, including bleeding and possibly decannulation tracheal risks. To improve safety, performance of percutaneous dilatory tracheostomy, use of bronchoscopic visualization during any technique, has been advocated. Creating the stoma with a single, long-tapered dilator, instead of using serial dilators has reduced procedural time and exposure of the team to the patient's blood. A common, but usually insignificant complication is fracture of a tracheal ring. To reduce the likelihood of fracturing a tracheal ring during the forced dilation, Fantoni developed a method of passing the dilator from inside the trachea to the outside using a specially designed tracheostomy tube and a rigid bronchoscope. The complexity of this method has limited its dissemination. Another approach to reduce tracheal trauma has been developed using a screw-like device to gently separate the trachea rings (PercuTwist®), however, ring fractures still occur.

Ultrasonography of the neck identifies underlying anatomy with more precision than palpation. Tracheal rings are easily appreciated, and an overlying large vessel or thyroid gland can be seen and avoided during the procedure. With adequate experience it may be possible to correctly identify the entry point, but confirmation of correct entry and tube placement is best achieved with direct visualization using a fibre optic bronchoscope.

A variant on the dilator technique of tracheostomy placement begins by first creating a small surgical incision, using blunt dissection, and a gloved finger to palpate the trachea. The fingertip is used to identify the cricoid ring and tracheal rings. Operators using this

technique often dispense with the fibre optic bronchoscope, relying on tactile identification of correct position for needle entry.

Whatever technique is chosen, there are major advantages to performing the procedure in the ICU. Unstable patients experience less deterioration in vital signs and avoid the risks of travel to the operating room. Multiple caregivers, already familiar with the patient, can monitor and care for the patient if the procedure is performed in the unit. Charges for the procedure are usually less when performed in the ICU, but actual costs are difficult to calculate, and payments are unrelated to charges or costs. Occasionally, a bedside procedure fails or a problem arises that would benefit from having operating room resources, such as high intensity lights or electrocautery. Whether to move a patient to the operating room if a surgical tracheostomy is needed—or to perform it in the ICU and bring required the equipment—is an institutional decision. Excellent results have been reported with all of the percutaneous dilatory, as well as surgical techniques performed in either the operating room or at the bedside. Local policy and resources guide the decision of where to perform a tracheostomy.

Complications

The overall rate of complications associated with tracheostomy is low. Reported complications range from pneumothorax, subcutaneous emphysema, haemorrhage, stomal infections, granulation tissue, tracheal stenosis, tracheomalacia, and to (rarely) death. These complications have to be weighed against the identified risks of long-term translaryngeal intubation, including oedema, inflammation, ulcerations, granulomas, arytenoid injury, and laryngeal or tracheal stenosis, fibrosis, or necrosis.

Contraindications

Absolute contraindications for tracheostomy, such as soft tissue infections or anatomic aberrations of the neck, are rare. Severe respiratory failure with refractory hypoxaemia and/or hypercapnia may be considered as relative contraindications requiring delay. Haematological and coagulation disorders may be considered as contraindications for tracheostomy, although percutaneous tracheostomy has been safely performed in patients with severe thrombocytopenia and other coagulation abnormalities.

PART 4.5

Acute respiratory failure

CHAPTER 83

Dyspnoea in the critically ill

Paolo Tarsia

Key points

- Dyspnoea is a common clinical finding in patients with respiratory, cardiovascular, neuromuscular, and neoplastic diseases. It may also be present in healthy obese and/or deconditioned subjects.
- Dyspnoea is thought to derive from the conscious awareness of a mismatch between outgoing motor command to the respiratory system and afferent information on the ventilatory response to the command.
- At least three qualitatively distinct sensations of breathing discomfort have been recognized—air hunger, effort of breathing, and chest tightness.
- Dyspnoea quantification measures should be employed to better assess dyspnoea and evaluate response to treatment.
- Both pharmacological and non-pharmacological treatment options are available for dyspnoea relief. In refractory dyspnoea, interventions aimed at reducing the affective component of breathlessness that do not necessarily modulate symptom intensity may be of use.

Introduction

In healthy conditions, the human respiratory system is built in such a way that, lungs, airways, and respiratory muscles adequately satisfy the ventilatory demands imposed by the entire organism, even during vigorous exercise conditions. However, a number of common clinical conditions are associated with dyspnoea. Dyspnoea may be defined as a subjective experience of discomfort associated with breathing. An American Thoracic Society Statement on dyspnoea recognizes that 'the experience derives from interactions among multiple physiological, psychological, social, and environmental factors, and may induce secondary physiological and behavioural responses' [1]. Being a subjective experience, each individual perceives, interprets, and reacts differently to the sensation of dyspnoea depending on circumstances, previous experiences, values, and beliefs. Dyspnoea and pain share both neurological pathways and perceptive behaviours. Both consist of sensory (intensity) and affective (unpleasantness) dimensions. The sensation of dyspnoea is not unique to respiratory diseases, but may be also be experienced in cardiovascular, neuromuscular, and malignant diseases. Furthermore, dyspnoea may be present in healthy individuals who are obese and/or deconditioned.

Dyspnoea is common in the acute setting, affecting up to 50% of patients requiring hospital admission or 25% of patients seeking ambulatory assistance [2]. Chronic shortness of breath is reported in over 90% of advanced chronic obstructive pulmonary disease (COPD) patients and > 60% of patients with advanced heart disease [3]. Among the general population mild-to-moderate dyspnoea may be observed in roughly 15% of adults aged over 40 years, and roughly 30% of adults aged over 70 years [4].

Pathophysiology

Breathing discomfort arises as a result of complex interactions between signals relayed from the upper airways, the chest wall, the lungs, and the central nervous system. Integration of this information with higher brain centres provides further processing. The final aspects of the sensation of dyspnoea are influenced by contextual, environmental, behavioural, and cognitive factors.

Chemoreceptors

Blood variations in pH, $PaCO_2$ and PaO_2 are sensed by central chemoreceptors in the medulla and peripheral chemoreceptors in the carotid and aortic bodies. The effect of $PaCO_2$ is primarily mediated through chemoreceptor changes in hydrogen ion (and thus pH). Increased chemoreceptor activation results in afferent information reaching respiratory motor centres, triggering their activity. In healthy subjects, hypercapnia and severe hypoxaemia cause breathlessness. Studies in quadriplegics with spinal cord transaction indicate that hypercapnia elicits a reflex increase of respiratory centre motor output. Resulting dyspnoea is therefore an expression of involuntary reflex respiratory activity, rather than increased voluntary respiratory muscle activity [5]. Patients with congenital central hypoventilation syndrome lack a ventilator response to CO_2. These subjects do not feel breathless during CO_2 rebreathing or protracted breath hold.

Chest wall receptors

Mechanoreceptors in the joints, tendons, and muscle spindles of the chest sense muscle tension and contraction, and send afferent signals to the somatosensory cortex in the brain. This information contributes to proprioception and kinaesthesia. The central areas receiving information from chest wall afferents may have a role in gating the intensity of the dyspnoea sensation. Vibrations of the chest wall in phase with respiration (vibration of inspiratory muscles during inspiration and expiratory muscles during expiration) attenuate breathlessness, whereas out-of-phase vibrations worsen dyspnoea [6]. Thus, chest wall mechanoreceptors may have an important modifying effect on dyspnoea, rather than playing an essential role in generating the perception of dyspnoea per se.

Airway vagal receptors

Receptors present in the airways and the lung relay afferent information via vagus nerve fibres. These include cold receptors, slow-adapting stretch receptors (SARs) and rapidly-adapting stretch receptors (RARs), and C-fibre receptors. Stimulation of cold receptors in the upper airways relieves dyspnoea, as evidenced by sources of cool air directed onto the face [7]. SARs are present in the smooth muscle cells of the large airways. Stimulation of these receptors is also associated with reduced sensation of dyspnoea. RARs react rapidly to sustained inflation or deflation of the lungs, and may be associated with dyspnoea sensation in conditions such as pneumothorax and asthma. Stretch receptors are mainly involved in pulmonary stretch and cough reflexes, modulating airway calibre and ventilator pattern. Their activation permits awareness of the level of ventilation and dilation of the lungs, thus contributing to the overall sensation of dyspnoea. Juxta-pulmonary capillary receptors (J receptors) are localized close to alveolar capillaries and respond to increases in interstitial fluid. Pulmonary C-fibres are located in the lung parenchyma, whereas bronchial C-fibre receptors are located in the airways. Stimulation of these receptors with a number of agents (e.g. capsaicin) induces respiratory sensations such as cough, but not breathlessness in humans. In contrast, adenosine activation of C-fibre receptors is dyspnogenic [8].

Central processing of dyspnoea

Afferent information from chemoreceptors, airway and chest sensors reach the nucleus tractus solitarius (NTS) in the medulla. The NTS is a key site where all peripheral afferent signals are processed prior to presentation to higher centres. Information from the NTS is first projected to the thalamus. The thalamus relays information to areas of the limbic system, such as the insula, the amygdala, and the anterior and posterior insular cortex. These cortical structures are also involved in the perception of other sensations, such as pain, nausea, hunger, and thirst. It is possible that common areas of the brain process the unpleasant perception of different sensations. The anterior insular cortex is thought to play a central role in the conscious awareness of dyspnoea, rather than just processing information. Patients with lesions of the insular cortex present reduced perception of dyspnoea and pain [9].

Corollary discharge

When the brainstem and the motor cortex send outgoing efferent commands to the ventilator muscles, a neurological copy of this information is sent to the sensory cortex. This exchange between the motor and sensory cortex is known as corollary discharge. Corollary discharge is thought to be the mechanism through which conscious awareness of the effort of breathing occurs.

Therefore, afferent information from chemoreceptor and peripheral receptors shapes the motor neural output to the respiratory system. A copy of this information is relayed to the sensory cortex. If afferent feedback to the sensory cortex indicates that the neural motor output does not produce the expected results in terms of airflow or ventilation, a sensation of dyspnoea is generated [10]. It is assumed that the cortical centres possess a pre-existing memory of expected respiratory response to given intensity of motor commands, and that a mismatch between afferent/efferent information and pre-existing memory determines the intensity of dyspnoea. Respiratory disruption leads to distressing emotions, thus eliciting behavioural adaptations.

Qualitatively distinct sensations of dyspnoea

Dyspnoea is not a single sensation. Using patient questionnaires, at least three qualitatively distinct sensations have been employed to describe discomfort in breathing. These are:

- Air hunger.
- Increased effort or work of breathing.
- Chest tightness.

These different sensations are, at least in part, associated with diverse pathophysiological mechanisms.

The sensation termed as 'air hunger' may be defined by patients as unsatisfied inspiration, needing more air, not getting enough air, an unpleasant urge to breath, etc. Air hunger has been shown to be associated with the stimulation of chemoreceptors, such as by hypoxia, hypercapnia, or acidosis, which results in increased spontaneous respiratory drive. Information regarding this increased spontaneous respiratory motor drive activity of the brainstem is conveyed to the cerebral cortex as corollary discharge. When this is not matched by an adequate ventilator response, individuals perceive air hunger. This seldom happens in healthy individuals, except at strenuous exercise levels. Conversely, in cardiac or respiratory conditions, the capacity to provide the additional ventilation required by the increased motor drive activity is limited. This creates an imbalance between the motor drive to breathe, as sensed by corollary discharge, and afferent feedback from mechanoreceptors on the ventilatory response of the respiratory system. The intensity of the sensation of air hunger may be regulated by inhibitory activity from mechanoreceptors. In fact, pulmonary stretch receptor and chest wall afferent information is capable of relieving the sensation of air hunger through signalling the level of current ventilation. Therefore, the perceived severity of the sensation of air hunger is the result of a balance between medullary respiratory motor discharge and simultaneous mechanosensor feedback. Air hunger is not specific to any particular disease or stimulus.

A sense of increased effort of breathing has also been termed as 'difficult breathing', 'breathing takes a lot of work', or 'breathing takes effort'. Chest wall volume variations during breathing activate respiratory muscle afferent information that projects to the cerebral cortex. During normal breathing or exercise in healthy subjects, unless physiological capacity to match ventilation to metabolic demand is surpassed, afferent mechanoreceptor feedback signals that breathing is appropriate to the prevailing respiratory drive. In clinical conditions that impair respiratory muscle performance through abnormal mechanical loads (COPD, asthma, or interstitial lung disease) or when respiratory muscles are weakened (neuromuscular diseases), increased work of breathing generates greater muscle afferent cortical projections that induce motor cortical increase in voluntary breathing drive. Corollary discharge from cortical motor centres to cortical sensory centres increases awareness of cortical motor command and thus contributes to generating the work/effort dyspnoea sensation. Therefore, whereas air hunger is the result of perceived increased **spontaneous** brainstem ventilatory drive through chemoreceptor stimulation, work/effort is the result or perceived increased **voluntary** cortical motor centre activity associated with increased work of breathing.

A sensation of 'chest tightness' is often experienced by asthmatic patients during episodes of acute bronchoconstriction and may alternatively be described as 'chest is constricted' or 'chest is tight'. This sensation may be prevalent during the early phases of

an asthma attack. With increasing severity of bronchoconstriction, hyperinflation may ensue, giving rise to a work/effort sensation. In fact, patients describe that the feeling of chest tightness rapidly responds to albuterol administration [11], whereas the work/effort sensation is best alleviated by mechanical ventilation. It has been suggested that chest tightness develops through stimulation from pulmonary receptor afferents, such as C-fibres or RARs, which respond to bronchoconstriction. Blocking such afferent information relieves the sensation of tightness.

Quantification of dyspnoea

Measurement of dyspnoea is essential in order to assess it adequately and monitor response to treatment. Dyspnoea assessment may be carried out thorough different scales, questionnaires or exercise tests. It must be recognized that different tools measure different aspects of breathlessness. For example, some tools address the intensity of dyspnoea, others the unpleasantness associated with breathlessness, whereas others investigate the impact on dyspnoea on performing tasks or on quality of life. It is important to understand whether a patient is reporting 'how much' or 'how bad' the symptom is. Rating may be influenced by the condition giving rise to the dyspnoeic symptom: healthy adults under laboratory conditions are more prone to report dyspnoea intensity, whereas a COPD patient may give ratings dominated by unpleasantness.

Measures of intensity include the Borg scale, and the visual analogue scale. So far, measures of the affective component have been relatively little used in the context of dyspnoea compared with other sensations such as pain. However, there is evidence that intensity and affective dimensions of breathlessness can meaningfully be distinguished during laboratory challenges [12], and may be thus usefully employed in clinical practice.

Measures of the impact of dyspnoea on functional ability or quality of life encompass both one- and multidimensional rating scales. Examples of the former include the Medical Research Council (MRC) five-point scale that asks the patient to indicate the level of activity that evokes dyspnoea, ranging from strenuous exercise to resting conditions. Multidimensional ratings include the Saint George Respiratory Questionnaire (SGRQ), a 76-item questionnaire involving three areas—symptoms, activity, and impact on daily life.

Dyspnoea management

Management of both acute and chronic forms of dyspnoea should be targeted to optimizing medical treatment of the underlying condition. However, in many cases, maximal medical treatment is ineffective in controlling breathlessness and the symptom persists. This requires the adoption of measures that impact on the symptom per se. Strategies in controlling dyspnoea should not focus uniquely on decreasing dyspnoea intensity. Patients may favourably profit from interventions that decrease the unpleasantness associated with breathlessness without necessarily affecting the intensity component of the symptom. Consequently, both pharmacological and non-pharmacological coping strategies may be of use in bedside clinical management.

Opioids

Administration of opioids relieves dyspnoea in a number of different clinical conditions such as COPD, interstitial lung diseases, cancer, and heart failure. Opioids may attenuate breathlessness via different mechanisms. On the one hand, opioids are respiratory depressants that blunt the central processing of neural signalling related to breathing status and result in decreased motor respiratory command and ventilatory drive. On the other hand, these drugs also alter perceptual sensitivity, thus decreasing patient perception of breathlessness. Therefore, these agents affect both the 'intensity', and the 'unpleasantness' associated with dyspnoea. The side effects of opioids include altered mental status, hypercapnic respiratory failure, constipation, nausea, and vomiting. Opioid administration is still underused in conditions such as COPD, possibly due to clinician fear of precipitating respiratory acidosis. Nonetheless, a systematic review [13] indicated that opioids are associated with a significant 16% improvement in dyspnoea intensity, and a randomized control trial supports the notion that opioids are both effective and safe in patients with refractory dyspnoea [14]. Although opioid receptors are present on sensory nerves in the airways, current evidence does not support the use of nebulized morphine in relieving dyspnoea [13].

Anxiolytic agents

Similarly to opioids, anxiolytic agents may exert a two-fold positive effect in breathless patients by depressing hypoxic—or hypercapnic-induced increases in respiratory drive and dampening emotional responses to dyspnoea. Nonetheless, clinical trials have failed to indicate consistent superiority over placebo for various benzodiazepine derivatives [15], indicating that these drugs should not be routinely employed in the management of dyspnoea. Their use may be considered in individual patients, particularly when anxiety components are critical symptom determinants.

Oxygen therapy

In hypoxic patients, oxygen administration decreases peripheral chemoreceptor activity, thereby causing a reduction in hypoxic ventilatory drive, and thus relieving dyspnoea. Conversely, oxygen use in non-hypoxaemic advanced-stage respiratory and cardiac patients has not been convincingly demonstrated to be of benefit as a symptom reliever, and should not be routinely employed.

Other pharmacological approaches

Novel treatment approaches are currently being evaluated in the management of dyspnoea. Nebulized furosemide decreases breathlessness in healthy volunteers, possibly through the mediation of vagal efferents [16]. Retrosternal block with injection of 35–50 mL of lidocaine 1% attenuates dyspnoea, either through changes in afferent information from chest wall and respiratory muscles, or by direct inhibitory effects on cholinergic airway pathways [17].

Non-pharmacological approaches

Pulmonary rehabilitation in patients with chronic lung diseases is associated with reduced exertional dyspnoea and improves exercise tolerance. The benefit likely derives from multiple mechanisms, including improved physical conditioning, pacing of activities, and desensitization to respiratory distress. Chest wall vibration in COPD patients relieves dyspnoea at rest, but not during exercise [6], probably through the activation of muscle spindles in the intercostals muscles causing modified respiratory sensations. Dyspnoeic patients report that movement of cool air through a fan is associated with symptom relief. Cold

air on the face attenuates dyspnoea in healthy individuals [7], and preliminary data indicate some activity in clinical practice [18]. Neuromuscular electrical muscle stimulation over 4–6 weeks attenuates dyspnoea in COPD patients, and may be of particular use in patients who are unable to exercise [19]. A number of additional techniques have been insufficiently tested as dyspnoea-relief modalities, such as acupuncture, yoga, or relaxation, self-efficacy dyspnoea management, cognitive-behavioural psychotherapy, and educational counselling, and are currently not recommended for routine use [20].

CHAPTER 84

Pulmonary mechanical dysfunction in the critically ill

Umberto Lucangelo and Massimo Ferluga

Key points

- Modern ventilators display real time curves, which can help the physician to understand the interactions between the patient and the ventilator.
- In patients undergoing mechanical ventilation, measurements of respiratory mechanics can be performed at the bedside in dynamic or static conditions.
- In flow-limited chronic obstructive pulmonary disease (COPD) patients, the expiration is interrupted by the next breath and, therefore, the end-expiration volume remains trapped into the alveoli. This phenomenon is called **dynamic hyperinflation** and also depends on the tidal volume, the expiratory time, the resistance and the compliance of the respiratory system.
- Patient–ventilator synchrony represents a main goal in the management of the mechanically-ventilated patient. The correct interpretation of the waveforms provided by the monitor can help the physician to set properly the ventilator.
- The variables that should be monitored during mechanical ventilation are airway pressure, flow, tidal volume, and minute ventilation, whereas positive end-expiratory pressure (PEEP) and mean airway pressure gain significance in acute respiratory distress syndrome.

Introduction

Modern ventilators employed in intensive care units (ICUs) display in real time and breath by breath flow ($\dot{V}$), volume (V), and pressure (P_{aw}) curves, both as a function of time and as a loop. Data obtained from curve analysis can help the physician to understand the interactions between the patient and the ventilator. The right interpretation of information provided from modern ventilators allows real time monitoring of the actual needs of the patient, ensuring a custom ventilatory support and reducing the risk of complications that can increase the mortality and prolong the ICU length of stay. In patients undergoing mechanical ventilation, measurements of respiratory mechanics can be performed at the bedside in dynamic (no flow interruption) or static (occlusion techniques) conditions. From these, it's also possible to derive the values of pulmonary compliance and airway resistance [1].

Dynamic conditions

In dynamic conditions, without flow interruption, the values of resistance (R_{rs}) and compliance (C_{rs}) of the respiratory system are obtained by inserting in the equation of motion, the values of airway pressure (P_{aw}), flow, and volume, provided by the ventilator time after time, and applying a multiple linear regression (least square fitting, LSF) [2]. This allows the derivation of the mean values of compliance and resistance of the respiratory system using the numerical values derived from repeated statistical operations performed on a single breath. If there is a limitation of expiratory flow, such as in chronic obstructive pulmonary disease (COPD) patients, it is appropriate to restrict the analysis at the inspiratory phase alone, since it was shown that this condition significantly undermines the accuracy of the measurements of resistance and compliance, compared with traditional (end-inspiratory occlusion). Since in volume-controlled ventilation (VCV) the flow remains constant during the whole inspiratory tract, the pressure–time curve can be considered as a pressure–volume or elastance curve. From the analysis of his shape it is possible to recognize hyperinflation of the lung, which can lead to barotrauma, and the alveolar recruitment phenomenon—both requires an adjustment of the ventilatory parameters [3].

Static conditions

Instead, in static conditions, the monitoring is provide by the multiple occlusion technique and requires a square flow waveform. If a pause is inserted at the end of the inspiratory phase, it can be possible to distinguish, analysing the pressure–time curve of the ventilator, the drop in pressure due to the resistive forces from that due to the elastic component of the respiratory system. The pressure–time curve takes a characteristic shape, with an end-inspiratory peak (P_{peak}) followed by a rapid drop (P_1), which precede a slow decay until the achievement of the plateau pressure (P_{plat}). If the end-inspiratory pause is long enough to permit both lungs to reach equilibrium, the plateau pressure can be assimilated to the alveolar pressure (P_{alv}). The pressure difference between P_{peak} and P_1 depends on the flow and resistance variations of the endotracheal tube and the airways, whereas P_1–P_{plat} depends on the **pendelluft** phenomenon, i.e. the shift of air from alveoli with short time constant to alveoli with fast time constant, and on the visco-elastic properties of the respiratory system (Fig. 84.1). The analysis of the pressure–time curve can give some useful information about the respiratory system: the P_{peak} can rise during bronchospasm episodes or presence of bronchial secretions and if a too small endotracheal tube size is used. A slow achievement of the P_{plat} suggests the presence of a flow limitation disease, whereas the missed reaching of it can tell on leaks of the respiratory circuit [4].

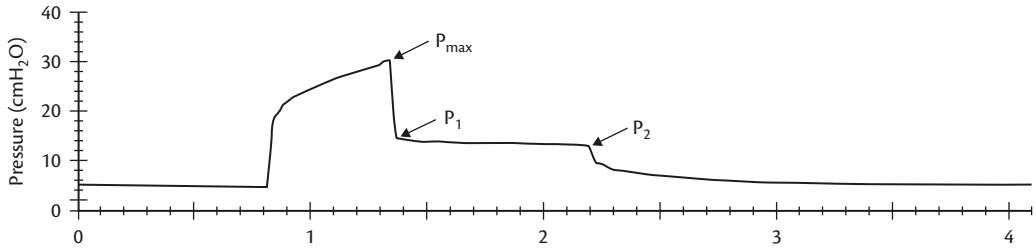

Fig. 84.1 Post-inspiratory and expiratory occlusion is performed. P_{max} is the maximum (peak) airway pressure. P_1 points to the end of the rapid post-occlusion pressure drop. P_2 points to the end of the slope pressure decay plateau.

Dynamic hyperinflation

In physiological conditions, at the end of expiration, the lungs reach the functional residual capacity, but if a flow limitation subsists, i.e. COPD patients, the expiration is interrupted by the next breath and, therefore, the end-expiration volume do not reach the functional residual capacity (FRC) and remain trapped into the alveoli, whereas it can be seen as a continuous expiratory flow. This phenomenon is called **dynamic hyperinflation** (also note as auto-PEEP or $PEEP_i$) and also depends on the tidal volume, the expiratory time, and the resistance and the compliance of the respiratory system [5]. This phenomenon could also present in the absence of conditions limiting the expiratory flow, such as high volume ventilation or an increase in the resistance of the ventilation circuit (i.e. the presence of secretions in the endotracheal tube with narrowing of the lumen) with the consequence that the lungs do not have the time to reach the functional residual capacity, which means that at the end of expiration it is still possible to detect the presence of an expiratory flow, supported by the pressure gradient between the alveoli and the atmosphere.

In paralysed patients or patients who have become well adapted to the ventilator and undergoing mechanical ventilation, it is possible to recognize the existence of dynamic hyperinflation of the lungs observing the flow and pressure curves at the end of expiration (dynamic autoPEEP). Whenever the end-expiratory flow does not reach zero, the respiratory system is considered to be hyperinflated, i.e. the alveolar pressure is greater than the atmospheric pressure or the PEEP applied. The autoPEEP can be also measured by inserting an end-expiratory occlusion, and is called static autoPEEP. This is because the dynamic autoPEEP reflects the instantaneous pressure value of short time constant lung units, while the longer time constant pulmonary units are still being emptied. The occlusion manoeuvre allows the lung units to equilibrate. Furthermore, to avoid underestimation, the value of static compliance should be measured correctly according to the presence of autoPEEP. The increase in volume due to the application of a PEEP or a condition of dynamic hyperinflation can be measured disconnect the patient from the ventilator or prolonging the expiratory time to allow the patient to reach the FRC. Once they reach the equilibrium, the patient is reconnected to the ventilator and it can be seen that the initial volume inspired will be greater than the volume expired. In the absence of extrinsic PEEP, the difference between the volume inspired and expired corresponds to the volume of air trapped in the lungs at the end of expiration. If an extrinsic PEEP is applied, the end-expiration volume observed will be the result of the sum of two components—the PEEP applied and the PEEP due to dynamic hyperinflation.

Patient–ventilator interaction

Patient–ventilator synchrony represents one of the main goals in the management of the mechanically-ventilated patient in the ICU [6]. It has been shown that up to 25% of ventilated patients exhibit problems of interaction with the ventilator and that this may be associated with increased duration of ventilatory support. The correct interpretation of the waveforms provided by the monitor can help the physician to correctly set the ventilator. Two variables determine the breath delivery in a modern positive pressure ventilator—the trigger and the cycling-off variable. The first one determines the start of the mechanical breath and can be pressure- or flow-regulated. With pressure triggering, the ventilator is able to detect the drop in airway pressure generated by the inspiratory effort of the patient—if the effort is effective, i.e. the reduction of pressure is equal to or above the threshold value set by the machine (usually between –0.5 and –1 cmH_2O), the ventilator delivers a breath. The erroneous application of a pressure trigger (e.g. a too high value in relation to the patient's muscle strength) increases the work of breathing and promotes patient–ventilator asynchrony. The consequence of this phenomenon is the need for patient sedation, lengthening the weaning from mechanical ventilation. When the physician reduces the sensitivity of the pressure trigger (i.e. the patient must generate more negative pressure to trigger the ventilator), that inevitably increases the number of ineffective breaths. They appear on the monitor like negative deflections on the pressure curve, which would not be followed by a positive deflection in the volume curve, in other words, the effort of the patient is not followed by the provision of a mechanical breath.

With a flow trigger system, the ventilator provides the ventilation circuit with a constant flow (bias flow), measured continuously at the inlet and at the outlet. When the value of the bias flow in output is lower than that in entry (and in the absence of leak in the system or when that is compensated), it means that the patient has performed an inspiratory effort and the ventilator then provides a breath even before any change of pressure in the system. The flow trigger decrease the inspiratory work, but on the other hand, promotes the phenomenon of self-triggering, i.e. incorrect triggering of breaths due to registration of changes in flow, which are not attributable to a patient's inspiratory effort (e.g. leak in the circuit, water in the circuit, and cardiogenic oscillations). Understanding the mechanisms that regulate the ventilation with flow triggering is crucial during non-invasive ventilation through a helmet or mask. The presence of leak in the system means that the bias flow needs to be set higher in order to avoid the phenomenon of self-triggering and promote patient–ventilator synchrony, ensuring adherence to the treatment.

The cycling-off variable determines how the ventilator terminates the inspiration. Usually, the criterion used in patients without inspiratory effort is time, whereas during assisted ventilation flow or pressure was preferred. When pressure is used, the ventilator opens the expiratory valve and begins the expiration when the airway pressure increases above a predetermined threshold (usually 1–3 cmH_2O), due to expiratory muscle contraction or sudden relaxation of inspiratory muscles. On the contrary, flow cycling-off occurs when inspiratory flow decreases to a preset flow value (usually a percentage of the peak inspiratory flow, 25–50%). Regardless of the type of cycling-off criterion used, the end of mechanical inspiration should coincide with the end of neural inspiration, but this synchrony is as yet not obtainable. In fact, expiratory asynchrony is common in ICU and occurs in two ways—premature or delayed termination of mechanical inspiration. The first one occurs when the exhalation valve is open, while the neural inspiration is still ongoing. The flow wave did not reverse from inspiratory to expiratory due to elastic recoil of the respiratory system, but remained around the zero line, indicating that the inspiratory effort should continue. In addition, if the remaining effort is sufficient to meet the trigger set, it generates another mechanical breath, leading to the phenomenon of so-called double trigger or breath stacking. In other words, the delayed opening of the exhalation valve can be observed on the ventilator when there is a rapid decrease of the inspiratory flow toward the end of mechanical inspiration. It should be noted, that, as mentioned previously, if the premature expiratory effort increases the pressure of the system above a predetermined threshold, the exhalation valve opens, and the expiration can start.

Capnography and CO_2 clearance

The advanced technology combination of airway flow monitoring and mainstream capnography enables a non-invasive breath-by-breath bedside calculation of CO_2 elimination per breath, independent of set ventilatory parameters. Carbon dioxide kinetics depend on three factors—peripheral production, cardiac output, and alveolar ventilation. If catabolism is assumed to be constant, haemodynamic or alveolar ventilation modifications produce typical volumetric capnographic curves. It is generally known that all situations producing a decrease in lung flow (pulmonary embolism and severe haemorrhage) affect the capnographic wave, which decreases in width. This phenomenon is due to the decrease in pulmonary blood flow, alveolar ventilation being equal. In this situation, the shape of phase III on volumetric capnograms (CO_2/V_T curve) does not vary except in width, and VCO_2 elimination decreases. Lung pathologies affect CO_2 washout, altering both convective and diffusive processes, as well as the time, available cross-section, and intra-airway concentration gradient. Bronchial obstruction makes regional alveolar ventilation inhomogeneous, altering the normal V/Q ratio. This determines different readings of CO_2 alveolar pressure that are asynchronously exhaled, changing the shape of the CO_2/V_T curve, with a prevalent increase in the slope of phase III [7].

Recently, a new index, the fraction between alveolar ejection volume and tidal volume (V_{AE}/V_T), was introduced by Lucangelo et al. [7]. Briefly, VCO_2 plotted as a function of expired volume originates a VCO_2/V_T curve (Fig. 84.2). From this curve, the last 50 points of every cycle were back-extrapolated by least-square linear regression analysis representing the ideal lung behaviour. Assuming a fixed amount of dead space contamination of 5% (dead space allowance), a straight line having its maximal value at end-expiration and slope of 0.95 (1-dead space allowance) times that of the ideal line is plotted. Alveolar ejection begins at the intersection between the VCO_2/V_T curve and the linear regression. The volume between this point and end-expiration is V_{AE}, and this is expressed as a fraction of expired tidal volume. Lucangelo et al. [7] demonstrated that V_{AE}/V_T represents a valid prognostic value in acute respiratory distress syndrome patients and is less dependent on haemodynamic variations.

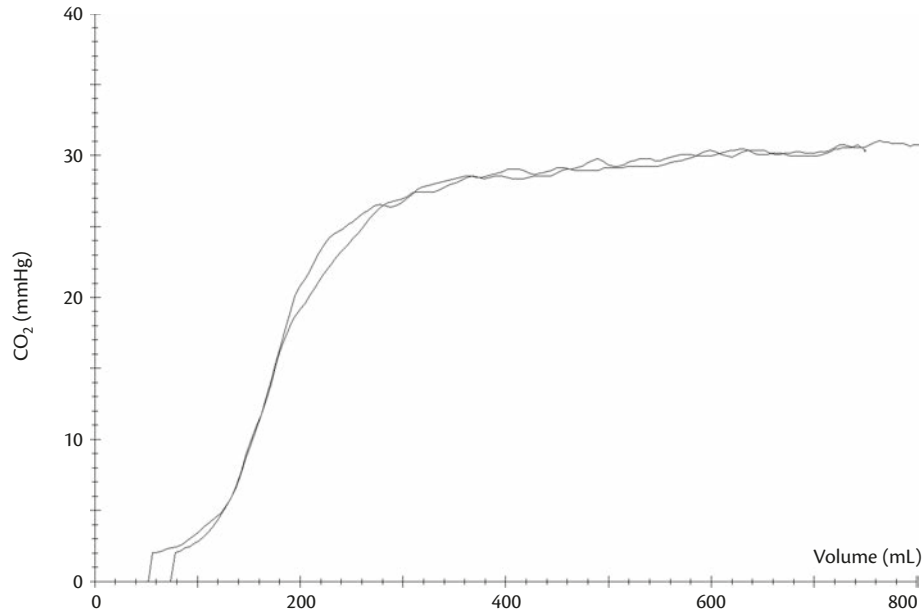

Fig. 84.2 Normal volumetric capnogram.

Conclusion

In conclusion, the only variables of crucial significance to the vast majority of patients are airway pressure, flow, tidal volume, and minute ventilation, which also provides useful data regarding the synchrony of patient–ventilator interactions.

CHAPTER 85

Hypoxaemia in the critically ill

Susannah Leaver and Timothy Evans

Key points

- Hypoxaemia is reduced arterial oxygen tension (usually below 8 kPa). Hypoxia is an inadequate oxygen supply to the tissues.
- Hypoxaemia can result from a ventilation (V)/perfusion (Q) mismatch, anatomical (intrapulmonary, intracardiac) shunt, diffusion limitation, and/or hypoventilation. In clinical practice, a combination of these factors is usually responsible.
- Diagnosis is based on a clinical history and examination, with appropriate blood tests, imaging and physiological tests.
- Management involves securing the airway (if required), correcting hypoxaemia by increasing inspired oxygen concentration (FIO_2) and where necessary instituting respiratory support (mechanical, extracorporeal, non-invasive/invasive).
- The precipitating cause should be identified and treated.

Definition

The term hypoxaemia is defined by a reduction in the partial pressure of oxygen in the blood below 8 kPa/60 mmHg (normal range 10–13.3 kPa/75–100 mmHg). Hypoxia has no precise or quantitative definition, but describes inadequate oxygen supply to the tissues.

Acute respiratory failure (ARF) has conventionally been divided into hypoxaemic (type I) and hypoxaemic/hypercapnic (type II) subgroups. Type I is the principle focus of this chapter. Ventilatory/hypercapnic (type II) respiratory failure is the presence of hypoxaemia with hypercapnia ($PaCO_2$ >6.5 kPa/50 mmHg, normal range 4.5–6.2 kPa/35–45 mmHg). In clinical practice, type II can occur following type I if the underlying cause is not corrected.

Pathophysiology of hypoxaemia

Different causes of hypoxaemia are discussed below as separate entities [1], but in the critically ill a combination of these is usual.

- **Ventilation/perfusion mismatch:** In the perfect lung, each alveolus would be ventilated by a volume of gas equal to that of the blood perfusing it. However, even in normal physiological circumstances ventilation/perfusion (V/Q) mismatch exists. Both V and Q are greater in the anatomically dependent parts of the lung, which vary with posture (i.e. erect supine and prone), although while ventilation diminishes slowly across the relevant gradient (bases to apices when upright) perfusion decreases faster. V/Q mismatch is therefore greater in the lung apices. V/Q mismatch is responsible for the normal alveolar–arterial (A–a) gradient. In the diseased lung, V/Q mismatch increases as both become more heterogeneous resulting in hypoxaemia. If alveoli are ventilated and not perfused, such as occurs following pulmonary thromboembolism, a proportion of ventilation is wasted and behaves as dead space. By contrast, if alveoli are perfused and not ventilated, for example, in pneumonia, oxygenation of the blood is impaired through intrapulmonary shunt. Increased V/Q mismatch increases A–a gradient and is the commonest cause of hypoxaemia.
- Right-to-left shunt occurs when blood bypasses ventilated areas of lung. There are two types:
  - **Anatomical**: alveoli are bypassed, for example, via intracardiac shunts or pulmonary arteriovenous malformations.
  - **Physiological (intra-pulmonary) shunt**: blood passes through non-ventilated areas, for example, when alveoli are collapsed (atelectasis), consolidated (pneumonia), or fluid-filled (pulmonary oedema).
- **Diffusion limitation**: transfer of oxygen across the alveolar-capillary membrane is impaired due to alveolar and/or interstitial inflammation or fibrosis.
- **Hypoventilation**: causing low alveolar oxygen tension (PAO_2). PAO_2 is determined by the rate of oxygen extraction from the blood by the tissues, and is therefore dependent on the metabolic demands of tissues (oxygen consumption); and the supply of oxygen to the alveoli, which reflects alveolar ventilation. Low PAO_2 thereby reduces the rate of diffusion of oxygen from the alveoli to the pulmonary capillaries and hypoxaemia ensues. Carbon dioxide is retained, and arterial and alveolar PCO_2 rise. In accordance with the simplified alveolar gas equation (eqn 1) alveolar oxygen concentration falls further, but will rise if supplementary oxygen is administered.

$$PAO_2 = PIO_2 - \left(PaCO_2 / R\right) \qquad \text{[eqn 1]}$$

where PAO_2 is the alveolar partial pressure of oxygen, PIO_2 is the inspired partial pressure of oxygen, $PaCO_2$ is the arterial tension of carbon dioxide, R is the respiratory quotient.

Other causes of hypoxaemia include decreased inspired oxygen tension, such as occurs at high altitude, decreased mixed venous oxygen saturations (e.g. in anaemia or low cardiac outputs states) and changes in affinity of haemoglobin for oxygen due to a shift in the oxygen dissociation curve.

Diagnosis

History and examination

Hypoxaemia can manifest clinically in a number of ways (Box 85.1). The history and physical examination must be comprehensive as ARF may result from pulmonary or extrapulmonary causes.

Box 85.1 Signs of respiratory distress

- Respiratory rate >25/min or <8/min—the most sensitive indicator.
- Cyanosis.
- Inability to speak full sentences.
- Use of accessory muscles of respiration.
- Sweaty/clammy.
- Tachycardia/arrhythmias.
- Stridor/obstructed airway.
- Inability to lie flat.
- Pulsus paradoxus.
- Restlessness/agitation.
- Reduced conscious level.

Recording observations and calculating a clinical (early warning) score may facilitate recognition of impending or actual hypoxaemia. By contrast, delays adversely affect outcome. ARF is a dynamic process and frequent reassessment is required. A differential diagnosis of acute type I hypoxaemia is displayed in Box 85.2.

Investigations

Blood tests and infection screen

Abnormalities in common haematological and biochemical indices aid diagnosis (raised C-reactive protein indicating infection, raised B-type natri-uretic peptide indicating pulmonary oedema) and the identification of other organ system failures (e.g. acute kidney injury, disseminated intravascular coagulopathy) and/or previously unknown premorbid conditions. Furthermore, anaemia contributes to tissue hypoxaemia and polycythaemia might be secondary to chronic hypoxaemia.

Sepsis is commonly associated with acute respiratory insufficiency and a full infection screen should be sent. In immunosuppressed or immunocompromised patients evidence of fungal infection and tuberculosis should be sought. *Pneumocystis jirovecii* can induce type 1 respiratory failure.

Box 85.2 Differential diagnosis of acute type I hypoxaemia

- Exacerbation COPD/asthma.
- Pulmonary oedema.
- Pulmonary embolism.
- Pneumonia.
- Aspiration.
- Lobar collapse.
- Pneumothorax.
- Pleural effusion.
- Pulmonary contusion (blunt chest trauma).
- ALI/ARDS (pulmonary or extra-pulmonary).

Arterial blood gas

Arterial blood gas measurement quantifies the severity of hypoxaemia, identifies the type of respiratory failure and can provide information regarding metabolic status, haemoglobin, electrolytes, and lactate.

The defining criteria for respiratory failure are most applicable to patients breathing room air. When oxygen supplements are administered, calculating the A–a gradient or PaO_2:FIO_2 ratio is more useful in determining the severity of hypoxaemia.

The alveolar–arterial (A–a) gradient

The A–a gradient is the difference between the amount of oxygen in the alveoli (PAO_2) and the amount of oxygen in the blood (PaO_2) (eqn 2). Therefore:

$$\text{A} - \text{a gradient} = PAO_2 - PaO_2 \qquad \text{[eqn 2]}$$

PaO_2 is measured by arterial blood gas analysis and PAO_2 derived from the alveolar gas equation (eqn 1). Normal A–a gradient is age-dependent and in healthy adults is <3.5 kPa (26 mmHg). Hypoxaemia with a normal A–a gradient is secondary to alveolar hypoventilation (raised $PACO_2$), low PIO_2 or low barometric pressure <760 mmHg, whereas hypoxaemia associated with an elevated A–a gradient is secondary to V/Q mismatch, right–left shunt, a diffusion defect or increased oxygen extraction.

The PaO_2:FIO_2 (P:F) ratio

The ratio of partial pressure of oxygen in the blood to inspired oxygen concentration also defines the severity of hypoxaemia (normal value of > 40 kPa, >300 mmHg). P:F ratio is used to define acute respiratory distress syndrome (ARDS) with mild moderate and severe ARDS defined as values of <40 kPa, <300 mmHg; <26.6 kPa, 200 mmHg, and <13.3 kPa, <100 mmHg, respectively.

Imaging

Chest radiography is mandatory in any patient with respiratory failure and may reveal abnormalities suggestive of pneumonia, lobar collapse, pulmonary oedema, or pneumothorax. Conversely, in asthma or chronic obstructive pulmonary disease (COPD) it might be normal.

Bedside ultrasound is an increasingly recognized useful diagnostic adjunct, which can assist in revealing pleural effusions, and facilitates safe diagnostic aspiration or therapeutic drainage. Removal of fluid can improve hypoxaemia through enhanced ventilation and increased pulmonary compliance. In experienced hands, ultrasound can aid the diagnosis of a pneumothorax when suspected clinically.

Transporting critically-ill patients is not without risk, but thoracic computed tomography (CT) can identify pathologies such as pulmonary emboli, pneumothoraces, small pleural effusions, parenchymal infiltrates, and abscess cavities that are not apparent on plain chest radiography.

Electrocardiogram and echocardiography

Electrocardiogram (ECG) and echocardiography can help to exclude a cardiac cause of hypoxaemia, and differentiate between acute pulmonary oedema and ALI/ARDS, as well as identify right heart strain secondary to massive pulmonary embolism.

Fibre optic bronchoscopy

Fibre optic bronchoscopy can be used for therapeutic reasons such as to alleviate endobronchial obstruction or for diagnostic purposes

to obtain samples for microbiology or cytology, or to identify the source or bleeding in patients with haemoptysis.

Principles of management

Clearly, if the patient is 'in extremis' or in cardiopulmonary arrest the airway breathing circulation disability exposure (ABCDE) algorithm advocated by advanced life support guidelines should be adopted [2].

Once identified, the principles of management of hypoxaemia are:

- Securing the airway if required.
- Correcting hypoxaemia by increasing inspired oxygen.
- Identifying and treating the precipitating cause.
- Control of secretions.
- Instituting respiratory support (invasive/non-invasive) if necessary.

Airway management

In assessing a critically-ill patient ensuring a patent airway and adequate oxygenation takes priority even in the absence of a specific diagnosis. Simple procedures, such as head positioning (head tilt, chin lift, jaw thrust), removal of obstructions, such as vomitus or dentures, and airway adjuncts, such as nasopharyngeal or oropharyngeal airways may be sufficient. However, application of positive pressure using bag-mask supplementation, escalating to non-invasive intermittent positive pressure ventilation (NIV) administered by mask or other interface, or to endotracheal intubation and invasive ventilatory support might be required. Common indications for endotracheal intubation are displayed in Box 85.3.

Box 85.3 Indications for intubation

Inability to protect airway

- Excessive secretions.
- Obtunded patient (GCS <8).

Failure of ventilation

- Airway obstruction.
- During cardiopulmonary or respiratory arrest.
- Hypercapnia with impaired conscious level.
- Respiratory rate <10 breaths/min.

Failure of oxygenation

- Life threatening hypoxaemia.
- PaO_2 <8 kPa or sats <90% despite FiO_2 >0.6 and CPAP.

Anticipated need for ventilation

- Failure of NIV or CPAP.
- Deteriorating parameters despite optimal treatment.
- Exhaustion RR>40 breaths/min.
- In patients with neuromuscular disease (vital capacity <15 mL/ kg (normal 65–75), <1 L or <30% predicted).

Correcting hypoxaemia

Supplementary oxygen is always indicated in patients with acute hypoxaemia and should improve oxygenation in all cases except those with true right to left shunt. Oxygen can be delivered via a number of devices. However, in the initial management of a critically-ill hypoxaemic patient, who does not require immediate intubation, high dose oxygen therapy should be administered via reservoir mask at 10–15 L/min. Following stabilization this can be titrated to achieve arterial oxygen saturations estimated by oximetry of 94–98%, or escalated to supportive ventilation should the patient deteriorate. In patients at risk of hypercapnic respiratory failure controlled oxygen therapy administered via a venturi mask aiming for saturations of 88–92% should be given. Concerns regarding the provocation of hypercapnia through suppression of respiratory drive should not take precedence over the need for oxygenation.

Identify and treat the precipitating cause

Hypoxaemia is the final common pathway of a number of conditions. It may not be possible to identify the cause of the deterioration immediately, in which circumstances general respiratory and haemodynamic support should be applied. However, if the cause is identified immediate specific treatment should be instituted (see Table 85.1).

Control of secretions

Patients with ARF may produce copious secretions, for which physiotherapy and mucolytics can be helpful. Ultimately, if these cannot be controlled, endotracheal intubation can alleviate sputum retention and airway obstruction.

Non-invasive ventilation (NIV)

NIV is the delivery of a mechanically-ventilated breath, either via a portable or standard intensive care unit (ICU) ventilator, through an appropriate interface (e.g. nasal mask, full face mask, or nasal pillows), rather than an endotracheal tube or tracheostomy. The term NIV incorporates systems that deliver bi-level positive pressure ventilation (BiPAP), in which inspiratory and expiratory pressures are set at required levels, and continuous positive airway pressure ventilation (CPAP), where one pressure is maintained throughout inspiration and expiration. The rationale for NIV is to support the patient during respiratory failure, but avoiding the need for intubation and its associated complications. While there is evidence for the benefits of NIV in patients with hypercapnic respiratory failure, especially secondary to COPD, its use in hypoxaemic respiratory failure remains less evident. However, a trial of NIV in patients who do not require immediate endotracheal intubation and who have no contraindications is recommended (Box 85.4), instituted in the high dependency unit or ICU setting, and monitored over a preset time (e.g. 1–2 hours).

Acute pulmonary oedema

NIV improves pulmonary compliance in cardiogenic pulmonary oedema through alveolar recruitment and redistribution of intra-alveolar fluid. A Cochrane review comprising 21 studies found NIV to be safe and effective in reducing hospital mortality, and the need for intubation compared with standard treatment [3]. However, more recent randomized controlled trials showed

Table 85.1 Identification and treatment of common causes of acute hypoxaemia

Condition	Aids to diagnosis	Specific management
Obstructive airways disease	Previous history and lung function. Wheeze on examination. Hyperexpanded chest X-ray.	Nebulised B2 agonists and ipatropium bromide. Steroids. **Consider**: ◆ Theophyllines. ◆ Magnesium. ◆ NIV. ◆ Volatile anaesthetic agents. ◆ Ketamine. ◆ Heliox.
Pneumonia	History of cough and sputum. Signs of sepsis +/– septic shock. Raised inflammatory markers. Consolidation on chest X-ray. Positive microbiology.	Early antibiotic therapy according to local hospital policy. **Control of secretions**: ◆ Mucolytic agents. ◆ Physiotherapy.
Pulmonary oedema	History of cardiac disease. Clinical examination. ECG and chest X-ray. Raised troponin/BNP.	Diuretics. iv nitrates. CPAP. Treat acute coronary syndrome if indicated.
Pneumothorax	Clinical examination: Chest X-ray.	Decompression/intercostal drainage. Oxygen therapy.
ARDS	Presence of risk factors for ARDS. P:F ratio. Chest X-ray and ECHO.	Treat underlying cause. Conservative fluid balance [9]. Low tidal volume ventilation [8].
Pulmonary embolism	History and examination: presence of risk factors. ECG/ECHO. CTPA.	Thrombolysis if massive PE. Anti-coagulation.
Pleural effusion	History and examination. CXR.	Drainage and search for underlying cause.

NIV, Non-invasive ventilation; CPAP, continuous positive airway pressure; ECG, electrocardiogram; BNP, B-type natri-uretic peptide; ECHO, echocardiogram; PE pulmonary embolism; CTPA, CT pulmonary angiogram.

that, despite rapid improvement in physiological parameters and dyspnoea scores, NIV does not confer a mortality benefit [4,5]. Furthermore, in these patients no significant difference in the combined endpoint of death or intubation within 7 days was found between CPAP and BiPAP. Despite this, it is usual to treat hypoxic patients with acute pulmonary oedema who do not require immediate intubation with CPAP as it is easier to implement.

Severe community-acquired pneumonia

If secretions are controlled, NIV can be applied successfully in community-acquired pneumonia (CAP) [6]. In those with successful NIV, ICU stay was shorter and mortality was lower. Variables independently associated with failure of NIV were maximum sepsis-related organ failure assessment (SOFA) score during NIV, worsening infiltrates on chest X-ray at 24 hours, and higher heart rate, lower PaO_2:FIO_2 ratio and bicarbonate after 1 hour of NIV. The increased duration of NIV prior to intubation was associated with increased mortality. Thus, emphasizing the importance of a short trial of NIV with early endotracheal intubation and mechanical ventilation if no improvement is seen after a preset time.

ARDS

While small studies have shown improved oxygenation and reduced intubation rates compared with oxygen therapy alone, the majority of patients with ARDS require ventilation.

Asthma

One small trial in severe asthma found NIV improved rates of hospitalization and simple indices of lung function [7]. However, until larger randomized controlled trials are performed NIV is not routinely recommended in asthmatic patients and should only be considered in an ICU setting.

COPD

The use of NIV in hypercapnic respiratory failure is well established.

Invasive ventilation

In patients unresponsive or unsuitable for other forms of support, endotracheal intubation should be instituted in those with reversible pathology. The decision to intubate is based on clinical grounds, with the assistance of arterial blood gases and the investigations mentioned previously. Indications are outlined in

Box 85.4 Contraindications to NIV

- Life threatening hypoxaemia.
- **Non-respiratory organ failure**: haemodynamic instability.
- Inability to protect airway:
  - Reduced GCS.
  - Excessive/inability to clear secretions.
  - Gastrointestinal (GI) aspiration.
- Undrained pneumothorax.
- Agitation/confusion.
- Vomiting.
- Recent surgery involving:
  - Face.
  - Upper airway.
  - Upper GI tract.
- Facial burns or trauma.

Box 85.3. Ventilation is applied as support to facilitate treatment of the underlying condition while minimizing side effects. The optimal mode depends on the nature of the underlying disease process. Ventilator strategies should include first, titration of PEEP to maximize alveolar recruitment, increase FRC, and minimize intrapulmonary shunt, and secondly, lung protective ventilation using low tidal volumes to minimize alveolar damage secondary to cyclical opening and closing of damaged lung units [8]. These approaches can result in reduced CO_2 clearance and, therefore, a respiratory acidosis. While evidence is lacking regarding the safe level of acidosis, 'permissive hypercapnia' is accepted as long as oxygenation is not compromised. In patients with refractory hypoxaemia, despite conventional ventilation prone positioning, nitric oxide, high frequency oscillation ventilation, and extracorporeal membrane oxygenation can be considered but are beyond the scope of this chapter.

CHAPTER 86

Hypercapnia in the critically ill

John G. Laffey and Brian P. Kavanagh

Key points

- Hypercapnia is a central component of current 'protective' ventilator management.
- Hypercapnia and the associated acidosis, has potentially important biological effects on immune responses, injury, and repair.
- There are distinct patient groups, such as patients with limited intracranial compliance or elevated pulmonary vascular pressures, in which hypercapnia may be poorly tolerated and must be carefully titrated.
- Hypercapnia can suppress the immune response to bacterial infection.
- Hypercapnia is usually well tolerated in health and in the critically ill, with intact survival reported even following exposure to extreme levels.

Causes of hypercapnia

The causes of elevated (or lowered) arterial carbon dioxide tension ($PaCO_2$) reflect the balance of its production, elimination and (rarely) the presence of any CO_2 in the inspired gas:

$$PaCO_2 \propto [(\text{Produced } CO_2 / \text{Eliminated } CO_2) + \text{Inspired } CO_2] \quad \text{[eqn 1]}$$

The key cause of hypercapnia in critical illness is reduced elimination. CO_2 elimination depends on alveolar ventilation ($\dot{V}_A$), i.e. the minute ventilation (tidal volume × respiratory rate) minus the dead space ventilation ($\dot{V}_D$). In severe lung or neurological disease states, a combination of low minute ventilation and/or elevated $\dot{V}_D$, means that the alveolar ventilation—and, hence CO_2 elimination—is reduced. Increased $\dot{V}_D$, e.g. due to a pulmonary embolism, also decreases CO_2 elimination unless minute ventilation is significantly increased.

Inspired CO_2 is usually negligible, but it can be elevated due to circuit misconnection, or with rebreathing circuits if CO_2 absorption fails. Increased CO_2 production is common, but rarely results in hypercapnia except in rare crises, such as malignant hyperthermia or thyroid storm, where production is massively increased. Administration of bicarbonate to buffer H^+ can transiently increase CO_2 production.

Physiological responses to hypercapnia

Physiological buffering

Hypercapnia results in higher concentrations of H^+, by combining with H_2O to form carbonic acid (H_2CO_3), which then dissociates into bicarbonate (HCO_3^-) and H^+. Because acidosis suppresses many cellular functions, physiological strategies maintain intra- and extracellular pH within narrow ranges. First, tissue buffering occurs over minutes to hours via active cell membrane ion transporters that extrude H^+ in exchange for sodium. Secondly, acidaemia inhibits production of organic acids. Finally, the kidney (if function is preserved) generates additional HCO_3^- and, by different mechanisms, directly excretes H^+; such 'renal compensation' occurs over hours to days.

Physiologic effects of $PaCo_2$ versus H^+

While many effects of hypercapnia appear to be mediated by changes in H^+, CO_2 may also have direct effects. CO_2 molecules may react directly with free amine groups, forming carbamate residues that can modify protein structure and function, e.g. the rightward shift of the Hb-O_2 dissociation curve induced by elevated $PaCO_2$ (the Bohr effect). This may explain why at a similar pH, metabolic, and hypercapnic acidosis can have different consequences.

Respiratory physiology

Hypercapnic acidosis has important effects on the pulmonary vasculature, the airways and on control of breathing. Hypercapnic acidosis increases pulmonary vascular resistance and intensifies hypoxic pulmonary vasoconstriction. CO_2 administration improves $\dot{V}/\dot{Q}$ matching (and oxygenation) in healthy volunteers. In ARDS, the increase in venous admixture during permissive hypercapnia probably occurs due to airway closure and atelectasis, rather than from a direct effect of the hypercapnic acidosis [1].

Hypercapnia can directly dilate small airways and, by indirect vagus nerve-mediated mechanisms, constrict larger airways; However, there is little net impact on airway resistance. Finally, hypercapnic acidosis stimulates respiration predominately via central chemoreceptors, which respond to increased H^+ levels in the cerebrospinal fluid. In addition, both hypercapnia and acidosis augment the responses of the peripheral chemoreceptors to hypoxia.

Cardiovascular physiology

The cardiovascular impact of hypercapnic acidosis is complex, with direct effects including diminished vascular and myocardial contractility opposed by the indirect sympatho-adrenal stimulation causing increased preload and heart rate, and decreased afterload. The net effect is an increase in cardiac output.

Hypercapnia enhances tissue oxygen delivery by increasing cardiac output, improving lung $\dot{V}/\dot{Q}$ matching and tissue blood flow. Both hypercapnia and acidosis cause a shift to the right of the Hb-O_2 dissociation curve, augmenting O_2 release at the tissues. In addition, hypercapnic acidosis may slightly elevate haematocrit, incrementally increasing O_2 delivery. At the cellular level,

hypercapnic acidosis may reduce oxygen consumption; thus, in aggregate, hypercapnic acidosis tends to augment O_2 supply and reduce demand.

Central nervous system effects

Hypercapnic acidosis causes cerebral vasodilation, mediated predominantly by local pH altering potassium channels and neuronal nitric oxide synthase, which results in an increase in cerebral blood flow and blood volume. However, when administered over a prolonged period, hypercapnic acidosis becomes buffered and the cerebral vascular tone returns towards normal. Exposure to profound levels of CO_2 (e.g. accidental exposure) causes acute narcosis and coma.

There are significant neuromuscular effects. Short-term exposure may cause reversible impairment in muscle contractility, whereas prolonged hypercapnia (e.g. for weeks) can result in structural alterations including increased slow-twitch (and decreased fast-twitch) fibres.

Mechanisms of action

Immunology and inflammation

Hypercapnia and acidosis modulate diverse components of the host immune system, especially in terms of mediator and cellular responses. Important signalling molecules, such as IL-6, IL-8, TNFα, and IL-1 are suppressed by hypercapnic acidosis. In addition, hypercapnia can inhibit expression of binding molecules, such as selectins and intercellular adhesion molecules.

Hypercapnic acidosis can inhibit NF-κB activation [2], an important early step in inflammatory gene activation; while this may have useful anti-inflammatory effects, it may also impair resolution of injury [2].

Elevated CO_2 may directly alter cellular immune responses, including neutrophil [3] and macrophage recruitment and phagocytosis. Oxidant generation, a critical step in neutrophil and macrophage function, is reduced by hypercapnia (and increased by hypocapnia). Hypercapnia can minimize depletion of (the anti-oxidant) glutathione and directly inhibit xanthine oxidase [4]. However, while free radicals contribute to tissue injury, they are also necessary for bacterial killing. The impact of hypercapnic acidosis on free radical injury may be injury-specific; e.g. hypercapnic acidosis decreases tissue nitration following reperfusion injury [5], but increases it in sepsis [6].

Injury effects: hypercapnia versus acidosis

Most of the protective effects of hypercapnic acidosis are due to acidosis, rather than hypercapnia. In the lung, buffering hypercapnia reduces the protection against injury [5], while in cultured cells it inhibits epithelial wound healing [7]. Metabolic acidosis attenuates reperfusion injury less effectively than hypercapnic acidosis [5]. Some effects of hypercapnia appear to be a function of CO_2 and not pH, such as the worsening injury in prolonged pulmonary sepsis [3], inhibition of the NF-κB pathway and altering development, as demonstrated in *Drosophila* [8].

Organ-specific effects in acute injury (laboratory and clinical)

Acute respiratory failure

The alveolus

Hypercapnia reduces alveolar-capillary permeability [4], but can also inhibit fluid clearance by alveolar epithelial cells whereby CO_2, (but not H^+) activates AMP-activated protein kinase, which promotes endocytosis (and sequestration) of Na/K-ATPase [9]. In addition, hypercapnia inhibits pulmonary epithelial healing by reducing activation of NF-κB, effects more closely associated with elevations in PCO_2 than H^+ [7].

Status asthmaticus

Although the studies of limiting tidal volume predominantly focus on ARDS, the practice was first described in status asthmaticus—the result was greater survival (and less barotrauma) versus historical controls [10].

Ventilator-associated lung injury

The potential for reduced tidal volume (V_T) to lessen mortality in ARDS was first demonstrated by Hickling et al. in two pivotal studies [11,12]. A retrospective analysis of 50 patients with severe ARDS who had limitation of P_{AW} (<30 cmH_2O) resulting in significant hypercapnia, demonstrated mortality was far less than predicted by APACHE II score (16 versus 40%) [11]. A survival advantage was again found in a series of prospectively studied patients, managed with 'permissive hypercapnia' with an actual mortality of 26.4% (versus predicted 53.3%) [12]. These pivotal studies, coining the term 'permissive hypercapnia', are the clinical basis for adoption of protective mechanical ventilation in adults with ARDS.

A retrospective analysis of the largest randomized controlled trial of tidal volume in ARDS [13] suggested that the presence of hypercapnic acidosis was associated with increased survival among patients randomized to higher—but not lower—V_T [14].

Hypercapnic acidosis directly reduces ventilator-induced lung injury in pre-clinical studies (Fig. 86.1) [15], and a key mechanism of this is attenuation of stretch-induced activation of the NF-κB pathway [16].

Gas exchange in ARDS

In patients with ARDS, reduction of V_T, with concomitant permissive hypercapnia, increases both cardiac output and intrapulmonary shunt [1]. The modest decrease in PaO_2 is a result of increased shunt fraction (because of atelectasis caused by low V_T without recruitment), as well as the decrease in alveolar ventilation; these effects are countered by the increased cardiac output and central venous oxygenation.

Pulmonary hypertension

Acute hypercapnic acidosis worsens pulmonary hypertension in patients. However, prolonged experimental hypercapnia can lower pulmonary hypertension and reverse vascular hypertrophy, in part by increasing expression of L-arginase (produces local NO) or inhibiting expression of the vasoconstrictor endothelin [17].

Pulmonary infection

Hypercapnia reduces the severity of lung injury following endotoxin [6], and in the short-term, following experimental *E. coli* inoculation [18]. However, in the longer term (~72 hours) *E. coli* pneumonia, hypercapnic acidosis worsens injury because of neutrophil inhibition (Fig. 86.2) [3]. Mortality in *Drosophilia* infected with different bacteria (*S. aureus, E. fecalius, E. coli*) is increased by the presence of elevated CO_2 (but not by lowered pH), and this is mediated in part by suppression of Rel/NF-κB, an important signalling pathway that is conserved in higher mammals [8].

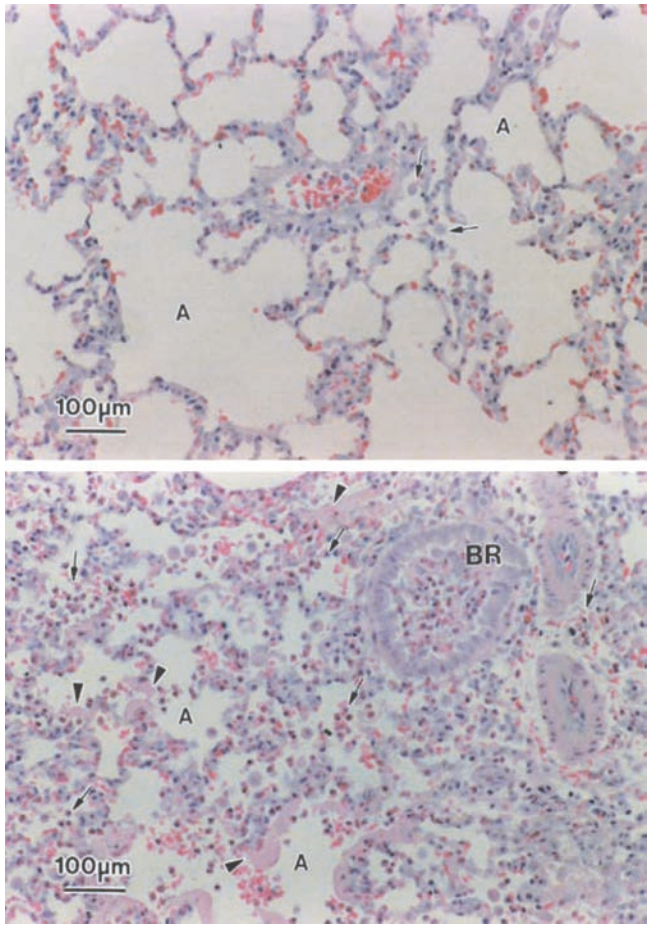

Fig. 86.1 Hypercapnic acidosis attenuates ventilation-induced lung injury. Histological injury is less in the setting of hypercapnic acidosis (PCO_2 80–100 mmHg; Panel a) compared with normocapnia (PCO_2 40 mmHg; Panel b). *Symbols:* Arrow, macrophage; arrowhead, hyaline membrane formation; 'BR', bronchiole. The circulation in critical illness

Effects on the myocardium

Hypercapnic acidosis protects against experimental myocardial ischaemia-reperfusion injury; in addition, it directly reduces contractility and in vivo infarct size by reducing myocardial calcium loading and increasing coronary vasodilation.

Effects on the vasculature

In experimental abdominal sepsis, hypercapnic acidosis mitigates the onset of shock, with a comparable haemodynamic profile to dobutamine (i.e. augmentation of cardiac output and $\dot{D}O_2$) [9]; this appears to be due to the elevated CO_2 and not acidosis [7]. Finally, hypercapnia augments microcirculation in experimental models, and enhances tissue oxygenation in patients during surgery.

Hypercapnia and brain injury

Perfusion and intracranial pressure

Hypercapnia increases cerebral blood flow, and can raise intracranial pressure and, in the setting of critically raised intracranial pressure (ICP), potentially cause brainstem herniation; at very high levels it causes narcosis and coma.

Brain protection

Several studies have demonstrated protection in experimental brain injury. One study reported that hypercapnic acidosis protected against hypoxic-ischemic injury in the immature rat brain [19], although it is possible that the magnitude of the effect (i.e. the between-group difference) reflected a lowering of the $PaCO_2$ in the control group, rather than an elevation of the CO_2 in the intervention group. Hypercapnia reduces excitatory amino acids (e.g. glutamate) in cerebrospinal fluid, and coupled with inhibition of oxyradicals and neuronal apoptosis, this may contribute to CNS protection.

Renal, hepatic, and splanchnic impact

Acidosis can delay the onset of cell death in anoxic hepatocytes and renal tubules. In the gastrointestinal mucosa, elevated CO_2 preserves oxygenation during experimental haemorrhage; in addition, raised $PaCO_2$ during experimental sepsis lessens depletion of ATP and protects the mucosal permeability barrier. However, patients with ARDS exposed to permissive hypercapnia demonstrated no important alterations in splanchnic circulation.

Tolerance and contraindications

Tolerance to hypercapnia

The potential for full recovery exists following exposure to extreme levels of hypercapnia, sometimes called 'supercarbia'. Several children exposed to high levels (e.g. $PaCO_2$ 150–270 mmHg), as well as one patient with asthma ($PaCO_2$ 293 mmHg, pH 6.77) have been described with no long-term sequelae. However, extremes of hypercapnia are less likely to be well tolerated in the critically ill.

Contraindications

Contraindications are more apparent when the underlying concerns (e.g. pulmonary hypertension, raised ICP, uncontrolled metabolic acidosis) are more severe, when the extent hypercapnic acidosis is greater and its onset more acute.

Management of hypercapnic acidosis

Buffering hypercapnic acidosis

Buffering of the hypercapnic acidosis in patients with ARDS remains a common intervention with uncertain benefit. There are several buffers in clinical use.

Sodium bicarbonate

Buffering hypercapnic acidosis with bicarbonate was undertaken in several ARDS clinical trials, but concerns remain. Bicarbonate causes generation of additional CO_2, which must be excreted in order for pH to be buffered. In permissive hypercapnia, the excretion of CO_2 is limited because a lower V_T is targeted. Bicarbonate has been removed from most routine cardiac arrest algorithms.

Tromethamine

Tromethamine (*tris*-hydroxymethylaminomethane, THAM) readily penetrates cell membranes and buffers pH, while reducing $PaCO_2$. In contrast to bicarbonate, THAM is effective in a closed system. In a study of 12 patients with ARDS, acute hypercapnic

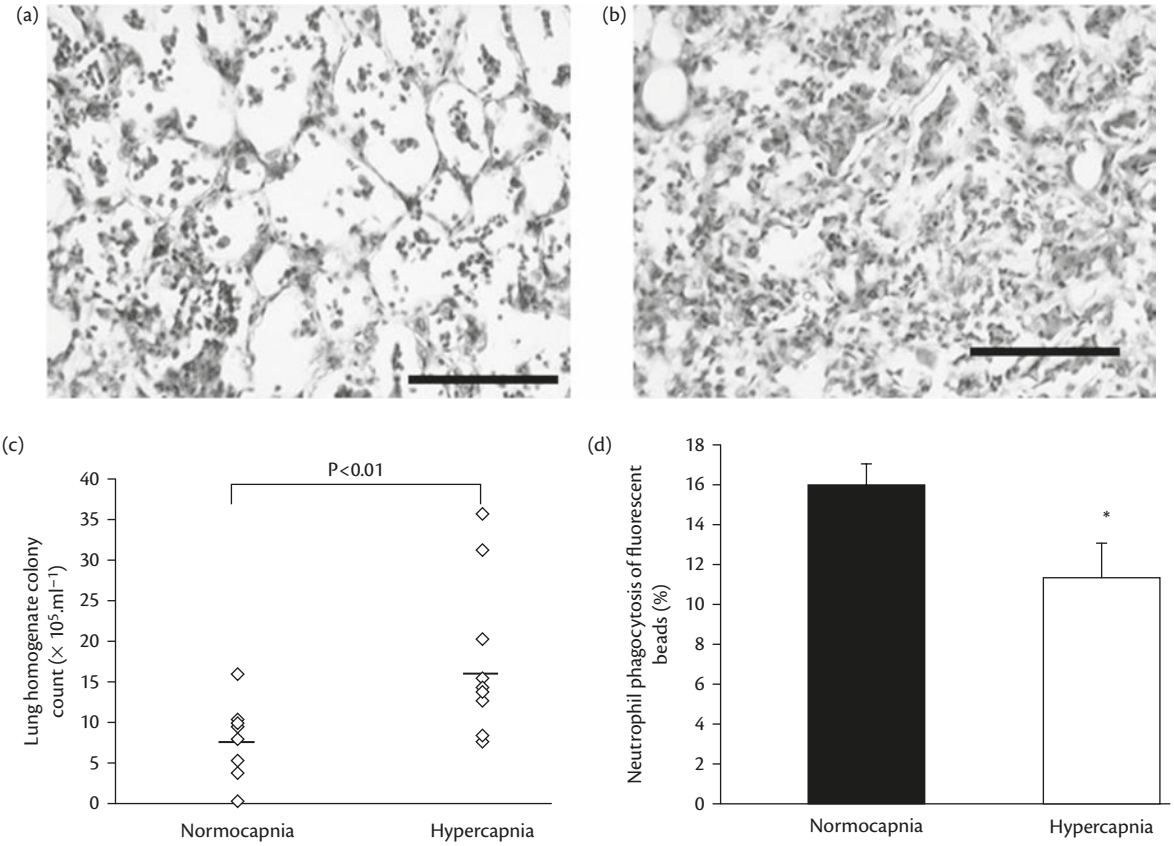

Fig. 86.2 Hypercapnic acidosis worsens lung injury and increases bacterial load in model of prolonged pneumonia. Lung tissue sections at 48 hours after infection with *E. coli* (normocapnia control; Panel a) demonstrated more severe lung injury in the setting of environmental hypercapnia (Panel b; inspired CO_2 5%). The bacterial load was greater following hypercapnia compared with normocapnia (Panel c), and neutrophils from animals exposed to hypercapnia (versus normocapnia) demonstrated reduced capacity to phagocytose fluorescent latex beads (Panel d).

acidosis decreased systemic vascular resistance, myocardial contractility and systemic mean arterial pressure, and increased cardiac output and pulmonary arterial pressure; buffering with THAM lessened these changes [20].

Carbicarb

Carbicarb is an equimolar mixture of sodium carbonate and sodium bicarbonate (Na_2CO_3 0.33 M **with** $NaHCO_3$ 0.33 M). It buffers hypercapnic acidosis without increasing lactate, but has no haemodynamic advantages.

To summarize, no outcome data support buffering hypercapnic acidosis. In the absence of correcting the primary problem, buffering hypercapnic acidosis with bicarbonate is not likely to be of long-term benefit. If the clinician elects to buffer hypercapnic acidosis in individual cases, the immediate rationale should be clear (e.g., to ameliorate potentially deleterious haemodynamic consequences) and the responses measured. THAM and carbicarb may have a role in such clinical situations.

Augmenting CO_2 clearance

Tracheal gas insufflation (TGI)

This approach delivers fresh gas into the trachea so that each inspiration commences with lower concentrations of CO_2 (than would otherwise exist from the terminal stages of the previous exhalation). However, intrinsic PEEP in invariable elevated and the overall safety profile has not been established.

Extracorporeal support

Extracorporeal membrane oxygenation (ECMO) provides oxygenation and CO_2 removal. Extracorporeal CO_2 removal can be achieved using a simpler (pumpless) circuit operating at a lower flow, which removes CO_2 from the blood at a membrane and returns blood *via* a venous cannula.

Conclusion

Permissive hypercapnia means accepting the hypercapnia that results from V_T reduction, and is undertaken to reduce the likelihood of ventilator-associated lung injury. Elevated $PaCO_2$ causes many physiological alterations, which may be neutral, harmful, or potentially beneficial. Nonetheless, high V_T can clearly cause harm and the physician must decide, for each patient individually, the optimal balance between avoiding high V_T and the potential cost of hypercapnia.

CHAPTER 87

Cardiovascular interactions in respiratory failure

Jae Myeong Lee and Michael R. Pinsky

Key points

- Spontaneous ventilation is exercise.
- Acute respiratory failure placed an increased metabolic demand on the cardiovascular system.
- Spontaneous inspiration increases venous return and impedes left ventricular ejection increasing intrathoracic blood volume.
- Positive pressure ventilation decreases venous return and augments left ventricular ejection decreasing intrathoracic blood volume.
- Lung hyperinflation, either by spontaneous ventilation or mechanical ventilation, increases pulmonary vascular resistance and can cause acute cor pulmonale.

Introduction

Acute respiratory failure (ARF) can directly alter cardiovascular function in a number of seemingly unrelated ways. However, many of these effects are predictable from a knowledge of the determinants of cardiovascular function. The respiratory and the cardiovascular systems are not separate, but tightly integrated. The ultimate cardiovascular response to ARF is dependent on the patient's baseline cardiovascular state, the type of respiratory dysfunction present, and the ventilatory pattern and ventilatory support being used.

Hypoxaemia causes increased demand on the cardiovascular system to deliver higher cardiac output (CO) to sustain a constant O_2 delivery. Spontaneous inspiratory efforts during acute bronchospasm and acute lung injury (ALI) induce marked/prominent negative swings in intrathoracic pressures (ITP) as the muscles of inspiration try to increase lung volume against increased airflow resistance or stiff lungs, respectively. Both of which also increase the work of breathing. Both lung under- and hyperinflation will increase pulmonary vascular resistance directly impeding right ventricular (RV) ejection. Lung hyperinflation also limits diastolic filling. Furthermore, spontaneous inspiratory efforts will decrease ITP, increasing venous return and intrathoracic blood volume, whereas positive-pressure ventilation by increasing ITP will have the opposite effect. These specific processes explain all the relevant determinants of heart–lung interaction.

Thus, heart–lung interactions involve four basic concepts:

- Inspiration increases lung volume above the end-expiratory volume.
- Spontaneous inspiration decreases ITP.
- Positive-pressure ventilation increases ITP.
- Spontaneous ventilation is exercise.

Haemodynamic effects of changes in lung volume

Lung inflation alters autonomic tone, pulmonary vascular resistance, and at high lung volumes, compresses the heart in the cardiac fossa. The associated diaphragmatic descent also increases intra-abdominal pressure and compresses the liver increasing hepatic vascular resistance. Each of these processes may predominate in determining the final cardiovascular state. Small tidal volumes (<10 mL/kg) increase heart rate (HR) by vagal (parasympathetic) withdrawal, causing an inspiration-associated cardiac acceleration called **respiratory sinus arrhythmia**. Whereas large tidal volumes (>15 mL/kg) decrease HR, arterial tone, and cardiac contractility by sympathetic withdrawal.

The haemodynamic response to increases in lung volume are mainly mechanical [1]. Lung inflation, independent of changes in ITP, primarily affects cardiac function and CO by altering RV preload and afterload, and left ventricular (LV) preload. First, inspiration induces diaphragmatic descent that increases hepatic outflow resistance, while simultaneously increasing intra-abdominal pressure. Systemic venous return to the heart is a function of the pressure difference between the right atrium and the systemic venous reservoirs and the resistance to venous return. Since a large proportion of the venous blood volume is in the abdomen, increases in intra-abdominal pressure will increase the venous pressure in this vascular space augmenting venous blood flow [2]. However, diaphragmatic descent will compress the liver increasing hepatic outflow resistance thus decreasing flow from the splanchnic venous reservoirs to the right heart. Complicating this further, inspiration will shift venous flow from high resistance splanchnic circuits, which must drain through the liver, to low resistance systemic venous circuits, making flow greater for the same driving pressure. Thus, inspiration may increase, decrease, or not alter venous return depending on which of these factors are predominant. Inspiration will increase venous return in volume overloaded states, whereas in hypovolaemic states and with hepatic cirrhosis, the same inspiratory effect will decrease venous return.

RV output is sensitive to changes in pulmonary outflow resistance. Alveolar collapse occurs in ALI and is associated with increased pulmonary vasomotor tone due to hypoxic

pulmonary vasoconstriction [3]. Alveolar recruitment by restoring end-expiratory lung volume back to functional residual capacity (FRC) and improving oxygenation often decreases hypoxic pulmonary vasoconstriction, thus decreasing RV outflow resistance. Increasing lung volume above FRC in increases RV outflow resistance [4] due to progressive increases in transpulmonary pressure (airway pressure relative to ITP) associated with increasing lung volume. Since the heart and great vessels exist in the thorax, and sense ITP as their surrounding pressure, increases in transpulmonary pressure will induce pulmonary vascular collapse if transpulmonary pressure exceeds pulmonary artery pressure [1]. Thus, hyperinflation increases pulmonary vascular resistance and impedes RV ejection. Using the smallest tidal volumes, least PEEP, and other protective lung ventilation strategies will also improve RV ejection.

LV end-diastolic volume can be altered by ventilatory changes in three ways. First, since the RV and LV outputs are in series, changes in RV preload will eventually alter LV preload. Secondly, by ventricular interdependence changes, RV end-diastolic volume inversely changes LV diastolic compliance [5]. Ventricular interdependence is a major factor in altering LV output during spontaneous ventilation when RV end-diastolic volumes may vary widely from expiration (small volumes) to inspiration (large volumes). Thirdly, increasing lung volume restricts absolute cardiac volume by directly compressing the heart [1]. As the lungs expand, the heart is compressed in the cardiac fossa and absolute bi-ventricular volume is limited in a fashion analogous to cardiac tamponade.

Haemodynamic effects of changes in intrathoracic pressure

The heart within the thorax is a pressure chamber within a pressure chamber. Thus, changes in ITP will affect the pressure gradients for both systemic venous return to the RV and systemic outflow from the LV, independent of the heart itself [1,4]. Increases in ITP, by both increasing Pra and decreasing transmural LV systolic pressure, will reduce these pressure gradients, decreasing intrathoracic blood volume. Whereas decreases in ITP, using the same argument, will augment venous return and impede LV ejection, increasing intrathoracic blood volume. Variations in Pra represent the major factor determining the fluctuation in pressure gradient for systemic venous return during ventilation [2]. Increases in ITP, as seen with positive-pressure ventilation or hyperinflation, by increasing Pra decrease venous return, whereas decreases in ITP, as seen with usual spontaneous inspiration, by decreasing Pra increase venous return.

Spontaneous inspiratory efforts by decreasing ITP both increases lung volume and decreases right atrial pressure accelerating blood flow into the RV [6] and increasing pulmonary blood flow on the subsequent beat. Thus, normal respiration-associated haemodynamic changes maximize ventilation–perfusion temporal matching because inspiration matches increased alveolar capillary flow. However, this venous flow augmentation is limited because if transmural vascular pressure falls below zero the extrathoracic veins collapse at the thoracic inlet, limiting flow [7]. This 'flow-limitation' is useful, because ITP can decrease greatly with obstructive inspiratory efforts. Without this flow-limitation, the RV could overdistend and fail.

Thus, we can see that spontaneous ventilatory efforts performed against a resistive (bronchospasm) or elastic (ALI) load, decrease LV stroke volume via a complex mechanism collectively called pulsus paradoxus that decreases LV end-diastolic volume and LV ejection. Transient intraventricular septal shift into the LV lumen by the dilated right ventricle plus pericardial volume restraint decreases absolute LV end-diastolic volume [1,5]. Furthermore, increases in LV afterload (LV ejection pressure minus ITP) increase LV end-systolic volume [8].

LV afterload is approximated by maximal systolic wall tension, which is proportional to the product of transmural LV pressure and LV volume. Since increasing ITP will mechanically decrease transmural LV pressure, if arterial pressure is constant, increases in ITP will unload the LV, whereas decreases in ITP have the opposite effect [8]. Thus, in ventricular failure due to fluid resuscitation, increases in ITP may increase CO by decreasing LV afterload [8,9].

Sudden increases in ITP increase arterial pressure to an amount equal to the increase in ITP without changing aortic blood flow. If the increase in ITP is sustained, however, then the ITP-induced decrease in systemic venous return will eventually decrease LV output, decreasing arterial pressure. In the steady state, changes in ITP that result in altered CO also alter peripheral vasomotor tone through baroreceptor mechanisms. Baroreceptor reflexes tend to keep arterial pressure and CO constant. Thus, if ITP increases arterial pressure without changing transmural arterial pressure, then the periphery would vasodilate to maintain a constant extrathoracic arterial pressure-flow relation [4]. Since coronary perfusion pressure is not increased by ITP-induced increases in arterial pressure, whereas mechanical constraint from the expanding lungs may obstruct coronary blood flow, coronary hypoperfusion from a combined coronary compression, and a decrease in coronary perfusion pressure is a potential complication of increased ITP.

Although increases in ITP should augment LV ejection by decreasing LV afterload, this effect has limited therapeutic potential, just as all afterload reducing therapies are limited by both the minimal end-systolic volume and the obligatory decrease in venous return. Thus, the potential augmentation of LV ejection by increasing ITP is limited because increasing ITP, by reducing LV ejection pressure, can only decrease end-systolic volume, which is usually already small and cannot decrease much more except in markedly dilated cardiomyopathies. However, the decrease in venous return associated with the increase in ITP can continue to total circulatory arrest.

From the perspective of the ejecting LV, there is no difference between increasing ITP from a basal end-expiratory level and eliminating negative end-inspiratory ITP swings seen in spontaneous ventilation. Removing negative swings in ITP may be more clinically relevant than increasing ITP for many reasons. First, many pulmonary diseases are associated with exaggerated decreases in ITP during inspiration. In restrictive lung disease states, such as interstitial fibrosis or acute hypoxaemic respiratory failure, ITP must decrease greatly to generate a large enough transpulmonary pressure to ventilate the alveoli. Similarly, in obstructive diseases, such as upper airway obstruction or asthma, large decreases in ITP occur owing to increased resistance to inspiratory airflow. Secondly, exaggerated decreases in ITP require increased respiratory efforts that increase the work of breathing, taxing a potentially stressed circulation. Finally, the exaggerated decreases in ITP can only increase venous blood flow increasing intrathoracic blood

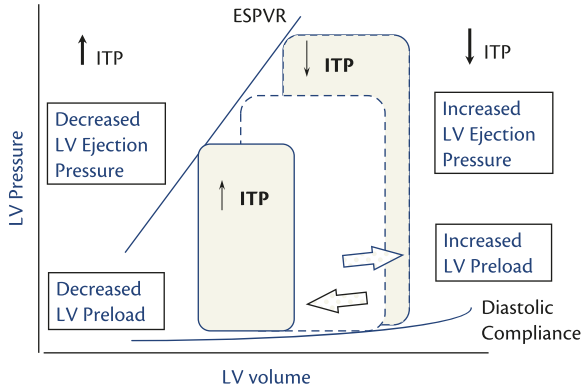

Fig. 87.1 The effect of increasing (dark shading) and decreasing (no shading) intrathoracic pressure (ITP) on the left ventricular (LV) relation with LV contractility is normal. The slope of the LV end-systolic pressure volume relationship (ESPVR) is proportional to contractility. The slope of the diastolic LV pressure-volume relationship defines diastolic compliance.

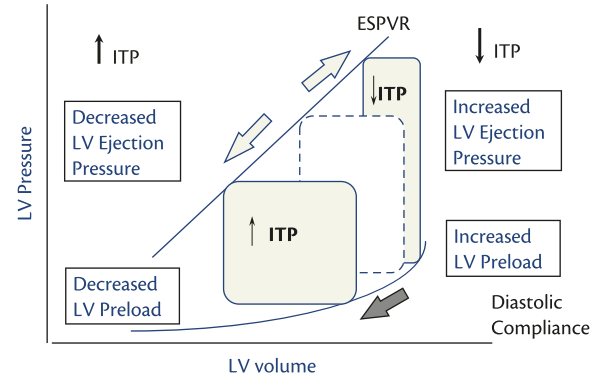

Fig. 87.2 The effect of increasing (dark shading) and decreasing (no shading) intrathoracic pressure (ITP) on the left ventricular (LV) relation in congestive heart failure when LV contractility is reduced and intravascular volume is expanded. The slope of the LV ESPVR is proportional to contractility. The slope of the diastolic LV pressure–volume relationship defines diastolic compliance.

volume. The level to which ITP must decrease to induce venous flow-limitation is different in different circulatory conditions but occurs in most patients below an ITP of –10 cmH_2O [1]. Thus, further decreases in ITP will further increase only LV afterload without increasing venous return. Accordingly, abolishing these markedly negative swings in ITP should disproportionally reduce LV afterload more than venous return (LV preload). These concepts of a differential effect of increasing and decreasing ITP on cardiac function are illustrated for both normal and failing hearts in Figs 87.1 and 87.2 using the LV pressure-volume relationship during one cardiac cycle to interpose venous return (end-diastolic volume) and afterload (end-systolic volume). Using this logic, one would predict that by endotracheal intubation and ventilation in patients requiring markedly negative swings in ITP to breath will abolish the increased LV afterload without impairing systemic venous return. These interactions have important implications in the decision to both institute and withdraw mechanical ventilatory support, as in acute cardiogenic pulmonary oedema.

Ventilation as exercise

Spontaneous ventilatory efforts require muscular activity, consume O_2 and produce CO_2, they represent a metabolic load on the cardiovascular system. Although ventilation normally requires less than 5% of total O_2 delivery to meet its demand, in lung disease states where the work of breathing is increased, such as pulmonary oedema or bronchospasm, the requirements for O_2 may increase to 25% or more of total O_2 delivery [10]. Furthermore, if cardiac output is limited, then spontaneous ventilation may not be possible without additional cardiovascular support. The institution of mechanical ventilation for ventilatory and hypoxaemic respiratory failure may reduce metabolic demand on the stressed cardiovascular system, decrease O_2 consumption, and thus for the same cardiac output, mixed venous oxygen saturation (SvO_2) will increase. In patients with right-to-left intrapulmonary shunts, this increased SvO_2 will increase PaO_2 independent of changes in ventilatory status. Intubation and mechanical ventilation, when adjusted to the metabolic demands of the patient, may dramatically decrease the work of breathing, resulting in increased O_2 delivery to other vital organs.

Functional haemodynamic monitoring

Positive pressure inspiration by increasing ITP passively increases right atrial pressure, venous return transiently decreases. This dynamic flow variation will alter both RV filling and RV output, if the RV is volume responsive and then after a short pulmonary transient time alter LV filling and LV output if the LV is volume responsive. Numerous studies have documented that the associated LV stroke volume variation (SVV) and arterial pulse pressure variation (PPV) will vary in direct proportion to volume responsiveness and can be used for clinical decision making about fluid therapy in ARF [11–13]. A PPV >13% or a SVV >10% on positive-pressure ventilation is highly predictive of volume responsiveness and the accuracy of these variations was excellent in predicting volume responsiveness (PPV 0.94 (receiving operation curve), systolic pressure variation (SPV) 0.86, and SVV 0.84) with PPV significantly better than SPV or SVV ($p < 0.001$) [14].

If chest wall compliance is normal, however, a minimal tidal volume (V_T) of 8 mg/kg is required to cause a large enough swing in ITP to induce theses effects. Since lower V_T ventilation is recommended in the management of patients with ALI, the ITP swings may not be large enough to allow PPV and SVV thresholds to be predictive [9]. Still, many patients with ALI also have increased intra-abdominal pressure owing to fluid resuscitation and ileus [15]. This increased intra-abdominal pressure decreases chest wall compliance, making the ITP swings during positive-pressure ventilation still predictive of volume responsiveness despite low V_T breathing [16,17]. Therefore, PPV or SVV often has a lesser predictive value of identifying volume responsiveness when measured in patients receiving a V_T <8 mL/kg [18,19], but if present signifies volume responsiveness.

PART 4.6

Ventilatory support

CHAPTER 88

Physiology of positive-pressure ventilation

Göran Hedenstierna and Hans Ulrich Rothen

Key points

- Positive-pressure ventilation (PPV) compared with spontaneous breathing increases airway and alveolar pressures.
- It also distributes ventilation preferentially to non-dependent, possibly less perfused lung regions.
- PPV squeezes blood flow to regions with lower alveolar pressure, possibly less or not at all ventilated regions.
- It impedes venous return to the right heart that may lower cardiac output.
- PPV elevates systemic capillary pressure that promotes vascular leakage, at the same time abdominal lymph drainage may be impeded, all-in-all promoting oedema formation.

Introduction

Ventilatory support can be provided by different techniques, the dominating one being positive pressure ventilation (PPV), with the breath forced into the lungs via the airways by increasing airway pressure. The force applied to the respiratory system (lung and chest wall) is the upper airway pressure (P_{AW}) minus the pressure surrounding the body, normally atmospheric pressure (P_B). This pressure difference can be partitioned into P_{AW} minus pleural pressure (and its substitute, oesophageal pressure, P_{ES}) for expanding the lung and the pressure required to expand the chest wall (ribcage and the diaphragm), P_{ES} minus P_B. In principle, these pressures generate the volume changes also during a spontaneous breath.

Respiratory muscle tone

Although pressure differences over the respiratory system may be similar during spontaneous breathing (SB) and PPV, the effects on the ventilation distribution and lung perfusion are different. In addition, with PPV there is frequently a fall in respiratory muscle tone, either by the deliberate use of muscle relaxants, anaesthetics, or sedatives or by reduced consciousness of the patient. This causes a lowering of the resting lung volume (FRC) [1], which has an additional and substantial effect on respiratory and circulatory mechanics.

With SB, the major respiratory muscle is the diaphragm and when it contracts the dome is flattened and the thoracic cavity will be increased. In the supine position, the tensing of the diaphragm will mainly shorten the dorsal fibres, which are the ones that are most elongated because they have been pushed cranially by the abdominal organs. In addition, the distribution of muscle fibres in the diaphragm may vary with more fibres in the dorsal part studied by Decramer et al. in dogs [2]. Moreover, dependent lung regions (dorsal in supine position) are located on the lower, steeper part and non-dependent regions are located higher up on the upper, flatter part of the pressure–volume curve. An inspiration is assumed to cause similar change in the transpulmonary pressure along the whole pleural space, causing larger volume change for dependent than non-dependent lung regions.

Ventilation distribution

With mechanical ventilation, the distribution of the breath may be different from that by spontaneous breathing. The reason is two-fold. First, the lung volume is reduced because of loss of respiratory muscle tone as discussed in 'Respiratory Muscle Tone', and this promotes airway closure that occurs primarily in more dependent lung regions [3]. The closure prevents at least the initial inspiration to go to the dependent regions, but during the succeeding inflations, the airways may open up so that some ventilation goes to lower lung (dorsal regions in the supine subject). If airways are continuously closed, which is also possible in a healthy lung when breathing at low lung volume, atelectasis will eventually develop because of gas absorption behind the continuously closed airways. The time it takes until collapse occurs depends on the inspired oxygen concentration, from a few minutes with 100% oxygen to a few hours with air [4]. The other reason for a different distribution of the breath is that the diaphragm is no longer acting as an active muscle, but just as a passive membrane separating abdominal content from the thoracic cavity. Since the abdominal pressure increases down from anterior to posterior in the gravitational orientation, more pressure is needed to move the dependent part of the diaphragm and the abdominal content than the non-dependent region of the diaphragm. Volume expansion of the thoracic cavity will thus be facilitated in the upper regions [5].

The smaller lung volume that is frequently seen in the mechanically-ventilated subject increases airway resistance and the difference will be larger between the dependent, narrower, and upper, non-dependent, less narrowed airways [6]. This adds to the shift in ventilation to upper lung regions.

Pulmonary circulation

The pulmonary circulation is a low pressure system and is, therefore, susceptible to increased intrathoracic pressure. The lower the vascular pressure is, the larger is the difference in perfusion

to upper and lower lung units [7]. With increase in vascular pressure as, for example, during physical exercise, perfusion of the lung will be more homogeneous. If alveolar pressure is increased, as during a mechanical breath, it may exceed that of the surrounding capillaries, compressing them so that the alveolus is non-perfused. This is possible, even likely, in the non-dependent lung regions where perfusion pressure is the lowest. Due to hydrostatic forces vascular pressure increases down the lung by approximately 1 cm H_2O (0.7 mmHg) per cm distance so there may be a pressure difference between top and bottom of the lung by 11–12 mmHg. A mechanical breath will thus force the blood flow towards dependent regions, whereas ventilation is forced towards non-dependent regions. The ventilation/perfusion ratio (V/Q) departs from an ideal ratio of 1 to well above 1 ('high V/Q') in non-dependent regions (a dead space like effect) to a ratio well below 1 ('low V/Q') in dependent lung regions causing a shunt-like effect [8] (Fig. 88.1).

The spontaneous breath may more easily recruit collapsed lung tissue in the dependent regions because of larger tidal swing of the diaphragm in the dorsal part than in the mechanically-ventilated subject, where the diaphragm moves more in the non-dependent regions, as mentioned in 'Ventilation Distribution'. A prerequisite for such beneficial effects is that the spontaneous breath is large enough to overcome the forces that keep collapsed alveoli together (e.g. surface tension [9]). This should reduce shunting and improve oxygenation of blood. However, even without recruitment of collapsed lung by the spontaneous breath a beneficial effect can still be seen. This is because the spontaneous breath attracts blood flow to ventilated regions from collapsed areas, whereas the mechanical breath squeezes blood away from the ventilated region to atelectatic and consolidated regions [10,11].

Systemic circulation

PPV may impede return of venous blood to the thorax and the right heart [12]. With high enough pressure, stroke volume and also heart rate can be reduced to zero. A hypovolaemic subject will be more susceptible to a decrease in cardiac output when intrathoracic pressure is elevated as during mechanical ventilation [12].

Impeded venous return raises venous pressure that is causing an increase in systemic capillary pressure with increased capillary leakage and possible oedema formation in peripheral organs. Lymph vessels will take care of an increased capillary leakage and there is also a return of fluid in the distal end of the capillary back to the venous system. However, in the abdomen lymph flow may be impeded because the thoracic duct is the main channel for the abdominal lymph return. It passes through the thorax and with an elevated intrathoracic pressure as during mechanical ventilation, the thoracic duct may be compressed and lymph flow impeded [13]. Thus, there may be a double cause of abdominal oedema formation in the mechanically-ventilated subject—increased capillary leakage and impeded lymph drainage. PPV may also impede

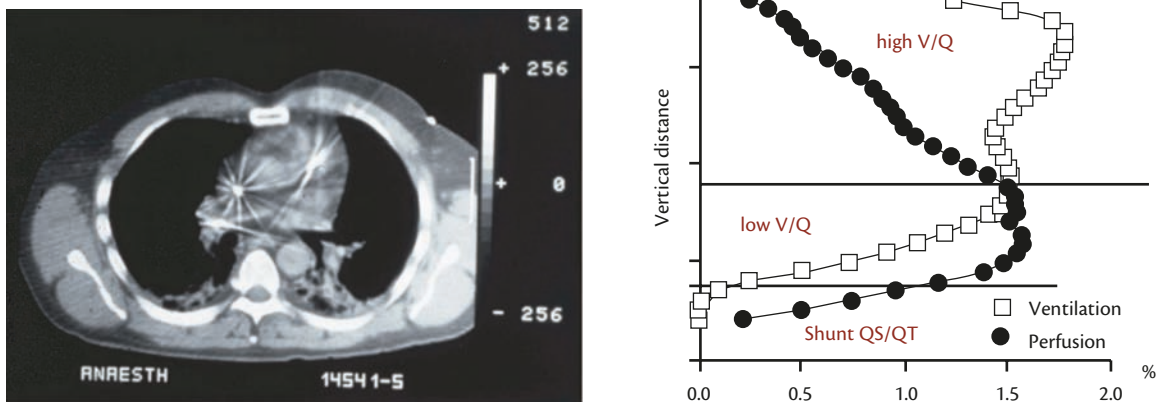

Fig. 88.1 Atelectasis (left panel) and distributions of ventilation and blood flow in an anaesthetized and mechanically-ventilated (ZEEP) subject (right panel). Note the atelectasis and absence of ventilation in the bottom of the lungs, causing shunt (QS), the poor ventilation in a zone above the atelectasis, causing low V/Q, and the preferential ventilation of the upper half of the lung, well in excess of perfusion, causing high V/Q and adding to dead space as measured by CO_2 technique. Compare also with the schematic drawing of ventilation and perfusion distributions in awake, upright man in the insert (upper right).
Data from Tokics L et al., 'V/Q distribution and correlation to atelectasis in anaesthetized paralyzed humans', *Journal of Applied Physiology*, 1996, **81**(4), pp. 1822–33.

drainage of the lung tissue and increase lung fluid. PPV with positive end-expiratory pressure (PEEP), has been shown to impede lung lymph flow [14] and this can be one of several mechanisms behind the fluid accumulation. However, conflicting results have also been reported [15].

How to reduce negative effects of positive pressure ventilation?

What then can be done to counter the negative effects of mechanical ventilation? First, an increase in lung volume by recruitment of the collapsed lung, the application of appropriate PEEP to keep the aerated lung open, and to prevent cyclic airway closure should redirect ventilation to more dependent lung regions. Secondly, maintaining normo- or even hypervolaemia should make the pulmonary circulation less vulnerable to increased airway and alveolar pressures, and result in a better match of ventilation and perfusion. Thirdly, maintenance of any respiratory muscle tone or mimicking spontaneous breaths in addition to the mechanical breaths may improve matching of ventilation and blood flow, facilitate venous return and decrease systemic organ oedema formation (keeping in mind respiratory muscle fatigue and even overexpansion of lung if uncontrolled).

Different forms of positive pressure ventilation

A short note will also be made on different forms of PPV. Different inspiratory flow patterns can be used to fine-tune the ventilator settings, but with limited effects on respiratory function [16]. A combination of slow mechanical respiratory rates, e.g. 8 breaths/min, on top of which the patient can breathe spontaneously (airway pressure release ventilation (APRV), or bi-level positive airway pressure, (BiPAP)) appears also to improve gas exchange [17,18]. Applying a cuirass around the chest enables negative pressure selectively over the thorax. This will be as close to a spontaneous breath as possible and it will cause an improvement of blood flow to the lung [19]. This is different from negative pressure ventilation with a patient in a tank just keeping the head outside the tank. With this technique the whole body is exposed to the same pressure variation and there will be no favourable return of venous blood to the heart.

The spontaneously breathing subject changes both respiration rate and size of the tidal volume, and will intermittently also take deep breaths, which may even mimic a recruitment manoeuvre. In conventional mechanical ventilation, respiratory rate and tidal volume are kept constant with a monotonous ventilatory pattern. If anything, this will promote successive deterioration of surfactant function and also promote alveolar collapse. One can speculate on other negative effects on vascular pressures and perfusion distribution. There are reports showing that the gas exchange is improved if the ventilatory pattern is varying in a random fashion [20].

Conclusion

To summarize, positive pressure ventilation differs from spontaneous breathing by exposing the lung to higher pressures, impairing matching of ventilation and blood flow, and impeding cardiac output. At the same time, PPV may be a life-saving treatment, but not necessarily the optimum technique for ventilatory support.

CHAPTER 89

Respiratory support with continuous positive airways pressure

Francesco Mojoli and Antonio Braschi

Key points

- Continuous positive airway pressure (CPAP) is a mode of respiratory assistance in which the patient breaths spontaneously at higher than atmospheric pressure.
- In heart and/or respiratory failure patients, CPAP application can provide favourable haemodynamic and respiratory effects.
- CPAP is indicated in patients with parenchymal respiratory failure, and normal respiratory drive and muscular pump.
- The CPAP apparatus not only keeps the airway pressure positive throughout the respiratory cycle, but also regulates FIO_2, humidity and temperature of inspired gases.
- CPAP may be delivered by different flow generators and interfaces—the final choice depends on patient's disease and compliance, environment, material availability, and clinical practice.

Introduction

Continuous positive airway pressure (CPAP) is the simplest mode of respiratory assistance. A CPAP respiratory device is less sophisticated than a ventilator and is designed to keep the patient's airway pressure at a higher level than atmospheric pressure during the whole respiratory cycle. CPAP also conditions the inspired gas in terms of oxygen concentration (FIO_2), humidity, and temperature. Essentially, ventilation is performed by the patient's own respiratory drive and muscular pump.

Mechanical ventilation (MV) was introduced in clinical practice for patients with respiratory pump failure and healthy lungs (during the epidemic of poliomyelitis in the 1950s) as opposed to CPAP, which is indicated in patients with respiratory failure and a normal drive and muscular pump. CPAP was first employed in the early 1970s to treat acute respiratory distress syndrome (ARDS). However, in 1938, Barach used it for acute cardiogenic pulmonary oedema (ACPE), while others found CPAP useful in military medicine and aeronautics. Nowadays, CPAP is largely used in critically-ill patients with parenchymal respiratory failure in various clinical settings.

Physiological effects of CPAP

The use of CPAP leads to an increase of transpulmonary pressure (P_{TP}). P_{TP} is the pressure that distends the lung parenchyma, and will end up in an increase of lung volume at end expiration, i.e. the functional residual capacity (FRC). When an increase in FRC is due to recruitment of previously collapsed alveoli, lung compliance improves, whereas shunt and low ventilation/perfusion conditions decrease within the lungs [1]. Therefore, CPAP can significantly improve gas exchange and reduce the work of breathing (WOB). On the other hand, when an increase in FRC is due to overdistention of already open alveolar spaces, lung compliance can decrease, whereas dead space (both anatomical and functional) and pulmonary vascular resistance increase [2].

Although CPAP does not directly assist patients' inspiratory efforts, its use often provides favourable effects on spontaneous ventilation. CPAP can decrease every single component of patients' WOB (resistive, elastic, and threshold loads) by improving respiratory mechanics (both airway flow resistance and compliance) [3] and by opposing flow limitation. Progressive collapse of small airways during expiration promotes intrinsic positive end-expiratory pressure ($PEEP_i$), i.e. a pressure gradient between alveoli and proximal airways at the end of expiration. $PEEP_i$ represents a threshold load for the inspiratory muscles, which can be substantially decreased by PEEP and CPAP in chronic obstructive pulmonary disease (COPD) flow-limited patients. In asthmatic patients, PEEP and CPAP use can be detrimental due to pulmonary hyperinflation. Finally, CPAP increases the ability of the expiratory muscles to share the workload with the inspiratory muscles.

CPAP use has some haemodynamic effects, mainly mediated by an increase of intrathoracic pressure secondary to greater elastic recoil of the chest wall and/or lower inspiratory efforts. The corresponding fall in right atrial transmural pressure decreases venous return and preload, especially in hypovolaemic patients, whereas the fall in left ventricle transmural pressure translates into lower afterload, particularly in heart failure patients. Moreover, the CPAP-induced increase in oxygen delivery may result in a better myocardial oxygen supply-demand balance, improving diastolic function, ventricular relaxation, and compliance.

Clinical indications for CPAP

Acute cardiogenic pulmonary oedema

By the early twentieth century, evidence showed the application of a positive pulmonary pressure to a patient experiencing ACPE allowed haemodynamic and respiratory mechanics to improve together with less clinical symptoms of respiratory distress. CPAP has been shown to reduce hospital mortality, endotracheal intubation rate, and ICU length of stay in patients with acute pulmonary oedema [4]. In addition, CPAP can also effectively treat ACPE patients with established respiratory muscle fatigue [5]. Accordingly, hypercapnic ACPE patients had similar recovery times and similar gas exchange responses when treated by CPAP or NIV [6]. Compared with NIV, CPAP is less dependent on the experience of the care team and is a simpler technique. This also makes CPAP useful in the out-of-hospital setting.

Post-operative respiratory failure and post-extubation failure treatment/prevention

CPAP is a widely-used strategy to prevent or to treat post-operative pulmonary complications. Several studies have demonstrated the efficacy of CPAP to reduce atelectasis and improve oxygenation in post-operative settings [7]. The efficacy of CPAP in hypoxaemic patients after abdominal surgery is strictly related to the length of use. Therefore, interfaces that improve patient tolerance and length of treatment, such as the helmet, are preferred [8]. The use of CPAP in obese patients following bariatric surgery is questioned because of concerns that pressurized air may inflate the stomach and proximal intestine, resulting in anastomotic disruption. However, it was recently proved that CPAP can be a safe and effective method for respiratory support in this context, provided it is used as early as possible after extubation [9]. CPAP has been shown to reduce reintubation rate in post-extubation hypoxaemic failure after cardiac surgery [10].

Chest trauma

CPAP should be used in patients with chest wall trauma who remain hypoxic despite adequate regional anaesthesia and high-flow oxygen. Several studies have shown that CPAP resulted in fewer treatment days when compared with immediate intubation followed by intermittent positive pressure ventilation. This improvement is obtained mainly through a decrease of infection rate in non-intubated patients. In view of the risk of pneumothorax, patients with chest trauma who are treated with CPAP or non-invasive ventilation (NIV), especially in presence of multiple rib fractures, should be monitored in the intensive care unit (ICU).

Community-acquired pneumonia

In patients with community-acquired pneumonia (CAP), time is needed for conventional therapy to show its effect; during this period, the maintenance of a satisfactory oxygenation represents the main goal in the management of acute respiratory failure (ARF). CPAP can rapidly improve oxygenation in CAP patients, but the beneficial effects disappear early after its discontinuation. The choice of helmet improves tolerance by allowing expectoration and ameliorating patient–environment interaction, and could be the right choice in patients with pneumonia who may need longer periods of CPAP treatment [11].

Respiratory failure in immunocompromised patients

Any less invasive method able to avoid the use of endotracheal ventilation appears to be particularly useful in immunocompromised patients. CPAP used at an early stage of hypoxaemic ARF is effective in reducing intubation and ICU admission rate, often related to an increased risk of infectious complications and death in these patients [12].

Mild/moderate acute respiratory distress syndrome

In patients with acute lung injury (ALI), applying positive pressure to the airways has been shown to lessen the reduction in functional residual capacity, and to improve respiratory mechanics and gas exchange. However, the efficacy of CPAP to prevent subsequent clinical deterioration and to reduce the need for endotracheal intubation has never been certainly shown. Despite early physiological benefits, CPAP delivered via face mask did not reduce the need for endotracheal intubation among ALI patients, and did not impact the length of hospital stay or hospital mortality [13]. Whether the use of the helmet interface, allowing prolonged administration of high PEEP levels, could improve outcome in patient affected by mild ARDS, has to be definitively demonstrated [12].

COPD exacerbation

The increase in WOB during COPD exacerbations is due to both an increased resistive load and dynamic hyperinflation; $PEEP_i$ imposes an additional inspiratory threshold load, while decreasing the effectiveness of the inspiratory muscle. CPAP can counterbalance $PEEP_i$ without causing further hyperinflation, decreasing inspiratory effort and dyspnoea, while improving the pattern of breathing. Arterial blood gases tend to remain the same or improve slightly, probably due to improvement in breathing pattern at constant minute ventilation, and eventually to decreased WOB. For these reasons, despite the evidence demonstrating NIV effectiveness in COPD exacerbation, also the use of CPAP can be considered, especially in particular settings where NIV is not available.

High-risk fibre optic bronchoscopy

CPAP delivered by full face mask allows better tolerance of fibre optic bronchoscopy compared with oxygen therapy. In hypoxaemic patients undergoing bronchoscopy, CPAP improves oxygenation and reduces the rate of subsequent respiratory failure.

Techniques for CPAP administration

The main goal of CPAP delivering is to maintain pressure in the proximal patient's airways at the same desired level during the whole respiratory circle, together with full control of inhaled gas mixture. This means low difference between set and delivered oxygen fraction, low level of CO_2 rebreathing, temperature, and humidity according to invasive or non-invasive setting. Additional goals are patient's compliance, safety and monitoring, and technique's easiness and cheapness.

CPAP can be delivered by different flow generators and interfaces. The final choice depends on patient's disease and compliance, environment, material availability, and clinical practice.

Continuous flow systems

Continuous flow systems consist of a mixer-flow meter (or two separate flow meters for air and oxygen, or a Venturi system), a heater-humidifier, a pressure stabilizer, a PEEP valve, and a manometer. Oxygen fraction delivered by Venturi systems depends on flow and pressure in the CPAP circuit, and should be monitored at every setting change. Ideally, to maintain constant positive pressure in the patient's airways, a continuous flow at least equal to patient's peak inspiratory flow should be set. Anyway, besides a great gas wasting, very high (50–100 L/min) fresh gas flows have some drawbacks. Gas conditioning can be suboptimal, noise substantially increases, and the effect of even small expiratory circuit resistance is magnified. The increase of pressure during expiration can put a significant brake on the patient's expiratory flow. A large volume (10 L at atmospheric pressure) and highly compliant (500 mL/cmH_2O) balloon provides good pressure stabilization in the CPAP circuit without the need of very high fresh gas flow. Its optimal position is in the inspiratory limb nearest the patient's airways opening. Gas flow lower than 30 L/min favours CO_2 rebreathing, both in an invasive and non-invasive setting.

PEEP valves

Commercially-available PEEP valves, such as water valves, and adjustable or precalibrated spring-loaded valves, are threshold resistors. Ideally, exhaled gas freely flows away through the valve until airway pressure decreases to a preset level, at which time the valve abruptly closes. In practice, these valves are not pure threshold resistors, but offer a small (and variable among different devices) resistance to flow, eventually to be added to the resistive behaviour of the expiratory limb of the circuit, and of the expiratory port of mask and helmet interfaces [14]. This small resistance to flow has significant effects on patient's airways pressure when high flow rates are used. Therefore, when administering CPAP with continuous flow systems, pressure must be monitored with a manometer placed as near as possible patient's airways, to control the effective pressure applied, and detect respiratory oscillations. Excessive pressure oscillations (>3–4 cmH_2O) correspond to significant additional respiratory load for the patient. In this case, the use of a high-volume high-compliance balloon becomes mandatory, an increase of gas flow, and the use of the helmet interface should be considered. Recently, the Boussignac valve has been proposed for non-invasive CPAP delivery [15]. This device consists of a plastic tube open to atmosphere and provided with microchannels in the tube wall. The gas injected into the system accelerates through the microchannels, leading to turbulence, and finally positive pressure, corresponding to a 'virtual' valve at the patient's side of the tube. Generated pressure depends on the flow administered; therefore, CPAP level and oxygen concentration cannot be adjusted separately. Moreover, the Boussignac device is not able to maintain a stable positive pressure value in the case of forced breathing and/or high respiratory rate [16]. Anyway, special features of this device (an 'open' system with small dimensions and easy to use) make it a good choice in particular settings, like pre-hospital treatments [15] and bronchoscopy procedures.

Demand-flow systems

Mechanical ventilators can be used as demand-flow systems to administer CPAP, where the alternate opening of the inspiratory and the expiratory valves should provide the inhalational gas volume required by the patient and allow its exhalation, respectively. When the control systems of the mechanical ventilator assure both fast detection of patient's respiratory activity and a rapid reaction of mechanical valves, pressure oscillation in the airways will be not clinically significant. This was not the case with old generation ventilators—the inspiratory decrease and expiratory increase of pressure were significant, leading to additional work to inhale and braked exhalation. Technological improvements allow new generation ventilators to perform, as well as continuous flow systems, with some differences among models. Additional benefit of ventilator-delivered CPAP is respiratory monitoring and alarming that is necessarily incomplete with continuous flow systems. Higher costs and low availability of both instruments and practice, limit the use of mechanical ventilators to specific settings.

Interfaces

CPAP can be administered by different interfaces: nasal and face masks, nasal pillows and helmets. Nasal devices need cooperation of the patient that has to breathe with a closed mouth to effectively receive CPAP. Among full-face devices, the helmet is more efficient than the mask because of its high internal volume and compliance, making it an additional pressure stabilizer in the CPAP circuit [17]. Moreover, the helmet provides a good tightness by non-traumatic adhesion of the soft collar to the neck of the patient with less discomfort and skin lesions compared with face masks. Because high pressures inside masks—but not inside helmets—increase leaks [18], higher PEEP levels can be administered with helmets. Therefore, acute hypoxaemic patients needing high-level CPAP without interruptions may particularly take advantage from the helmet device [11,12]. CO_2 rebreathing during mask CPAP is limited mainly by leaks, both unintentional and intentional through expiratory ports. Conversely, during helmet CPAP significant CO_2 rebreathing may occurs when the amount of fresh gas flowing through the device is not well matched with patient's CO_2 production. A minimum fresh flow delivery of 30–35 L/min is always mandatory, to be increased to 50 L/min or more in case of higher metabolic requirements. This also means that the use of mechanical ventilators, that provide fresh gas flow equal to patient's minute ventilation, must be avoided for helmet CPAP. Mean inhaled CO_2 can be easily monitored by gas sampling at the outlet port of the helmet [19]; this value should be maintained below 0.5% by adjusting fresh gas flow in order not to increase patient's ventilatory workload.

Comfort data suggest that humidity of inspired gases during CPAP should be at or above 15 mgH_2O/L with temperatures ranging from 25 to 30°C. Heated humidifier can provide this gas conditioning [20].

CHAPTER 90

Non-invasive positive-pressure ventilation

Giulia Spoletini and Nicholas S. Hill

Key points

- Exacerbations of chronic obstructive pulmonary disease (COPD), cardiogenic pulmonary oedema and acute respiratory failure in immunocompromised patients are the main indications for non-invasive ventilation (level 1 evidence).
- Weaker evidence supports the use of non-invasive ventilation (NIV) in other forms of hypercapnic respiratory failure (acute asthma, cystic fibrosis, obesity–hypoventilation syndrome) and in hypoxaemic respiratory failure (pneumonia, acute respiratory distress syndrome (ARDS), chest trauma).
- Proper selection of patients, considering both indications and contraindication to NIV, plays a key-role in NIV success.
- Trained staff with knowledge and skill in the proper application of NIV is another determinant of success.
- Avoid delays in the initiation of NIV as well as in intubation when NIV fails.

Introduction

Non-invasive ventilation (NIV) is a technique that provides respiratory assistance and avoids airway invasion in patients with certain kinds of acute respiratory failure (ARF). The most common NIV application is non-invasive positive pressure ventilation (NIPPV), which conducts pressurized gas from a positive pressure ventilator to the patient via an external interface strapped over the nose and/or mouth. This technique avoids airway invasion, and can thereby avoid complications related to intubation and invasive mechanical ventilation (INV), especially ventilator-associated pneumonias. Furthermore, it avoids the trauma associated with intubation and usually augments comfort compared with INV, thereby reducing the need for analgesia and sedation. It is suitable for intermittent use, allowing breaks for eating and communicating. It may also reduce morbidity and mortality, and shorten ICU stays or avoid the need for ICU altogether, thus reducing costs. This brief review will focus on current indications for NIV, selection of appropriate patients, and proper application.

Indications with level 1 evidence: NIV is first choice for ventilatory support

Chronic obstructive pulmonary disease

The main indication for NIV in chronic obstructive pulmonary disease (COPD) is an exacerbation with persistent acute or acute on chronic hypercapnic respiratory failure (AHRF) despite initial medical treatment. In these patients, NIV combines positive end expiratory pressure (PEEP) to counterbalance auto-PEEP and pressure support to assist inspiratory muscles, thereby reducing the work of breathing and averting inspiratory muscle fatigue. Compared with standard medical care in COPD patients, NIV more rapidly improves vital signs (especially respiratory rate) and gas exchange, and reduces the need for intubation, complications, length of hospital stay, and mortality [1]. In particular, NIV is strongly recommended in those patients with a $7.25 < pH < 7.35$. With a $pH < 7.25$, NIV could still be successful, but should be managed in an ICU with very close observation in order to intubate without delay if necessary [2,3].

Not only is NIV indicated for moderate to severe COPD exacerbations, but also for COPD patients with respiratory failure in a number of other settings including:

- When associated with pneumonia.
- Post-operative patients, especially after lung resection.
- To facilitate extubation in COPD patients requiring INV initially.
- To avoid extubation failure after a standard extubation.
- In do-not-intubate patients.

Cardiogenic pulmonary oedema

In patients with cardiogenic pulmonary oedema (CPE), CPAP (10–12.5 cmH_2O) compared with standard oxygen supplementation increases intrathoracic pressure and raises functional residual capacity, thus re-expanding alveoli, rapidly improving oxygenation, improving lung compliance, reducing left ventricular afterload, and often increasing cardiac output. These benefits translate into the avoidance of intubation and reduced mortality. In the past decade, a number of studies have compared 'bilevel' ventilation (combining inspiratory pressure support with positive expiratory pressure) with CPAP alone to treat CPE, but have found no differences between the modes in intubation, myocardial infarction and mortality rates [4]. The European Society of Cardiology considers CPAP as first-line treatment of CPE [5], but the Canadian NIV Guideline group considers them equivalent and recommends either CPAP or 'bi-level' ventilation for CPE patients in the absence of shock or need for coronary revascularization [6]. These positive results from in-patients have been replicated in the field where a number of randomized trials have demonstrated that CPAP administered by ambulance crews reduces intubation and mortality rates in CPE patients prior to hospitalization [7].

Immunocompromised patients

INV in immunocompromised patients is associated with infectious and haemorrhagic complications, including septic shock and high mortality rates. NIV can reduce the occurrence of nosocomial infections and septic shock and avoid INV in such patients, thereby improving survival [8]. It should be emphasized, however, that such patients should be started early on NIV, closely monitored in an ICU, and promptly intubated if they continue to deteriorate with worsening oxygenation and haemodynamic instability.

Weaker evidence—NIV is an option

Other forms of hypercapnic respiratory failure

Asthma

Some earlier uncontrolled cohort series have associated improvements in gas exchange and low intubation rates with use of NIV in patients with severe asthma, but no controlled trials have confirmed these benefits. Some of the few randomized trials reported have demonstrated that NIV increases airflow more rapidly than a sham mask [9] or standard oxygen [10] during severe asthma attacks, suggesting a bronchodilator effect of positive pressure. One study also showed a lower hospitalization rate from the ED with NIV [9]. Thus, NIV with close monitoring is an option for severe asthma that does not respond promptly to standard medical treatment, perhaps combined with helium oxygen mixtures and/or continuous bronchodilator nebulization. However, considering that supportive evidence is weak, patients should be monitored closely and promptly intubated if they fail to improve.

Cystic fibrosis

NIV has been used for cystic fibrosis in the chronic or subacute setting as a bridge-to-transplant [11]. It may also serve a role as an adjuvant to secretion clearance techniques. However, few studies have evaluated its use in acute care. It remains an option in the acute setting, but for patients with acute pneumonias and secretion retention, prompt intubation followed by transition to NIV once the patient has stabilized may be the preferred approach.

Obesity-hypoventilation syndrome

Morbid obesity is often associated with chronic hypoventilation, defining the obesity-hypoventilation syndrome (OHS). Episodes of acute on chronic respiratory acidosis occurring in this entity may be treated with NIV, avoiding INV. Some of these patients are initially too ill for NIV, due to altered neurological status, excessive secretions, or decompensated congestive heart failure, but can be transitioned to NIV when stabilized. In one cohort, initiation during acute exacerbations, rather than the chronic state, and cardiovascular morbidities were associated with worse long-term NIV outcomes [12].

Hypoxaemic respiratory failure

ARDS/pneumonia

Pneumonia and ARDS are associated with a substantially higher risk of NIV failure than most other forms of acute respiratory failure, and NIV is not routinely recommended to treat them. Oxygenation needs are high, necessitating higher PEEP levels, which detracts from mask comfort and predisposes to greater mask leak. In addition, the underlying process often progresses, rendering the patient too ill to be safely managed with NIV. Thus, patients with ARDS or pneumonia treated with NIV must be selected with great caution. They must not have multi-organ dysfunction or haemodynamic instability, and must be watched very carefully in an ICU. If their oxygenation does not improve substantially within 1–2 hours of NIV initiation, they should be promptly intubated [13].

Chest trauma

Chest trauma patients may develop hypoxaemic ARF after lung contusion or acute lung injury related to activation of the inflammatory cascade. They may also develop hypercapnic ARF after rib fractures, leading to flail chest. A randomized controlled trial showed avoidance of respiratory muscle fatigue and the need for intubation in severely hypoxemic chest trauma patients [14]. A subsequent meta-analysis [15] showed that NIV not only reduces intubation rate, but also length of ICU stay and mortality, and may be a preferable alternative to INV in these patients.

Do-not-intubate

Many patients with chronic respiratory conditions decide to forego heroic measures and decline intubation. NIV can still help many of these patients, especially those with COPD or CPE who have a reasonably good chance of surviving hospitalization for an acute exacerbation [16]. NIV may also be used for palliative purposes, mainly to relieve dyspnoea in terminal patients, or to extend life long enough for relatives to visit or settle their affairs. However, it is important to make certain that patients and their families who wish for NIV understand such circumstances and establish realistic goals for its use. If these goals are not being met, NIV should be stopped and alternative palliation instituted.

Practical aspects

The success of NIPPV depends not only on the disease underlying NIV, but also on the proper selection of patients, timing, and setting of the treatment.

Selection of patients

All patients in respiratory distress, defined as tachypnoea, use of accessory muscles, hypoxaemia, diagnosed with ARF (pH < 7.35 and PCO_2 > 45 mmHg, or PO_2/FIO_2 < 200), should be considered as soon as possible for NIV. Delay in starting the treatment can increase the risk of complications and NIV failure. Before starting NIV, it is mandatory to determine whether they have contraindications, such as respiratory arrest, septic shock with multiple organ failure, or the inability to fit the mask or to protect the airways, in which case they should be promptly intubated. Some patients have relative contraindications, such as unstable medical conditions, agitation, the presence of excessive secretions, or recent thoracic or upper abdomen surgery, and should be evaluated on a case-by-case basis. In marginal cases at higher risk of NIV failure, a NIV trial of 1–2 hours could be tried and intubation undertaken if there is no improvement [17].

Interface

The choice of a comfortable and properly fitted interface is key to a favourable NIV outcome, since it can improve patients' tolerance and adherence to the treatment, minimize air leaks, and optimize patient–ventilator synchrony. Oro-nasal (or full-face) are generally preferred, since they are associated with less air leaking through the mouth. On the other hand, nasal masks can facilitate speech

and expectoration, and may be better tolerated by claustrophobic patients. The helmet is an alternative interface that consists of a soft clear plastic cylinder that seals over the neck and shoulders, and has been extensively studied, mainly in Italy. It has proven quite effective in delivering CPAP, but requires high air flow to minimize rebreathing, which are quite noisy. When used to deliver pressure support and PEEP, patient–ventilator asynchrony can be a problem with the helmet [18], but a newer, stiffer version may counter this problem.

Ventilator selection

Either ICU ventilators using pressure- or volume-limited modes or portable bi-level ventilators can be used for NIV with equal expectations of success. However 'bi-level' devices designed specifically for delivery of NIV are the most often chosen for hypercapnic ARF, whereas ICU ventilators may be selected more often for hypoxaemic respiratory failure. Many ICU ventilators now have 'NIV' modes that facilitate delivery of NIV, but may require additional adjustments in the face of leaks.

Ventilator settings

Successful NIV requires that sufficient ventilator support is provided in synchrony with the patient's breathing efforts. Thus, proper adjustment of ventilator settings is very important. Usually, the pressure-support (or bi-level) mode starting with lower settings (inspiratory pressure 8–12 cmH_2O, expiratory pressure 4–5 cmH_2O) enhances tolerance for patients. Inspiratory pressure can then be gradually adjusted upward to alleviate persistent respiratory distress, within the patient's limit of tolerance. Expiratory pressure can be increased to improve triggering in the presence of auto-PEEP or to improve oxygenation. Oxygen supplementation is titrated to achieve a desired O_2 saturation (>90–92%). Humidification is not necessary for brief applications (such as for CPE), but helps to avoid mucosal drying and enhances comfort for longer applications [18].

Monitoring

Close monitoring of NIV is important for success, especially during the early adaptation period. The value of frequent checks to optimize mask fit and ventilator settings, and to encourage the patient cannot be overemphasized. Acutely-ill patients should be monitored in an ICU or intermediate care unit until they are more stable. NIV can be administered on regular wards by experienced staff, but only for cooperative patients who are relatively stable and can call for help if needed [19].

All patients undergoing NIV should be monitored at least with:

- Clinical examination of:
  - Dyspnoea.
  - Respiratory and heart rate.
  - Other signs of respiratory distress—abdominal paradox, accessory muscles use, etc.).
  - Mask comfort, fit.
- Gas exchange:
  - Arterial blood gases before initiation, after 1–2 hours of NIV and as needed.
  - Continuous O_2 saturation.
- Blood pressure and EKG.
- Ventilator:
  - Synchrony with patient.
  - Tidal volume (target 6–7 mL/kg ideal body weight).
  - Air leaks from mask and tubing.

Complications

NIPPV is usually a safe and well-tolerated technique. The adverse effect are related to the interface, which can cause skin reddening or ulceration, especially over the nasal bridge, claustrophobia, sinus or nasal pain, and dryness of eyes and mouth due to air leaks. Improbable, but possible complications include pneumothoraces, painful gastric insufflation, and aspiration of gastric contents. Patient agitation interferes with efficacy, but can be ameliorated by sedation.

Predicting outcome

When applied in properly selected patients using optimal techniques by an experienced staff, success rates of NIV, especially for COPD and CPE, are generally over 80%. However, some patients fail, especially if they have diagnoses like pneumonia or cancer. In hypercapnic ARF, APACHE II score > 34, pH < 7.25, respiratory rate > 35, and Glasgow Coma Score ≤ 11 have all been shown to predict NIV failure, especially if they persist for the first 2 hours [17]. In hypoxaemic ARF, having ARDS, pneumonia, or shock are the strongest predictors of failure, but other predictors include older age, high acuity of illness, and lack of improvement in PaO_2/FiO_2 after the first hour of NIV [20].

Conclusion

NIV has been one of the most important developments in the field of mechanical ventilation over the past 20 years and its use is increasing around the world. This increase has been associated with improved outcomes for patients with ARF due to COPD and CPE, and it is being used increasingly in other types of ARF as well. To achieve optimal results, it must be applied in carefully-selected patients, using appropriate techniques implemented by a skilled staff with conscientious monitoring.

CHAPTER 91

Indications for mechanical ventilation

Neil R. MacIntyre

Key points

- Mechanical ventilation can be life-sustaining, but is associated with significant risk.
- Mechanical ventilation with a guaranteed rate/tidal volume is indicated when the patient's ventilatory control system is unreliable.
- Mechanical ventilation with appropriate muscle unloading is indicated when a mechanical load–metabolic demand imbalance exists.
- Mechanical ventilation with end-expiratory pressure is indicated when alveolar patency is compromised.
- Mechanical ventilation with low level inspiratory pressure is indicated if an artificial airway imposes an uncomfortable muscle load.

Introduction

Mechanical ventilation is the process of using positive pressure devices to provide O_2 and CO_2 transport between the environment and the pulmonary capillary bed. The desired effect of mechanical ventilation is to maintain adequate levels of PO_2 and PCO_2 in arterial blood, while also unloading the inspiratory muscles. At the same time, this process should be done in a manner that avoids injury to the lungs and other organ systems. Ventilator-induced lung injury [1], infection [2], and the need for potentially harmful sedatives/neuromuscular blockers [3], all underscore the need to assure that initiation of mechanical ventilatory support is worth these risks.

The basic components of a mechanical ventilatory support system are:

- An artificial airway (or sometimes a mask) that provides the interface between the mechanical ventilator and the patients airways.
- A source of oxygen enriched positive pressure breaths delivered either in accordance with a set timer or in response to a patient effort.
- The capability to maintain an end expiratory positive pressure.

These features are designed to address the following clinical problems that constitute the 'indications' for providing mechanical ventilatory support:

- The need for providing a reliable number of breaths in patients without an appropriate spontaneous ventilatory controller.
- The need for unloading fatigued or impaired ventilatory muscles that are incapable of providing adequate tidal breaths.
- The need for maintaining alveolar patency in patients with inflamed or flooded lung units.
- The need to support an artificial airway in a patient who cannot maintain and/or protect the natural airway.

In a large survey of over 5000 mechanically-ventilated patients in 361 ICUs worldwide [4], the vast majority required mechanical ventilation because of either acute cardio-pulmonary failure (68%) or acute on chronic cardio-pulmonary failure (13%)—the second and third indications 2 and 3 in the list above. The remainder (the first and fourth indications in the list above) were patients requiring mechanical ventilation for largely neuromuscular issues.

The remainder of this chapter will review the underlying pathophysiology of these indications and clinical signs/thresholds that usually trigger institution of mechanical ventilatory support. There will also be brief discussions on how modern systems are designed to address these indications.

Controller failure
