Recent consensus guidelines have considered the importance of patient factors in making recommendations regarding the choice of antimicrobial regimen [6]. These guidelines stratify patients according to their risk of treatment failure, i.e. low- or high-risk, with a view to tailoring antimicrobial coverage. Decision-making around antimicrobial selection is partly based on data showing that factors such as patient physiology, severity of the pathological process, and healthcare-associated infection can influence the microbial flora of infections. For example, Table 185.2 illustrates the change towards more multi-resistant microbes when comparing patients with 'off-the-street' community-acquired peritonitis

Table 185.2 Changes in microbial flora recovered in patients with community-acquired peritonitis compared to postoperative peritonitis

Strain	Community-acquired	Post-operative
Enterococci	5	21
Escherichia coli	36	19
Enterobacter spp.	3	12
Bacteroides sp.	10	7
Klebsiella sp.	7	7
Staphylococcus aureus	1	6
Coagulase negative taphylococci	1	5
Candida sp.	7	4
Pseudomonas sp.	2	6
Streptococci	14	4
Haemolytic streptococci	3	0
Other	11	9

Table 185.3 Recommendations for antimicrobial treatment of community-acquired intra-abdominal infections

Mild/moderate infections	High-severity infections
Single agent regimen	
◆ Cefoxitin ◆ Ticarcillin/clavulanic acid ◆ Ertapenem ◆ Moxifloxacin ◆ Tigecycline	◆ Piperacillin/tazobactam ◆ Imipenem/cilastatin ◆ Meropenem ◆ Doripenem
Combination regimen	
Cefazolin, cetriaxone, cefuroxime, cefotaxime. fluoroquinolone (FQ)-based therapy + metronidazole	◆ Ceftazidime, cefepime plus metronidazole ◆ FQ + metronidazole

Adapted from Solomkin et al., 'Diagnosis and management of complicated intra-abdominal infection in adults and children: guidelines by the Surgical Infection Society and the Infectious Diseases Society of America', *Clinical Infectious Diseases*, 2010, **50**(2), pp. 133–64, by permission of Oxford University Press and Infectious Diseases Society of America.

to post-operative peritonitis due to disruption of a surgical anastomosis [8]. Guidelines separate patients into those with community-acquired or health care associated infection. The former is further subdivided into 'mild-to-moderate severity' and 'high severity' where high-risk defines patients at increased risk of treatment failure. Box 185.1 lists factors causing patients to be designated 'high-risk'. Based on this separation, the authors recommend specific treatment regimens (Table 185.3). In the 'mild-to-moderate' group, agents which cover enteric Gram negative aerobic and facultative bacilli and enteric Gram-positive *streptococci* are recommended, with the addition of anti-anaerobe coverage if the perforation is in the colon or in obstructed or paralytic small bowel. Broader-spectrum agents including anti-enterococcal treatment are indicated for 'high risk' patients, given the higher probability of multi-resistant organisms. Importantly, refinement of antimicrobial agents should be made based on cultures taken at surgery.

Box 185.1 Factors which define patients as being high-risk for treatment failure

- High severity of illness (i.e. physiological derangement as defined by APACHE II).
- Advanced age.
- Co-morbidity and degree of organ dysfunction.
- Immunological suppression (including malnutrition, malignancy, immunosuppressive agents).
- Diffuse peritonitis.
- Poor control of underlying pathological process.
- Prolonged preoperative hospital stay.
- Prior use of antimicrobial agents.

Adapted from Solomkin et al., 'Diagnosis and management of complicated intra-abdominal infection in adults and children: guidelines by the Surgical Infection Society and the Infectious Diseases Society of America', *Clinical Infectious Diseases*, 2010, **50**(2), pp. 133–64, by permission of Oxford University Press and Infectious Diseases Society of America.

Finally, patients developing peritonitis in the health care setting are likely to harbour multi-resistant bacteria. In essence, antibiotic selection should be similar to those for 'high severity' community-acquired infections plus addition/replacement of agents based upon susceptibility patterns at the individual Institution. The regimen should be tailored to culture and sensitivity data derived from the infection, including anti-fungal therapy as indicated.

Until recently, treatment duration for perforated viscus was based on retrospective studies where defervescence and normalization of leukocyte count correlated with low probability of recurrent infection following antibiotic discontinuation [9]. Treatment for 4–7 days was usually required for this response. Recently, a National Institutes of Health-sponsored prospective randomized clinical trial evaluating duration of antimicrobial use for intra-abdominal infection was published [10]. This study reported that a fixed duration of four days of antimicrobial therapy resulted in equivalent outcomes to the traditional approach of using physiological parameters to dictate antimicrobial duration. Finally, short-duration (<24 hours) antimicrobial therapy is recommended for patients with perforated peptic ulcer or traumatic perforation of the GI tract [6].

An intravenous route is preferred for initial antimicrobial treatment. Switchover to oral antibiotics with good bioavailability is acceptable once the GI tract has resumed function [6].

Source control

This describes physical measures employed to remove or limit the focus of infection, and to mitigate local factors that promote

recurrent or residual infection [11]. Adequate source control is essential for successful management, the incidence of inadequate source control as a cause for treatment failure in eight clinical trials studying anti-infective therapy ranged from 5–29% [12]. Inadequate source control resulted in a two-fold increase in post-operative length of stay and ~55% increase in mortality [13].

Depending on the ability of the host peritoneal defence mechanisms to contain the perforation, visceral perforation is manifested as either localized abscess or diffuse peritoneal infection. Abscesses may also develop following surgery for diffuse peritonitis (e.g. after surgery for an anastomotic disruption) when residual infection is localized by peritoneal host defences. As previously noted, diffuse contamination and contained infection are usually clinically distinguishable, CT can reliably distinguish between a well-demarcated fluid collection for abscess, and less well-defined fluid 'collections' for diffuse peritoneal soiling.

Intra-abdominal abscesses

Percutaneous drainage (PCD) is the preferred technique for management of intra-abdominal abscesses as it is a safe, effective alternative to surgical intervention [14].

Criteria for the use of PCD have broadened as experience has evolved. There are few absolute contraindications, although efficacy may be limited when thick abscess contents preclude drainage, or there are early post-operative collections, indicative of diffuse infection. The weight of evidence, albeit not methodologically robust, suggests that PCD should be used for initial management of discrete intraperitoneal fluid collections.

Management of diffuse peritonitis due to visceral perforation

Treatment should focus on reducing the bacterial burden and necrotic material, managing the underlying pathological process responsible for leaking GI content, and preventing residual or recurrent infection.

Purulent, faecal and necrotic material should be aspirated and debrided. This lessens bacterial burden and reduces the presence of adjuvant materials known to promote bacterial growth (e.g. haemoglobin) and impair local host defence mechanisms (e.g. particulate faecal matter). Surgical options include closing and/or patching the defect, resecting the pathology + primary anastomosis of the bowel ends, or exteriorizing the defect. Decision-making should take into account the organ affected, the underlying pathological process, local conditions within the abdomen, and the patient's general status. The following paragraphs briefly address the commonest causes of GI tract perforation (Table 185.1).

Appendicitis

Perforated appendicitis is usually managed by appendectomy. Both open and laparoscopic appendectomy are effective in managing the appendicitis, but the latter appears superior with respect to hospital length of stay, post-operative complications and return to work [15]. A recent meta-analysis suggested that laparoscopic appendectomy was associated with increased fetal loss during pregnancy, although included studies were of poor quality [16].

Sigmoid diverticulitis

For patients with purulent or faecal peritonitis (Hinchey class III and IV), a two-stage procedure (i.e. Hartmann's procedure) is performed whereby the diseased sigmoid is resected, an end-sigmoid stoma and rectal stump created, and delayed reconstruction planned. Intestinal continuity may be safely restored by a primary anastomosis (PA) at the time of the initial emergency surgery with or without proximal diversion [17]. There has been recent enthusiasm for laparoscopic lavage and drainage for managing Hinchey III-perforated diverticulitis, although the quality of studies was evaluated as low [18].

Perforated peptic ulcer disease

The management of perforated peptic ulcer disease is dictated by the manifestations of the perforation. In some patients, the perforation is well walled off and can be managed conservatively with antibiotics alone. In others, the perforation has been localized, but there is an abscess present which is amenable to PCD. Finally, perforation with diffuse spread of gastroduodenal contents throughout the peritoneal cavity usually warrants surgical intervention. At surgery, the defect is managed by direct closure when the defect is small with easily opposable edges, reinforced by patching of the defect with vascularized omentum. Intraoperative lavage of GI content and particulate matter should be performed. A laparoscopic approach to this procedure is comparable to open surgery, with a modest reduction in the requirement for pain medication in the former [19].

Perforated small intestine due to mesenteric ischaemia

Here, the perforation is a manifestation of loss of wall integrity at ≥1 sites within a segment of infarcted small intestine. The demarcation sites between live and dead bowel is usually obvious for mesenteric vascular embolus or intestinal volvulus. In non-occlusive mesenteric ischaemia, gangrenous perforation may occur at ≥1 sites with intervening areas where the bowel looks dusky (i.e. ischaemic, but not necrotic). Here, one should resect the obviously gangrenous parts of intestine (which presumably include the sites of perforation), and plan for a second-look laparotomy 24–48 hours later when any residual ischaemic/infarcted bowel should be resected. A primary intestinal anastomosis after the second-look should take into consideration local factors in the peritoneal cavity and systemic factors such as patient haemodynamics and comorbidities.

Prevention of residual or recurrent infection

Lavage of the peritoneal cavity is generally repeated at the end of surgery. There is no benefit to including antibiotics in the solution nor is there a role for continuous post-operative peritoneal lavage through indwelling catheters placed intra-operatively. 'Scheduled repeat laparotomy', where a laparotomy is performed by protocol every 24–48 hours for peritoneal lavage is not superior to 'on-demand' laparotomy [20]. Similarly, leaving the fascia open (i.e. the 'open abdomen') with frequent laparotomy for peritoneal lavage is not superior to planned re-intervention based on clinical criteria of infection.

Conclusion

Visceral perforation presents with either localized or diffuse abdominal pain and tenderness depending on the ability of the peritoneal host defence mechanisms to contain the spread of GI content from the site of perforation. The diagnosis is based on clinical symptoms and signs, supported by appropriate imaging. CT scanning is an accurate method of diagnosing perforation and can

provide information about the underlying pathological process. The principles of treatment include adequate physiological support, appropriate antimicrobial therapy and intervention to control the source of infection and prevent its recurrence.

CHAPTER 186

Ischaemic bowel in the critically ill

A. G. Peppelenbosch and Martijn Poeze

Key points

- The cause of acute mesenteric ischaemia, i.e. occlusion of visceral arteries, thrombosis of the mesenteric veins, and non-occlusive mesenteric ischaemia influences survival.
- A high index of suspicion is necessary and should be followed by administering therapeutic low molecular weight heparins (LMWH) or systemic heparin infusion. Newer laboratory detection techniques may become available in the near future.
- Resuscitation and support are essential, but should not delay further diagnosis.
- Emergency CT angiography (CTA) for visualizing visceral arteries, with emergency percutaneous transluminal angioplasty (PTA) and stenting of the superior mesenteric artery (SMA) is a priority.
- Thereafter, laparotomy should be performed with resection of necrotic bowel without anastomoses, followed, if possible, after 24–48 hours by a second-look laparotomy and bowel anastomoses.

Introduction

As visceral arteries have an extended collateral network, occlusion of one branch may occur without any symptoms. This is probably the reason for the low incidence rate of acute mesenteric ischaemia (AMI), which is reported to be as low as 0.63 cases per 100,000 person years [1]. However, this incidence rate is probably an underestimate. In an autopsy study an incidence of 8.6 per 100,000 person years was reported [2] even higher than that of ruptured abdominal aortic aneurysm (5.6 per 100,000 person years).

Aetiology

Three different pathways can cause AMI. The first consists of an occlusion of the visceral artery, arteries, or its outflow tract (Fig. 186.1). Usually, the superior mesenteric artery (SMA) is involved. Involvement of ≥2 arteries was previously considered essential in order to develop AMI, but several reports with only one artery involvement make this assumption less likely.

The second pathway involves thrombosis of the mesenteric veins or its outflow tract causing a rise in mean venous pressure, thereby jeopardizing inflow through the mesenteric arteries, and finally inducing bowel ischaemia.

The third pathway is called non-occlusive mesenteric ischaemia (NOMI). This is based on the theory that flow in the visceral arteries becomes too low to sustain adequate mucosal blood flow. The pathogenesis for such a critically low flow state involves a wide variety of conditions of non-mesenteric related origin such as failure of organ function during sepsis, multiple organ failure, cardiogenic and haemorrhagic shock.

The relative occurrence of these three main causes of intestinal ischaemia varies, with non-thrombotic ischaemia reported in 15.4–60% of cases, embolism in 30–38%, thrombus (superimposed on a stenosis) in 36–40%, and venous occlusion in 5–26% [2–4].

Symptoms and signs

Presenting symptoms are usually non-specific. Classically, acute intestinal ischaemia presents with severe abdominal pain out of proportion to objective physical signs. However, especially in

Fig. 186.1 Intra-operative view of acute small bowel ischaemia during laparotomy due to occlusion of the superior mesenteric artery. Note the clear demarcation between viable and ischaemic intestine. Pre-operative revascularization was performed with resection of the demarcated necrotic small bowel.

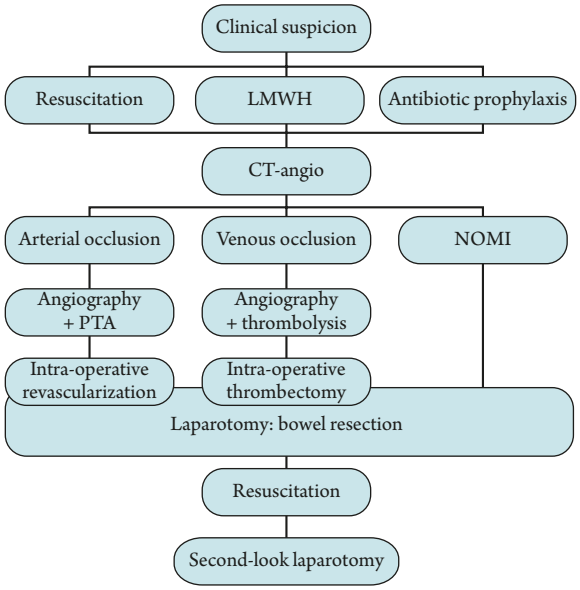

Fig. 186.2 Treatment flow chart for patients with acute intestinal ischaemia. LMWH, low molecular weight heparin; PTA, percutaneous transluminal angioplasty; NOMI, non-occlusive mesenteric ischaemia; CT, computed tomography.

critically-ill (ventilated) patients, the signs and symptoms (of NOMI) are usually inconclusive. Likewise, in elderly patients the clinical symptoms and signs of acute occlusive intestinal ischaemia leading to peritonitis can be very deceptive. Irrespective of the initial presentation, the clinical features during transmural ischaemia will inevitably progress to dysfunction of multiple organs, with tachycardia, hypotension, respiratory distress, oliguria, and, finally, cardiorespiratory arrest.

Diagnosis and surgical treatment

Treatment should start promptly when there is a clinical suspicion of AMI (Fig. 186.2). Even before the diagnosis is confirmed, therapeutic dose LMWH should be administered [5]. Resuscitation is commenced based on clinical signs, especially in patients with organ failure and peritonitis. This is guided by haemodynamic profile and urine output, with replacement of fluid, electrolytes, and protein losses. A broad-spectrum antibiotic should be administered based upon hospital guidelines. Animal studies suggest that antibiotics may have a beneficial effect on outcome [5].

At present blood sampling is not of critical importance in the diagnosis, but is used to evaluate the extent of metabolic acidosis and organ dysfunction. New biomarker developments indicate that products of intestinal cell damage may be useful in diagnosing acute intestinal ischaemia, increased urine concentrations of intestinal fatty-acid binding protein have an excellent likelihood ratio in diagnosing and excluding mesenteric ischaemia in patients suspected of having this condition [6].

The second step is to perform arterial and late venous phase CTA expeditiously. With current scanners, a total-body CT scan takes less than 1 minute. Therefore, in our opinion, scans should include the thorax and abdomen, and extend down to the groins. When there is a clear occlusion of the origin of the SMA and/or coeliac trunk (Cx) with signs of bowel infarction, the next step should be a revascularization procedure. Nowadays it is common practice to perform an endovascular revascularization of the SMA and to stent its origin. In case of multi-vessel involvement in chronic mesenteric ischaemia one vessel revascularization (SMA) is as good as two vessel revascularization (SMA and Cx) [7]. In patients with AMI, revascularization and stenting of the SMA alone is suggested to minimize the time of the procedure and to get the patient as quickly as possible to the third step. After revascularization, or in the absence of occlusion of the SMA or Cx, an expeditious laparotomy should follow.

The third step is a laparotomy to diagnose the (amount of) ischaemia and to resect any necrotic bowel without anastomoses. If angiographic revascularization of the SMA is not successful, a surgical revascularization procedure is of the utmost importance although this will substantially increase the complexity and length of the operation. One option is to identify the SMA, cannulate it, and then revascularize the occluded stenotic artery retrogradely by angioplasty. If the occlusion is caused by an embolus, the SMA can be transversely incised and an embolectomy performed. If this fails, a bypass operation (preferably venous) is the only other option, but this will significantly prolong the operation.

Another advantage of stenting prior to operation is that the bowel has time to recompensate, which probably results in less necrotic bowel to resect.

Any patchy segments of bowel should not be resected, but left *in situ*. The patient should then be transported to the ICU for further stabilization. A second look can be performed after 24–48 hours, during which a re-assessment of the viability of the patchy segments should be performed. Bowel continuation can now be performed with an anastomosis if the patient is stable and vasoactive support minimized.

Treatment of a venous occlusion is aimed at restoring the outflow. This can be performed by administering thrombolytic therapy directly with an angiography catheter placed in the SMA [5]. The patient is subsequently monitored carefully and, if deterioration occurs, surgery must be performed to check for necrotic bowel. Another option is to perform a venous thrombectomy. If necrotic bowel is suspected a laparotomy should be performed with resection, but without any intestinal anastomoses. Similarly, a second look operation should be performed after 24–48 hours. However, the literature is scarce as to what constitutes the best treatment option [3].

The treatment of NOMI is to treat the underlying cause. Surgery is only aimed at resecting any necrotic bowel, after which a stoma is usually placed primarily as the affected patients are generally severely ill and not expected to recover within 24–48 hours to allow bowel anastomoses to be performed. Therefore, any patchy segments are also directly resected. Some advocate papaverine infusion directly into the SMA [5], but no good clinical evidence is currently available.

Intensive care treatment

Patients with AMI are severely ill and should be monitored and treated on the ICU. The point of ICU admission and the treatment policy can both vary depending on the patient's clinical condition. If a patient is admitted to ICU after an assumption of AMI, but before CT scan confirmation, the treatment strategy should be initially focused upon patient stabilization. This includes providing LMWH in a therapeutic dose, inserting central venous and arterial

lines, urinary catheterization, administering fluid and antibiotics, taking blood samples, and providing respiratory and haemodynamic support, as needed. However, as none of these strategies is life-saving without bowel revascularization, there should be no delay in performing CT angiography and undertaking endovascular revascularization or surgery, as necessary.

Once the first three steps have been performed, the ICU and surgical staff should decide when to perform the second-look operation as the fourth step. This depends on any haemodynamic instability and other signs of deterioration of organ function. It may thus be advisable to perform this second look operation earlier, preferably in the operating theatre, but in case of gross instability, on the ICU. If vasoactive support is reduced, the second look operation may be delayed a little longer than 48 hours to allow bowel anastomosis without the need for a stoma.

Outcome

The time a patient spends on the ICU depends on many issues and is therefore unpredictable. An open revascularization may lead to pancreatic problems, e.g. (necrotic) pancreatitis and pseudocysts. The necrotic bowel can produce abscesses while suture dehiscence may occur with bowel anastomoses. The revascularization procedure can fail and create new bowel necrosis or hepatic insufficiency/necrosis. With an atherosclerotic aetiology underlies the AMI, other organs may also be affected such as the heart, kidneys, and peripheral arterial system.

If the AMI is secondary to NOMI, the options are more limited. Necrotic bowel should be resected since this causes a systemic inflammatory reaction. Again, no anastomoses are performed and, usually, stomata are directly fashioned. By observing the stoma any new ischaemia can be seen although this is a weak follow-up tool. If new bowel ischaemia is suspected, a second look operation should be performed, even in the absence of a necrotic stoma.

The overall in-hospital mortality of AMI in patients receiving supportive care is 74%. However this varies greatly, from 44% in venous thrombosis and 71% in SMA embolism to 87% in SMA thrombosis and 80% in NOMI [8]. In this systematic review there were suggestions that an aggressive approach of early diagnosis, early restoration of perfusion to the intestine, resection of necrotic bowel, second-look laparotomy, and ICU treatment has improved outcomes for arterial embolism and venous thrombosis, whereas mortality rates following treatment for arterial thrombosis and NOMI had not changed [8].

CHAPTER 187

Intra-abdominal sepsis in the critically ill

Jeffrey D. Doyle and John C. Marshall

Key points

- Intra-abdominal infection encompasses a broad group of infections arising both within the peritoneal cavity and the retroperitoneum.
- The likely bacteriology reflects patterns of normal and pathologic colonization of the gastrointestinal tract, anaerobic bacteria are found in the distal small bowel and colon.
- The duration of antibiotic therapy depends on the success of source control, and can be very short when source control is successful.
- Source control measures—drainage of fluid, debridement of infected tissue, and definitive control of the source of contamination—are needed for most intra-abdominal infections.
- In an unstable patient, damage control measures and a staged surgical approach can be life-saving.

Introduction

The abdomen is the second most common site of infection leading to sepsis in critically-ill patients [1]. Intra-abdominal infections can be complex to manage and require excellent collaboration between intensivists, diagnostic and interventional radiologists, surgeons, and sometimes gastroenterologists, and infectious disease specialists. Prompt diagnosis, appropriate antimicrobial coverage, and timely source control are the cornerstones of successful management. The spectrum of pathological conditions responsible for intra-abdominal infection is broad. However, some common biological features facilitate an understanding of their diagnosis and management.

Biological considerations

Anatomy and physiology of the peritoneal cavity

The peritoneal cavity is a continuous space created by the layer of mesothelial cells that covers most of the abdominal viscera [2]. In health, the potential space contains approximately 50–100 mL of protein-rich fluid, as well as scattered peritoneal macrophages. This fluid is produced continuously, circulates superiorly as a consequence of negative pressure created by diaphragmatic movements, and is resorbed into the lymphatics through specialized fenestrations at the diaphragm.

Bacteria, damaged tissues, or other damage-associated molecular patterns (DAMPs) activate the resident peritoneal macrophage population and incite a vigorous local inflammatory response. Chemo-attractants such as interleukin-8 from the macrophage induce a robust influx of neutrophils, while up-regulation of tissue factor on the macrophage surface activates coagulation factors in the peritoneal fluid, resulting in fibrin deposition. Together these processes serve to contain the threat through the creation of an abscess—a fibrin-encased structure containing neutrophils, bacteria, and tissue fluid (Fig. 187.1). The peritoneal membrane is exquisitely pain-sensitive, and inflammation results in pain and tenderness localized to the site of the inflammatory response.

The abdominal viscera, on the other hand, do not have visceral pain fibres, and visceral pain is experienced as localized to the vascular supply of the organ and its embryological origin as the **foregut** (supplied by the coeliac axis and extending from the gastro-oesophageal junction to the duodenum), the **mid-gut** (supplied by the superior mesenteric artery and extending from the duodenojejunal flexure to the splenic flexure of the colon), or the **hindgut** (supplied by the inferior mesenteric artery and extending from the splenic flexure to the rectum). Visceral pain is experienced in the midline, with foregut pain in the epigastrium, midgut pain in the peri-umbical region, and hindgut pain in the suprapubic region. The nature and location of abdominal pain is highly informative in establishing a diagnosis. Colicky epigastric pain suggests obstruction of a foregut organ, most commonly the gall bladder. Constant severe peri-umbilical pain suggests ischaemia, for example from an acute superior mesenteric artery thrombosis, while localized left lower quadrant pain and tenderness is characteristic of the peritoneal inflammation resulting from acute diverticulitis.

Microbiology of the gastrointestinal tract

The lumen of the gastrointestinal tract houses an enormously dense and complex flora, and it is these organisms that emerge as the dominant infecting species in intra-abdominal infections. Numerically, bacterial cells in the gut exceed the total number of host cells by a factor of 10:1, and current estimates are that there are at least as many as 1000 distinct microbial species present in the human gastrointestinal tract [3]. Anaerobic organisms are uncommon in the upper gastrointestinal tract, which is typically lightly colonized by Gram-positive species, and occasional Gram-negative organisms, the latter being more common when gastric acid secretion is reduced. The diversity of the flora increases in a

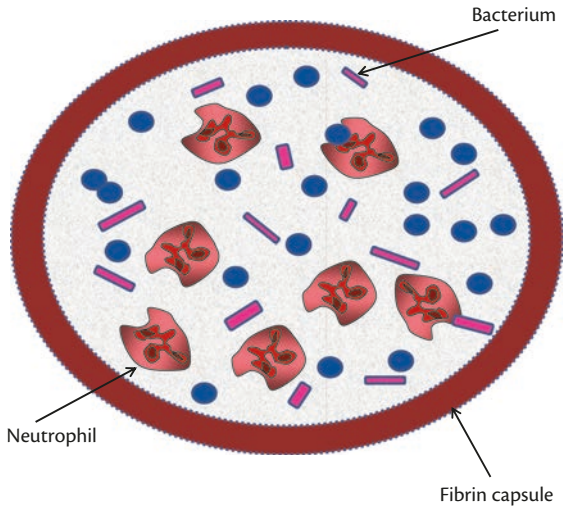

Fig. 187.1 The anatomy of an abscess. An abscess consists of a collection of inflammatory cells (predominantly neutrophils), bacteria, and tissue fluid, enclosed within a fibrin capsule whose formation is triggered by local activation of coagulation.

caudal direction, and anaerobes predominate in the distal small bowel and colon.

The indigenous flora plays a key role in normal host homeostasis, including the development of the gut epithelium, the digestion of intraluminal nutrients, and the maturation of the innate and adaptive immune systems. Critical illness is associated with striking changes in both the composition and the virulence of the gut flora, changes that contribute to the complications of severe intra-abdominal infection. Microbial overgrowth and a reduction in the numbers of anaerobic organisms promote the passage of intact, viable organisms across the gut mucosa—a process known as bacterial translocation [4]. Changes in the luminal environment of the gastrointestinal tract can promote the expression of virulence factors in bacteria such as *Pseudomonas* [5].

Definitions and classification

The term, 'intra-abdominal infection' encompasses a heterogenous group of infectious processes, associated with differing approaches to clinical management and strikingly different outcomes. While the patient with acute appendicitis may be managed by appendectomy and a very brief hospital stay, or the patient with acute diverticulitis may respond to outpatient antibiotic therapy alone, similar patients with infected peri-pancreatic necrosis or intestinal infarction typically face a substantial risk of mortality and a prolonged stay in the intensive care unit (ICU).

Intra-abdominal infection denotes any infectious process occurring within the abdomen, between the diaphragm superiorly and the pelvic cavity inferiorly. These infections may arise within the peritoneal cavity or in the retroperitoneal space, e.g. in pancreas or kidneys. Peritonitis refers to inflammation of the peritoneal cavity, and may result from sterile insults such as an early perforated duodenal ulcer, as well as from intra-abdominal infection. Peritonitis can further be classified as **primary**, **secondary**, or **tertiary** [6]. **Primary peritonitis** arises spontaneously, in the absence of a breach of the gastrointestinal tract. It is characteristically caused by a single micro-organism, such as occurs in young women with streptococcal infection, and in cirrhotics with spontaneous bacterial peritonitis. **Secondary peritonitis** is peritonitis arising from disruption of the gastrointestinal tract, with contamination of the peritoneal space with gut micro-organisms. It is typically polymicrobial in nature, the microbial flora reflecting normal patterns of colonization of the GI tract where the perforation occurred. **Tertiary peritonitis** is defined as peritonitis recurring or persisting after apparently adequate treatment of primary or secondary peritonitis. The infecting species in tertiary peritonitis are generally resistant organisms such as yeast, *Enterococcus* species, coagulase-negative *Staphylococcus* and multi-resistant Gram-negative bacilli [7].

Intra-abdominal infections can be further classified on the basis of the organ involved and whether the infection is **uncomplicated** (associated with minimal physiological derangement and amenable to successful treatment by surgical resection or systemic antibiotics) or **complicated** (associated with significant physiological derangement, and less readily managed using simple source control measures).

Diagnosis

The diagnosis of intra-abdominal infection in patients initially presenting to hospital is usually quite straightforward, based on the results of a comprehensive history and physical examination, supported by findings on diagnostic imaging. The history is of sentinel importance. The location of the abdominal pain, and its radiation and aggravating and relieving factors, all point to a diagnosis that may be definitive, even in the absence of laboratory data or diagnostic imaging. Physical findings support the impression derived from the history, tenderness associated with localized pain suggests a localized inflammatory process, whereas pain in the absence of tenderness suggests ischaemia in the absence of inflammation of the overlying peritoneum. Imaging modalities such as ultrasonography and computerized tomography (CT) scanning can confirm the diagnosis, although clinical findings of peritonitis with instability, or simple radiographic findings such as free air on plain films, may render more sophisticated imaging studies unnecessary.

In contrast, patients who develop intra-abdominal infection in the ICU are more difficult to evaluate. The history and physical examination are challenging. Signs of infection may be masked by co-existing disease processes or immunosuppression, while manifestations such as leukocytosis and metabolic acidosis are prevalent in the critically-ill patient and thus non-specific for the identification of intra-abdominal infection. The clinical context is key. Has the patient had a prior abdominal procedure? Has he or she had a prior episode of significant hypotension that could result in mesenteric ischaemia? Does the patient have risk factors such as peripheral vascular disease, atrial fibrillation, recent myocardial infarction, or a hypercoagulable state? Physical examination will often reveal focal tenderness, even in the presence of moderate analgesia or sedation. However, most patients who are haemodynamically stable should undergo abdominal imaging to clarify the diagnosis. Imaging also facilitates a more targeted approach to source control, including non-operative management or minimally invasive approaches, such as percutaneous drainage. Ultrasonography is particularly useful in evaluating the gall bladder and biliary tree. However, the primary diagnostic imaging modality is CT, with oral and/or intravenous contrast. A diagnosis—at least indicating a

Table 187.1 Empiric antimicrobial therapy of community-acquired intra-abdominal infection

	Mild-to-moderate severity	High risk or severity
Single agent	Cefoxitin, ertapenem, moxifloxacin, tigecycline, or ticarcillin-clavulanic acid	Imipenem-cilastatin, meropenem, doripenem, or piperacillin-tazobactam
Combination	Cefazolin, cefuroxime, ceftriaxone, cefotaxime, ciprofloxacin, or levofloxacin, each in combination with metronidazole	Cefepime, ceftazidime, ciprofloxacin, or levofloxacin, each in combination with metronidazole

problem for which source control is indicated—is usually possible, and exploratory laparotomy in the absence of radiographic support should be uncommon in the contemporary ICU patient.

Management

Successful management of intra-abdominal infection in the critically-ill patient is grounded in three principles—adequate haemodynamic resuscitation, appropriate antibiotic therapy, and effective source control. The principles of haemodynamic resuscitation do not differ from those applied to any cause of haemodynamic instability, and will not be discussed further here.

Antibiotic therapy

Despite the complexity of the indigenous gut flora that is responsible for secondary bacterial peritonitis, animal studies reveal that adequate antibiotic therapy can be achieved using agents that target enteric Gram negative organisms such as *E. coli* and obligate anaerobes such as *B. fragilis*; the utility of agents directed against common Gram positive organisms such as the *Enterococcus* is uncertain. Based on these principles, a number of antibiotic regimens are available, and none show clear evidence of superiority Table 187.1 [8]. Hospital-acquired infections and tertiary peritonitis typically yield resistant species, and so the initial selection of empiric therapy must reflect the expanded spectrum of infecting organisms. Initial therapy with an agent or combination that is recommended for high-risk community-acquired infection is appropriate. However the selection must be tailored based on prior patterns of patient colonization and resistance patterns within the institutional environment. Antibiotics should be administered as soon as the diagnosis is entertained as delay in initiating appropriate therapy is associated with an increase in mortality [9].

Although identification of *Enterococcus* in peritoneal samples is correlated with worse outcomes, it is not clear whether *Enterococcus* is a pathogen or simply a marker of more complicated disease [10]. Specific anti-enterococcal therapy should be considered in the immunocompromised patient or in the patient with a prosthetic heart valve or other implanted intravascular device [11]. Fungi are common isolates from patients with health care-associated infections and recurrent gastrointestinal perforations. While systemic antifungal therapy is the standard of care, the benefits of treatment are difficult to establish [12].

The optimal duration of antibiotics for intra-abdominal infection is unknown, although most recommend treatment for no more than 4–7 days if source control has been successful [8], and even less for uncomplicated infections such as appendicitis or perforated peptic ulcer disease. Patients who manifest persistent signs of infection at 4–7 days post-operatively should be re-evaluated for the adequacy of source control.

Source control

The phrase '**source control**' encompasses all physical measures that are undertaken to eliminate a source of infection, control ongoing contamination, and restore optimal anatomy and function [13]. Source control measures are particularly important in the management of intra-abdominal infection. While laparotomy has been the classical approach to achieve source control in intra-abdominal infections, laparoscopy, percutaneous drainage for contained intra-abdominal abscesses, or endoscopic decompression for ascending cholangitis are less invasive approaches that are the preferred mode of intervention in specific circumstances.

Methods of source control

Source control measures include drainage, debridement, device removal, and definitive measures.

Drainage is the creation of a controlled *fistula* (an abnormal communication between two epithelial-lined surfaces) or *sinus* (a communication between a closed space and a single epithelial surface) in order to externalize a focus of invasive infection. Drainage can be achieved through surgical intervention, however, image-guided percutaneous drainage provides safe and effective source control for many intra-abdominal infections. Percutaneous drainage does not require general anaesthesia, results in minimal physiologic disruption, and maximizes the options for later definitive measures. Moreover, it can be performed at the bedside in the ICU. Percutaneous drainage should be considered as an initial modality for source control whenever possible. It is, however, not effective for patients with generalized peritonitis or diffuse free fluid or free air on imaging, and its effectiveness of drainage may be limited by highly viscous material or multiloculated abscesses. Patients with ongoing enteric drainage from their percutaneous drains will often need subsequent operative management, but this can be safely deferred until the patient is more stable.

Debridement is the physical removal of solid infected or necrotic material. As a general principle, surgical excision of infected necrotic tissue, for example, in the patient with intestinal infarction, is an emergency that should be undertaken as quickly as possible. The exception to this principle is infected peripancreatic necrosis. Case series and a randomized trial have shown that delayed surgical intervention is associated with improved survival, because intervention before the infected retroperitoneal necrosis has adequately demarcated from adjacent viable tissue runs the risk of uncontrollable retroperitoneal bleeding [14]. An approach that combines earlier percutaneous drainage of peripancreatic fluid collections with delayed, minimally invasive debridement of infected peripancreatic necrosis has been demonstrated to minimize the complications of intervention, and to maximize survival [15] (Fig. 187.2).

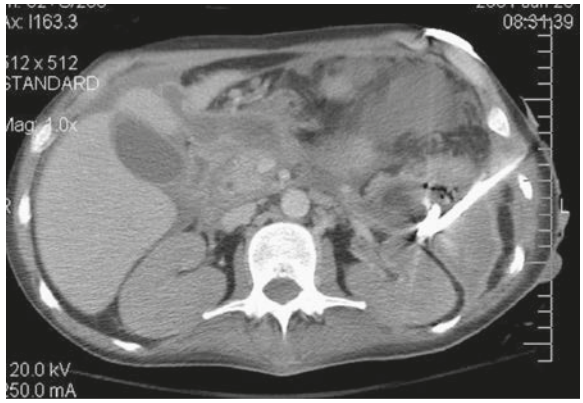

Fig. 187.2 A step-up approach for the management of infected peripancreatic necrosis. A complex retroperitoneal infection arising in a focus of necrotic peripancreatic tissue was managed by early percutaneous drainage to evacuate the liquid component of the infection and reduce the pressure within the infectious focus (black arrow), followed several weeks later by a minimally-invasive pancreatic necrosectomy, inserting the camera through the tract created by the percutaneous drain.

For complex intra-abdominal infections in the unstable critically-ill patient, a **damage control** approach is commonly used—draining or debriding the responsible focus, but deferring reconstruction and abdominal wall closure until the patient has been stabilized in the ICU. For example, a segment of gangrenous intestine can be resected, leaving the ends of the viable bowel stapled off, any areas of persistent bleeding packed, and the abdomen temporarily closed. Re-exploration in 24–72 hours enables evaluation of the viability of the remaining bowel, re-anastomosis or creation of a stoma, and definitive abdominal wall closure (Fig. 187.3).

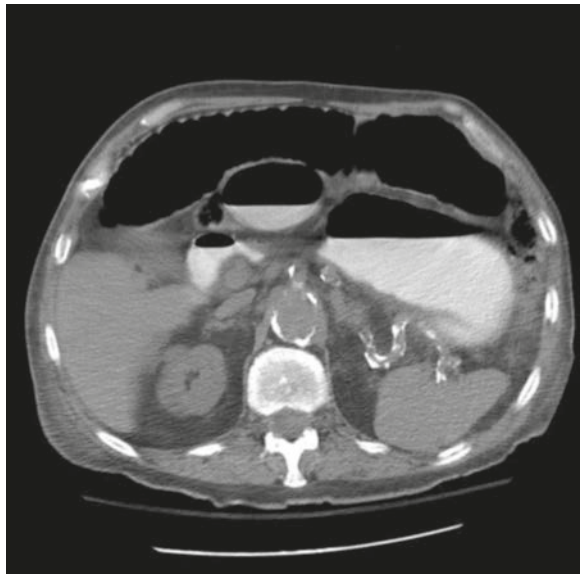

Fig. 187.3 Damage control laparotomy. This 57-year-old man with coronary artery disease and dialysis-dependent chronic renal failure presented with septic shock and CT evidence of right colon ischaemia. He was managed emergently by laparotomy to resect the ischaemic colon, leaving the ends of the viable intestine stapled off, and the abdomen open. Two days later, and following haemodynamic stabilization, re-exploration was undertaken, and an anastomosis created between the two ends of defunctional bowel. A further 2 days later the abdomen was closed.

If at all possible, it is preferable to avoid open abdomen management of intra-abdominal infection. Moreover, planned relaparotomy has not been proven to improve outcomes when compared to laparotomy on demand [16]. An open abdomen approach may be necessary in the setting of damage control surgery, for the treatment of intra-abdominal compartment syndrome, or when there has been extensive loss of the abdominal wall. It also simplifies management in patients for whom re-exploration is planned—most commonly patients with intestinal ischaemia or infarction.

Conclusion

Intra-abdominal infections make up an anatomically and clinically heterogeneous group of potentially life-threatening illnesses. Adequate source control is key to their successful management, and close collaboration between the intensivist, surgeon, and interventional radiologist is key to a maximally successful outcome. Advances in diagnostic imaging and in the understanding of host-microbial interactions are facilitating focused and more minimally disruptive management strategies—specifically image-guided source control and short duration focused antibiotic therapy. Nonetheless, for some patients, a staged or damage control approach provides the simplest solution to a complex problem.

CHAPTER 188

Acute acalculous cholecystitis in the critically ill

Vanessa P. Ho and Philip S. Barie

Key points

- Acute acalculous cholecystitis should be suspected in every critically-ill patient with sepsis in whom the source of infection cannot be found immediately.
- Suspicion should be especially high if the patient is injured, has undergone recent major surgery, has had a period of hypotension or hypoperfusion for any reason, or becomes jaundiced.
- The preferred diagnostic modality is ultrasound, which is inexpensive, non-invasive, and can be brought to the bedside of the unstable patient.
- Once diagnosed, the treatment of choice is percutaneous cholecystostomy, but if the response to drainage is not prompt and favourable, an alternative diagnosis must be considered and abdominal exploration may be required.
- If percutaneous drainage is successful and a cholangiogram verifies that there are no gallstones present, then the catheter may be removed after resolution of the disease with no further treatment.

Introduction

Acute acalculous cholecystitis (AAC) is the development of acute inflammation of the gallbladder in the absence of gallstones. The development of AAC is not limited to surgical or injured patients, or even to the intensive care unit, although it is generally considered to be a complication of serious medical and surgical illnesses [1,2]. It is especially related to patients with trauma, burns, sepsis, prolonged fasting, or total parenteral nutrition. The diagnosis may be elusive as the clinical symptoms of fever, leukocytosis, and abnormal liver function tests are nonspecific in this population, even abdominal pain is not necessarily a reliable symptom. Despite the diagnostic difficulties, more cases of AAC are being identified as a result of increased numbers of critically-ill patients, increased physician awareness, and improved imaging modalities [3]. The mortality rate remains at least 30% because, the diagnosis of AAC remains challenging to make, the affected patients are already critically ill, and the disease itself can progress rapidly owing to the high prevalence of gangrene (~50%) and perforation (~10%) [4].

Clinical patterns of acute acalculous cholecystitis

AAC may occur in surgical or injured patients, critically-ill patients, and systemically ill patients. Reports of acute cholecystitis complicating surgery, multiple trauma, or burn injury are widespread and well-described [5,6]. The incidence of AAC following open abdominal aortic reconstruction is 0.7–0.9%, and has also been reported to complicate endovascular aortic reconstruction. After cardiac surgery, the incidence of acute cholecystitis is 0.12%, with an overall mortality rate of 45% [4].

Among medical patients, a variety of systemic diseases have been associated with the development of AAC. Diabetes mellitus, abdominal vasculitis, congestive heart failure, cholesterol embolization of the cystic artery, and resuscitation from haemorrhagic shock or cardiac arrest have been associated with AAC [2,4]. AAC has also been described in patients with end-stage renal disease, cancer, bone marrow transplant recipients, and autoimmune deficiency syndrome.

Acalculous cholecystitis may also develop as a secondary infection of the gallbladder during systemic sepsis for a wide range of infections. Small case series and case reports have described AAC associated with disseminated candidiasis, leptospirosis, *Salmonella* spp., cholera, tuberculosis, malaria, brucellosis, and dengue fever [4,7]. Extrahepatic biliary obstruction can also cause AAC from infectious or non-infectious causes. Obstructive infectious causes include ascariasis and echinococcus; non-infectious obstructive causes include haemobilia, choledochal cyst, and ampullary stenosis [4].

Children may also be affected, especially following a viral illness. Acute acalculous cholecystitis represents 50–70% of all cases of acute cholecystitis in children [7]. Acalculous cholecystitis is recognized in young children and neonates, as well as older children. Dehydration is a common precipitant, as are acute bacterial infections and viral illnesses such as hepatitis and upper respiratory tract infections [8]. Portal lymphadenitis with extrinsic cystic duct obstruction may be aetiological in viral infections.

Pathogenesis

The pathogenesis of AAC is complex and multifactorial. Ischaemia and the associated pro-inflammatory response and oxidative tissue stress is likely the initial insult resulting in microvascular occlusion of the gallbladder, this is likely potentiated by bile stasis, which allows bile and bacterial infiltration into the gallbladder wall [9]. Gallbladder specimen arteriography supports the theory that vascular occlusion is an important step in pathogenesis, arteriography after AAC shows multiple arterial occlusions and minimal-to-absent venous filling. In contrast, gallbladder specimen arteriography in gallstone-related disease is markedly different with arterial dilatation and extensive venous filling [10].

Box 188.1 Imaging Criteria for the Diagnosis of AAC [7,12,13,20]

Ultrasound

Either two major, or one major criterion and two minor criteria, satisfy the ultrasound diagnosis of AAC.

Major criteria

- Gallbladder wall thickening >3.5 mm.
- Striated gallbladder (i.e. gallbladder wall oedema).
- Sonographic Murphy sign (inspiratory arrest during deep breath, while gallbladder is being insonated; unreliable if patient is obtunded or sedated).
- Pericholecystic fluid.
- Mucosal sloughing.
- Intramural gas.

Minor criteria

- Gallbladder distension (>5 cm in transverse diameter).
- Echogenic bile (sludge).

Computed tomography (CT)

Either two major, or one major criterion and two minor criteria, satisfy the CT diagnosis of AAC.

Major criteria

- Gallbladder wall thickening >3 mm.
- Subserosal halo sign (intramural lucency caused by oedema).
- Pericholecystic infiltration of fat.
- Pericholecystic fluid (absent either ascites or hypoalbuminaemia).
- Mucosal sloughing.
- Intramural gas.

Minor criteria

- Gallbladder distension (>5 cm in transverse diameter).
- High-attenuation bile (sludge).

Hepatobiliary scintigraphy

- Non-visualization or questionable visualization of the gallbladder 1 hour after administration of 5 mCi of a ^{99m}Tc iminodiacetic acid derivative, in the presence of adequate hepatic uptake of tracer, and excretion into the duodenum.
- Morphine sulphate, 0.04–0.05 mg/kg intravenously, may be given after 30–40 minutes of non-visualization to increase specificity at 1 hour.
- Enhanced accumulation of radiotracer in the gallbladder fossa may be indicative of gallbladder gangrene or perforation.

Data from: Barie PS and Eachempati SR, 'Acute acalculous cholecystitis', *Current Gastroenterology Reports*, 2003, **5**, pp. 302–9; Mirvis SE et al., 'The diagnosis of acute acalculous cholecystitis: a comparison of sonography, scintigraphy, and CT', *American Journal of Roentgenology*, 1986, **147**, pp. 1171–5; Deitch EA and Engel JM, 'Acute acalculous cholecystitis. Ultrasonic diagnosis', *American Journal of Surgery*, 1981, **142**, pp. 290–2; Hopfer K and Ziessman H, 'Nuclear medicine hepatobiliary imaging (cholescintigraphy)', *Gastrointestinal Endoscopy*, 2011, **74**, pp. 375–7.

Bile stasis is also an important risk factor for the development of AAC. Volume depletion from dehydration or lack of oral intake leads to concentration of bile, which can inspissate in the absence of a stimulus for gallbladder emptying. Opioid analgesics lead to increased biliary pressure secondary to spasm of the sphincter of Oddi; ileus and mechanical ventilation may also contribute to bile stasis. Bile stasis potentially contributes to the development of AAC by two separate mechanisms. Firstly, bile stasis may alter the chemical composition of bile allowing for local gallbladder mucosal injury. Secondly, stasis may potentiate gallbladder ischaemia by increasing intraluminal pressure and increasing gallbladder wall tension, which would allow bacterial invasion of ischaemic tissue as a secondary phenomenon. Reperfusion may lead to further injury [4].

Fasting and bile stasis may be potentiated by the administration of total parenteral nutrition (TPN) in the pathogenesis of AAC [11]. Parenteral nutrition is associated with both gallstone formation and acalculous cholecystitis in both adults and children. The incidence of AAC during long-term TPN may be as high as 30%. Formation of gallbladder 'sludge' occurs among 50% of patients on long-term TPN at 4 weeks and is ubiquitous at 6 weeks. However, neither stimulation of gallbladder emptying with cholecystokinin nor enteral alimentation can prevent AAC among critically-ill patients [11].

Although bacterial infection is likely a secondary phenomenon, the host response to Gram-negative bacteraemia or splanchnic ischaemia/reperfusion injury may also be an important contributor to the disease. In several non-human mammalian experiments, intravenous injection of *Escherichia coli* lipopolysaccharide (LPS), a potent stimulus of inflammation and coagulation that mimics clinical sepsis, produces AAC as well as decreased gallbladder contractility and mucosal injury. Cholecystitis has also been induced by factors that lead to cystic artery spasm in experimental models. The inflammation appears to be mediated by pro-inflammatory eicosanoids as it is inhibited by non-specific cyclooxygenase inhibitors [7].

Diagnosis

AAC poses major diagnostic challenges. Most afflicted patients are critically ill and unable to communicate their symptoms. Cholecystitis is but one of many potential causes in the differential diagnosis of the systemic inflammatory response syndrome or sepsis in such patients. Rapid and accurate diagnosis is essential, as gallbladder ischaemia can progress rapidly to gangrene and perforation. Acalculous cholecystitis is sufficiently common that the diagnosis should be considered in every critically ill or injured patient with a clinical picture of sepsis or jaundice and no other obvious source.

Physical examination and laboratory evaluation are unreliable. Fever is generally present, but other physical findings cannot be relied upon, particularly physical examination of the abdomen. Leukocytosis and jaundice are commonplace, but non-specific in the setting of critical illness. The differential diagnosis of jaundice in the critically-ill patient is complex and context-sensitive, including intrahepatic cholestasis from sepsis or drug toxicity and 'fatty liver' induced by TPN, in addition to AAC. Other biochemical assays of hepatic enzymes are of little help. The diagnosis of AAC thus often rests on radiologic studies.

Radiological studies

Three radiological modalities (ultrasound, CT, hepatobiliary scanning) are generally used for the diagnosis of AAC Box 188.1. Only a single retrospective study has compared all three modalities [12], ultrasonography and CT were comparably accurate and superior to hepatobiliary imaging. Ultrasound of the gallbladder is generally the first-line modality for the diagnosis of AAC in the critically-ill patient as it is rapid, low-risk, and portable. In calculous cholecystitis, ultrasonography is useful for detecting gallstones and measuring biliary duct diameter; in AAC, these measurements are not valuable. Thickening of the gallbladder wall is the single most reliable criterion, with reported specificities of 90% at 3.0 mm and 98.5% at 3.5 mm wall thickness, and sensitivities of 100% at 3.0 mm and 80% at 3.5 mm [13]. Accordingly, gallbladder wall thickness ≥3.5 mm is generally accepted to be diagnostic of AAC. Other helpful ultrasonographic findings for AAC include pericholecystic fluid, the presence of intramural gas, or a sonolucent intramural layer, or 'halo', which represents intramural oedema. Distension of the gallbladder of more than 5 cm in transverse diameter has also been reported [2,13]. False-positive ultrasound examinations may occur in particular when conditions including sludge, non-shadowing stones, cholesterolosis, hypoalbuminaemia, or ascites mimic a thickened gallbladder wall [12,13].

CT appears to be as accurate as ultrasound in the diagnosis of AAC. Diagnostic criteria for AAC by CT are similar to those described for ultrasonography Box 188.1. Low cost and the ability to perform ultrasonography rapidly at the bedside make it the preferred diagnostic modality in possible AAC in the ICU setting. Preference may be given to CT if other thoracic or abdominal diagnoses are under consideration. While technetium ^{99m}Tc iminodiacetic acid imaging is approximately 95% accurate to diagnose acute calculous cholecystitis, it is less useful for the diagnosis of AAC in the setting of critical illness [14]. Intravenous morphine (0.05 mg/kg) given after initial non-visualization of the gallbladder may increase the accuracy of cholescintigraphy among critically-ill patients, by enhancing gallbladder filling due to an increase in bile secretory pressure [14].

Laparoscopy

Bedside laparoscopy has been used with success for the diagnosis and therapy of AAC [15]. However, bringing the equipment to the ICU bedside is cumbersome. Laparoscopy can be performed under local anaesthesia and intravenous sedation at the bedside, and is possible in patients who have undergone recent abdominal surgery if 'gasless' techniques are used. Diagnostic accuracy is high, and both laparoscopic cholecystostomy and cholecystectomy have been performed if AAC is diagnosed, although no randomized trial data have been published. It may be reasonable to perform laparoscopy in critically-ill patients in whom AAC is suspected, but cannot be ruled out, and would otherwise require an exploratory laparotomy for diagnosis.

Therapy

Historically, the treatment for AAC was cholecystectomy, owing to the ostensible need to inspect the gallbladder and perform a resection if gangrene or perforation was discovered. Open cholecystostomy may be accomplished under local anaesthesia through a short right subcostal incision, but the ability to visualize elsewhere in the abdomen is limited. A laparotomy or laparoscopy would be required to drain distant fluid collections or identify other pathology that may mimic acute cholecystitis in the case of a misdiagnosis (e.g. perforated ulcer, cholangitis, pancreatitis). Currently, percutaneous cholecystostomy is now established as a life-saving, minimally-invasive alternative [16]. Percutaneous cholecystostomy controls the AAC in 70–90% of patients [17,18]. The gallbladder is usually intubated under ultrasonographic (occasionally laparoscopic) control via an anterior or anterolateral transhepatic approach (through the right hepatic lobe) in order to minimize leakage of bile, but transperitoneal puncture has been described [16,18]. Rapid improvement should be expected when percutaneous cholecystostomy is successful. Cholecystostomy will not decompress the common bile duct if cystic duct obstruction is present, therefore the common duct must be decompressed by some manner, e.g. endoscopic retrograde cholangiopancreatography [ERCP] with sphincterotomy, laparoscopic, or open common bile duct exploration, if cholangitis is suspected.

If percutaneous cholecystostomy does not lead to rapid improvement, the tube may be malpositioned or not draining properly, or the patient may have gangrenous cholecystitis. Other reported causes of failure include catheter dislodgement, bile leakage with peritonitis, or an erroneous diagnosis. Perforated ulcer, pancreatic abscess, pneumonia, and pericarditis have been discovered in the aftermath of percutaneous cholecystostomy when patients failed to improve. Reported major complications occur after 8–10% of procedures, including dislodgment of the catheter, acute respiratory distress syndrome (ARDS), bile peritonitis, haemorrhage, cardiac arrhythmia, and hypotension due to procedure-related bacteraemia [17,18]. An open cholecystostomy or cholecystectomy may be required if other sources of sepsis are ruled out and the patient continues to deteriorate. The 30-day mortality rates of percutaneous and open cholecystostomy are similar, and influenced heavily by the underlying severity of illness.

Empiric percutaneous cholecystostomy has been advocated for patients who have sepsis, but lacking a demonstrable source. In one report of 24 patients receiving vasopressor therapy for septic shock, 14 patients (58%) improved as a result of cholecystostomy [19]. Pneumonia was diagnosed subsequently in three of the ten non-responders, but an infection was never found in the other seven patients. Such an approach is not recommended routinely, but the importance of considering AAC in the differential diagnosis of occult sepsis is underscored.

Antibiotic therapy does not substitute for drainage of AAC, but is an important adjunct. The most common bacteria isolated from bile in acute cholecystitis are *E. coli, Klebsiella,* spp., and *Enterococcus faecalis,* thus antibiotic therapy should be directed against these organisms [4,17,19]. However, critical illness and prior antibiotic therapy alter host flora, and resistant or opportunistic pathogens may be encountered. *Pseudomonas,* staphylococci (including methicillin-resistant strains), *Enterobacter* and related species, anaerobic organisms (e. g. *Clostridium* spp., *Bacteroides* spp.), or fungi may be recovered [4]. Anaerobes are particularly likely to be isolated from bile of patients with diabetes mellitus, in those older than 70 years of age, and from patients whose biliary tracts have been instrumented previously.

Complications

The prevalence of gallbladder gangrene in AAC exceeds 50%, and leads to additional morbidity, including gallbladder perforation.

Fig. 188.1 Cholangiogram following percutaneous cholecystostomy, demonstrating a patent cystic duct and no gallstones present.

One variant—emphysematous cholecystitis—is particularly associated with gangrene and perforation. Crepitus to palpation of the right upper abdomen or radiographic identification of gas in patients with acute cholecystitis mandates immediate cholecystectomy in view of the fulminant nature of untreated emphysematous cholecystitis as percutaneous cholecystostomy does not achieve reliable source control. *Clostridium* spp., rather than aerobic Gram-negative bacilli, are isolated most commonly in emphysematous cholecystitis (45% of cases). Antimicrobial therapy specific for *Clostridium* (such as penicillin G) may be added to agents directed against the typical bacterial flora of acute cholecystitis.

Perforation of the gallbladder occurs in 10% or more of cases of AAC [3,4], either localized into the subhepatic space or free perforation with generalized peritonitis. Perforation into the liver or biliary tract has been reported rarely in AAC, as has perforation into the retroperitoneum with iliopsoas abscess. Rare causes of death from gallbladder perforation in AAC include haemorrhage from the liver, and pulmonary bile embolism. Serious complications of gallbladder gangrene without perforation include acute pancreatitis, colon perforation, and obstruction of the common hepatic duct. Empyema of the gallbladder may also complicate AAC.

Follow-up

Patency of the cystic duct can be determined immediately after the cholecystostomy is performed by tube cholangiography (Fig. 188.1). This should be performed again after the patient has recovered to determine the presence of gallstones that may have not been detected initially. If gallstones are present, an elective cholecystectomy is usually recommended, with the drainage tube remaining in place during the inter-procedure interval. For patients without gallstones, interval cholecystectomy is usually not indicated, and the cholecystostomy tube can be removed after tube cholangiography confirms that gallstones are absent. Recurrent episodes warrant cholecystecomy.

CHAPTER 189

Management of the open abdomen and abdominal fistulae in the critically ill

Philip Stevens and Gordon Carlson

Key points

- Leaving the abdomen open when it is possible to close it confers no benefit and may increase morbidity.
- 50–80% of enterocutaneous fistulae close spontaneously, compared to only 10% of colonic fistulae.
- Entero-atmospheric fistulae are associated with significant mortality and prevention is paramount.
- Controversy exists regarding the risk of entero-atmospheric fistula with negative pressure wound therapy.
- Refistulation rates are high despite operative repair of gastrointestinal fistulae.

Introduction

Management of the open abdomen and intestinal fistulae remain significant challenges. Most patients will initially be critically ill and morbidity and mortality are significant. Management is best undertaken within an adequately equipped and experienced multidisciplinary team. Management priorities are discussed in the following sections, accompanied with levels of evidence and grading of recommendations according to the Oxford Centre for Evidence-based Medicine definitions [1].

The open abdomen

Indications

The abdomen may be left open deliberately at the end of a laparotomy (laparostomy) as part of a 'damage control' strategy in an unstable patient with abdominal trauma, or in other conditions in which it may be impossible to close the abdomen because swollen intestinal loops, retroperitoneal haematoma or oedema may lead to Abdominal Compartment Syndrome Table 189.1.

It may also be inappropriate to close the abdomen when there has been infection which cannot be readily controlled, for example, by resecting or exteriorising the source, or where there have been multiple previous surgical attempts to deal with intra-abdominal infection (tertiary peritonitis).

Pathogenesis

Conditions necessitating management with an open abdomen are invariably emergencies. Patients are (or frequently become) profoundly catabolic and malnourished. Protection of exposed and inflamed viscera is vital in order to avoid fistulation, which increases the complexity of management, delays recovery and may increase mortality.

Management

Leaving the abdomen intentionally open should be undertaken with an explicit strategy of either closing the abdomen as soon as the patient's condition allows (delayed primary closure) or leaving the abdomen to heal by secondary intention. Viscera should be covered by the omentum to reduce the likelihood of injury.

Temporary abdominal closure

Temporary closure may be achieved by patch interposition, negative pressure wound therapy (NPWT), silos (such as the Bogota bag), or by simple application of a non-adhesive 'sandwich' dressing. The aim is to protect the bowel from mechanical injury, allow removal of exudate and prevent the loss of 'domain' which otherwise occurs as a result of lateral retraction of the rectus muscles. Preservation of the domain into which the oedematous loops of bowel can be returned is essential if delayed primary closure is planned.

Patch techniques involve securing prosthetic material over the exposed viscera, usually with sutures. The artificial bur (Wittmann patch®) involves an interposition patch with hook-and-loop fastening in the midline. Absorbable mesh (e.g. polyglactin) is popular and inexpensive, allows the escape of exudate, and can be left in place to allow healing by secondary intention, granulation or later skin grafting, with late ventral hernia formation.

Silo techniques also employ synthetic material sutured to the abdominal wall. The 'Bogota bag' involves suture of an opened sterile, fluid irrigation bag circumferentially around the abdominal wall. Transparency of the bag allows inspection of viscera through a non-adherent protective barrier.

NPWT simplifies nursing care, avoiding the need for frequent changes of dressing and leakage. There is no evidence that

Table 189.1 Indications for open abdominal management

Intra-abdominal sepsis/ tertiary peritonitis/severe pancreatitis (**level 2b** evidence) [2,3]	Inability to defunction or exteriorise septic foci Technically impossible to close
Abdominal compartment syndrome (**level 3b** evidence) [4]	Intra-abdominal pressure >20 mmHg and evidence of organ dysfunction
Trauma/damage control laparotomy (**level 3b** evidence) [5]	No clear recommendations, but an inability to defunction, close or risk of ACS mandates laparostomy
Intracranial hypertension (**level 5** evidence) [6]	Observations of reduced intracranial pressure following decompressive laparostomy require further evaluation before recommendations can be made

Data from various sources (see references).

it enhances wound healing. Direct application against exposed bowel is not recommended because of the risk of fistulation, which may be considerably higher when NPWT is used for abdominal infection rather than trauma [7]. A recent large observational study has suggested that NPWT seems safe, although the rate of delayed primary closure was reduced (**level 2b**) [8]. The rate of fistulation confirmed the findings of an underpowered prospective randomized study that failed to demonstrate clear benefit from NPWT (**level 2b**) [9].

Nutritional support in the open abdomen

In many cases in which the abdomen has been left open, intestinal dysfunction or fistulation will preclude satisfactory enteral feeding, in which case parenteral nutrition is required. Where possible, enteral nutrition is preferable to promote intestinal adaptation and maintenance of gastrointestinal function. Early enteral feeding (within 4 days of operation) has been associated with a significant reduction in fistula rate, earlier primary abdominal closure and lower treatment costs compared with delayed enteral feeding (**level 3b**) [10].

Fistulae

A fistula is an abnormal communication between two epithelial surfaces. Nomenclature reflects the organs involved; 'enterocutaneous' indicating communication between intestine and skin, and 'enterovesical' from intestine to bladder. Although strictly a misnomer, 'entero-atmospheric' neatly describes the disturbing appearance of intestinal mucosa in the open abdominal wound.

Epidemiology

Post-operative intestinal fistulae are associated with considerable morbidity and mortality. Eradication of sepsis, improved wound and skin care, safe nutritional support and appropriate timing of surgical intervention have reduced mortality with from 65% to <10% over the last 30 years [11]. However, mortality from fistulation within the open abdomen has remained disturbingly high [12–14]. and may exceed 5%, even in highly selected patients treated under optimal conditions in specialist centres [15].

Aetiology

Fistulae are classified as primary or secondary, according to whether they result from the underlying disease, or as a complication of subsequent treatment. Primary fistulae are rare and arise largely in the context of Crohn's disease. They are also seen with diverticular disease, radiation enteritis, or malignancy. Secondary fistulae are much commoner and usually arise as a consequence of surgical management due to accidental injury to the gut or anastomotic leakage. The overwhelming majority of post-operative fistulae arise from the small intestine. Almost half follow surgery where no bowel resection has occurred, but the bowel has been injured and repaired.

Pathogenesis

Gastrointestinal fistulae result in catabolism due to a combination of sepsis and reduced nutrient intake. Fistulae are the commonest cause of severe acute intestinal failure (i.e. inability to maintain nutritional status in the absence of artificial nutritional support). Fistulae are described as simple or complex, the latter indicating the presence of multiple fistula tracks, an associated abscess cavity, or involvement of other organs. Fistulae are also described as 'high' output when volume excreted exceeds 500 mL per day (>200 mL per day for pancreatic fistulae). High output fistulation is strongly predictive of catabolism and mortality.

Management

General management principles are summarized by the four 'R's (Box 189.1).

Resuscitation

Initial management must address resuscitation to ensure adequate oxygenation, hydration, and perfusion, with escalation to a higher level of care as appropriate.

Restitution

Sepsis

Most deaths in patients with intestinal fistulae are caused by inadequate treatment of sepsis, so effective management of sepsis is a priority [15]. This requires early imaging and drainage of abscess cavities, which should be undertaken percutaneously with the support of a radiologist, in order to avoid further laparotomy and the potential for bowel injury. When laparotomy is required, intestinal suture lines should be avoided as further fistulation is likely.

Box 189.1 Management of fistulae

- **R**esuscitation.
- **R**estitution:
  - **S** Sepsis, skin.
  - **N** Nutrition.
  - **A** Assessment.
  - **P** Plan.
- **R**econstruction.
- **R**ehabilitation.

Exteriorization of fistulating bowel, and delayed intestinal reconstruction until after the patient's condition has improved, are crucial in reducing mortality.

Skin care

Contaminated effluent macerates and burns skin, perpetuating the catabolic response and causing severe discomfort. Management of fistulation into the open abdomen is especially difficult. The Eakin bag is a large stoma appliance, secured around the wound edges with adhesive and often connected to a drainage system. It may occasionally be preferable to fashion a proximal stoma in the upper abdomen to protect the wound from uncontrollable fistula effluent.

Nutrition

Safe, complication-free nutrition is essential once sepsis is controlled. This may necessitate parenteral nutrition until it is clear that enteric defects are not feeding undrained abscess cavities, or if insufficient length remains for adequate enteral absorption. There is no evidence that parenteral nutrition expedites spontaneous closure of fistulae through 'bowel rest'. Enteral nutrition can be delivered orally, via a feeding tube (nasogastric, gastrostomy, or jejunostomy), or via a gastrostomy tube inserted into the distal limb of a proximally situated fistula (fistuloclycis), provided integrity of the distal gastrointestinal tract has first been confirmed by contrast study and more than 150 cm of small bowel remains (**level 4**) [16].

Assessment

Once restitution is established with control of sepsis and safe nutrition, systematic assessment of gastrointestinal anatomy with contrast studies is required to rule out distal obstruction and to plan definitive management. These are best performed from the proximal gastrointestinal tract first.

Plan

Between 50–80% of small bowel enterocutaneous fistulae will close spontaneously with conservative management (Box 189.2). Retrospective series suggest only 10% of colonic fistulae close spontaneously (**level 4**) [17]. Fistulae in the open abdomen require surgical intervention to facilitate closure. Premature attempts at surgical repair risk further enterostomy and fistulation. Retrospective data support the suggestion that definitive surgery should be postponed for at least 6 months after the index event and resuscitation (**level 4**) [18]. This will allow resolution of obliterative peritonitis, fistula maturation, neoperitonealization (demonstrable by stomal prolapse on coughing) and optimization of nutritional status.

Reconstruction

Recurrence rates following surgical closure of intestinal fistulae are high. A review of 205 cases reported a 20.5% recurrence of fistulae within three months of surgery. This was lowest with resection compared with simple closure of enteric defects, which is almost invariably doomed to fail (**level 4**) [18]. Recurrence is also higher in stapled versus hand-sewn techniques (**level 4**) [19]. The method used for reconstruction of the abdominal wall is an important determination of outcome in patients with large defects associated with intestinal fistulation. Replacement of abdominal wall defects with prosthetic mesh is associated with a considerably higher rate of refistulation than simple suture repair (**level 4**) [20].

Box 189.2 Factors predictive of spontaneous closure

- No distal obstruction.
- No intrinsically diseased bowel underlying the fistula.
- No abscess cavity associated with fistula.
- No foreign body.
- Absence of mucocutaneous/atmospheric continuity.

Rehabilitation

The disruption of physical, mental, and social well-being that follows gastrointestinal fistulation can be catastrophic for patients and their families. Specialized nursing care and dedicated psychological support are essential for adjustment.

Conclusion

If at all possible, the abdomen should be closed at the end of surgery as leaving it open appears to confer no benefit and may increase morbidity (**level 2b**) [2]. Techniques to reduce the risk of entero-atmospheric fistula in the open abdomen include coverage of hollow viscera with omentum, avoidance of serosal injury and closure of fascia or skin as soon as possible. The choice of temporary abdominal closure should be individualized, based on the disease process and the surgeon's familiarity with the technique. Enteral nutrition should be provided when possible. Reconstruction should be undertaken only when the patient's condition has been optimized. Management of intestinal fistulation, particularly when associated with the open abdomen, should preferably be undertaken by experienced multidisciplinary teams.

PART 6.6

Pancreatitis

CHAPTER 190

Pathophysiology, diagnosis, and assessment of acute pancreatitis

James R. A. Skipworth and Stephen P. Pereira

Key points

- The incidence of acute pancreatitis continues to increase, but the attendant mortality has not decreased for >30 years.
- The pathogenesis remains poorly understood, but the initial mechanism appears to be intracellular activation of pancreatic enzymes, with micro- and macrovascular dysfunction, in conjunction with a systemic inflammatory response acting as a key propagating factor and determinant of severity.
- A multitude of causes or initiators exist, but there is a common pathophysiologic pathway.
- The use of conventional scoring systems, combined with repeated clinical and laboratory assessment, remain the optimal method of predicting early severity and organ dysfunction.
- Death occurs in a biphasic pattern with early mortality (<2 weeks) secondary to SIRS and MODS; and late deaths (>2 weeks) due to superinfection of pancreatic necrosis. Assessment of severity should reflect this, with early severity being diagnosed in the presence of organ failure for >48 hours, and late severity defined by the presence of pancreatic and peripancreatic complications on CT or other appropriate imaging modalities.

Introduction

The revised Atlanta classification system (2008) defines acute pancreatitis (AP) as 'an acute inflammatory process of the pancreas, with variable involvement of regional tissues or remote organ systems' [1]. It is diagnosed if ≥2 of the following features are identified:

- Abdominal pain characteristic of AP.
- Serum amylase (or lipase) ≥3 times the upper limit of normal.
- Characteristic findings of AP on ultrasonography (USS) or CT.

Mild and self-limiting in many cases, up to a quarter will suffer severe disease. In Western societies, approximately 80% are secondary to cholelithiasis or ethanol abuse, although many other causes exist (Box 190.1). It is a common condition, affecting twice as many men as women. Although the incidence per 100,000 population per year varies throughout the developed world (9.8 UK, 15.9 Netherlands, 19.7 Germany, 43.8 USA), it continues to rise in Europe and North America, especially in females under the age of 35 [2–6]. Associated mortality has not decreased [2], and up to 10% still die [2].

Pathophysiology

AP initiation and propagation

Precise mechanisms driving pancreatic inflammation remain poorly understood. However, the initial insult results in increased intracellular calcium, which leads to conversion of the inactive proenzyme trypsinogen to active trypsin within pancreatic acinar cells. Premature trypsin activation triggers a cascade of digestive proenzyme activation resulting in pancreatic vacuolization and auto digestion, allowing dissemination of enzymes to act directly on both surrounding acinar cells and local extra-pancreatic structures (see Fig. 190.1). Vascular endothelial barriers are similarly disrupted, increasing vascular permeability and allowing further propagation of activated enzymes.

Significant cellular destruction follows, releasing reactive oxygen species and various pro-inflammatory mediators including TNF-α, IL-6 and IL-8. A systemic inflammatory response syndrome is subsequently triggered with characteristic micro- and macrovascular changes resulting in a hyperdynamic circulation, capillary leak, and significant third space fluid losses. Without intervention, hypovolemia, hypotension, and secondary organ dysfunction and failure occur.

Organ failure

Pulmonary dysfunction

This represents the commonest form of secondary organ dysfunction in AP. Hypoxemia secondary to ventilation/perfusion mismatch and right-to-left intrapulmonary shunting occurs in 50–60% of cases, often before radiographic abnormalities can be seen [7]. Atelectasis (to which decreased surfactant production, and diaphragmatic splinting contribute) is commonly encountered [7]. Pleural effusions occur secondary to increased capillary permeability, blockage of trans-diaphragmatic lymph channels, or formation of pancreaticopleural fistulae following retroperitoneal pancreatic duct disruption, and their presence is an independent predictor of severity and prognosis. An acute respiratory distress syndrome (ARDS) can result in approximately 33% of patients with severe AP, leading to death in >50% of those affected [7].

Cardiovascular dysfunction

This results primarily from hypovolaemia and decreased cardiac preload, but is further exacerbated by vasodilatation secondary to SIRS, and cytokine-mediated direct myocardial depression.

Box 190.1 Common causes of acute pancreatitis

- Post-procedure: e.g. ERCP/surgery.
- Alcohol.
- Neoplastic: e.g. pancreatic/ampullary.
- Cystic fibrosis and genetic disorders: e.g. hereditary pancreatitis.
- Rheology: e.g. vasculitis/hypoperfusion/hypothermia.
- Ischaemia: intra-abdominal surgery/CABG/embolic.
- Endocrine/autoimmune: e.g. hypercalcaemia/SLE.
- Anatomical and functional abnormalities/obstruction: e.g. pancreatic cancer/ampullary tumour/pancreas divisum/sphincter of Oddi dysfunction/ascariasis.
- Triglyceridaemia/hyperlipidaemia.
- Idiopathic and iatrogenic: drugs, e.g. steroids/NSAIDs/ACE-inhibitors/azathioprine/metronidazole/Furosemide/oestrogen/tetracyclines/tamoxifen/sulphonamides.
- Traumatic.
- Infections: e.g. mumps/EBV/CMV/Coxsackie/HIV/adenovirus.
- Stones (Cholelithiasis / Microlithiasis / Choledocholithiasis).

ERCP, endoscopic retrograde cholangiopancreatography; SLE, systemic lupus erythematosus; NSAIDs, non-steroidal anti-inflammatory drugs; ACE, angiotensin-converting enzyme; EBV, Epstein–Barr virus; CMV, cytomegalovirus; CBD, common bile duct; HIV, human immunodeficiency virus; CABG, coronary artery bypass graft.

Monitoring of cardiac preload and output are often required to guide both fluid and inotrope administration.

Renal dysfunction

Renal dysfunction can follow circulatory failure and reduced perfusion, or occur via raised intra-abdominal pressure [8]. Acute renal failure occurs in 15% of patients with AP, a higher incidence than other causes of ICU admission [9], and when present it is associated with a mortality of 50% [10]. Careful circulatory support and the avoidance (where possible) of intravenous contrast, and other potential nephrotoxic insults, is crucial to reduce this risk.

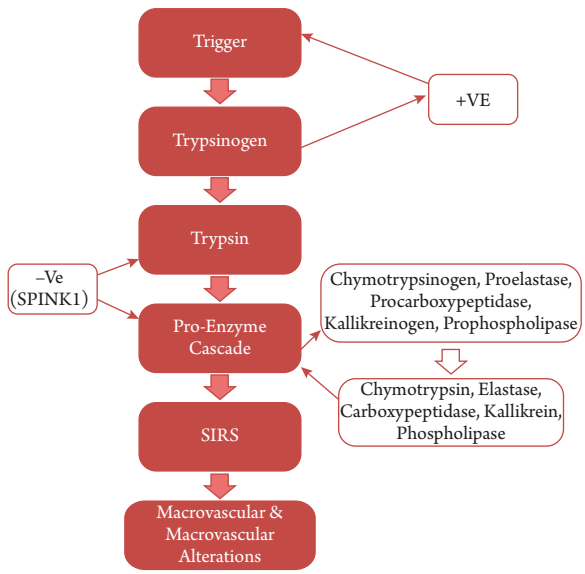

Fig. 190.1 Pathogenesis of acute pancreatitis.

Coagulation dysfunction

Coagulation dysfunction can also follow on from AP-induced SIRS. Raised levels of fibrinogen, D-dimers and activated platelets, as well as coagulation cascade abnormalities can result in a coagulopathy and secondary haemorrhage. Significant coagulation abnormalities occur in up to 50% of patients. D-dimer levels >414 mcg/L are associated with organ failure in AP [11].

Pancreatic consequences

Pancreatic necrosis

The pancreas is particularly susceptible to ischaemic injury: each lobule is supplied by an end vessel so reductions in local pancreatic perfusion are disproportionately greater than those in global cardiac output. Pancreatic necrosis appears early (72–96 hours), starts peripherally and proceeds in a lobular pattern. Over the subsequent 3–4 weeks, necrotic tissue usually remains sterile. Complete resolution can occur via liquefaction and reabsorption. However, necrotic tissue can become infected with diverse species in up to 50%, with translocation of intestinal Gram-negative organisms or *Staphylococcus* species being particularly predominant. Differentiating sterile from infected necrosis remains challenging, as both are characterized by the presence of SIRS. However, confirmation of infection is associated with a significantly increased incidence of multi-organ failure and mortality. Super-infection should be clinically suspected in the presence of fever, hypotension, and tachycardia with raised inflammatory markers. It usually develops at least 2 weeks following AP onset and is identified on CT by the presence of retroperitoneal gas in non-enhancing areas in the presence of infection with Gram-negative organisms. In some centres fine needle aspiration is utilized for the diagnosis of infected necrosis, for which it has a high sensitivity and specificity combined with an infection risk <1%. Other centres confirm infection via microbiological assessment of blood or drain cultures to avoid even this low potential risk of introducing infection into a previously sterile collection.

Pancreatic collections and pseudocysts

Acute peripancreatic fluid collections, rich in inflammatory fluid and pancreatic enzymes, often form within anatomical boundaries (often in the lesser sac). The majority resolve spontaneously as the disease process settles, but in approximately 10% a well-defined wall of fibrous or granulation tissue forms over a 3–4 week period, encapsulating sterile fluid to form a pseudocyst [12,13]. Up to 85% of pseudocysts resolve spontaneously, but those that are large, expanding rapidly or causing complications (e.g. pain, secondary infection, haemorrhage, bile duct, or duodenal obstruction) often require treatment via percutaneous, endoscopic or surgical drainage [12,13].

Pseudo-aneurysms

These form as proteolytic enzymes weaken peripancreatic vascular walls, especially within pseudocysts, and can be multiple. While some remain stable, others can rupture directly into the peritoneal cavity or gastrointestinal tract, resulting in death from

haemorrhagic shock in up to 20% [14]. Presentation can thus be with a pulsatile abdominal mass, haematemesis or melena, or cardiovascular instability related to occult bleeding. CT angiography is the optimal imaging method and should be performed prior to oesophagogastroduodenoscopy in patients with AP and evidence of gastrointestinal bleeding.

Diagnosis

Clinical presentation

AP is characterized by the presence of acute epigastric pain, which can be referred through to the back, and is often associated with nausea and vomiting (see Box 190.2). There may be evidence of hypovolemia due to third space losses, and fever due to SIRS. Jaundice may occur secondary to biliary obstruction whether primary, or secondary to ampullary oedema. Rarely, exudates from pancreatic necrosis can track along the falciform ligament and into the retroperitoneum, resulting in bruising and discoloration in the peri-umbilicus (Cullen's sign) or flank (Grey–Turner's sign). Extension of inflammatory exudates from the peripancreatic region to the diaphragm may also result in shallow respiration and increased respiratory frequency.

Serum diagnostic markers

Given the substantial variation in clinical presentation, enzymes derived from pancreatic acinar cells are used as biochemical markers to confirm diagnosis.

Serum amylase

Serum amylase is considered the gold-standard diagnostic test for AP, with 91–100% sensitivity and 71–98% specificity [15]. Levels usually rise sharply within the first 12 hours after symptom onset, but can return to normal within three days and, therefore, may be falsely low in patients with a delay between symptom onset and presentation. Levels may also be normal in patients with pancreatic insufficiency (e.g. chronic pancreatitis, cystic fibrosis), raised (in the absence of pancreatitis) in those with impaired renal clearance, perforated duodenal ulcer, acute cholecystitis, shock, and macroamylasemia, and low in hypertriglyceridaemia.

Serum lipase

This marker has a sensitivity (85–100%) and specificity (95–99%) higher than serum amylase for the diagnosis of AP [15]. Levels may remain elevated and detectable for up to 14 days, thereby providing greater accuracy in patients with a delayed presentation. However, falsely high levels may be seen in patients with other intra-abdominal pathology or renal insufficiency and it is less readily available than serum amylase.

Box 190.2 Clinically important differential diagnosis of acute pancreatitis

- **Acute coronary syndrome**: particularly inferior myocardial infarction.
- **Peptic ulcer disease**: particularly perforated peptic ulcer.
- **Symptomatic cholelithiasis**.
- **Mesenteric or intestinal ischaemia**.
- **Small bowel obstruction**.
- **Aortic aneurysm**.

Trypsinogen-2

This pro-enzyme can be measured by serum immunofluorometric assay or bedside urine dipstick. It has a reported sensitivity and specificity of 86–100% for the diagnosis of AP [16], but is not widely available.

Imaging

Ultrasonography

Useful in documenting the presence of gallstones and bile duct dilatation, and for assessment of pancreatic oedema. It has a false negative rate of 20–40% for detecting common bile duct stones, particularly in patients with a high body mass index or those with overlying air-filled bowel loops.

Computed tomography

Contrast-enhanced CT is the imaging procedure of choice under circumstances of inconclusive clinical, ultrasonographic, and biochemical findings. It can assess the presence and extent of any pancreatic necrosis or local complications, and also rule out the presence of alternate abdominal pathology.

Magnetic resonance imaging

Rarely used for diagnosis, but can be helpful in further elucidating the presence of microlithiasis or choledocholithiasis not confirmed on ultrasound, or in patients with impaired renal function.

Assessment of severity

Clinical course

Most patients develop a self-limiting, mild, oedematous-interstitial pancreatitis. This is associated with minimal organ dysfunction and usually improves within 48–72 hours following conservative management. However, up to a third of patients develop severe disease, characterized by pancreatic necrosis, organ failure, acute fluid collections, and later pseudocyst or pseudo-aneurysm formation. Mortality follows a biphasic pattern: early deaths (<2 weeks) occur as a result of multi-organ dysfunction syndrome, while later deaths (>2 weeks) are generally secondary to sepsis associated with infected necrosis or complications of sterile necrosis.

Definition of severity

The revised Atlanta classification [1] defines mild AP as pancreatitis without the presence of SIRS, organ failure, pancreatic necrosis, or other acute complications. However, the definition of severity is complicated by the biphasic nature of AP mortality. Severe disease during the early phase is classified as the persistence of organ failure for >48 hours as characterized by a suitable scoring system such as the Marshall Score (Table 190.1), which can be repeated on a daily basis for evaluation of progress. Severe late disease is defined by the presence of peripancreatic complications (that may give rise to systemic symptoms), reflecting the predominant cause of mortality in this time period. This should be assessed by contrast-enhanced CT to identify morphologic abnormalities of the pancreatic and peripancreatic region.

Predictors of severity

Common diagnostic markers such as serum amylase have no value in the early assessment of disease severity or prognosis.

Table 190.1 Marshall Scoring System for the determination of AP severity in the early phase of disease (score ≥ 2 for organ failure)

Score	0	1	2	3	4
Respiratory system PO_2/FiO_2	>400	301–400	201–300	101–200	<101
Renal system serum creatinine (μmol/L)	134	134–169	170–310	311–439	>439
Cardiovascular system systolic blood pressure (mmHg)	>90	<90 Fluid responsive	<90 Not fluid responsive	<90 pH <7.3	<90 pH <7.2

Development of severe AP is therefore predicted in the first 48 hours following presentation, utilizing various clinical and laboratory scoring systems, supplemented by inflammatory markers. However, specific mechanisms underlying progression from SIRS to organ failure remain poorly elucidated. Although the use of scoring systems to allow swift identification of patients likely to benefit from early, aggressive treatment is likely to improve outcome, such scoring systems have limited accuracy and clinical value (up to 69% positive predictive value) and do not replace careful and repeated clinical assessment and examination [17] (Table 190.2).

Ranson's or modified Glasgow score (Imrie)

These scoring systems were developed specifically for the assessment of pancreatitis and are the most commonly utilized. They are easy to perform, utilizing routinely assessed blood tests. A score ≥3 in both of these scoring systems has a high negative predictive value for severe AP [18].

Apache II score

This assesses 12 physiologic variables, age and chronic health status, and can be used at hospital admission unlike the 'Ranson' and 'Glasgow' criteria that can only be fully utilized after 48 hours. It is more complex to perform and not specific to pancreatitis, but remains the most accurate tool for predicting mortality [17].

Panc 3 score

This simple assessment method reflects the findings that an elevated haematocrit (>44 mg/dl) due to hypovolemia, pleural effusion, and body mass index >30 kg/m^2 (mechanism unknown) are independent predictors of AP severity [19]

Inflammatory markers

Serum C-reactive protein (CRP) levels are useful in predicting both AP severity (CRP≥150 mg/l at 36 hours) and super-infection of pancreatic necrosis (CRP >81 mg/l). An elevated white cell count (>13x10^9/L) is also an indicator of pancreatic superinfection [20].

Novel biomarkers

Several have been associated with AP severity, e.g. the acute phase serum reactant, procalcitonin; the pro-inflammatory cytokine IL-6 which is one of the main inducers of hepatic CRP synthesis and peaks earlier than CRP; or elastase, an enzyme released by activated polymorphonuclear leukocytes. However, these remain research tools requiring further validation at present, and are yet to be established in routine clinical practice.

Radiological imaging for assessment of severity

Computed tomography

CT remains the mainstay of severity assessment late in the course of disease. Mild AP is identified by the presence of enhancing but

oedematous pancreatic parenchyma, whereas severe AP is associated with non-enhancing pancreatic parenchyma or peripancreatic tissues, indicative of necrosis, with or without peripancreatic fluid collections, pseudocysts and pseudo-aneurysms. The degree of necrosis is usually quantified as comprising <30%, 30–50% or >50% of the total pancreatic parenchyma.

Radiological scores such as the CT severity index (CTSI), Balthazar score and 'extra-pancreatic inflammation on CT' (EPIC) score (Tables 190.3, 190.4, and 190.5) can quantify pancreatic and peripancreatic morphology and provide a repeatable assessment of patient progress. The CTSI is based upon the degree of pancreatic inflammation and necrosis seen at initial CT; a CTSI score ≥3 is associated with a poor prognosis.

Magnetic resonance imaging

MRI is capable of accurately delineating pancreatic and biliary duct disruption, and is comparable to CT in the assessment of severity, while avoiding the risks associated with radiation exposure. It has a particular role in assessing pancreatic ductal anatomy prior to planned intervention, and in follow-up of patients requiring multiple sequential imaging.

CHAPTER 191

Management of acute pancreatitis in the critically ill

Rajkumar Rajendram

Key points

- Acute pancreatitis (AP) can be divided into three broad categories: mild, moderately severe AP (SvAP) and necrotizing SvAP. The severity determines the management stratagem.
- Monitoring and support of pulmonary, renal, circulatory, and hepatobiliary function may minimize the systemic consequences of SvAP.
- Adequate pain control requires administration of intravenous opiates (e.g. fentanyl), usually as patient-controlled analgesia.
- In SvAP, initiate enteral nutrition early (within 72 hours) via a nasogastric tube (Grade 1B evidence). If the target rate is not achieved within 48–72 hours and SvAP has not resolved, parenteral nutrition should be considered.
- For gallstone pancreatitis, perform ERCP and sphincterotomy early if there is cholangitis or a high suspicion of cholestasis (Grade 1B evidence). Cholecystectomy should be performed after recovery in all patients with gallstone pancreatitis.

Introduction

The main causes of morbidity and mortality in acute pancreatitis are organ dysfunction and infection of necrotic tissue. The likelihood of these complications depends upon the severity of pancreatitis which is subdivided into three broad categories [1]:

- Mild acute pancreatitis.
- Moderately severe acute pancreatitis.
- Necrotizing severe acute pancreatitis.

While acute pancreatitis is usually mild and recovers within seven days, severe acute pancreatitis (SvAP) occurs in about 20% and is associated with significant morbidity and mortality. In the absence of major co-morbidities patients with mild pancreatitis do not require admission to intensive care. Early (fulminant) SvAP causes extensive pancreatic necrosis, multiple organ dysfunction syndrome, and results in a high mortality (25–30%) [1]. Moderately severe acute pancreatitis only causes local complications so the mortality is low, but the morbidity is similar to that of necrotizing SvAP [1].

The aims of management are to prevent, or to diagnose and treat, the complications of pancreatic inflammation and any predisposing factors to avoid recurrence. The systemic consequences of SvAP may be reduced by admission to an intensive care unit (ICU) for monitoring and organ support.

Supportive care

Medical management is essentially supportive with supplemental oxygen, fluid resuscitation, analgesia, and correction of metabolic abnormalities. Patients can recover and resume oral intake with supportive treatment alone.

Fluid and electrolyte replacement

Necrotizing pancreatitis causes vascular leak and hypovolemia which exacerbate damage to the pancreatic microcirculation thus worsening necrosis. Inadequate resuscitation results in hypotension and acute kidney injury, and may exacerbate pancreatic necrosis. Faster initial fluid resuscitation reduces mortality [2].

Although several approaches to fluid resuscitation have been described, data on the type and amount of fluids required are limited. Fluid resuscitation is best guided by haemodynamic variables and urine output (>0.5 mL/kg/hour). The serum urea level on admission and the trend over the next 24 hours can predict mortality [3]. Maintenance rates >300 mL/hour may be required for 48 hours to reduce the urea level and the raised haematocrit. Fluid balance should be optimized if the urea does not improve. However, if oliguria reflects acute kidney injury rather than hypovolemia, aggressive fluid replacement may cause oedema without improving renal function.

Serum electrolytes should be measured frequently in patients with electrolyte and metabolic disturbances. Hypocalcaemia should be corrected if the ionized calcium is low. Hypomagnesaemia can cause hypocalcaemia and should also be treated.

Hyperglycaemia may be caused by insulin resistance, increased gluconeogenesis, reduced metabolism of glucose, and parenteral nutrition (PN). Hyperglycaemia may increase secondary pancreatic infections. Blood glucose should be measured hourly and insulin used to control blood glucose.

Analgesia

Fluid resuscitation can improve the pain from ischaemic pancreatitis due to hypovolemia. However, adequate analgesia often requires intravenous opiates. Pethidine has traditionally been preferred to morphine. However, the half-life of pethidine is short and repeated doses can lead to accumulation of norpethidine; a toxic metabolite. Although morphine increases sphincter of Oddi pressure, it does

not cause nor exacerbate pancreatitis or cholecystitis. Fentanyl may be safer, particularly in patients with renal impairment, and can be given in boluses, as an infusion or as patient-controlled analgesia.

Nutrition

Mild pancreatitis can often be managed with intravenous fluids alone as patients usually recover and resume oral intake within a week. However, patients with SvAP are unlikely to resume oral intake for 5–7 days and so nutritional support should be provided early.

Enteral nutrition

Enteral nutrition (EN) maintains the intestinal barrier and prevents bacterial translocation from the gut. Translocation of organisms is a major cause of secondary infection. Raised pancreatic enzymes or fluid collections are not absolute contraindications to EN. Even partial gastric outlet obstruction can resolve as inflammation can subside and fluid collections mature, becoming drainable while EN is being administered. Enteral nutrition avoids the complications of PN; in comparison, EN significantly reduces mortality, multiple organ failure, systemic infections, and the need for surgery [4,5].

A controlled trial comparing nasogastric and nasojejunal feeding found no significant difference in APACHE II score, C-reactive protein, pain or analgesic use [6]. Post-pyloric feeding is thus not required if nasogastric feeding is tolerated. However, EN—whether oral, gastric or post-pyloric—can cause pain, recurrence of pancreatitis, or increase fluid collections. This often occurs in patients with disrupted pancreatic ducts and fluid collections. It may be possible to resume enteral nutrition after drainage of collections. If the collections are not drainable or the target rate of EN is not achieved within 72 hours, PN is required.

Parenteral nutrition

While patients intolerant of EN should receive PN, supplementing EN with PN may be harmful. A randomized multicentre trial of 4640 critically-ill adults showed that early PN supplementation (within 48 hours of ICU admission) increased the incidence of new infections and the duration of mechanical ventilation, ICU admission, and hospital admission [7].

Resumption of oral intake

In SvAP, oral intake is limited by postprandial pain, nausea, or vomiting as gastroduodenal inflammation and/or extrinsic fluid collections cause gastric outlet obstruction. Enteral or parenteral nutrition is required until oral intake is tolerated. Patients traditionally progress from clear fluids to solid food.

Infection

Approximately a third of patients with SvAP develop infection of the necrotic pancreas. This often occurs late (>10 days) and is a common cause of morbidity and mortality. Most infections (about 75%) are monomicrobial. Causative organisms are predominantly gut-derived, e.g. *Escherichia coli, Pseudomonas, Klebsiella*, and *Enterococci*. Infection with fungi or Gram-positive organisms is unusual, but more likely if prophylactic antibiotics are administered for >10 days. Fungal infections occur in approximately 10%, but it is not yet clear if fungal infection *per se* increases mortality [8].

Treatment of infections includes systemic antimicrobials, EN, percutaneous aspiration, and/or necrosectomy (surgical debridement of pancreatic necrosis).

Antibiotics

Antibiotics should be given if there is clinical or microbiological evidence of infection. The role of prophylactic antibiotics is controversial. Although a systematic review concluded that prophylactic antibiotics decreased mortality in SvAP, but not the rate of infected pancreatic necrosis [9], a subsequent meta-analysis found no mortality benefit or reduction in the rate of infected necrosis [10]. Although the American Association of Gastroenterology recommends antibiotic prophylaxis if >30% of the pancreas is necrotic, prophylactic antibiotics are associated with selection of resistant organisms and fungal infection [8].

Percutaneous CT-guided aspiration

Acute pancreatic fluid collections do not require drainage unless infected or obstructing bowel. Conservative management allows organization of necrotic fluid collections. Endoscopic or percutaneous minimally invasive debridement can then clear any necrotic debris. CT-guided percutaneous aspiration should be considered for microscopy and culture should infected pancreatic necrosis be suspected [11], or if there is no improvement after a week of empirical antibiotics in a patient with >30% pancreatic necrosis and clinical signs of infection without any other obvious source [12].

If the aspirate is sterile, conservative treatment should continue for 4–6 weeks. However, a negative fine needle aspiration does not exclude infection. If signs of systemic toxicity persist >5–7 days, repeat aspiration may be required. If there is evidence of bacterial infection, antibiotics should be changed according to culture and sensitivity results and necrosectomy considered [13].

Necrosectomy

Indications include infected pancreatic necrosis and symptomatic sterile pancreatic necrosis preventing oral intake. Necrosectomy can be performed endoscopically, percutaneously, or as an open procedure. Compared with open necrosectomy, a minimally invasive step-up approach consisting of percutaneous drainage followed, if necessary, by open necrosectomy, reduces morbidity and mortality in patients with infected necrotizing SvAP [14].

Abdominal compartment syndrome

Patients with SvAP may develop intra-abdominal hypertension. Contributory factors include tissue oedema from aggressive fluid resuscitation, peripancreatic inflammation, ascites, and ileus. Abdominal compartment syndrome (ACS) is a life-threatening complication that occurs when intra-abdominal pressure rises >20 mmHg causing ischaemia and tissue necrosis. Most patients who develop ACS are critically ill and unable to communicate so intra-abdominal pressures should be monitored with serial measurement of urinary bladder pressures. However, nearly all patients with a significant ACS have a tensely distended abdomen, progressive oliguria and increased ventilatory requirements.

If ACS is confirmed, either percutaneous catheter or surgical decompression may be considered [15]. Surgical decompression typically requires a midline laparotomy. Following decompressive laparotomy, temporary abdominal closure is used until the laparotomy is no longer required. The abdomen is then closed primarily, functionally, or using skin grafts.

Splenic vein thrombosis

Splenic vein thrombosis occurs in nearly 20% of patients with acute pancreatitis [16]. Anticoagulation may be necessary if the thrombus compromises liver or bowel perfusion by extension into the portal or superior mesenteric vein. However, the thrombosis may resolve spontaneously with treatment of pancreatitis while anticoagulation increases the risk of haemorrhage into areas of pancreatic necrosis or into collections [16]. Variceal bleeding is uncommon in patients with splenic vein thrombosis due to SvAP so prophylactic splenectomy is not required [16].

Treatment of gallstone pancreatitis

Any predisposing factors require treatment. Gallstones are the commonest cause of pancreatitis that requires specific treatment. As removal of stones may reduce the severity of pancreatitis, an endoscopic retrograde cholangiopancreatography (ERCP) should be performed within 72 hours if there is co-incident cholangitis or it is likely that a stone is obstructing the bile duct or ampulla of Vater (i.e. visible common bile duct stone on non-invasive imaging, persistently dilated common bile duct, jaundice or worsening liver biochemistry). Placement of a biliary stent reduces the risk of post-ERCP pancreatitis.

The role of ERCP in the absence of cholangitis or suspicion of a persistent common bile duct stone conflict is unclear. Two meta-analyses found that early ERCP in patients without cholangitis reduced the risk of overall complications and mortality regardless of the predicted severity [17]. In another meta-analysis of five prospective randomized trials (702 patients), early ERCP reduced complications, but not mortality in SvAP; there was also no benefit in mild pancreatitis [18].

Patients with biliary pancreatitis can undergo ERCP before cholecystectomy in the absence of persistent bile duct stones, cholangitis, persistently abnormal liver biochemistry, or worsening liver biochemistry. However, endoscopic ultrasound (EUS) or magnetic resonance cholangiopancreatography (MRCP) can determine the need for ERCP if the patient is pregnant; too unstable to allow timely laparoscopic cholecystectomy and intraoperative cholangiography; if ERCP is likely to be difficult (altered surgical anatomy or coagulopathy); if the probability of a retained common bile duct stone is intermediate; and if the patient is too unstable for cholecystectomy with cholangiography.

Cholecystectomy

Patients should have a cholecystectomy after recovery from gallstone pancreatitis. The risk of recurrent pancreatitis, cholecystitis, or cholangitis is 30% within 18 weeks if cholecystectomy is not performed [19]. This risk is highest in patients who have not had a sphincterotomy.

Cholecystectomy can be performed within seven days of recovery from mild pancreatitis. In a randomized study of 50 patients with mild gallstone pancreatitis, laparoscopic cholecystectomy within 48 hours of admission reduced admission more than cholecystectomy performed after resolution of pain and biochemical abnormalities [20]. However, the risk of post-operative infection is increased by SvAP so delaying cholecystectomy for over 3 weeks after SvAP may be appropriate.

If the clinical suspicion of common bile duct stones is high, pre-operative ERCP is the investigation of choice because therapeutic intervention (sphincterotomy, stone extraction) will probably be required. However, if the suspicion of persistent common bile duct stones is low (e.g. if liver biochemistry returns to normal), MRCP, EUS or an intra-operative cholangiogram during cholecystectomy can be used to avoid the risks of ERCP.

Conclusion

Effective management of acute pancreatitis requires a co-ordinated multidisciplinary approach. The mainstay of management is supportive with analgesia, intravenous fluids, nutrition, prevention, and treatment of complications, infection and organ failure to avoid or delay surgery. A minimally invasive step-up approach including conservative therapy with percutaneous drainage of infected collections followed, only if absolutely necessary, by open necrosectomy, reduces morbidity and mortality [14]. The diagnosis and treatment of the cause of pancreatitis is important to prevent recurrence of pancreatitis and the long-term consequences of pancreatic failure.

PART 6.7

Jaundice

CHAPTER 192

Pathophysiology and causes of jaundice in the critically ill

Anand D. Padmakumar and Mark C. Bellamy

Key points

- Jaundice is commonplace in the intensive care unit (ICU) patient with a prevalence as high as 30–55% in specific patient subgroups.
- Severity of jaundice is proportional to the number of failing organs and mortality.
- Commonly used therapies, such as vasopressors, positive end-expiratory pressure (PEEP), and parenteral nutrition, can increase the risk of ICU jaundice.
- A lag phase exists between hepatocyte injury and elevation of serum markers.
- An unselective battery of tests often confuses the clinical picture; therefore a systematic and logical diagnostic approach should be used to identify the aetiology of jaundice.

Introduction

This chapter focuses only on the acutely jaundiced adult intensive care unit (ICU) patient. Detailed discussion encompassing chronic and neonatal jaundice is beyond the scope of this chapter.

Jaundice is defined as a serum bilirubin concentration >2 mg/dL (40 μmol/Ll). It becomes clinically recognizable when above 3 mg/dL (60 μmol/L). Clinically, it can be identified as yellowish discoloration of skin, lateral aspect of conjunctiva and sublingual mucosa.

Jaundice is common in the ICU and is often the only symptom of liver dysfunction or other systemic disease. The prevalence of hyperbilirubinaemia has been quoted as high as 30–55% in various ICU patient subgroups (trauma, post-cardiac surgery, shock, sepsis) [1]. The median onset time is approximately three days. Risk factors include hypotension, severe sepsis, Gram negative infections and major surgery; these increase the risk of developing liver dysfunction by 3–4-fold [2]. Overall mortality for liver dysfunction alone has been reported at 56%, and 61% for liver dysfunction following sepsis or major surgery. Strassburg introduced the concept of 'shock liver', a term used collectively to describe deranged liver function tests (LFTs) or clinical evidence of liver dysfunction, varying degrees of which have been identified in about 50% of ICU patients [3].

Commonly used interventions such as positive end-expiratory pressure (PEEP), vasopressors and parenteral nutrition are also risk factors for the development of jaundice [4]. It remains unclear whether these associations are causative. Elevated liver enzymes and bilirubin are markers of hepatocyte damage. Although uncommon, isolated hyperbilirubinaemia can occur as a result of intra- or extrahepatic causes (e.g. haemolysis, Gilbert's syndrome). Derangement of liver function can be closely monitored as part of routine ICU blood testing. However, there is usually a lag phase of several days between the development of hepatocyte damage and a rise in serum markers.

At physiologic levels, bilirubin exerts beneficial effects due to its anti-oxidant properties [4,5]. However, when levels are elevated, it causes more harm than good. See Table 192.1.

Severity of jaundice has a direct relationship with the number of failing organs and mortality [6]. Animal studies have shown that obstructive jaundice may also have a direct cardiac depressant effect (bradycardia, hypotension, diminished catecholamine responsiveness) [7]. Therefore, it is crucial to request appropriate investigations (guided by clinical presentation) and to interpret biochemical abnormalities accurately in order to detect hepatocellular damage early on. In addition to good general supportive therapy, this offers opportunities for improved patient management and outcome.

Metabolism of bilirubin

To appreciate the causes of jaundice and have a rationale for ordering specific investigations, an understanding of bilirubin metabolism is essential [8]. Bilirubin is a tetrapyrrole, lipophilic molecule derived as an end-product of haeme catabolism. It undergoes a complex conjugation process within the liver to be excreted in bile and urine (Fig. 192.1).

Most of the haeme (80–85%) is derived from senescent red blood cells (RBC) by microsomal haeme oxygenase present in reticuloendothelial cells of the spleen. The remainder is derived

Table 192.1 Pathophysiological effects of bilirubin

Beneficial effects	Harmful effects
◆ Reduces risk of coronary artery disease.	◆ Reduces cell survival due to increased oxidative stress.
◆ Reduces cancer-related mortality.	◆ Causes red blood cell lysis.
◆ Protection against pulmonary fibrosis and cyclosporin-induced nephrotoxicity	◆ In sepsis, it is an independent predictor of mortality from and development of acute respiratory distress syndrome

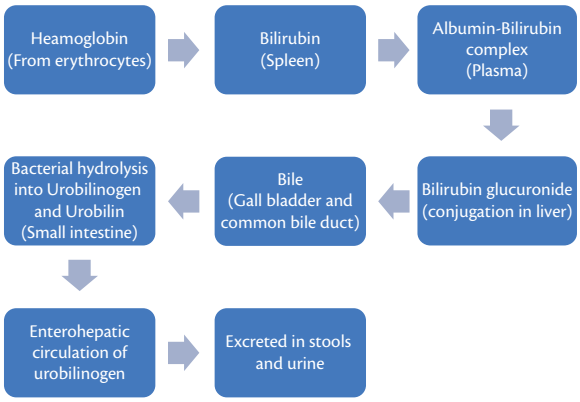

Fig. 192.1 Summary of metabolism of bilirubin and enterohepatic circulation.

from cytochrome P450 and some immature erythrocytes from the spleen and bone marrow. Haeme is initially converted to biliverdin (water-soluble) that, in turn, is reduced to bilirubin (lipid-soluble) by biliverdin reductase. This unconjugated bilirubin is bound to plasma albumin and transported to the liver.

Hepatocytes have specialized functions that uptake bilirubin (after separating albumin), then conjugate it by glucuronidation, and finally excrete it as water-soluble bile into the biliary canaliculi. Bile is stored within the gall bladder and excreted into the second part of duodenum (via the ampulla of Vater) through the common bile duct. In the colon, conjugated bilirubin is again rendered lipid-soluble by colonizing bacteria that produce urobilinogen and urobilin that are excreted in the stool and urine. There is some reabsorption and recirculation through the enterohepatic circulation.

Pathophysiologic classification of jaundice

A multiplicity of aetiological factors has been identified which can be classified into three main pathophysiological domains—prehepatic, intrinsic hepatic, and post-hepatic Table 192.2.

Pathophysiological mechanisms

Current understanding of the pathophysiology of hyperbilirubinaemia is predominantly derived from animal studies. Exact mechanisms remain incompletely elucidated. Hawker has classified intrahepatic causes of liver dysfunction (LD) in the ICU into two main syndromes—ischaemia-related hepatic injury and 'ICU jaundice'. The characteristic feature of **ischaemic hepatitis** is a raised level of serum (aspartate- and alanine-) aminotransferases (AST, ALT) that usually occurs within the first day of insult. Bilirubin levels can be normal or mildly elevated. Other abnormalities such as hepatomegaly, deranged clotting and acidosis have also been linked to injury secondary to low-flow states. In contrast, **ICU jaundice** has a much slower onset with a significantly higher and proportional increase in bilirubin and bile salts compared to AST and ALT levels. Histopathologically, centrilobular necrosis is typically seen in ischaemic hepatitis while most patients with ICU jaundice show intrahepatic cholestasis [9].

Hepatocytes are highly susceptible to hypoxic damage, especially in low-flow states. This could be multi-factorial and accurate measurement of variables such as liver blood flow can be difficult. Pathogenetic mechanisms leading to LD in the ICU are shown in Table 192.3 [4,10,11].

Once LD is identified, clinicians should also actively explore and treat its potential knock-on effects [10] such as:

- **Immunosuppression**: possibly mediated by Kupffer cell activation, and depression of cell-mediated immunity.
- **Altered drug pharmacokinetics**: loss of cytochrome P450 enzyme activity can significantly alter drug handling; reduced liver blood flow can affect uptake and breakdown of certain drugs.
- **Multi-organ dysfunction**: LD can predispose to many systemic effects involving multiple organs (heart, lung, kidney, brain). This may be related to Kupffer cell activation and release of inflammatory mediators into the systemic circulation.

Table 192.2 Classification of jaundice

Classification	Mechanisms	Etiology
Prehepatic (UCB)	Increased production of unconjugated bilirubin	**Haemolysis** ◆ *Intravascular*: hereditary spherocytosis, malaria, G6PD deficiency, mismatched transfusion, autoimmune haemolysis, drug-related ◆ *Extravascular*: trauma, haematoma, splenic sequestration (sickle cell crisis)
Intrahepatic (UCB +/− CB)	◆ Reduced uptake of bilirubin ◆ Hepatocellular damage ◆ Reduced conjugation	◆ *Infection*: hepatitides, sepsis ◆ *Inherited*: Gilbert's, Crigler–Najjar syndromes ◆ *Infiltration*: malignancy ◆ *Ischaemia*: coronary (heart failure), hepatic ◆ *Injury*: trauma, drug-induced (rifampicin, chemotherapy), alcohol-induced cirrhosis
Post-hepatic (CB)	◆ Obstruction to flow of bile ◆ Leakage of bile due to injury to hepatocytes	◆ *Infection:* AIDS, parasites, TB, hepatitides ◆ *Inherited*: Dubin–Johnson and Rotor syndrome ◆ *Inflammation:* cholecystitis, cholangitis, NASH ◆ *Infiltration:* carcinoma (gall bladder, pancreas) ◆ *Injury:* trauma, surgery, alcohol-related, drugs ◆ *Impaction and impingement:* gall stone disease, tumours

NB: UCB, unconjugated bilirubin; CB, conjugated bilirubin; G6PD, glucose-6-phosphate dehydrogenase deficiency; AIDS, acquired immunodeficiency syndrome; TB, tuberculosis; NASH, non-alcoholic steatohepatitis.

Table 192.3 Overview of possible pathogenetic mechanisms involved in ICU jaundice

Aetiology	Pathogenetic mechanisms
Ischaemia/low flow states	◆ Selective splanchnic vasoconstriction (vasopressors) ◆ Reduced bile flow/excretion of conjugated bilirubin from hepatocytes [13] ◆ Altered portohepatic haemodynamics as a result of increased right heart pressures (mechanical ventilation, PEEP, congestive heart failure, etc.) [4]
Sepsis	◆ Endotoxin/inflammatory mediators (bacterial translocation from gut) → failure of phagocytosis by Kupffer cells (drug induced/ischemic injury) → further cascading of inflammatory mediators (IL-1, IL-6, TNF) causing local and distant organ injury/dysfunction ◆ Endotoxin-mediated inhibition of Na-K-ATPase causing cholestasis (reduced secretion of bile) ◆ Inhibition of cytochrome-P450 enzymes by IL-1 (causing impaired drug metabolism)
Drug-induced	◆ Cholestasis (ACE-I, anticonvulsants, tricyclic antidepressants) ◆ Hepatocellular inflammation/death (paracetamol, NSAIDs, methyldopa) Both forms can be immune (indirect) or non-immune mediated (direct) hepatocellular or canalicular injury.
TPN	◆ **Steatosis:** due to perilobular deposition of fat (increased fatty acid synthesis due to reduced clearance of triglycerides and availability of excess free calories, possible local effects of insulin promoting lipogenesis, nutritional deficiencies, etc.) ◆ **Cholestasis:** reduced production of bile salts and enterohepatic circulation ◆ **Cholecystitis:** calculous (reduced gall bladder motility promotes formation of sludge and gallstones) or acalculous (biliary stasis, reduced CCK production) ◆ **Bacterial translocation:** prolonged disuse of intestines promotes bacterial overgrowth; endotoxin mediated injury
Congestive heart failure	◆ **Passive congestion of liver:** reduced hepatic flow, increased venous congestion, reduced oxygen delivery to hepatocytes (causing cell death) ◆ **Ischaemia:** due to oxygen demand supply mismatch ◆ **Ischaemia-reperfusion injury:** Kupffer cell and TNF-mediated cell injury

PEEP, positive end expiratory pressure;, IL, interleukin; TNF, tumour necrosis factor; ACE-I, angiotensin-converting enzyme inhibitor; NSAID, non-steroidal anti-inflammatory drug, CCK, cholecystokinin.

Data from: Minetti M et al., 'Bilirubin is an effective antioxidant of peroxy nitrite-mediated protein oxidation in human blood plasma', *Archives of Biochemistry and Biophysics*, 1998, **352**, pp. 165–74; Levinson MJ, 'Jaundice in the intensive care unit', *Hospital Practice*, 1993, **30**, pp. 51–60; Johnson EE et al., 'End-expiratory pressure ventilation and sulfobromophthalein sodium excretion in dogs', *Journal of Applied Physiology*, 1997, **43**, pp. 714–20.

◆ **Reduced synthetic function**:

- *Albumin*—can affect drug binding and transport, peripheral oedema due to alterations in tissue oncotic pressure.
- *Clotting factors*—can precipitate disseminated intravascular coagulation.
- *Glucose*—hypoglycaemia can be a presentation of 'shock liver'.

Prehepatic causes for unconjugated hyperbilirubinaemia arise from various sources, but are commonly due to transfusion-related haemolytic reactions, drug-induced haemolysis, and breakdown of excessive free or old erythrocytes. Hereditary conditions (e.g. spherocytosis, elliptocytosis, red cell fragility disorders, glucose-6-phosphate dehydrogenase deficiency) can lead to jaundice when exposed to certain stressful situations (exercise, hypoxia, hypothermia, acidosis, etc.). Reduced clearance of bilirubin due to other predisposing factors (pre-existing liver disease) can also predispose to unconjugated hyperbilirubinaemia. Acquired haemolytic conditions include paroxysmal nocturnal haemoglobinuria (Marchiafava–Micheli syndrome) and autoimmune haemolytic anaemia.

Diagnostic approach

A good understanding of the aetiology, pathogenesis, and impact of LD is key to developing a step-wise, logical diagnostic strategy. Many diagnostic dilemmas exist, e.g. what tests to order, their interpretation, and whether hyperbilirubinaemia should be investigated further. Such difficulties can impede prompt initiation of therapy, especially when there is limited guidance in the literature.

It is useful to have a system to explore potential causes. The importance of a good history and general physical and focused examination of the gastrointestinal system cannot be overemphasized. Bilirubin by itself is only one of many indicators of hepatocellular dysfunction, yet is commonly used in organ failure scoring systems [12,13]. A major limitation of using bilirubin as a marker of liver dysfunction is the time delay between the hepatocellular insult and the rise in serum levels [11]. This could be due to overcompensation by unaffected hepatocytes. There is a strong association between hyperbilirubinaemia and sepsis (up to 33% of patients); Franson et al. highlighted that if the rise in bilirubin levels has no obvious cause, then a septic source should be actively explored [14].

Ordering an unselective battery of tests can often generate unwanted results and confuse the clinical picture. The following flowcharts help to formulate a logical approach to the jaundiced ICU patient. In the acute setting, depending on presentation severity, initial stabilization is required before commencing a detailed evaluation of jaundice [15]. The aim is to prevent any secondary damage to vital organs, including the liver. In Stage 1 (Fig. 192.2) the aim is to generate basic information as a guide to planning further tests [16]. The second stage (Fig. 192.3) fine-tunes the diagnostic strategy. However, this general approach should be adapted using clinical judgement to individualize it to both patient and local

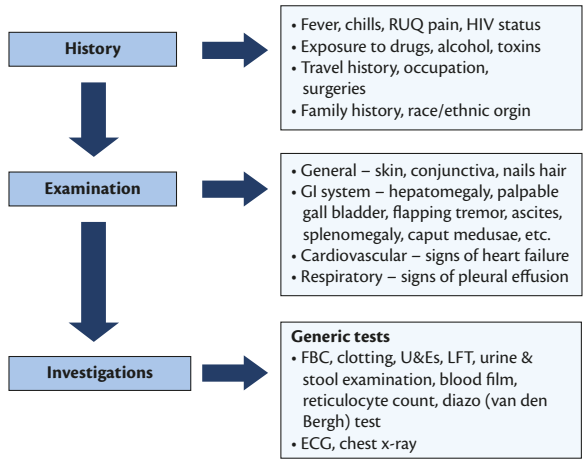

Fig. 192.2 Fundamental steps in initial evaluation of ICU jaundice.

guidelines. Early involvement of medical and surgical gastroenterology teams is crucial.

Hyperbilirubinaemia can occur when there is hepatocellular (prehepatic) disease or cholestatic (intra- and post-hepatic) conditions. Plasma levels of hepatic enzymes (e.g. AST, ALT) are variably affected. A diazo (van den Bergh) test can check the proportion of direct (conjugated) to indirect (unconjugated) bilirubin and should be considered in every patient presenting with jaundice [15].

Computer-assisted decision-support algorithms are gaining popularity [17]. However, while useful in improving efficiency by 'ordering the right test for the right patient', they are not without limitations, biases, and inconsistencies [18].

Nevertheless, by using some of these objective principles of probability and with the results from the initial (Stage 1) assessment, acutely jaundiced patients can be generally categorized into pathophysiologic subgroups (blue boxes in Fig. 192.3) [7]. This helps to plan definitive therapy. The practical difficulties of arranging further investigations and the severity of illness can preclude the possibility of undertaking certain tests. For example, transfer to the radiology department may compromise patient safety if the patient is haemodynamically unstable. If coagulation is deranged, invasive procedures may be relatively contraindicated. Therefore a pragmatic, multi-disciplinary team approach should be adopted in such circumstances. Where a specific line of diagnostic possibility is identified, appropriate specialist input from radiologists, gastroenterologists, hepatologists, and hepatobiliary surgeons should be sought. Wherever possible, less invasive procedures (preferably at the bedside) should be given priority over invasive tests (such as ERCP) in unstable patients. Demarcation into pathophysiological

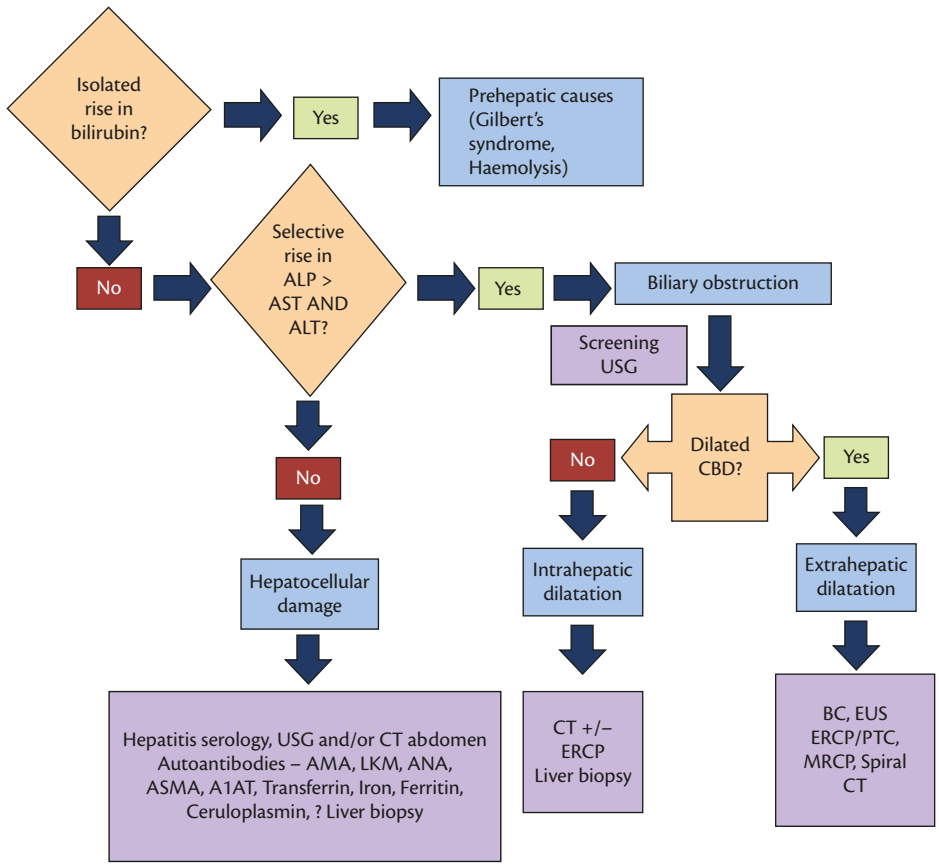

Fig. 192.3 Stage 2 investigations based on results of Stage 1 tests.
ALP, alkaline phosphatase; AST, aspartate transaminase; ALT, alanine transaminase; USG, ultrasonography; CBD, common bile duct; CT, computed tomography; AMA, anti-mitochondrial antibody; LKM, liver kidney microsomal antibody; ANA, antinuclear antibody; ASMA, anti-smooth muscle antibody; ERCP, endoscopic retrograde cholangiopancreatography; BC, blood culture; EUS, endoscopic ultrasonography; PTC, percutaneous transhepatic cholangiography; MRCP, magnetic resonance cholangiopancreatography.

subgroups may not always be clear-cut and there can be some overlap in both biochemical and clinical pictures.

Special considerations

Not uncommonly, patients are admitted to ICU with an unusual presentation. While many presentations of jaundice in ICU non-specifically reflect systemic disease, there are some specific causes such as a complication of pregnancy, paracetamol toxicity, and liver transplantation Table 192.4. Care must be taken to identify these high-risk patients early and tailor management accordingly. Any woman in the reproductive age group should have a pregnancy test to direct specific tests relevant to pregnancy itself and to identify rarer causes of jaundice. Drug dyscrasias, non-A non-B hepatitis and halothane hepatitis are discussed elsewhere.

Supplementary investigations

Based on presentation, some additional investigations may need to be ordered, e.g. [7,19]

- For haemolysis, a direct Coombs (antihuman globulin) test, lactate dehydrogenase and serum haptoglobulin may be required.
- Serum albumin and vitamin K-dependent clotting factors are markers of synthetic liver function.
- In obstructive jaundice, fat-soluble vitamins (A, D, E, K) are poorly absorbed. This may also impact on synthesis of the clotting factors II, VII, IX, X, and proteins C and S.
- Urine dipstick to check for the presence of bilirubin aids in diagnosis (negative test suggests cholestatic picture), and urine pregnancy testing to rule out pregnancy.
- Sepsis-related liver injury can cause jaundice and should be investigated with blood cultures, blood gas analysis, and measurement of serum lactate to assess severity of illness and guide further management.
- Diagnostic paracentesis (microscopy, cell count, cytology, cultures, serum ascites-albumin gradient, etc.) should be performed in all patients with ascites, especially in cirrhotic patients with encephalopathy, renal failure, signs of peritoneal infection, or if the source of sepsis is unclear.
- Serum amylase and leucocyte count may be elevated in pancreatic injury and can be suggestive of an obstructive cause for the jaundice (head of pancreas tumours, common bile duct stones, stricture at ampulla of Vater).

Table 192.4 Jaundice: special considerations and pathophysiology

Special consideration	Pathophysiology
Jaundice during pregnancy	◆ Intrahepatic cholestasis (3rd trimester) ◆ Acute fatty liver (3rd trimester) ◆ Hyperemesis gravidarum (usually 1st trimester) ◆ HELLP syndrome, PET (rare causes)
Paracetamol and salicylate overdose	Hepatocellular damage (check serum drug levels)
Post-liver transplantation	◆ Rejection ◆ Biliary obstruction/stenosis ◆ Hepatitis, delayed primary function, primary non-function, ischaemic biliopathy (vanishing bile duct syndrome)

Novel diagnostic methods

Investigations such as bilirubin, ALP, ALT, and clotting studies are 'static' tests providing indirect evidence of liver dysfunction [20]. 'Dynamic' tests measure the ability of the liver to metabolize or eliminate substances such as indocyanine green (ICG), caffeine, galactose, or lidocaine. Of these, ICG has been most studied because of its physical properties (inert, water-soluble, anionic nature) and ability to be excreted in bile (without being metabolized). The rate of disappearance of serum ICG, measured at specific intervals after injection, may be used as a surrogate marker of dynamic liver function. Advantages of these novel experimental methods are offset by limitations such as their time-consuming nature and cost. Their use is generally limited to animal models; further research is needed to correlate them with improvement in outcome or reversibility of hepatic dysfunction.

Conclusion

Jaundice is not a disease in itself, but can be a frightening symptom for the patient and a diagnostic and therapeutic challenge for the ICU clinician. Establishing the underlying diagnosis with a systematic approach can lead to positive patient outcomes. This chapter reviews the various pathophysiological and aetiological considerations of an acutely jaundiced ICU patient. Recommendations are made for developing a diagnostic strategy based on literature review, and for future areas of research. As many of the studies reviewed have their own limitations and the very fact that technological advances in the health care industry are progressing so rapidly, it is impossible to have a rigid framework for investigating jaundice in a pre-set manner.

Critically-ill jaundiced patients could have a wide range of aetiologies. Special circumstances such as overdose, drug-induced liver injury, and pregnancy will need careful attention during the process of diagnosis and management. Newer diagnostic tools are on the horizon bringing newer promises, but a balanced view with good clinical evaluation should always underpin a meticulous investigation process of identifying the cause for jaundice. This, along with early involvement of specialist teams, can reduce morbidity and mortality. A secondary advantage is reduction in health care costs, not just by improving outcomes, but also by using resources wisely.

CHAPTER 193

Management of jaundice in the critically ill

Anand D. Padmakumar and Mark C. Bellamy

Key points

- Primary prevention of hepatic injury may not always be possible, but management principles should aim to reduce secondary insults.
- Definitive management should not delay initial resuscitation measures.
- Early categorization into the pre-, intra- and post-hepatic pathophysiological groups will help to channel therapy accordingly.
- Intensive care unit (ICU) jaundice is more commonly non-obstructive in nature, but obstructive causes should be actively excluded due to their high impact on morbidity and mortality.
- Novel strategies (pharmacological and extracorporeal methods) have shown some promise in the management of the jaundiced ICU patient.

Introduction

In the previous chapter we reviewed epidemiology, the diverse aetiopathogenesis, consequences and diagnostic conundrums of jaundice in the intensive care unit (ICU) patient. A systematic diagnostic strategy, guided by sound knowledge of pathophysiology and good clinical assessment, will help intensivists to provide better quality treatment and, potentially, to prevent mortality. Here we focus on management aspects related to the jaundiced *adult* ICU patient only.

Jaundice itself is not a diagnosis, however, arriving at a diagnosis of its cause will assist the overall management goals. Once done, generic and specific treatment can be guided accordingly, to target and, if possible, eliminate the source.

The management approach is divided into two main sections—*preventive* and *therapeutic* with an intention of providing a systematic approach to managing the acutely-ill jaundiced ICU patient.

Prevention strategies

The same principles of management can be applied outside the ICU setting, ideally prior to the onset of critical illness. However, in routine clinical practise, hyperbilirubinaemia often presents late. This could be due to the natural time delay for biochemical markers to rise following the actual insult or injury. Primary prevention may be impossible in such cases. However, it is possible to prevent secondary injury to the liver by providing well-rounded and meticulous supportive care. When biochemical or clinical evidence of hyperbilirubinaemia becomes obvious, expeditious planning and treatment should be undertaken. As discussed in the previous chapter, knowledge of factors that predispose to liver dysfunction (LD) plays a key role in effective prevention of secondary insults.

ICU jaundice is more commonly non-obstructive in nature. However, an obstructive cause should be actively excluded as any delay in treatment will significantly increase morbidity and mortality. The key principles of elimination of these precipitating factors include:

- Initial resuscitation.
- Monitoring.
- Supportive therapy.

Initial resuscitation

Resuscitation strategies should be guided by a focused history and examination and the acute clinical situation. These strategies should be in line with basic and advanced ICU management principles: securing a definitive airway, mechanical ventilation, appropriate and timely fluid resuscitation, use of vasopressors, etc. However, such measures can affect hepatoportal haemodynamics and carry the potential to cause secondary insult. Therefore cardiac output monitoring and frequent clinical re-assessment should guide resuscitation. The consequences of hypotension can be dire (compensatory reduction in splanchnic circulation leading to bacterial translocation from the gut may cause or worsen sepsis, cause 'shock liver' [1], etc.). Appropriate resuscitation may require transfusion of blood and its components [2].

Where an infective aetiology is suspected, Surviving Sepsis guidelines should be followed with appropriate antibiotics instituted early [3]. If a precipitating cause for the jaundice, e.g. a drug, is identified, its administration should be stopped immediately. Additionally, in cases of hepatocellular injury due to paracetamol (acetaminophen) overdose, acetylcysteine (N-acetylcysteine, NAC) should be commenced immediately (without waiting for blood levels) as risks are small and, historically, have been overstated.

Monitoring

Profound haemodynamic disturbances presenting either as a cause (sepsis, heart failure, chronic liver disease, severe trauma, drug

overdose, systemic inflammatory response, etc.) or effect of primary hepatic injury should be closely monitored to guide fluid and vasopressor management. While surrogate measures for liver blood flow are available in some specialist centres, such as indocyanine green clearance or the 'MEGX' test (based on lidocaine metabolism), liver blood flow is not accurately measured in daily clinical practice. Hence, cardiac output (CO) can be used as a surrogate marker of the adequacy of global organ perfusion [4]. It must be emphasized that CO monitoring devices have limitations, their degree of invasiveness must be balanced against the risks involved and the level of information necessary for optimizing treatment.

Supportive therapy

The fundamental goal of supportive therapy is to improve oxygen delivery to organelles within the cell, aiming to maintain homeostasis. Adequate hydration, glycaemic control, and correction of electrolyte disturbances play key roles in maintaining homeostasis.

Careful attention to nutrition, head-end elevation, prevention of venous thromboembolism, physiotherapy, stress ulcer prophylaxis (especially in the coagulopathic patient), selective decontamination of the oropharyngeal and digestive tract, bowel care, and so forth have been shown to improve outcome.

Therapeutic strategies

Treatment relies upon the underlying diagnosis. Strategies have been categorized into the following subsections:

- Treatment of associated symptoms.
- Treatment of associated complications.
- Treatment of underlying causes.
- Novel therapies.

Treatment of associated symptoms

Although there are few specific treatments for jaundice itself, several medical therapies are available for controlling symptoms associated with jaundice.

- **Itching** is a common complaint and can be treated with agents such as cholestyramine (bile salt binding resin), ursodeoxycholic acid, and anti-histamines (used mainly for its sedative effect). Rifampicin, phenobarbitone, naloxone, ondansetron, and steroids have been tried with a variable response and should be used cautiously in view of their potential side-effect profile. Phototherapy, plasmapheresis, and liver transplant may be necessary depending on the underlying pathology or in treatment-resistant cases [5].
- **Abdominal pain** (commonly right upper quadrant pain) can be associated with jaundice and should be addressed with appropriate analgesia. This is especially relevant in patients where the stress response caused by pain can cause or worsen an oxygen demand-supply mismatch, e.g. ischaemic heart disease or cerebrovascular injury.
- **Ascites** is a common presentation of cirrhosis [6]. Treatment involves dietary salt restriction, step-ladder diuretic therapy with spironolatone (first-line), furosemide (second-line), or amiloride, and therapeutic large-volume paracentesis with concomitant volume expansion with human albumin solution, approximately 100 mL of 20% albumin is required for every 3 L of ascitic fluid drained. There is no conclusive evidence to support the use of fluid restriction [7].

Surgical or radiological treatment of an obstructive cause will also help to relieve these symptoms.

Treatment of associated complications

Various physiologic and biochemical abnormalities can accompany ICU jaundice including coagulopathy, multi-organ dysfunction (including liver and renal failure), electrolyte abnormalities, and sepsis. Acute liver failure (ALF) carries a high mortality and management can be challenging. Detailed management strategies for ALF are discussed elsewhere.

- **Coagulopathy** in a jaundiced patient can be due to decompensated liver disease or disseminated intravascular coagulation due to sepsis. The lack of absorption of vitamin K-dependent clotting factors (II, VII, IX, X) in obstructive jaundice compounds the problem further. This may require correction if there is active haemorrhage, e.g. variceal, peptic ulcer, trauma. However, there is no evidence to support routine correction of deranged clotting parameters (with blood components) prior to invasive procedures such as central venous catheterization, chest drain, or tracheostomy insertion, unless there is active bleeding [8].
- **Multi-organ failure** is essentially managed by supportive therapy (as described elsewhere). Protecting the airway by intubating the trachea, mechanical ventilation, vasopressor support, and renal replacement therapy (RRT) are commonly used strategies for supporting various failing organs. Dietician team input, nutritional therapy, meticulous care of invasive catheters, physiotherapy, and early mobilization are also important.

Treatment of underlying causes

The three main pathophysiological categories of jaundice comprise pre-, intra-, and post-hepatic groups. Causes are myriad and, for reasons of brevity, the management strategy of only some causes in each of these three groups will be covered.

Prehepatic group

Haemolytic conditions cause unconjugated hyperbilirubinaemia and can be due to primary (e.g. autoimmune, hereditary spherocytosis, elliptocytosis, sickle cell disease) or acquired (e.g. trauma, mismatched blood transfusion, drug-induced) causes.

- **Diagnosis**: based on peripheral blood smear examination (schistocytes, raised reticulocyte count) and reduced haptoglobin levels, raised levels of unconjugated (indirect) bilirubin and lactate dehydrogenase (LDH) [9].
- **Therapy**: for congenital causes the mainstay is to prevent haemolytic or sickle cell crises by maintaining adequate hydration and analgesia, avoiding known triggers (drugs, acidosis, stress, hypothermia, etc.) and correcting electrolyte disturbances. The resultant haemolytic anaemia may require folic acid and iron supplementation, or rarely, blood transfusion if symptomatic or a history of ischaemic heart disease is obtained. Splenectomy may be indicated in haemolytic crisis secondary to hereditary spherocytosis [10].
- **Pitfalls**: with autoimmune aetiologies there is a risk of haemolysis with transfused blood, causing further hyperbilirubinaemia. Specific cross matching may be necessary. Transfusion should be

undertaken at a slower rate and there may be a role for corticosteroids and intravenous immunoglobulin. Such cases should be discussed early with a haematologist.

Intrahepatic group

Hepatitis can be caused by various conditions, e.g. infection, hypoperfusion or 'shock liver', drugs, alcohol, congestive heart failure. It may become evident through history and abnormal liver enzymes [9]. A viral aetiology often has pre-icteric, icteric and post-icteric phases.

- **Diagnosis**: the pattern of injury is characterized by a rapid and disproportionate rise (10–100 times normal) in serum aminotransferase levels in comparison to alkaline phosphatase (ALP), a slow rise in bilirubin levels, a plateau phase, and quick recovery to the normal range. Liver biopsy is not advisable until after recovery from acute critical illness, but may show centrilobular necrosis [9]. It is important to highlight that untreated hepatitis has a higher chance of progressing to chronic liver disease.
- **Therapy**: therapy for viral hepatitis depends upon the severity of symptoms and liver dysfunction. The British Society of Gastroenterology recommends interferon (IFN) and antiviral agents (ribavirin, lamivudine) either as mono- or combination therapy [11]. Immunosuppression with steroids is the mainstay of treatment for autoimmune hepatitis. Other agents such as azathioprine and tacrolimus may be considered when resistance is encountered to steroid therapy. Septic foci should be actively explored and eliminated (drainage of collections, antibiotics, etc.).
- **Pitfalls**: hypoglycaemia is common in patients with acute liver dysfunction and should be treated without delay. Signs of encephalopathy may be subtle; it is important to clinically rule out ALF [12].

Post-hepatic group

Cholestasis describes any interference with bile flow or formation, and can be extra- or intra-hepatic [5]. **Extrahepatic** cholestasis is due to mechanical obstruction due to gall stone disease or malignancy. In **intrahepatic** cholestasis, there is no physical blockage visible on ultrasonography or cholangiography; causes include drugs, infection, or sepsis and inflammatory conditions (primary sclerosing cholangitis). Patients may present with jaundice (usually late-onset), excessive itching, fever with chills, and rigors, right upper quadrant pain, and malabsorption. Benign post-operative intrahepatic cholestasis, total parenteral nutrition (TPN)-related cholestasis and inherited conditions (Dubin-Johnson and Rotor syndrome) are other, relatively uncommon, causes.

- **Diagnosis**: early screening ultrasonography will help differentiate between intra- and extra-hepatic cholestasis. This is important as further management will differ. Blood cultures and urgent endoscopic retrograde cholangiopancreatography (ERCP) are warranted in the extrahepatic group while, in the intrahepatic group, computed tomography (CT) of the liver, magnetic resonance cholangiopancreatography (MRCP), or ERCP and biopsy may be indicated. In both groups, serum biochemistry will show raised conjugated bilirubin, gamma glutamyl transpeptidase (GGT) and a more than three-fold rise in ALP. Peripheral blood smear may show 'target cells' due to deposition of cholesterol in red cells.
- **Therapy**:
  - Untreated patients may die within a very short time span. Therefore, initial resuscitation and appropriate antibiotic therapy (providing cover for Gram-negative organisms) are vital. The choice and degree of invasive therapy (i.e. surgical or medical management) relies heavily on the underlying cause.
  - ERCP-guided stent insertion is the treatment of choice for obstruction due to strictures or stenosis, although this carries the risk of causing pancreatitis and a systemic inflammatory response. ERCP/MRCP in an unwell patient may be challenging and the benefits must be weighed against the inherent risks of transfer to a remote site. Patients can destabilize during or just after transfer and help may not be immediately available. Equipment compatibility, limited resources during transfer and lack of familiarity are commonly encountered issues.
  - Appropriate antibiotic prophylaxis (presumed sepsis of biliary origin) and vitamin K supplementation may be necessary in coagulopathic patients prior to invasive procedures. Patients requiring multiple CT scans are at risk of contrast-induced nephropathy (CIN), which can worsen the clinical picture and outcome. The ideal preventive agent still remains elusive. The role of NAC in preventing CIN and improving outcomes has yet to be conclusively shown [13].
- **Surgery** in the form of open or laparoscopic cholecystectomy, radiological decompression (percutaneous transhepatic cholangiography) or drainage under CT guidance may be necessary in selected cases. Occasionally, in cases of neoplastic obstruction, biliary diversion with a Roux loop or bypass plus curative resection is the intervention of choice for the acutely ill jaundiced patient. Conclusive evidence of outcome benefit is still lacking to support the role of preoperative biliary drainage (for distal obstruction), the risk of wound infection and intra-abdominal sepsis due to bile leak may be increased [14].
- **Pitfalls**: failure to recognize pregnancy (where the cause of the jaundice may be intrahepatic cholestasis of pregnancy) can place both fetus and mother at risk. Furthermore, delay in identifying the cause for the cholestatic jaundice significantly increases morbidity and mortality. This is especially true for ascending cholangitis where prompt therapy with antibiotics could be life-saving. A small proportion may require biliary drainage [12].

Novel therapies

Refractory itching can be a debilitating symptom for a jaundiced ICU patient. This may be due to accumulation of various endogenous substances such as bile acids and lysophosphatidic acid. There is increasing interest in liver support systems for the treatment of severe pruritus [15]. This is mainly aimed at symptom control, but sometimes can be used as an alternative or 'bridge' therapy for patients awaiting liver transplantation as definitive therapy. These devices will be dealt with in more detail elsewhere [16,17]. Extracorporeal liver assist devices (ELADs) are chiefly used to take over two of the main functions of the liver: elimination of albumin-bound endogenous and exogenous toxins or drugs. These can be classified into **bio-artificial devices** (cell-based models) and **non-bio-artificial devices** (non-cell-based models using albumin dialysis). All devices have varying short-term efficacy and inherent shortcomings with limited outcome benefit.

The role of such advanced and expensive techniques has to be tailored to the individual jaundiced ICU patient.

Novel anti-endotoxin peptides (P6 and C1) have shown some promise in treating endotoxaemia related to obstructive jaundice in animal models [18]. Kupffer-cell blockade (using gadolinium chloride) and reducing thromoboxane (TX) levels (TX synthase inhibitors, cyclo-oxygenase inhibitors and TX-receptor antagonists) are other avenues being explored by researchers in cholestatic animal models [19,20].

Despite the high prevalence of jaundice in ICU patients, there is still a lack of robust randomized studies and evidence base for management strategies that have been clearly shown to improve outcomes. Clearly, there is scope for further research that can hopefully enable a halt in the progression of, and mortality from, liver injury.

Conclusion

In critically-ill patients, liver dysfunction significantly affects hospital length of stay and overall outcome. Regardless of the cause, the final common pathway of liver failure is not only difficult to manage, but carries a high mortality. Primary prevention of hepatic injury may not always be possible, but management principles should aim to reduce secondary insults.

Early categorization into the pre-, intra-, and post-hepatic pathophysiological groups will help in channelling therapy accordingly. For example, gallstone disease is the commonest cause of post-hepatic disease, but can have fatal complications if left untreated. Initial resuscitation and adherence to sepsis care bundles improve outcomes in acutely ill jaundiced patients. Prompt referral to appropriate medical, surgical, and radiology teams are also important measures that can positively change the course of the illness.

PART 6.8

Acute hepatic failure

CHAPTER 194

Pathophysiology and causes of acute hepatic failure

Sameer Patel and Julia Wendon

Key points

- Acute liver failure (ALF) is a rare, life-threatening clinical syndrome occurring in a person with no prior history of liver disease.
- Several classifications exist incorporating time to encephalopathy from the onset of jaundice. O'Grady's classification is the most widely used.
- Viral hepatitis is the most common cause of ALF worldwide, with drug-induced liver failure the most common in the developed world.
- ALF is a multi-system disorder resulting in encephalopathy, coagulopathy, systemic inflammatory response syndrome, and multi-organ failure.
- Patients can be prothrombotic or have balanced coagulation disorders.

Introduction

Acute liver failure (ALF) is a rare, life-threatening, and unpredictable clinical syndrome consequent to a sudden and severe hepatic injury in a person with no prior history of liver disease, with subsequent loss of hepatic metabolic and immunologic function. Approximately 1–8 cases per million population occur per year in the developed world. This is likely to be much higher in developing countries where infective causes of ALF are more prevalent. Despite modern medical advances, mortality can still exceed 50%, notwithstanding the significant healthcare burden ALF represents.

ALF is characterized by hepatic encephalopathy and coagulopathy, occurring within days or weeks of symptom appearance, and is frequently associated with the development of progressive multi-organ dysfunction requiring ICU admission. The syndrome can be divided into hyperacute, acute, or subacute based on the development of encephalopathy from the time of onset of jaundice [1], or into fulminant and subfulminant categories [2]. O'Grady's description remains the most commonly used (Table 194.1).

Aetiology

Numerous causes of ALF exist (Table 194.2) and these vary in their course, severity, and outcome. Some patients, despite rigorous investigation, have no obvious precipitant and are classified as indeterminate or seronegative [4].

Viral infections

Acute viral infections are the predominant cause of ALF worldwide, principally affecting the developing world [5]. They constitute 40–70% of cases, with hepatitis A and E viruses (HAV and HEV) accounting for the majority. HAV and HEV are both transmitted via the faeco-oral route, and are endemic in the developing world with HEV the leading cause of ALF in the Indian and Southeast Asian subcontinents, China, and Africa. HAV, on the other hand, has become less prevalent following the introduction of vaccination worldwide. Infection with either HAV or HEV rarely leads to ALF, but typically follows a hyperacute or acute clinical course [5]. Less than 1% of HAV infection results in ALF. Pregnant women are susceptible to hepatitis E infection, especially in the third trimester [6].

Hepatitis B (HBV) is transmitted by exposure to contaminated blood or other bodily fluids. It runs an acute presentation typically resulting in viral clearance and immunity. HBV-induced ALF, presenting as seroconversion from chronic or inactive states, has a higher risk of developing liver failure with worse outcomes. As a preventable cause of ALF, patients should be screened for HBV carriage before institution of chemotherapy or high-dose steroids, as this may result in HBV-related ALF. If testing positive, patients should be treated with antivirals prior to instituting immunosuppressive or immunomodulatory therapy [7].

Other rare viral causes are shown in Table 194.2. These tend to be more prevalent in immunocompromised patients. Acute hepatitis C (HCV) is a very rare cause of ALF, more typically causing a chronic infection. Hepatitis D (HDV) is associated with superinfection in HBV carriers.

Drug-induced causes

Drug-induced ALF is the leading cause in the developed world and the second leading cause worldwide [5]. Drug-induced liver injury (DILI) may be idiosyncratic or dose-related, and may be attributable to the parent drug compound or its metabolites. Only rarely does this progress to liver failure. Paracetamol (acetaminophen) taken in excess is the most common culprit, either as deliberate self-harm or unintentionally, and either at a single time-point or over several days. It presents in the hyperacute form, often rapidly progressing to multi-organ failure. Toxicity is dose-dependent, and secondary to depletion of glutathione stores and accumulation of the toxic metabolite N-acetyl-P-benzoquinone-imine (NAPQI). Risk factors include extremes of age, regular alcohol consumption, concurrent administration of cytochrome p450 enzyme-inducing drugs

Table 194.1 Classifications of liver failure and causes

Classification	Time of onset jaundice to encephalopathy	Causes
O'Grady [1]		
Hyperacute	0–1 weeks	Paracetamol, ischaemia, recreational drugs, toxins (amanita)
Acute	1–4 weeks	Hepatitis B, A, and E
Subacute	4–26 weeks	Non-paracetamol drug-induced liver injury, seronegative hepatitis
Bernuau [2]		
Fulminant	<2 weeks	Viral hepatitis, paracetamol, toxins
Subfulminant	>2 weeks to several months	Viral infections, idiosyncratic drug reactions
Fujiwara [3]		
Acute	<10 days	Hepatitis A, B
Subacute	11 days–8 weeks	Asymptomatic hepatitis B carriers
Late onset hepatic failure (LOHF)	>8 weeks	Autoimmune hepatitis, seronegative

Encephalopathy should be Grade II or above, and PT ≤40% (i.e. prolonged) or INR ≥1.5.

Fujiwara Classification: Reproduced from Springer and *Journal of Gastroenterology*, **37**(Suppl. 13), 2002, pp. 74–7, 'Indications and criteria for liver transplantation for fulminant hepatic failure', Fujiwara K and Mochida S, with kind permission from Springer Science and Business Media.

(e.g. anticonvulsants), malnutrition, and staggered ingestion, often resulting in late presentation. Antimicrobial agents are a major class of drug associated with liver injury and failure. All classes of antibiotics have been implicated. Other recognized drug causes of ALF are listed in Table 194.2. Genetic polymorphisms are postulated as potential mechanisms for injury for many of these drugs.

Pregnancy-induced

Pregnancy-associated liver failure can be divided into three groups, which are widely considered to be part of one clinical and pathological spectrum: acute fatty liver of pregnancy (AFLP), HELLP (haemolysis, elevated liver enzymes, low platelets) syndrome and pre-eclampsia/eclampsia [8]. AFLP usually occurs in the third trimester and is characterized by sudden onset jaundice, altered mentation, hypoglycaemia, elevated urate, and elevated transaminases. HELLP syndrome is characterized by the features inherent in the mnemonic. Pre-eclampsia is characterized by gestational hypertension, proteinuria, right upper quadrant or epigastric pain, and seizures in eclampsia. It occurs in 6–8% of pregnancies and is a leading cause of maternal death. Pre-eclampsia may be

Table 194.2 Aetiology of ALF

Classification	Causes
Viral	Hepatitis A,B,D,E, EBV, CMV, HSV-1 and II, VZV, Parvovirus B19, adenovirus, viral haemorrhagic fevers
Drug-induced	◆ **Antibiotics**: co-amoxiclav, erythromycin, septrin, nitrofurantoin, flucloxacillin ◆ **Antifungals**: fluconazole, itraconazole ◆ **Antituberculous**: isoniazid, rifampicin, pyrazinamide ◆ **Antivirals**: nelfinavir, nevirapine, abacavir, efavirenz ◆ **Chemotherapy**: thalidomide ◆ **Anticonvulants**: phenytoin, valproate, carbamazepine ◆ **Analgesics**: paracetamol, NSAIDs ◆ **Other**: total parenteral nutrition, statins, halothane, oral hypoglycaemics, β-interferon, herbal remedies, cocaine, MDMA (ecstasy), propylthiouracil, antipsychotics
Pregnancy-induced	AFLP, HELLP, pre-eclampsia, and eclampsia
Toxins	Amanita phalloides, industrial solvents, phosphorus, carbon tetrachloride, *Bacillus cereus*
Vascular	Budd–Chiari syndrome, ischaemic hepatitis, thromboembolism
Infiltrative	Lymphoma, carcinoma, metastases, haemophagocytic syndromes
Miscellaneous	Seronegative hepatitis, heatstroke, trauma, Acute Wilson's disease, AIH

associated with spontaneous liver rupture, presenting with pain and significant transaminitis. The subcapsular collection may progress, resulting in hepatic ischaemia and/or an obstructed outflow to the hepatic veins. Pregnancy-related disease is associated with good clinical outcomes. In all types, prompt delivery of the fetus is usually enough to reverse the process. However, liver transplantation may be necessary in some cases [9]. Consideration should always be given to microvascular thrombosis, and hepatic vein occlusion or thrombosis.

Miscellaneous

Autoimmune hepatitis (AIH), typically a chronic disease, can present acutely in a small proportion of cases, although rarely as an ALF. Ischaemia following severe hypovolaemia, sepsis, or low cardiac output states, often in association with right-sided cardiac dysfunction, presents as hypoxic or ischaemic hepatitis. Hepatic vein outflow obstruction results in acute Budd–Chiari syndrome, often associated with prothrombotic disease, while small vessel veno-occlusive disease may complicate chemotherapy. Malignant infiltration and acute presentations of Wilson's disease are other causes; these patients often have splenomegaly unlike other presentations of ALF.

Pathophysiology

Despite the numerous aetiologies of ALF, common to all presentations is the unpredictable clinical course. Disease progression can often be rapid, frequently resulting in multisystem organ failure making treatment extremely challenging. Presenting symptoms are often non-specific, and include malaise, anorexia, abdominal pain, and jaundice.

Encephalopathy

Encephalopathy is an essential component for the diagnosis of ALF. Time of onset defines the subtype and, with the aetiology, will help determine prognosis. It is a clinical spectrum graded 1–4 on the Modified Parsons-Smith Scale (Table 194.3) ranging from mild confusion to coma, with associated complications of cerebral oedema and intracranial hypertension in the higher grades. The aetiology is poorly understood. Various theories postulated include increased brain uptake of ammonia, γ-aminobutyric acid (GABA) and other endogenous factors, neurotransmitters, and hormones. Ammonia accumulation results in an associated increase in glutamine, with loss of cerebral function and autoregulation. Being osmotically active, accumulation results in astrocyte swelling and cerebral oedema.

Table 194.3 Modified Parsons-Smith Scale for hepatic encephalopathy

Score	Clinical features
I	Mild confusion, poor concentration, slurred speech, mild tremor, ataxia
II	Disorientation, lethargy, tremor
III	Drowsy, but rousable, significant confusion, incoherent
IV	Coma (GCS < 8), may exhibit decerebrate posturing

Reprinted from *The Lancet*, **270**(7001), Parsons-Smith BG et al., 'The electroencephalograph in liver disease', pp. 867–71, copyright 1957, with permission from Elsevier.

Arterial ammonia levels >150 μmol/L were associated with cerebral death in a cohort of ALF patients in grade III/IV coma [10]; levels >120 μmol/L were associated with poor prognosis in India while, more recently, levels >200 μmol/L were associated with worse outcome [11]. Importantly, with regard to prognosis, is the delta change in arterial ammonia level. This appears to be significant for the development of cerebral oedema. Those with a fall show no increase in intracranial pressure.

Coagulopathy

Coagulopathy (International Normalized Ratio, INR >1.5) also forms part of the definition for ALF. The degree of coagulopathy can be highly variable, and is determined by the extent to which clotting factor synthesis in the liver is depressed, plus the excessive consumption of platelets and prothrombotic factors. Factors II, V, VII, IX, and X are synthesized in the liver, and their loss or reduced production results in a prolonged prothrombin time (PT) or INR. Platelet consumption and low fibrinogen levels are observed secondary to increased fibrinolysis as part of the disseminated intravascular coagulation (DIC) syndrome. Despite significant coagulopathy, spontaneous haemorrhage is rare unless platelets fall below 20,000/mL. Even in the context of highly abnormal INR levels, patients can be prothrombotic or have balanced coagulation disorders [12]. To this end, routine correction of coagulopathy with fresh frozen plasma (FFP) is not advised unless the patient is actively bleeding or due to undergo invasive procedures with a high risk of bleeding. More importantly, however, correction with FFP masks the trajectory of liver failure, as the INR (or prothrombin time) forms one of the criteria required to determine prognosis, and the need for transplantation. Vitamin K deficiency, however, increases the likelihood and severity of coagulopathy, and correction is advocated.

Systemic inflammatory response syndrome (SIRS)/sepsis

Acute liver failure and hepatocellular injury causes a surge in cytokine release. This is associated with circulation of endotoxins and cytokines that are normally cleared by the liver, resulting in a SIRS and, subsequently, multisystem organ dysfunction. Associated infection and sepsis are frequent phenomena. Patients tend to be immunocompromised secondary to dysfunction of their reticuloendothelial and innate immune systems. The incidence of positive blood cultures in a recent study was 30% [13]. An inflammatory phenotype is associated with a poor prognosis irrespective of sepsis [14], while the severity of SIRS is associated with progression of encephalopathy and mortality [13]. A low threshold for sending septic screens is recommended whenever infection is suspected. Hygiene and prevention of nosocomial infection is essential in this population.

Cardiorespiratory

Significant hemodynamic changes are common in ALF patients. They characteristically develop a low systemic vascular resistance (SVR) with elevated cardiac output resulting in functional hypovolaemia often compounded by decreased fluid intake. Adrenal dysfunction is also thought to play a role in refractory hypotension [15], warranting consideration of hydrocortisone therapy when hypotension persists despite volume repletion. However, no survival benefit has been demonstrated with steroid therapy.

Respiratory embarrassment is usually due to atelectasis, pleural effusions, intrapulmonary shunts with resultant ventilation–perfusion (V/Q) mismatch and, rarely, development of hepatopulmonary syndrome, the latter having been described in ischaemic hepatitis. ARDS can ensue, contributing to or exacerbating any respiratory compromise. Raised intra-abdominal pressures can contribute to respiratory, cardiovascular, and renal compromise, and should be monitored.

Renal

Renal failure is an independent risk factor for mortality in intensive care [16]. In ALF its causes are multifactorial. It can be related to the underlying cause of ALF, as occurs in direct paracetamol (acetaminophen)-related renal toxicity, or due to the pathophysiological processes associated with ALF. Hypovolaemia and hypotension reduce renal perfusion pressure leading to renal injury. Hepatorenal syndrome (HRS) is diagnosed when no causal factors are identified for the development of acute kidney injury (AKI), i.e. it is a diagnosis of exclusion. It is thought to be a functional renal failure associated with intrarenal vasoconstriction, and is rare in ALF as compared with cirrhosis.

Metabolic

Homeostatic mechanisms are frequently deranged in ALF resulting in metabolic abnormalities ranging from severe hypoglycaemia to metabolic acidosis or alkalosis. Impaired gluconeogenesis, glycogen store depletion, insulin resistance (hepatic and peripheral), and poor oral intake are likely mechanisms of hypoglycaemia. A recent study demonstrated an increase in morbidity and mortality associated with hypoglycaemia as a result of tight glycaemic control [17]. If extrapolated to the ALF population, it is evident that close surveillance of blood sugar levels and appropriate correction is mandatory. Metabolic derangement can arise from lactic acidosis, (tissue hypoperfusion/decreased tissue oxygen delivery, or decreased hepatic metabolism of lactate), and secondary to renal failure and uraemia. Other metabolic abnormalities include hyponatraemia, (potentiates encephalopathy), hypokalaemia, and hypophosphataemia (requiring treatment and representing an improved outcome) [18].

CHAPTER 195

Diagnosis and assessment of acute hepatic failure in the critically ill

Sameer Patel and Julia Wendon

Key points

- A thorough history and examination to determine the aetiology of ALF is essential for initiating appropriate and timely interventions.
- Clinical assessment forms the basis of risk stratification for identifying those patients who can be managed locally from those who need referral to tertiary specialist centres.
- Although the International Normalized Ratio (INR) is prolonged, more extensive assessment of coagulation shows a balanced loss of both pro- and anti-coagulant factors, explaining the low risk of bleeding.
- Prognostication is an essential part of assessment as accurate prediction of outcome is fundamental for the judicious application of donor liver organs, a resource-limited commodity.
- The King's College Hospital criteria are the best known, most widely applied and accepted prognostic tool, incorporating both aetiology and clinical indices.

Introduction

Implementation of correct and timely management is essential in cases of acute hepatic failure. A high index of clinical suspicion derived from an exhaustive history and examination is crucial in targeting investigations and initiating management, sometimes before results are available. Clinical assessment forms the basis of risk stratification, allowing identification of those patients who can continue to be managed locally from those best served in a specialist liver centre, which should have facilities for transplantation. Patient presentation may be hyperacute, acute, or subacute, the former displaying a greater degree of organ failure, but a better chance of spontaneous recovery without the need for liver transplantation. Investigations should encompass the variety of potential causes (Table 195.1), albeit guided by clinical features and presenting history.

History

An accurate history can provide vital clues as to the underlying aetiology. History should focus on the presenting problem, time of onset, and speed of deterioration. Time of onset of jaundice, reversal of sleep cycle and any changes in personality, concentration, or memory are all features inherent to the diagnosis of ALF. Establishing whether the features are consistent with hyperacute, acute, or subacute ALF may then guide subsequent history towards known precipitants and, more importantly, prognostication. A thorough drug history should ascertain current prescribed medication, in particular any new prescriptions in the last few months. Equally important are non-prescribed or over-the-counter medications, such as Chinese or herbal remedies, as these have also been implicated in the pathogenesis of drug-induced ALF. Non-intentional or deliberate drug overdose should be sought in the history. Where deliberate self-harm is considered, a more detailed psychiatric history is necessary. A history of recreational drug use/abuse, in particular ecstasy and cocaine, may provide other potential causes, while a history of foraging mushrooms might suggest amanita phalloides. A travel history may reveal potential hepatitis A (HAV) or hepatitis E (HEV) infection, especially if there has been recent travel to endemic areas, or even exposure to more rare causes of ALF, such as the viral haemorrhagic fevers (e.g. parts of central Africa). Risk factors for potential exposure to HBV should be elicited—intravenous drug use, sexual history, and use of potentially contaminated blood products from abroad. Patients with a history of sepsis, hypovolaemia or hypotension, or the presence of pre-existing cardiorespiratory disease, might suggest an ischaemic hepatopathy, whereas a history of weight loss, night sweats, and fevers may suggest an infiltrative process such as lymphoma. Unfortunately, in a number of cases eliciting a history is impossible as patients may present confused or encephalopathic. In such circumstances a collateral history from relatives, friends, or the patient's family doctor should be obtained.

Examination

Examination should initially focus on a rapid assessment of airway, breathing, circulation and disability (ABCD) with any necessary resuscitation before searching for signs leading to more specific differential diagnoses. Airway compromise is a frequent occurrence in reduced conscious levels, as commonly seen in patients with grade III or IV hepatic encephalopathy (HE). Progression of HE can be rapid, especially in hyperacute presentations. Prompt referral to intensive

Table 195.1 Investigations for ALF

Aetiology	Investigation
General	Full blood count
	Urea & electrolytes
	Liver function tests (AST/ALT/ALP/bilirubin/albumin/GGT)
	Clotting profile
	Glucose
	Arterial blood gas
	Arterial lactate
	Arterial ammonia*
	Liver USS ± CT abdomen (for liver volume/ascites/blood supply/portal hypertension/splenomegaly)
	Liver biopsy
Viral screen	
HAV	Anti-HAV IgM Antibody (Ab)
HBV	HBsAg (may be absent at presentation), anti-HBc IgM, HBeAg, hepatitis B DNA
HDV	Delta Ab
HEV	Anti-HEV IgM Ab
Others	PCR HSV, EBV, CMV, adenovirus, viral haemorrhagic fevers, anti VZV IgM, VZV DNA, Parvovirus B19 DNA
Overdose or toxins	Paracetamol level
	Salicylate level
	Toxicology screen (BDZs/TCAs/ecstasy/cocaine)
Autoimmune	ANA, anti-smooth muscle Ab, anti-liver/kidney/microsome Ab
	Immunoglobulin profile
Pregnancy-related	
HELLP	**Haemolysis:** raised LDH/reticulocyte count/Coombs' test positive, Elevated liver enzymes, low platelets, DIC—low fibrinogen
Pre-eclampsia	Elevated urate, proteinuria, hypertension, low platelets, DIC, reduced GFR, possible liver rupture
AFLP	Elevated urate, bilirubin, prolonged PT, neutrophilia, low glucose
Wilson's disease	Serum ceruloplasmin, urinary copper, Kayser–Fleischer rings: cirrhotic liver, splenomegaly, low alkaline phosphatase, Coombs-negative haemolysis
Malignancy	CT scan
	Leukopenia, pancytopenia
	Bone marrow biopsy
	Raised LDH (lymphoma)
Other	
Heatstroke	CK, myoglobinuria
Hypoxic Hepatitis	**ECG:** arrhythmia, Echocardiogram (low cardiac output syndrome/congestive cardiac failure)

*If patient has grade III or IV encephalopathy, or suspected raised intracranial pressure.

AST, aspartate aminotransaminase; ALT, alanine aminotransferase; ALP, alkaline phosphatase; GGT, gamma-glutamyltransferase; USS, ultrasound scan; HBsAg, hepatitis B surface antigen; HBeAb, hepatitis B envelope antibody; anti-HBc, hepatitis B core antigen antibody; IgM, immunoglobulin M; HBeAg, hepatitis B envelope antigen; HSV, herpes simplex virus; EBV, Epstein–Barr virus; CMV, cytomegalovirus; VZV, varicella zoster virus; BDZ, benzodiazepine; TCA, tricyclic antidepressant; ANA, antinuclear antibody; DIC, disseminated intravascular coagulation; GFR, glomerular filtration rate; CK, creatine kinase.

care is critical to secure the non-protected airway with intubation and mechanical ventilation [1–4]. Assessment of breathing should focus on eliciting signs consistent with respiratory embarrassment/failure secondary to atelectasis, pneumonia, ventilation–perfusion (V/Q) mismatch, shunting, or diaphragmatic splinting from abdominal distension. Tachypnoea may also reflect compensatory mechanisms secondary to metabolic acidosis, as occurs in Kussmaul breathing, and can also be seen in patients with significantly elevated ammonia as HE progresses. With regards to the circulation, examination should look for evidence of intravascular volume depletion. Such patients are normally hyperdynamic with warm bounding peripheries, but may present with hypotension that is volume-responsive. Hypotension refractory to fluid resuscitation warrants invasive haemodynamic monitoring providing dynamic volume status and cardiac output monitoring [3]. HE may present as overt and rapid falls in the Glasgow Coma Score (GCS), which should always be considered if such patients require transfer. Confusion, reversal of sleep cycle, agitation, and aggression are all signs of HE. Progression

to grade III or IV encephalopathy (GCS <7–9) can be associated with development of clinically significant cerebral oedema and, in rare instances, intracranial hypertension [5]. Abnormal posturing (decorticate or decerebrate) and fixed dilated pupils are late signs of cerebral oedema. Blood glucose measurement forms a vital part of the disability assessment. Hypoglycaemia, in particular, has been found to increase morbidity and mortality. Hyponatraemia is also common, usually due to vomiting and sodium losses, and should be treated appropriately, since it may precipitate and/or worsen HE.

Clinical examination may reveal either hepatomegaly or evidence of a shrinking liver. Lymphadenopathy occurs in lymphoma and malignancy. Ascites is more likely to occur in subacute ALF, which has a more gradual onset than hyperacute forms. A liver flap (asterixis), clonus, hyperreflexia, and positive Babinski's sign are sensitive markers of encephalopathy. Stigmata of chronic liver disease should typically not be present, although can be seen in subacute cases. Where Wilson's disease is suspected, a full neurological examination is warranted. Ataxia, cogwheel rigidity, bradykinesia (Parkinsonian symptoms), tremor and slurred speech are not uncommon features. Kayser–Fleischer rings may be seen on slit-lamp ophthalmic examination, and blood tests characteristically reveal a low alkaline phosphatase and haemolysis. The diagnosis of hypoxic hepatitis should always be considered and echocardiography performed. Subconjunctival haemorrhages are a typical and unique feature of hyperacute aetiologies and severe coagulopathy (commonly due to acetaminophen/paracetamol), and should be suspected in anyone presenting with ALF who has this sign.

Investigations

Investigations for determining the cause of ALF are manifold (Table 195.1) and should be used in conjunction with the history and examination. Although the International Normalized Ratio (INR) is prolonged, more extensive assessment of coagulation shows a balanced loss of both pro- and anti-coagulant factors, explaining the low risk of bleeding in these patients [6]. Paracetamol and salicylate levels should be sent, and treatment initiated while awaiting results if there is a high index of suspicion. A rare and transient cause of profound metabolic acidosis may result from transitory mitochondrial standstill in patients with very high levels of paracetamol without associated liver injury. In severe cases arterial ammonia levels are predictive of outcome and useful for risk stratification for development of intracranial hypertension [7,8]. High serum arterial ammonia concentrations (>150–200 μmol/L) increase the risk of developing cerebral oedema and raised intracranial pressure [5,8] if persistent and associated with grade III/IV coma. Liver imaging with ultrasound is mandatory to assess liver architecture, volume, and integrity of blood supply and drainage to exclude Budd–Chiari syndrome. Transjugular liver biopsy can be helpful in some cases where decisions regarding transplantation may depend upon aetiological features. Infiltrative, malignant or cirrhotic processes exclude the use of emergent transplantation. However, in most cases biopsy does not establish a cause [9], confirming only that necrosis is present.

Functional assessment

As well as the standard investigations outlined previously, specialist centres are able to perform more dynamic assessments of liver function (Box 195.1). These assess the metabolic function and

Box 195.1 Dynamic liver function tests

Test

ICG clearance

- Infrared absorbing, iodine containing dye.
- Inject 0.25–0.5 mg/kg iv.
- Bedside transcutaneous test.
- Measure plasma disappearance rate (PDR):
  - Normal PDR 18–25%.
  - PDR<16% poor prognostic sign.
  - PDR<8% extremely high mortality.

MEG-X

- Hepatic conversion of lidocaine to MEG-X by CYP450.
- Inject 1mg/kg iv.
- Laboratory test.
- Measure MEG-X pre and 15 minutes post-injection:
  - >50 ng/mL normal.
  - <25 ng/mL poor outcome.
  - <10 ng/mL very poor prognosis.

Bromosulfophthalein

- Inject 5 mg/kg iv.
- Measure serum levels at 30 and 45 minutes.
- At 30 minutes <10% normal, at 45 minutes <5% normal.
- Laboratory test only—largely abandoned now.

Amino acid clearance

- Tests liver's ability to clear amino acids.
- Patients fasted overnight.
- Amino acid infusion over 18 hours.
- Amino acid concentration and plasma clearance rate calculated.
- Largely obsolete test.

Galactose elimination capacity (GEC)

- Plot galactose serum concentrations over time.
- GEC calculated using decay of concentration curve (mg/kg/min).
- GEC reduced in liver injury.

Aminopyrine test

- Oral intake of radioactively-labelled aminopyrine.
- Exhaled $^{14}CO_2$ measured—marker of liver function.
- Established in chronic liver disease.

Caffeine test

- Caffeine 300 mg po.
- Metabolite/caffeine ratio measured at 4, 8, and 12 hours.
- Ratio lower in disease.
- Limited use in the critically ill.

Table 195.2 Comparison of King's College Hospital and Clichy Poor Prognostic Criteria for ALF*

Criteria	Parameters
King's College Hospital	
Paracetamol	pH < 7.30 **or**
Non-paracetamol	INR > 6.5/PT > 100s **and** Serum creatinine >300 µmol/L **and** Grade III or IV encephalopathy INR > 6.5/PT > 100s **or** Any three of the following: ◆ Age <10 years or > 40 years ◆ Unfavourable aetiology (seronegative hepatitis, non-paracetamol drug reaction) ◆ Serum bilirubin >300µmol/L ◆ INR > 3.5/PT > 50s ◆ Duration of jaundice before onset of encephalopathy > 7 days
Clichy	Grade III or IV encephalopathy **and** Age < 20 years with factor V level <20% **or** Age > 30 years with factor V levels <30%

*Fulfilment of criteria indicates poor prognosis with high risk of mortality, necessitating referral for consideration of urgent liver transplantation.

King's College Hospital Criteria: this information was published in *Gastroenterology*, **97**(2), O'Grady J et al., 'Early indicators of prognosis in fulminant hepatic failure', pp. 439–445, copyright Elsevier and AGA Institute 1989. Clichy Criteria: reproduced from Bernuau J et al., 'Criteria for emergency liver transplantation in patients with acute viral hepatitis and factor V below 50% of normal: a prospective study', *Hepatology*, **14**(S4), pp. S48–290, with permission from John Wiley and Sons. blood flow of the liver, and its ability to eliminate substrates over a fixed period of time. They are especially useful in critically ill patients with multi-organ failure, and are additive to the traditional static tests of liver function [10].

Indocyanine green (ICG) clearance measures the plasma disappearance rate (PDR) of ICG per unit time. It is almost exclusively eliminated in bile without undergoing enterohepatic recirculation. The plasma disappearance rate reflects hepatic function and liver perfusion. Non-invasive transcutaneous systems have been developed [11] (e.g. LiMON) for point of care utilization. Low clearance has been associated with high mortality, and ICG can also be used to predict complications following hepatectomy. In sepsis, ICG clearance can differentiate between survivors and non-survivors after initial resuscitation, with a low PDR being an independent risk factor for mortality [12]. Other potential functional assays are presented in Box 195.1.

Prognostication

Prognostication forms a critical part of assessment. It helps stratify patients who can remain in their local institution from those who would benefit from transfer to a specialist centre for a potentially life-saving transplantation. Accurate prediction of outcome is also essential for judicious application of a resource-limited commodity. Several risk stratification and predictive tools can differentiate those patients likely to recover, those unlikely to survive despite maximal intervention, and those who would potentially benefit from transplantation. Equally important is the prevention of inappropriate transplantation, subjecting patients to unnecessary surgery and a lifetime of immunosuppression with the potential complications that can ensue.

Table 195.3 Referral to specialist unit after paracetamol overdose

Day 2	Day 3	Day 4
Arterial pH < 7.30§. INR > 3 or PT > 50 seconds. Oliguria. Creatinine > 200 µmol/L. Hypoglycaemia	Arterial pH < 7.30§. INR > 4.5 or PT > 75 seconds. Oliguria. Creatinine > 200 µmol/L. Encephalopathy. Severe thrombocytopenia.	INR > 6.0 or PT > 100 seconds. Progressive rise in PT to any level. Oliguria. Creatinine > 300 µmol/L. Encephalopathy. Severe thrombocytopenia.

§After appropriate fluid resuscitation.

The King's College Hospital criteria [13] are the best known, and most widely applied and accepted prognostic tool (Table 195.2). This tool incorporates both aetiology and clinical indices into the scoring system. Fulfilment of the criteria is a strong predictor of mortality without transplantation, but lack of fulfilment does not guarantee survival. Additional criteria have been described to expedite referral to a specialist centre for both paracetamol and non-paracetamol induced ALF (Tables 195.3 and 195.4) [14].

The model for end-stage liver disease (MELD) [15] incorporates bilirubin, creatinine, and the INR into a mathematical formula. However, several variables considered to be of prognostic value are not incorporated into the score, namely age, aetiology, encephalopathy, and various other indices listed. The use of MELD is therefore not widely accepted.

Lactate levels have a strong correlation with survival in ALF due to paracetamol overdose [16]. Impaired metabolism and clearance, together with increased production are thought to correlate with hepatic injury. Its addition to the King's College Hospital Criteria has improved the score's sensitivity. Hyperphosphataemia has also been reported to be an accurate early marker of poor

Table 195.4 Referral to specialist unit for non-paracetamol aetiologies

Hyperacute	Acute	Subacute
INR > 2.0 or PT > 30 seconds. Oliguria/renal failure. Hypoglycaemia. Encephalopathy. Hyperpyrexia	INR > 2.0 or PT > 30 seconds. Oliguria/renal failure. Hypoglycaemia. Encephalopathy.	INR > 1.5 or PT > 20 seconds. Oliguria/renal failure. Hypoglycaemia. Encephalopathy. Serum Na < 130 mmol/L. Shrinking liver volume.

prognosis in paracetamol-related injury [17]. Other prognostic markers that have been used include the bilirubin, lactate, and aetiology (BiLE) score [18], alpha-foetoprotein, factor VIII/factor V ratio, galactose elimination capacity, Gc globulin concentration and arterial ketone body ratio [4]. Unfortunately, none have been validated in large prospective trials and their validity is, therefore, questionable.

CHAPTER 196

Management of acute hepatic failure in the critically ill

Deepak Joshi and Georg Auzinger

Key points

- Acute liver failure (ALF) occurs in patients with acute hepatic necrosis resulting in hepatic encephalopathy, jaundice, and coagulopathy.
- Acute liver failure is a multisystem disorder.
- The management is initially supportive. Intravenous N-acetylcysteine is recommended for all patients.
- Brain dysfunction is common. Elective intubation is recommended for all patients who develop Grade III hepatic encephalopathy.
- Liver transplantation is an appropriate and viable treatment for ALF. Early and safe transfer to a transplant centre for transplant assessment is advised.

Introduction

Acute liver failure (ALF) is characterized by the sudden loss of hepatic function due to acute hepatocyte necrosis resulting in hepatic encephalopathy (HE), jaundice, and coagulopathy. ALF is a multisystem disorder, leading to renal failure, sepsis, cardiovascular instability, and eventually multi-organ failure (MOF). Common causes of ALF include paracetamol (acetaminophen) overdose, viral infections including hepatitis B virus (HBV), hepatitis A virus (HAV), hepatitis E virus (HEV), and idiosyncratic drug reactions. Rarer causes include MDMA toxicity, mushroom poisoning (Amanita species), Wilson's disease, Budd–Chiari syndrome, acute fatty liver of pregnancy, and metastatic cancer. In some patients, a clear aetiology cannot be defined—these cases are termed seronegative ALF.

Although ALF is rare, with an incidence in the Western World of 1–6 cases per million per year, it is associated with a high mortality. ALF can be subdivided into three groups according to the onset of jaundice to the development of encephalopathy: 'hyper-acute' (0–7 days), 'acute' (1–4 weeks) and 'sub-acute' (4–12 weeks). Although most patients develop severe coagulopathy and cerebral oedema in 'hyper-acute' liver failure, most will survive without the need for liver transplantation. In stark comparison, although the coagulopathy is less severe and the incidence of cerebral oedema markedly lower, patients with 'sub-acute' liver failure develop more severe hyperbilirubinaemia and are more likely to require transplantation as any regenerative capacity of the organ is often exhausted.

Investigations

All patients with ALF require a comprehensive liver screen to establish the underlying cause (Table 196.1), as prognosis and transplant listing criteria both depend on aetiology. Certain caveats should be taken into account when interpreting blood results, e.g. the acute phase protein, ferritin is elevated in ALF in the absence of hemochromatosis. Conversely, serum ceruloplasmin and alpha-1 antitrypsin levels are low in ALF, independent of any underlying genetic deficiency, as they are liver-synthesized.

Imaging, Doppler ultrasound or cross-sectional imaging is required in all patients. Key questions are patency of the hepatic veins, evidence of chronic liver disease (signs of portal hypertension, nodular liver), and evidence of malignancy. Findings of a small liver or, in particular, a liver that is decreasing in size over time are poor prognosticators. Liver biopsy needs to be considered on an individual basis; in most cases, data provided by biopsy will not change management, are subject to sampling error and may be too high-risk in severely coagulopathic patients. Biopsy can prove useful in patients with a 'sub-acute presentation' by providing information that may exclude chronic liver disease or an underlying malignancy. In view of the bleeding risk, a transjugular approach is strongly advised.

Management

Over the last decade, survival of ALF patients not undergoing transplantation has improved considerably. Although reasons are not entirely clear, general improvements in the level of care including timely admission to level 3 care facilities and referral to tertiary referral centres appear important. To improve outcomes further, certain key principles must be adopted. The underlying aetiology should be sought and disease-specific treatment instigated as early as possible. Extra vigilance is required to prevent infectious complications in conjunction with aggressive treatment of organ dysfunction, including early extracorporeal device therapy to maintain metabolic stability, even in the absence of established renal failure. Finally, early identification of patients that are unlikely to survive without transplantation and transfer to a transplant centre is paramount.

Specific therapies

Few are available for ALF. Nucleoside analogues should be considered for ALF secondary to acute HBV or reactivation/flare of

Table 196.1 Investigation of acute liver failure

	Investigation	Notes
Haematology	◆ Full blood count and blood film	
	◆ Haemolysis screen	◆ Perform in patients with unconjugated hyper-bilirubinaemia
	◆ INR and clotting studies	
	◆ Pro-thrombotic screen	◆ Perform in patients with Budd–Chiari syndrome or veno-occlusive disease
	◆ Bone marrow aspirate and trephine	◆ Perform in patients where lymphoma or haemophagocytosis is being considered
Biochemistry	◆ Electrolytes, urea and creatinine	
	◆ Liver biochemistry	
	◆ Arterial blood gas and lactate	
	◆ Amylase	
	◆ Toxicology screen including paracetamol and salicylate levels	
	◆ Copper studies (serum copper, ceruloplasmin, urinary copper +/– pencillamine challenge)	◆ Perform in patients where Wilson's disease is being considered
	◆ Serum urate	◆ Perform in acute fatty liver of pregnancy
Immunology	◆ Auto-antibodies	
	◆ Immunoglobulin profile	
Virology	◆ Hepatitis A IgM	
	◆ Hepatitis B (surface Ag and Ab, IgM core Ab. If positive then test HBV DNA viral load, e Ag and Ab)	
	◆ Hepatitis C Ab	◆ HCV is a rare cause of ALF in the Western World: perform in pregnant women
	◆ Hepatitis E IgM. If positive then test HEV RNA viral load	
	◆ HIV Ab	◆ HIV co-infection is not an absolute contra-indication to LT:
	◆ CMV IgM and PCR	◆ Perform in immunocompromised patients i.e. solid-organ transplant recipients
	◆ HSV IgM and DNA	◆ Perform in immunocompromised patients or pregnancy
Imaging	◆ Doppler liver ultrasound	
	Or	
	◆ Computed tomography with contrast	

Ab, antibody; Ag, antigen; CMV; cytomegalovirus; HSV, herpes simplex virus; INR, international normalized ratio.

chronic HBV following chemotherapy or immunosuppression. acetylcysteine (N-acetylcysteine, NAC) is an effective treatment for paracetamol (acetaminophen)-induced hepatotoxicity [1]. Use of NAC is associated with improvements in circulatory dysfunction and oxygen delivery. As it is readily available, cheap, and generally tolerated well, we routinely use NAC for non-paracetamol-induced ALF. Although the evidence base is less established compared with paracetamol-induced ALF, benefit in transplant-free survival was seen in a subset of patients with low-grade HE, but no overall survival benefit was found [2]. Use of NAC is also associated with a decreased incidence of cerebral oedema and improved cerebral blood flow. Lymphomatous infiltration as the cause of liver failure may respond to chemotherapy, whereas acute presentations of the Budd–Chiari syndrome can, in some selected cases, be successfully managed with shunt procedures, such as emergency TIPS or surgical portocaval shunt.

Respiratory system

Airway protection and controlled mechanical ventilation are required in patients with ALF and high-grade HE (>grade III). Although hypoxaemia is not usually the primary indication for airway support, secondary respiratory complications are common. These include acute respiratory distress syndrome (ARDS), pleural effusions, atelectasis, and reduced compliance of the respiratory system due to raised intra-abdominal pressure or chest wall oedema. Intrapulmonary shunting and the hepatopulmonary syndrome are described in ALF secondary to hypoxic hepatitis.

ARDS was previously considered a relatively common sequelum of ALF, impacting significantly on morbidity and mortality. Current management guidelines for ARDS, such as low tidal volume ventilation and fluid restriction compete against the brain-protective and fluid requirement needs of the ALF patient. ARDS-induced increases in right ventricular afterload can be further exacerbated during liver transplantation by reperfusion injury, with ensuing risks of right ventricular failure and subsequent graft loss.

Recent data suggest that acute liver injury affects only 10% of patients with ALF [3] and, more importantly, does not affect overall mortality or length-of-stay. Early recognition of the disease process, adoption of 'pulmonary-protective' ventilation strategies in the initial stages, and improved intensive care unit (ICU) management all

seem to be contributory. The anti-oxidant effects of NAC may also protect against acute liver injury development.

Cardiovascular system

ALF shares many clinical characteristics with septic shock, i.e. hypotension, low systemic vascular resistance, and increased cardiac output. Assessment of fluid status is important, as intravascular volume depletion is common. As with general ICU patients, crystalloid, and colloid solutions can be used to augment preload; however, some particular points are worth considering in relation to ALF. Hartmann's solution is generally poorly tolerated as the failing liver cannot clear the additional lactate load. The use of N-saline can lead to hyperchloraemic metabolic acidosis, adding a non-anion gap component to the frequently present anion gap, while 5% glucose lacks any volume effect and can lead to hyponatraemia and risk of worsening cerebral oedema.

Starch solutions including newer low-molecular-weight preparations with high degrees of substitution have been associated with an increased incidence of renal failure and mortality in septic shock patients [4]. Gelatin-based colloids can interfere with von Willebrand Factor (vWF) activity and have been linked with increased transfusion needs. Human albumin solutions have experienced a renaissance since the SAFE trial [5] with trends to improved outcome over crystalloid resuscitation during shock treatment. As subgroup analysis showed worse outcomes in patients with traumatic brain injury, its role in ALF, where there is a high incidence of intracranial hypertension, is unclear.

Invasive haemodynamic monitoring is recommended in all ALF patients. Central venous oxygen saturations are invariably high and, in general, a sign of inadequate oxygen extraction. Its role as a marker of preload is limited. As with other disease processes, dynamic markers of preload dependence are preferred. Pulse pressure variation (PPV) may be superior to stroke volume variation (SVV) in the assessment of fluid responsiveness, dependent on the algorithm used, as the former is less dependent upon the influence of increased pleural pressure. This is especially true if pulse contour methods for stroke volume estimation are used.

Transpulmonary thermodilution monitoring devices may offer extravascular lung water measurement, which can be helpful in the early diagnosis of increased pulmonary vascular permeability. Understandably, concerns are raised regarding the insertion of these devices in the setting of a severe coagulopathy. In our experience, bleeding complications are rare when performed by experienced physicians. Ultrasound guidance can also help avoid complications. Fresh frozen plasma (FFP) cover for the insertion of central venous or arterial lines is not recommended, although administration of platelets in case of significant thrombocytopenia is appropriate. In general, the risk of bleeding in ALF is probably overestimated, as recently shown during functional assessment with thrombo-elastography; causative factors include a concomitant decrease in both pro- as well as anticoagulant proteins [6].

For refractory hypotension, norepinephrine is the recommended first-line vasopressor. Adrenal insufficiency is common in ALF, leading to haemodynamic compromise; it occurs most often in those with the most severe liver disease [7]. A short adrenocorticotrophin test should be performed on patients requiring vasopressors. Those with a subnormal response receive 'stress doses' of hydrocortisone (200–300 mg/day) for 5 days before gradual withdrawal. As in septic shock, vasopressin has significant pressor effects in ALF. We routinely use vasopressin plus hydrocortisone in the context of increasing norepinephrine requirements. Although the use of vasopressin, or its analogue terlipressin, has been associated with worsening intracranial pressure, a more recent trial using cerebral microdialysis did show improvements in cerebral perfusion pressure and a favourable lactate:pyruvate ratio suggesting improved cerebral oxygen consumption [8,9].

Gastro-intestinal system

ALF is a hypercatabolic state associated with muscle wasting and vitamin deficiency. Hypoglycemia is common and intravenous glucose infusion is recommended until feeding is established. Moderate glucose control (targeting 6–10 mmol/L) is recommended as hyperglycaemia can contribute to poor intracranial pressure control; tight glucose control can be detrimental as the injured brain is exquisitely sensitive to hypoglycaemia. Hypophosphataemia is common in patients receiving high-volume continuous haemofiltration, but may also occur during liver regeneration due to increased hepatic ATP production. Prompt intravenous phosphate replacement is required. Enteral feeding is the preferred route, although the parenteral route is an acceptable alternative. Glutamine supplementation in parenteral feeds should be avoided due to the integral role of glutamine in the pathogenesis of ALF-induced cerebral oedema. We have abandoned early, aggressive caloric provision, and advocate against hypercaloric alimentation during the acute phase of the illness. Pancreatitis not infrequently complicates ALF, especially when paracetamol-induced—this needs to be excluded, particularly if the patient is listed for emergency transplantation.

Intra-abdominal hypertension secondary to ileus or bleeding can complicate ALF. Development of portal hypertension and ascites, more common in subacute liver failure, may also contribute.

Systemic inflammatory response syndrome and sepsis

Systemic inflammatory response syndrome (SIRS) is associated with the progression of HE and confers a poor prognosis in ALF [10]. Complement deficiency, impaired Kupffer cell function, and increases in both pro- and anti-inflammatory cytokines lead to a state of immunoparalysis, thereby increasing susceptibility to both bacterial and fungal infections [11]. It is therefore unsurprising that sepsis is the leading cause of death in ALF patients. Prophylactic antibiotics and antifungal agents are recommended. Initial choice of antibiotic should be dictated by local policy and then guided by sensitivities. Meticulous attention should be given to universal precautions for preventing nosocomial infection.

Neurological system

Disturbance of brain function is common in ALF, and normal compensatory mechanisms of cerebral auto-regulation are impaired. Evidence of HE can be very subtle; mild confusion may be the only clinical manifestation. Sedative agents are not recommended as they can mask development of HE. However, progression from grade I HE (mild confusion and disorientation) to grade IV HE (coma, GCS <8) can be rapid. Patients with ALF and high-grade HE are at risk of cerebral oedema, a common cause of death in these patients. Risk factors for development of cerebral oedema include high-grade HE (grade III or IV), hyperammonaemia (> 150 μmol/L), hyponatremia, seizure activity, and young age (<35 years).

The pathogenesis of cerebral oedema in ALF appears to be primarily cytotoxic involving astrocyte swelling. Ammonia, produced by degradation of nitrogenous compounds or by mitochondrial metabolism of glutamine, causes astrocyte swelling and dysfunction. Cerebral glutamine metabolism is also impaired, resulting in increased nitric oxide production and subsequent vasodilatation. Hyponatraemia may further exacerbate astrocyte swelling due to differences in osmolality between intracellular and extracellular compartments. A vasogenic component may exist due to disruption of tight junction proteins in endothelial cells by inflammatory mediators resulting in an increase in blood–brain barrier permeability.

Patients with grade III HE should be electively intubated and ventilated. There is no role for lactulose or non-absorbable antibacterials. Patients should be nursed at 20–30° head-up tilt to optimize cerebral perfusion pressure. The endotracheal tube should not be tied too tightly to maintain adequate jugular venous return. Clinical signs of intracranial hypertension (ICH) may be subtle, e.g. systolic hypertension, bradycardia and pupillary abnormalities. As with traumatic brain injury and ICH, one should be meticulous about avoidance of secondary insults such as uncontrolled hyperpyrexia, arterial hypotension, hypoxaemia, and hypercapnoea.

Moderate hypothermia (32–33°C) prevented ICH in a small pilot trial [12]. We generally control body temperature at 35–36°C and avoid hyperthermia. Lower temperature targets are only used in patients with difficult-to-control intracranial pressures. Adequate sedation and analgesia (propofol, fentanyl) should be administered to avoid surges in intracranial pressure. For refractory hypertension, barbiturate coma may be induced although its routine use has been abandoned due to cardiovascular and immunological side effects.

Any patient with ALF and an acute deterioration in Glasgow Coma Score should undergo a non-contrast head CT to exclude intracranial haemorrhage. CT is not a reliable modality to exclude the presence of cerebral oedema. MRI provides greater sensitivity and specificity, but is generally not practicable in this population. We routinely use transcranial Doppler ultrasonography to screen for evidence of increased vascular resistance as a surrogate marker for raised intracranial pressure. Electroencephalography is not routinely performed, but may be helpful in patients where subclinical seizure activity is suspected.

Although intracranial monitoring is controversial, we recommend its use in all patients with pupillary abnormalities, unexplained systolic hypertension, bradycardia, and grade III/IV HE who are potential transplant candidates. High-resistance flows on transcranial Doppler provide further guidance. Ammonia levels >200 μmol/L may sometimes be used as a trigger. Prior to catheter insertion, the INR should be corrected below 2.0 with fresh frozen plasma and the plalelet count augmented (>50 × 10^9/L). Cryoprecipitate should be administered if fibrinogen levels are low (<1.5). We do not routinely use factor VII concentrate. In our experience, if sited in the extra- or subdural space, catheter-related bleeding complications are rare. A catheter positioned in the jugular venous bulb may provide further, albeit indirect, data of cerebral oxygen consumption and extraction, and therefore the adequacy of cerebral oxygenation.

Medical management of ICH includes adequate sedation, maintenance of CPP >50 mmHg, routine use of hypertonic saline to achieve target serum sodium levels of 145–150 mmol/L, plus moderate temperature and glucose control. Mannitol (0.25–0.5 mg/kg bolus) can be used in patients with persistently elevated intracranial pressures as a flow- and perfusion-enhancing strategy over and above its osmotic activity. If renal function is preserved adequate volume replacement must accompany any fluid losses through osmotic diuresis. Repeated mannitol boluses are only recommended provided serum osmolarity remains <320 Osm/L. The role of inducing hypocapnoea to control intracranial pressure is poorly understood, and should only be performed in individuals with some form of direct or indirect brain oxygen monitoring in place. The same holds true for treatment with pre-capillary vasoconstrictor agents such as indomethacin that has been used with anecdotal success.

Renal system and extracorporeal support

Renal failure is commonplace in ALF. Hypovolaemia and hypotension are the commonest causes, but other aetiologies include direct drug-induced nephrotoxicity and the hepatorenal syndrome.

Initial management should concentrate primarily on adequate volume resuscitation. Renal replacement therapy is generally commenced early, before significant metabolic disarray is evident. Continuous forms of extracorporeal support are the preferred mode as they reduce episodes of hemodynamic instability. Ultrafiltration rates of 35 ml/kg/hour are commonly used. Ultra-high-volume haemofiltration (90 mL/kg/hour) should be considered in ALF patients with severe metabolic failure and haemodynamic instability who are being considered for transplantation. Increasing ultrafiltration rates may also have a beneficial effect on ammonia production and clearance, and hence are sometimes used as an adjunct treatment for intracranial hypertension. Heparin anticoagulation is rarely used in view of the significant coagulopathy accompanying most cases of ALF. No anticoagulation or the use of epoprostenol (2.5–5 ng/kg/min) is our local standard. The use and safety of citrate anticoagulation in the context of ALF is subject to ongoing trials.

Other forms of liver-specific extracorporeal device therapy has been disappointing, with no device studied over the last three decades having shown a significant outcome benefit. High volume plasmapheresis has shown a small, but significant mortality reduction in patients fulfilling transplant criteria who did not undergo emergency liver transplantation [13].

Role of liver transplantation

Potential patients should be discussed early and transferred to a transplant centre where an ongoing assessment of the disease kinetic can be made. Transplantation remains the only definitive treatment for ALF patients who fail to recover spontaneously as other therapeutic modalities are essentially supportive. Prognostic models are widely used to identify adult patients with ALF that will benefit. The King's College criteria introduced in 1989, and subsequently modified to include serum lactate, differentiate between paracetamol-induced and non-paracetamol induced ALF. Other adopted criteria include the Clichy criteria that incorporate factor V levels, and the MELD (model for end-stage liver disease) score. The MELD score may disadvantage patients with subacute liver failure due to the relative late occurrence of renal dysfunction and sometimes only mild derangement of coagulation. Although transplantation is limited by the availability of blood-type specific organs, 1-year survival rates exceed 80% and have increased considerably over the last decade.

CHAPTER 197

The effect of acute hepatic failure on drug handling in the critically ill

Andreas Kortgen and Michael Bauer

Key points

- Liver failure may lead to profound and sometimes unpredictable changes in pharmacokinetics and pharmacodynamics.
- Changes in liver blood flow, enzyme function, excretory function, and/or further remote organ dysfunction are the most likely causes of pharmacokinetic and pharmacodynamic changes.
- Decrealsed levels of albumin and other transport proteins, and impaired binding capacity results in an increased free fraction of the drug and an increased volume of distribution.
- Clinicians must carefully evaluate drug therapy in this patient group.
- Knowledge of basic principles backed up by therapeutic drug monitoring represents an important tool to govern therapy.

Introduction

Impaired hepatic function is a common event in intensive care unit (ICU) patients. It may be due to the underlying reason for admission (e.g. acetaminophen-induced liver failure), to a pre-existing co-morbidity (e.g. patients with cirrhosis undergoing major surgery), to a complication of critical illness (e.g. sepsis) or critical care (e.g. drug-induced alterations), or combinations of any of these factors. The liver is a major site of metabolism. As many drugs used in critical care are metabolized and/or excreted by the liver, hepatic dysfunction may lead to profound changes in pharmacology. Patients with liver disease have an increased incidence of adverse drug effects.

Altered enzyme function

The liver plays a key role in biotransformation of xenobiotics. Lipophilic substances are usually metabolized to water-soluble products in a two-step process:

- Phase-I metabolism comprises intramolecular modifications via oxidation, reduction, or hydrolysis. Oxidative reactions are by far the most important and usually involve enzymes of the cytochrome-P450 superfamily (CYP). More than 20 of these enzymes exist in the liver, each named by a number, a letter and a further number, identifying the family, the subfamily and the gene product, respectively. Each enzyme can metabolize multiple substrates (Table 197.1). Products of phase-I metabolism can be highly active.
- Phase-II metabolism usually involves conjugation of intermediate products of phase-I metabolism as well as other substances, e.g. with glucuronic acid, glutathione, or amino acids.

While increased water-solubility and detoxification usually result from these phase-I and phase-II reactions, formation of toxic products is also possible. For example, oxidation of acetaminophen by CYP1A2, 2E1, and 3A4 forms N-acetyl-p-benzoquinonimine (NAPQI), a hepatotoxic product responsible for acute liver failure in acetaminophen overdose. Detoxification of NAPQI relies on glutathione conjugation.

Activity of enzymes of the cytochrome-P450 superfamily can be induced or inhibited by several xenobiotics, leading to marked changes in drug levels resulting in over- or underdosing. For example, macrolides such as erythromycin, and antifungal azoles are potent inhibitors of CYP3A4 (Table 197.1). Accordingly, in patients treated with statins that are metabolized by CYP3A4 risk of rhabdomyolysis is increased when they are concomitantly treated with CYP3A4-inhibitors due to resulting higher plasma statin levels. In addition, inflammatory reactions lead to alterations in gene expression and cytochrome activity, usually resulting in a decreased capacity for biotransformation. For example, CYP1A2 activity is decreased, leading to reduced theophylline clearance. Activity of the various CYP450 enzymes may be differentially affected in inflammation, and acute or chronic liver dysfunction. Phase-II metabolism appears less affected in mild liver disease, while substantial impairments are reported in advanced liver disease.

Esterases, another group of enzymes of phase-I metabolism, hydrolyse substances containing ester, amide, or thioester bonds. They have broad and overlapping substrate specificities, can be expressed in the liver and many other tissues, and are also present in plasma. Esterases such as butyrylcholinesterase may be involved in drug metabolism and prodrug activation. When a drug such as remifentanil can be metabolized by different enzymes, impaired elimination due to illness is unlikely. However, reduced activity of esterases has been described in acute inflammation.

Table 197.1 Examples of drugs that are substrates, inhibitors or inducers of enzymes of the cytochrome-P450 superfamily

Cytochrome P450 iso-enzyme	Substrates	Inhibitors	Inducers
1A2	Theophylline	Ciprofloxacin, verapamil	Tobacco
2C9	Fluvastatin, phenytoin	Fluconazole, amiodarone	Rifampicin
2C19	Omeprazole, pantoprazole, diazepam	Omeprazole	Rifampicin
2E1	Acetaminophen, volatile anaesthetics		Ethanol
3A4/5	Midazolam, cyclosporin, tacrolimus, atorvastatin	Antifungal azoles, macrolides, grapefruit juice	Rifampicin, phenytoin

Where groups of drugs are given, not necessarily all drugs of the group must be metabolized by the given enzyme.

Altered transporter protein function and cholestasis

Transport proteins located at the sinusoidal/basolateral and canalicular membranes of hepatocytes are needed for uptake of endogenous and exogenous substances from blood and their excretion into bile (Table 197.2). In addition, transport proteins mediate efflux of substances from hepatocytes into blood. While uptake into hepatocytes by solute carriers at the basolateral membrane is usually an energy-independent process, many efflux pumps located at the canalicular and basolateral membranes, such as multidrug resistance proteins (MDR) or multidrug resistance associated proteins (MRP), are ATP-dependent. Like cytochromes, transporter proteins are not substrate-specific but shuttle many different substances. Transporters may be inhibited or induced by several drugs while inflammatory diseases may lead to profound alterations in gene expression and protein amount and distribution. For example, macrolides can inhibit solute carriers such as OATP1B1 and OATP1B3 which are responsible for pravastatin uptake, leading to increased plasma levels of the drug.

In cholestatic liver disease, biliary excretion of drugs and their metabolites may be impaired, necessitating dosage adjustments. However, transporter proteins may be differentially affected in inflammatory diseases and liver failure.

Perfusion disorders

The liver is a highly perfused organ and there are complex mechanisms to regulate liver blood flow. Under pathophysiological conditions these regulatory mechanisms may be ineffective and impaired. Together with the macrocirculatory changes frequently seen in critically-ill patients, this can lead to reductions in effective sinusoidal blood flow. There may be overall reductions in blood flow (e.g. in haemorrhagic shock, right heart failure), or distribution disorders and shunting. Shunts can be both intra- and extrahepatic. Particularly in chronic liver disease with portal hypertension a large amount of portal blood can be redirected to extrahepatic shunts. On the other hand, increased liver blood flow is also described in acute hepatitis.

Plasma protein binding and volume of distribution

Critical illness, and acute or chronic liver failure lead to decreased levels of albumin and other transport proteins, and to altered proteins [2]. In addition, binding capacity (e.g. of albumin) may be impaired due to reduced hepatocellular clearance of endogenous and exogenous compounds, such as bilirubin or bile acids. Together this results in reduced binding and an increased free fraction of the drug. Reduced plasma protein binding leads to an increased volume of distribution; these alterations are more pronounced in drugs with high protein binding. A higher free fraction generally results in increased elimination and distribution of the drug and, therefore, a new equilibrium. However, elimination may be impaired due to organ dysfunction, especially in capacity-limited drugs, thus resulting in a truly increased free fraction. In drug monitoring of highly protein-bound substances, while overall drug levels may be reduced, free drug concentrations may be relatively higher.

Table 197.2 Examples of drugs that are substrates, inhibitors or inducers of hepatic membrane transporters

Transporter	Hepatic localization	Substrates	Inhibitors	Inducers
OATP2 (1B1) SLCO1B1	Basolateral	Rifampicin, statins, benzylpenicillin	Cyclosporin	
MDR1 (ABCB1)	Canalicular	Cyclosporin, tacrolimus, macrolides, statins	Antifungal azoles, cyclosporin	Rifampicin
MRP2 (ABCC2)	Canalicular	Ampicillin, ceftriaxone, cisplatin, pravastatin	Cyclosporin	

Where groups of drugs are given, not necessarily all drugs of the group must be transported by the given transport protein. OATP, organic anion transporting polypeptide; MDR, multidrug resistance protein; MRP, multidrug resistance associated protein.

In patients with ascites, water-soluble drugs have a higher volume of distribution [1,2]. Fat- soluble drugs may have a reduced volume of distribution in patients with malnutrition, or chronic liver disease due to reduced fat and muscle mass. Drug dosages may need to be adjusted.

Pharmacokinetic alterations

The amount of a drug removed from blood during liver passage is influenced by hepatic blood flow, the extent of binding to blood components such as proteins, and hepatocellular uptake [2]. Hepatic drug clearance (Cl_H), i.e. the volume of blood from which a drug is removed completely by the liver during a time period, depends on effective hepatic blood flow (Q_H) and the hepatic extraction ratio (E_H (= the difference between venous (C_V) and arterial (C_A) concentrations in relation to the arterial concentration ($E_H = (C_A - C_V) / C_A$)). Thus:

$$CL_H = Q_H \times E_H \quad \text{[eqn 1]}$$

The extraction ratio depends on hepatic blood flow, the unbound fraction of the drug (fu) and the intrinsic clearance of unbound drug (Cl_{int}):

$$E_H = (fu \times Cl_{int}) / (Q_H \times fu \times CL_{int}) \quad \text{[eqn 2]}$$

$$Cl_H = Q_H \times (fu \times Cl_{int}) / (Q_H \times fu \times CL_{int}) \quad \text{[eqn 3]}$$

For drugs with a high extraction (>0.6), e.g. lidocaine, verapamil, fluvastatin, morphine, hepatic clearance depends on liver blood flow (i.e. blood flow-limited), while for drugs with a low extraction ratio (<0.3), e.g. acetaminophen, rifampicin, levetiracetam), clearance is capacity-limited, i.e. depends on transporter and enzyme functionality [3].

Pharmacodynamic alterations

Clinically relevant alterations in pharmacodynamics have been reported for some drugs [1,3]. These include an attenuated response to a variety of vasoconstrictor agents, such as catecholamines, especially in cirrhosis. This may be due to various alterations associated with portal hypertension. For sedative drugs, pharmacokinetic and pharmacodynamic changes are also recognized with an increased susceptibility of the central nervous system to benzodiazepines and opioids. Vasoconstrictors, sedatives, and analgesics should be titrated carefully to clinical effect. Other drugs for which altered pharmacodynamics have been reported are ß-adrenoceptor antagonists and diuretics, such as furosemide or torasemide. Both groups of drugs exhibit reduced therapeutic effects in patients with liver cirrhosis.

Renal dysfunction in patients with liver failure

Patients with liver failure, whether acute or acute-on-chronic, usually present with multi-organ dysfunction. With respect to the pharmacology of xenobiotics, renal impairment is of utmost importance. Patients with chronic liver disease often present with concomitant renal impairment, though serum creatinine levels may be within the normal range. Creatinine clearance should thus be measured, acknowledging that the glomerular filtration rate may be overestimated by a factor of two in calculating creatinine clearance, even when this is actually measured, rather than estimated [2,3].

While many dosing recommendations exist for patients with renal impairment, e.g. based on creatinine clearance, concurrent liver and renal dysfunction makes the pharmacokinetics difficult to predict. This is particularly valid for those drugs that are metabolized/excreted by both kidney and liver. In addition, pathophysiological conditions accompanying renal dysfunction, e.g. disturbed acid-base balance, altered fluid balance or blocked protein-binding sites, can also change pharmacokinetics and pharmacodynamics.

Prescribing in liver failure

Patients with liver disease present with complex functional alterations leading to considerable pharmacological changes that may sometimes be virtually unpredictable. The clinician must therefore carefully evaluate medications given to such patients. Especially for those drugs with a narrow therapeutic index, the additional risk of (hepatotoxic) side-effects must be taken into account due to altered pharmacokinetics. Extreme caution is advised when using such drugs.

The optimal way to adjust drug dosages, especially in the ICU patient, is to perform therapeutic drug monitoring wherever possible. For some drugs, titrating dosage according to clinical effect may be sufficient, e.g. for sedatives or analgesics. Nevertheless, for some essential therapies, clinicians must avoid (initial) underdosing, e.g. in antibiotics early and effective drug levels are essential for survival in septic patients.

Some general recommendations for drug dosing in patients with liver dysfunction should be observed, assuming that the drug is eliminated by hepatic metabolism and excretion. In drugs with a high extraction ratio (>0.6), oral/enteral application leads to a high first-pass metabolism and, therefore, to low bioavailability. Patients with a reduced hepatic blood flow, e.g. due to shunting (intra-, extrahepatic, or artificial after, e.g. transjugular intrahepatic portosystemic shunt (TIPS) placement), as seen in patients with cirrhosis, may present with a substantial increase in bioavailability of such drugs [3]. Reduced initial doses and titration of maintenance doses should be considered for drugs with a high hepatic extraction ratio. Intravenous administration of drugs is usually more reliable and predictable. If liver blood flow is reduced, the maintenance dose should be reduced [2]. On the other hand, administration of prodrugs that require hepatic metabolism to their active forms can lead to reduced levels of active drug (e.g. clopidogrel, enalapril).

For drugs with a low hepatic extraction ratio (<0.3), clearance depends on the intrinsic capacity of the elimination mechanism and the fraction of unbound drug. Impairment of these specific elimination mechanisms should be considered. For drugs with protein binding <90%, initial dosing does not need to be modified, however, the maintenance dosage should be reduced. This can be estimated according to the severity of liver dysfunction. For example, a 50% reduction should be considered in Child–Turcotte–Pugh (CTP) Class A liver dysfunction, and to 25% in Class B cases; for Class C the use of drug monitoring is recommended [3]. These recommendations have limitations due to the rough classification of the CTP score and the variable impairment of the elimination

mechanisms. As phase-II metabolism is often less impaired, drugs solely metabolized via this pathway may be preferable.

For drugs with a low hepatic extraction ratio and high protein binding, changes in pharmacokinetics are unpredictable. Therefore, drug monitoring is recommended wherever possible and the unbound fraction ideally measured.

For hydrophilic drugs, such as ß-lactam antibiotics, an increased initial dosage should be considered in patients with ascites and oedema as the volume of distribution may be substantially increased. However, for maintenance dosage of these drugs, any potential renal dysfunction should be considered [2].

Recently, there have been reports of using liver function tests to predict the required drug dosage, i.e. the plasma disappearance rate of indocyanine green for calculating the argatroban maintenance dose in critically-ill patients with type II heparin-induced thrombocytopenia, and the methacetin breath test for assessing tacrolimus trough levels after liver transplantation [4,5]. This may be a future option to direct therapy where drug monitoring is not available in a clinical setting, or where initial correct dosing is crucial with respect to toxicity/side-effects or therapeutic effect.

CHAPTER 198

Extracorporeal liver support devices in the ICU

Rajiv Jalan and Banwari Agarwal

Key points

- There is an unmet need for a liver support system because of the increasing shortage of organs for transplantation and the complications associated with the procedure.
- In theory, acute liver failure and acute decompensation of chronic liver disease secondary to a precipitating event are potentially reversible. In this context, an extracorporeal liver support can temporarily substitute liver functionality to allow natural recovery through regeneration of hepatocytes and elimination of the precipitating event.
- Goals of liver support system are to provide all functions of the liver, including synthetic and metabolic functions, and to remove as well as reduce the production of pro-inflammatory mediators to attenuate the inflammatory process.
- Currently existing devices are either purely mechanical and/or cell-based. Detoxification is provided by both systems, but biological activities are limited only to the cell-based systems. Albumin dialysis is the major component of mechanical devices because albumin is irreversibly destroyed in liver failure.
- Cell-based or bio-artificial systems are essentially 'mini-livers', but their success is limited by the lack of a continuous and abundant supply of high-quality hepatocytes.

Introduction

The burden of liver disease continues to rise, with 10% of the current world population estimated to suffer from chronic liver disease. Annually, over a million people die from liver-related illnesses; severe acute liver failure is associated with 50–60% mortality, while deaths from cirrhosis-related complications are projected to be the ninth most common in the developed world by 2015 [1].

Liver transplantation (LT) remains the only optimal treatment for the majority of patients, but the expanding gap between organ availability and increasing waiting lists results in a significant mortality for patients awaiting transplantation. In the UK the average waiting time for chronic liver disease patients is between 3 and 18 months; >500 patients are on the waiting list at any one time with 15–20% dying without LT becoming available [2].

There is an urgent need for an extracorporeal liver assist device with the capacity to support liver function and provide a temporary holding measure as a bridge to transplantation, or ideally, facilitate natural recovery of native liver function. The quest for such devices dates back to the 1960s, but the realization of developing an ideal liver device has only been partially achieved.

Liver failure syndromes

Liver failure can be broadly viewed as a spectrum of disease ranging from acute to acute-on chronic and end-stage liver failure. This classification captures different clinical phenotypes of liver illness and allows formulation of appropriate treatment plans.

Acute liver failure

Acute liver failure (ALF) is characterized by a rapid decline in liver function (within days to weeks) secondary to massive necrosis of hepatocytes following an acute insult (infective, metabolic, vascular, or drug-induced). This occurs in patients with previously normal liver function, and results in varying degrees of coagulopathy and hepatic encephalopathy (HE), eventually progressing to extrahepatic organ involvement and failure. Cerebral complications, superimposed sepsis and the multiple organ dysfunction syndrome account for most deaths in these patients. ALF stratification, based upon the length of time elapsed between the appearance of first symptoms and the development of HE, into the hyperacute (1–7 days), acute (8–28 days), and subacute (28 days–24 weeks) subvarieties, in conjunction with markers of acute physiological derangement (blood pH and lactate levels), patient age, and the aetiology of ALF, informs prognosis and identifies patients unlikely to survive without emergency or super-urgent LT [3]. LT is a life-saving procedure, but is a major intervention with attendant morbidity and mortality, requires life-long immunosuppression, is expensive and limited by organ availability.

Acute on chronic liver failure

Acute on chronic liver failure (ACLF) is an increasingly recognized clinical entity referring to the coincidence of either an identified or unidentified acute precipitating event (either superimposed liver injury or extra hepatic factors, such as infection) in patients with existing compensated or decompensated cirrhosis, culminating in further deterioration of liver function, and development of end-organ damage leading to high short term mortality [4]. The final common pathway of a precipitating event—infection, variceal bleed, or additional liver injury—seems to be the development of an unquenched dysregulated systemic and hepatic inflammation resulting in worsening encephalopathy, aggravation of portal

hypertension, development of renal dysfunction and haemodynamic embarrassment, and retardation of liver regeneration.

End-stage liver disease

End-stage liver disease is an irreversible condition representing the terminal phase of liver failure, with little capacity for regeneration by the native liver. The only treatment known to improve survival in this situation is LT.

Liver support systems: types, technical issues, operational and functional characteristics, and current clinical evidence

The liver is a complex organ, central to the body's metabolic processes. It has an unparalleled ability to handle multiple tasks required to maintain metabolic homeostasis and to act as the major regulatory player in the organ cross-talk framework. Hepatocytes perform a range of functions including:

- Detoxification (of drugs, toxins and chemicals such as ammonia and lactate).
- Metabolic and biotransformation activities (e.g. drug metabolism, maintenance of glucose homeostasis and thermogenesis).
- Synthesis (of coagulation proteins, albumin, globulins, acute phase and transporter proteins.
- Immune modulation functions.

Hepatocellular failure results in toxin (ammonia, bilirubin, lactate, mercaptans, and bile acids) accumulation, an imbalance of metabolic substrates, and increased levels of inflammatory mediators.

The premise and concept behind an ideal extracorporeal liver support device therefore hinges on its ability to detoxify blood, perform synthetic, metabolic and immune functions, and to remove and/or inhibit production of inflammatory signalling molecules (e.g. cytokines). This breaks the vicious circle of liver injury characterized by production of inflammatory mediators and propagation of further liver injury, the ultimate aim being stimulation and promotion of liver regeneration. Because of the temporary nature of the support offered by the currently available devices, their clinical application is targeted largely to situations where liver injury is acute, as in ALF and ACLF. In addition, these devices can be used to improve and alleviate symptoms arising from cholestasis such as pruritus (Box 198.1).

There are two types of liver support systems, namely artificial (non-biological) systems, which are purely mechanical dialysis devices based on blood detoxification, and bio-artificial devices, which are cell-based devices incorporating hepatocyte-derived cells that can potentially substitute liver metabolic function. Blood purification devices are also added to some of these systems. For a summary of this section, see Tables 198.1 and 198.2.

Artificial devices

Conventional blood purification methods, such as continuous haemofiltration or haemodiafiltration, although highly effective in removing small, water-soluble toxins, are no longer used as the sole means of detoxification in liver failure patients. This is due to their inability to remove protein-bound substances and their ineffectiveness in liver failure. They are still used in conjunction with liver support devices to augment elimination of water-soluble toxins. The first generation of liver devices utilized activated charcoal haemoperfusion as the basis for toxin adsorption, but failed to demonstrate significant benefit and is now largely superseded by albumin-based systems. Albumin is the most abundant circulating plasma protein and maintains plasma oncotic pressure. In addition, current literature consistently points towards a number of other biological functions such as fatty acid transport, drug binding, metal chelation, and antioxidant activity performed by albumin, rendering it an important detoxification molecule and a candidate protein to be targeted in liver dialysis systems [5]. In addition to quantitative hypoalbuminaemia in liver failure, there is a severe functional impairment of the available albumin rendering it an inefficient transporter protein [6].

The two most commonly used artificial systems are the molecular adsorbent recirculating system (MARS) and the fractional separation of plasma and albumin dialysis (Prometheus). Both forms of treatment are relatively new; MARS was used clinically for the first time in 1993 and Prometheus in 2003.

Box 198.1 Potential indications for liver supportive therapy

ALF patients

- Failure to reach criteria for emergency LT, but remain at high risk of dying (10–15% of non-survivors do not fulfil King's College Criteria for emergency transplantation).
- Patients either precluded from LT due to medical, surgical, or psychological reasons, or those who continue to deteriorate rapidly, while on the emergency transplant list.

ACLF patients

- These patients are currently not considered for emergency LT in the UK, so a device can provide support until spontaneous recovery to pre-injury levels of liver function.
- As a bridge to LT, especially for those patients who are high up on the waiting list and would receive LT within the next few weeks.

End stage liver disease

Patients with ESLD lack reversibility. Since currently available liver assist devices are unable to sustain liver support for longer than a few weeks, the only role of liver devices pertains to symptom reduction and quality of life improvement as in:

- Intractable pruritus.
- Hepatic encephalopathy.
- Severe chronic fatigue.

Other indications

- Primary graft non-function after transplantation, and waiting for super-urgent re-transplant.
- Small-for-size syndrome:
  - Development of liver failure following extensive resection for malignancy.
  - Following donor hepatectomy in living donation liver transplantation.

Table 198.1 Artificial devices

Device	Principles of therapy	Clinical studies
SPAD (single-pass albumin dialysis)	Albumin dialysis against 2–5% albumin	Improvement in biochemical parameters, comparable with MARS. Only single case studies available [13], no RCTs
MARS (molecular adsorbent recirculating system)	Albumin dialysis against 20% albumin	Improved hepatic encephalopathy [14], improved quality of life, no significant survival benefit [9]
Prometheus (fractionated plasma separation and adsorption—Prometheus)	Plasma separation, adsorption using neutral resin, and anion adsorbers	Improvement in biochemical parameters. No significant benefit at 28 days [10]
SEPET (selective plasma filtration technology)	100 kDa hollow fibre membrane, albumin, and fresh-frozen plasma mixture as replacement fluid	No human RCTs. Animal models show improved survival [15]
HVPE (high volume plasma exchange)	Patient's plasma removed and replaced with fresh frozen plasma	Improved transplant-free survival in ALF [7]

Data from various studies (see references).

MARS (Gambro, Sweden) combines albumin dialysis with conventional haemodialysis to remove both water-soluble and protein-bound toxins. The patient's blood is detoxified of protein-bound substances via an albumin-impregnated polysulfone dialysis membrane (50 kDa) against a concentration gradient exchange mechanism by the albumin solution stored in the adjacent chamber (600 mL 20% human albumin). The selective pore size stops the patient's own toxin-laden albumin from crossing the membrane. The albumin dialysate is passed through an activated charcoal and anion exchange resin to regenerate the protein to allow its continued use as a detoxification medium (Fig 198.1a). The haemodialysis circuit in the system removes water-soluble substances.

Prometheus (Fresenius, Germany) combines plasma separation and adsorption in a double circuit design. A high cut-off membrane of 250 kDa filters the patient's albumin into a secondary plasma circuit. The albumin-rich plasma then passes through two columns of adsorbent resins (neutral and anion exchange, see Fig 198.1b), to remove bound toxins before recombining with the cell fraction prior to return to the patient. A high-flux dialysis system is applied to the blood circuit to enhance elimination of water-soluble toxins.

Single-pass albumin dialysis (SPAD) is a non-commercial simplified system of albumin dialysis designed to remove protein-bound toxins using an albumin solution (typically 5%) as the dialysate separated from the patient's blood by a high-flux albumin-impermeable membrane. Unlike MARS where the albumin dialysate is re-circulated, it is discarded after a single pass (Fig. 198.1c). Continuous veno-venous haemodiafiltration can be added to augment removal of water-soluble substances. The SPAD system is simple, safe, and has similar efficiency to MARS in removing bilirubin, ammonia, bile acids, and creatinine.

Plasmapheresis (plasma exchange) separates the patient's plasma from cellular blood components to be then replaced by donor fresh-frozen plasma and/or albumin. It is effective in removing circulating antibodies, inflammatory cytokines, and other toxic substances, as well as toxins bound to tissue sites, and is used for a number of autoimmune conditions. In liver failure, enhanced or high volume plasmapheresis (>10 L of plasma removed and replaced per day) has demonstrated clinical improvement in hepatic encephalopathy, hepatic and cerebral blood flow, and even a survival benefit in patients with ALF [7].

SEPET (selective plasma filtration technology) incorporates a 100 kDa hollow-fibre membrane where the ultrafiltrate is replaced by a mixture of electrolyte, albumin, and fresh-frozen plasma solutions.

Table 198.2 Bio-artificial devices

Device	Principle and cell type	Main concern	Clinical studies
Hepat Assist	Plasma separation, charcoal adsorption, porcine hepatocytes	Zoonoses	176 patients, no survival advantage in fulminant and sub-fulminant [16]
MELS (modular extracorporeal liver system)	Plasma separation, then plasma passed through human hepatocytes	Supplies low, function difficult to maintain	Eight patients, successfully bridged to transplant [17]
ELAD (extracorporeal liver assist device)	Human hepatoblastoma cell (C3A cells)	Tumourogenicity	Six human studies, 150 patients treated. Survival benefit in ACLF study in 49 patients [18]
BLSS (bio artificial liver support system)	Porcine hepatocytes	Zoonoses	Phase I study in four patients, no serious adverse events [19]
AMC-BAL	Porcine hepatocytes	Zoonoses	12 patients treated, 11 bridged to transplant [20]

Data from various studies (see references).

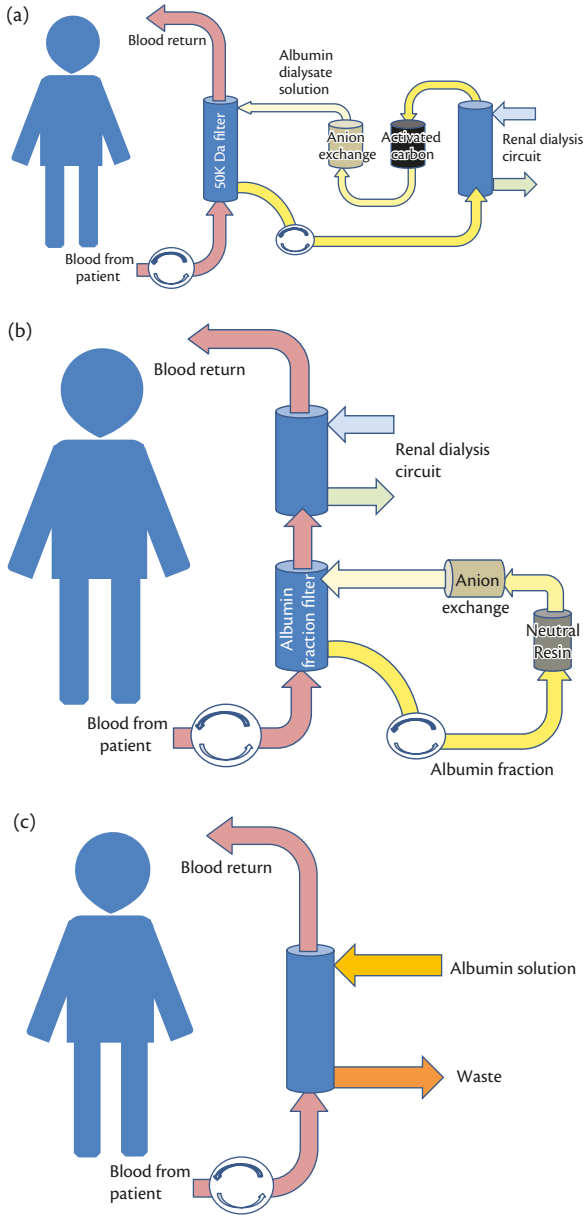

Fig. 198.1 Schematic representations of (a) molecular adsorbent recirculating system (MARS). (b) Fractional separation of plasma and albumin dialysis (Prometheus). (c) Single pass albumin dialysis (SPAD) artificial systems.

Safety profile and clinical efficacy of artificial devices

MARS is the most studied device with over 5000 patients having been treated for more than 20,000 therapy sessions, followed by Prometheus that has also been used extensively. These are largely safe procedures, with no serious side effects reported for either treatment. Reported complications have included modest thrombocytopenia, bleeding episodes, transient haemodynamic instability, a need for more anticoagulation treatment, and reversible leukocytosis unrelated to sepsis.

Both MARS and Prometheus effectively remove water-soluble and albumin-bound toxins, as well as cytokines, but without significant reduction in plasma cytokine levels, reflecting an imbalance between the modest cytokine elimination ability of these systems, and their continuous production during liver failure [8]. Both systems lose detoxification capability significantly after 6 hours' use.

Most of the published evidence relates to these two main artificial devices. The MARS system has received US FDA approval as a therapy for use in hepatic encephalopathy, in addition to previous approval for the management of drug toxicity. Both MARS and Prometheus are effective in supporting patients with severe liver dysfunction either following surgery or as a bridge to transplantation. Crucially, neither system could show an independent survival benefit (in the absence of transplantation) in phase III multicentre trials [9,10]. Albumin dialysis/detoxification has been shown to be very effective for intractable pruritus and provides symptom relief for prolonged periods (3–4 months) [11]. As these patients often will not qualify for LT based on their liver function, this treatment option can play a vital role in improving their quality of life (Table 198.1).

Biological or bio-artificial liver system

A bio-artificial liver system (BAL) system employs biochemically active cells contained in a bioreactor. In theory, it is capable of carrying out a proportion of the metabolic, synthetic, and immune function provided by the liver. A blood purification device is often added to improve efficacy. The essential pre-requisites for a functioning BAL system are:

- High quality, well-differentiated cells retaining a high degree of hepatocyte function, which are stable in vitro.
- Sufficient quantities of these cells equating to up to one-third of normal liver mass as extrapolated from data on large liver resections.
- Ready and unlimited availability of these cells at any time.

Cell sources most commonly studied have been derived from primary human and porcine sources, immortalized human cells, and cells derived from hepatic tumours such as hepatoblastoma. The cells are used as either tissue slices, homogenates or as single cell layer columns supported on matrices similar in appearance to dialysis filters.

The disadvantages of human cells are limited availability, while porcine hepatocytes tend to be less stable and carry a theoretical risk of xenozoonosis, which although not yet reported, will prevent their use in Europe and the USA. On the other hand, cell lines such as C3A derived from human hepatoblastomas lose functionality following transformation, e.g. their ureagenesis capacity is limited only to the arginine aspect of the urea cycle and thus cannot completely detoxify ammonia.

Currently available BAL systems

The ELAD C3A-based BAL system is currently under development and undergoing clinical trials (Vital Therapies, San Diego, USA). Small-scale studies have shown survival benefit or use as a bridge to transplantation, although a large-scale pivotal survival study has not yet been undertaken. Other systems are in varying stages of development, seeking to optimize the bioreactor design or the cell type contained within them. It is not yet clear as to how successful these technologies will be. A major limiting factor in whether BAL systems will be adopted widely would be the considerable cost of therapy associated with generating, shipping, and

maintaining bioreactors. Clinical studies therefore need to demonstrate clear, unequivocal survival benefit of ELAD over other treatment options before acceptance into the majority of healthcare systems (Table 198.2).

Conclusion

Specific therapies aimed at targeting factors identified in relation to the progression of liver injury are being developed for the next generation of liver dialysis systems. Proof-of-principle systems have shown clinical benefit by combining endotoxin removal filters with albumin dialysis [12]. These endotoxin filters, developed as therapies for sepsis, are used to reduce the ongoing inflammatory stimulus associated with end-stage liver disease. Another approach is to improve the quality and functional capacity of the patient's albumin during therapy. The disease process damages albumin binding and transport capability, so methods to replace the damaged protein to restore function rather than just to dialyse the bound toxins is the next logical step in system design. Improved BAL systems may be able to demonstrate a large functioning cell mass that can effectively replace liver function for a prolonged period, though this would still appear to be some way from the clinic. Current artificial liver dialysis systems offer effective support for a number of applications. Though they are not able to replace the failing liver, they do offer detoxification functions and can act as a bridge to transplantation.

PART 6.9

Acute on chronic hepatic failure

CHAPTER 199

Pathophysiology, diagnosis, and assessment of acute or chronic hepatic failure

Alastair O'Brien

Key points

- Cirrhosis is an increasing problem and prognosis following ICU admission is poor.
- Acute on chronic liver failure (ACLF) is a separate entity to cirrhosis with organ failure at the core of this syndrome.
- ACLF results from an acute 'new' insult that may/may not be related to the original cause of chronic liver disease.
- Infection and the associated SIRS response are the most important precipitants of ACLF.
- Clinical assessment should follow the standard ABCDE approach to the critically-ill patient.

Introduction

Cirrhosis is the end result of liver damage caused by a wide variety of insults including alcohol, chronic viral infection, non-alcoholic fatty liver disease, autoimmune disease, certain genetic conditions, and other less common conditions. It represents a leading cause of death worldwide. In the UK it is currently the fifth leading cause of death and, unlike many other common diseases, there is an upward trend in mortality. The average age of death from liver disease is only 59 years, compared with 82–84 years for cardiovascular and lung diseases.

Cirrhosis and intensive care unit admission

Cirrhosis is rarely reversible and the natural progression from compensated to decompensated disease results in a significant increase in morbidity and mortality, and a much decreased quality of life. This is a direct consequence of the impairment in liver function secondary to decreased functional hepatocytes and the architectural disruption that impairs a normal hepatic and enteric circulation. Management of the complications of cirrhosis, such as gastrointestinal bleeding, sepsis, and renal failure, frequently involves ICU admission. All studies in ICU patients report a poor prognosis with an overall hospital mortality of 44–71%, although a small improvement in mortality has been described over time. Patients admitted for airway protection following an upper gastrointestinal bleed fare well with a mortality of 20%. However, mortality in those with organ failure, septic shock, or hepatorenal syndrome may approach 85–100%. Liver transplantation is the only curative therapy for established cirrhosis, giving excellent 5-year survival rates of 75%. However, the limited number of available organs dictates that the vast majority of patients will not be considered. For example, approximately 600-800 transplants are performed annually in the UK, while over 550,000 patients were admitted with complications of cirrhosis during 2012. This mismatch results in a large number of intensive care unit (ICU) admissions of patients that will never be considered suitable for transplantation. The estimated number of ICU admissions related to cirrhosis in the United States is in excess of 26,000 per year with an estimated cost of $3 billion. In the UK this represents approximately 2.6% of total admissions per year (approximately 1250 patients).

Acute on chronic liver failure: definition

Acute on chronic liver failure (ACLF) refers to an acute deterioration in liver function in cirrhotic patients secondary to superimposed hepatic or extrahepatic injury, such as infection [1]. The most recent definition by the EASL-CLIFF consortium refers to an acute decompensation (ascites, encephalopathy, gastrointestinal bleeding, bacterial infection) associated with organ failure (worsening of liver function, and/or kidney failure or other organs). The previous definition proposed by a working group from the American Association for the Study of Liver Disease (AASLD) and the European Association for Study of the Liver (EASL) is 'acute deterioration of pre-existing, chronic liver disease, usually related to a precipitating event and associated with increased mortality at 3 months due to multisystem organ failure'. Ongoing studies are aimed at further refinements, however the most important message from studies published thus far is that in ACLF it is the degree of organ failure that determines outcome, rather than the severity of liver disease.

ACLF must be contrasted with acute or 'fulminant' liver failure that develops in patients without pre-existing liver disease and is described elsewhere. Distinction between the two is important as the treatment and prognosis is, in most cases, dissimilar.

Precipitating event

ACLF results from an acute 'new' insult that may/may not be related to the original cause of chronic liver disease [1,2]. This separates it

from cases of cirrhosis in which continued hepatocellular damage leads to progression and worsening of disease. Although this distinction has been made between ACLF and advanced cirrhosis for the purposes of this chapter and the ACLF management chapter, the recommendations made for assessment and management can be applied to any critically-ill patient with cirrhosis. Precipitants include bacterial infections, alcoholic hepatitis, superimposed viral hepatitis, drug (or hepatotoxin)-induced liver injury, variceal bleeding, ischaemia, and surgery. There is global variation, for example, viral infections are more common in Asia, while alcoholic and non-alcoholic fatty liver disease (NAFLD) are more common in Europe and the United States.

Reversibility

In contrast to the natural progression of cirrhosis, a key defining principle of ACLF is the element of reversibility if the patient is identified early and aggressive intensive care support given [1]. However, full recovery to the previous baseline is not likely. Indeed, in patients who survive to hospital discharge, there is a median survival of only 4 months if their admission APACHE III (Acute Physiology and Chronic Health Evaluation) score exceeded 90, and 17 months if <90. In addition, 72% of survivors reported a poor quality of life.

To ensure improved outcomes in cirrhosis, early identification and management of these events is essential. This is best achieved if the physician has a good understanding of the pathophysiology underlying ACLF.

Multi-organ failure and prognosis

Multi-system organ failure is the primary cause of death in ACLF. Studies demonstrate higher mortality rates for ACLF than expected in a population of similar patients awaiting liver transplant, i.e. cirrhotic patients without ACLF. The natural history of ACLF is varied, reflecting the heterogeneity of patients; it remains to be determined whether distinct subgroups exist. Methods of assessment include the Child–Turcott–Pugh or MELD scores and, possibly, biomarkers in development or new imaging modalities [1,2]. Recent hospitalization carries a grave prognosis. The precipitating insult will also have prognostic significance and infection, in particular, carries a poor prognosis. Increasing organ failure and increasing markers of systemic inflammatory response are associated with a poor prognosis [1,2]. The Sequential Organ Failure Assessment (SOFA) score is reflective, but not predictive of organ failure; as yet there is no system for early identification of patients likely to develop ACLF.

Pathophysiology

Infection and inflammation

Infection (bacterial, viral, or fungal) and the associated systemic inflammatory response (SIRS) is the most important precipitant. Many regard this as the central feature [1,2]. Patients with cirrhosis are highly susceptible to infection. In 50% of cirrhotic inpatients, infection was the precipitant for hospital admission, while a further 15–35% develop nosocomial infections compared with 5–7% of general ward patients. Of those cirrhotic patients who develop sepsis and organ dysfunction, up to 80–90% die. Portosystemic shunting of blood bypassing the liver coupled with impaired Kupffer cell activity probably increases the burden on innate immune cells within the peripheral circulation. Elevated endotoxin secondary to bacterial translocation, altered Toll-like receptor expression and endotoxin tolerance have also been proposed as causes of immunosuppression. In addition, elevated IL-10 and ammonia inhibit neutrophil function and this may be reversed by treatment with albumin. While this may appear important in the aetiology of cirrhosis-associated immune-suppression, a unifying mechanism remains elusive. Notwithstanding this, there is generalized acceptance of a defect in leukocyte mobilization to sites of infection and, once there, leukocytes have a decreased ability to secrete cytokines, phagocytose, and kill bacteria. While this defective innate immune response was first observed over 30 years ago, and is considered to underlie the predisposition to and poor outcome from, infection, precise factors that cause it are unknown. Infection precipitates hepatic encephalopathy, renal dysfunction, and variceal bleeding. The robust association between infection and deleterious outcomes in cirrhosis mandates aggressive surveillance and early treatment of suspected infection. A recent Cochrane meta-analysis, however, concluded that antibiotic prophylaxis is still far from being a substantiated prevention strategy. Nevertheless, a mortality benefit has been demonstrated with prophylactic antibiotics following an oesophageal variceal bleed.

Superimposed hepatotrophic viral infections in cirrhosis patients can have devastating consequences and must be considered, e.g. hepatitis E virus superinfection and reactivation of hepatitis B virus (HBV) in patients on immunosuppression.

Drugs and hepatotoxins may cause direct hepatocellular damage and precipitate ACLF. It is a common misconception that patients with chronic liver disease are at higher risk of hepatic damage from certain medications such as statins. Exceptions to this include methotrexate, anti-TB medication, anti-HIV treatment, and ibuprofen.

SIRS is closely linked to outcome in ACLF. Regardless of the precipitating factor, the final common pathway to multi-organ failure is an exaggerated activation of systemic inflammation followed by a period of immunoparalysis. The initial cytokine storm is responsible for profound macro/microcirculatory changes and subsequent multi-organ injury. Following this 'storm', an excessive compensatory anti-inflammatory response system can lead to immune dysfunction with possible episodes of nosocomial infection, sepsis, and further clinical deterioration.

Clinical features

Liver

Hyperbilirubinaemia is the central feature of hepatic ACLF [2]; although the pathophysiology is currently uncertain, it is likely to differ among patients according to the cause of their cirrhosis and precipitating insult. Bilirubin stasis represents a risk factor for subsequent infection and sepsis, while systemic inflammation generates increased tumour necrosis factor-α and interleukin-6 causing hepatic microcirculatory endothelial dysfunction, elevated portal pressures and decreased hepatic blood flow, further worsening liver function. Bacterial translocation and gut-derived endotoxaemia are considered to drive this process. Anti-TNFα therapy reduced portal pressures in severe alcoholic hepatitis. Furthermore, an upregulation of sympathetic tone in sepsis and ACLF is also associated with increased portal pressure.

Renal

Renal failure is the most common organ dysfunction associated with ACLF and carries a poor prognosis [2]. By common consensus,

the best definition of renal failure in cirrhosis is an increase in serum creatinine to 1.5 mg/dL (133 μmol/L), which represents a glomerular filtration rate of 30 mL/min. Unfortunately, this often represents an overestimate of glomerular filtration rate because of decreased creatinine production or reduced muscle mass. Hence, several biomarkers of renal dysfunction in cirrhosis are under investigation including neutrophil gelatinase-associated lipocalin (NGAL), kidney-injury molecule-1 (KIM-1) and serum cystatin C (CyC). However, as yet none are routinely used in current clinical practice. Hyponatraemia (<130 mmol/L) occurs commonly due to an impairment in renal capacity to eliminate solute-free water. This results in retention of water disproportionate to that of sodium, leading to a decrease in serum sodium concentration and hypo-osmolality. It is associated with a poor prognosis, the presence of ascites, hepatorenal syndrome (HRS), spontaneous bacterial peritonitis, and hepatic encephalopathy. Renal failure can be divided into four main categories: HRS, hypovolaemia-induced, parenchymal disease, and drug-induced. Bacterial infection is a major precipitant of all these categories. Patients with ACLF may present with any cause and outcome will vary accordingly. HRS is considered a functional disorder secondary to splanchnic vasodilatation and renal vasoconstriction, which is reversible following liver transplantation, but otherwise carries an extremely poor prognosis. In patients with cirrhosis and ascites the 1-year probability of developing HRS is 20% and, at 3–5 years, 50%. Hypovolaemia is most commonly due to gastrointestinal bleeding or excessive diuretic treatment. Any potentially nephrotoxic drug, such as NSAIDs or gentamicin should be avoided in cirrhotics. Interestingly, it was recently shown that cirrhotic patients with acute kidney injury (e.g. secondary to sepsis, nephrotoxic drugs, or intravenous contrast) who underwent liver transplantation had a higher 5-year mortality and incidence of renal dysfunction compared with those with HRS.

Brain

ACLF patients may present with an acute confusional state superimposed on varying degrees of cognitive impairment that can evolve to coma. This is considered a form of hepatic encephalopathy (HE) [2,3]. Once again, the difference between cirrhosis and ACLF-induced is a precipitating inflammatory factor. This enhances the disturbances attributable to liver failure (secondary to hyperammonaemia) or can exert a direct neuro-inflammatory effect on the brain. Precipitants include infection, SIRS, and circulatory dysfunction. Neurotoxins such as ammonia may have their effects exacerbated by inflammatory cytokines [3]. Equally, SIRS may increase blood–brain barrier permeability and cause nitric oxide (NO)-mediated astrocyte swelling. Other described defects include neurotransmission disruption, astrocyte injury, loss of autoregulation, and cerebral atrophy.

Cerebral oedema was considered a very uncommon finding in cirrhotics but has been reported in ACLF, although to a much lesser extent than in acute liver failure. Computed tomographic imaging or invasive measurement of intracranial pressure are not routinely performed in ACLF patients, so the true prevalence is unknown.

Cardiovascular system

A hyperdynamic, vasodilated cardiovascular state is well described in cirrhosis. Therefore, only small decreases in arterial tone may be required to reduce circulating blood volume and cause hypotension [2]. The subset of ACLF patients with reduced cardiac output is associated with a poorer outlook. Putative mechanisms are similar to those in sepsis, e.g. elevated levels of TNFα and NO.

Pulmonary system

An increased risk of bacterial pneumonia and aspiration pneumonia due to altered consciousness is recognized in cirrhosis patients. Ascites may lead to decreased chest wall compliance or pleural effusion (hepatic hydrothorax). Portopulmonary hypertension and hepatopulmonary syndrome are notoriously underdiagnosed. The former is a predominantly haemodynamic problem, while the latter is one of intrapulmonary shunting. Chest X-ray (CXR) and arterial blood gases are mandatory in any patient complaining of breathlessness or cough.

Coagulation

Prolongation of the prothrombin time consequent to impaired synthesis and increased consumption of coagulation factors is common [2]. However, spontaneous bleeding is rare and often occurs as a result of the short half-life of factor VII. Bleeding associated with trauma or acute variceal haemorrhage may be more dramatic. Infection is again a key precipitant in cirrhosis-induced coagulopathy with development of endogenous low-molecular-weight heparinoids and elevated portal pressure. This is likely to be a key reason underlying the reduction in early variceal rebleeding rates seen with prophylactic antibiotics.

Hepato-adrenal axis

Adrenal insufficiency (insufficient rise in cortisol following corticotrophin administration) is described in >50% of patients with cirrhosis and severe infection, especially those with advanced liver disease, and is associated with increased mortality [2]. Primary and secondary adrenal insufficiency with an inadequate pituitary response and low adrenocorticotropic hormone levels may co-exist.

Thrombosis

Extrahepatic portal venous thrombosis secondary to sluggish portal flow or underlying thrombophilia is common. The development is often insidious and recognized only on radiological imaging. However, an acute portal vein thrombosis in cirrhotic patients may precipitate ACLF. Finally, counter to widespread opinion, patients with a prolonged international normalized ratio can develop deep vein thrombosis and pulmonary emboli.

Assessment

Clinical assessment should follow the standard ABCDE approach to the critically-ill patient

A—airway

Does the patient have HE with a Glasgow Coma Scale <8? Intubation should then be considered. CT scanning is mandatory if localizing neurological signs are present.

B—breathing

Is the patient hypoxic? Oxygen (O_2) saturations and arterial blood gases should be checked though coagulopathy may worsen bleeding at the puncture site. The inspired O_2 (FiO_2) concentration should be increased and non-invasive or invasive ventilation

considered. An underlying aetiology should be sought with CXR, electrocardiogram (ECG), and CT scan of the thorax. Significant hepatopulmonary syndrome can be excluded by contrast echocardiography.

C—circulation

Peripheral venous access should be obtained, blood tests and cultures sent, and cross-matching performed as needed. Central venous and arterial access should be obtained if hypotension persists despite volume challenges guided by the right atrial pressure (RAP) response to fluid. A high RAP value may occur due to raised intra-abdominal pressure secondary to large-volume ascites, in which case paracentesis should be considered. If the central venous oxygen saturation is <70%, causes of hypovolaemia such as sepsis, gastrointestinal blood/fluid loss, or excessive diuresis should be sought. Values >70% may still be associated with fluid depletion. If the patient remains hypotensive despite volume replacement, then cardiac index/volume status should be assessed and an inotrope/pressor agent given as appropriate.

D and E—disability/exposure: metabolic

A haemoglobin value >8 g/dL should be targeted and clotting corrected only if active bleeding is present. Saline-containing fluid should be avoided if the patient is hyperchloraemic. A metabolic acidosis may be secondary to liver or renal dysfunction, or to tissue hypoperfusion. If severe, early renal replacement with bicarbonate buffer may be needed. Serum glucose, magnesium, and phosphate should be checked and corrected, if necessary.

Conclusion

ACLF is a distinct clinical syndrome within the natural history of advanced cirrhosis, which carries a poor prognosis. There are multiple causes, with infection the most common and sepsis/inflammation the central pathophysiological feature. Very few patients will be candidates for liver transplantation and ICU mortality rates have improved little over 20 years [4]. Therefore novel treatments are desperately needed.

CHAPTER 200

Management of acute or chronic hepatic failure in the critically ill

Alastair O'Brien

Key points

- Acute on chronic liver failure is associated with a very poor prognosis and early identification of the precipitating cause is essential to successfully attempt to reverse decompensation.
- The most common precipitant is infection and therefore a high index of suspicion is required.
- Other management is largely supportive with close attention to renal dysfunction particularly important.
- Regular, effective, and compassionate communication with the patient and family members is extremely important to update any changes in condition and provide a realistic prognosis.
- All patients admitted to ICU with complications of cirrhosis warrant consultation with a transplant centre to determine whether they fulfil criteria for transplantation, and for expert advice.

Introduction

Acute on chronic liver failure (ACLF) is characterized by an acute deterioration of liver function in a patient with previously compensated cirrhosis secondary to a precipitating event, most commonly infection. However, most of the management approach to ACLF described herein relates to studies performed in patients with advanced liver cirrhosis, rather than ACLF *per se* and may therefore be equally applied to any critically-ill cirrhosis patient.

The mortality of patients with decompensated cirrhosis has changed little in the last 20 years. Organ failure is the key determinant of mortality, approaching 95% in patients with ≥3 organ failures. Liver transplantation is an extremely successful treatment for end-stage liver failure, but lack of donor organ availability limits this option to a minority of patients with advanced liver disease. Early detection and aggressive treatment of precipitant factors or complications of ACLF by a team with expertise in both hepatology and critical care will improve the severe associated mortality. Such an approach is described here. Treatment goals are to reverse precipitating factors of ALCF and support failing organs, thereby preventing further deterioration and allowing time for liver function to recover.

Infection

Clinical signs of infection, such as pyrexia or tachycardia, are often absent, so a high level of suspicion is required. In those with suspected infection, a broad-spectrum antibiotic, preferably given within 1 hour of assessment, is recommended. Piperacillin–tazobactam (Tazocin) is often used empirically, but choice should be guided by local knowledge of prevalent organisms and resistance patterns. Further treatment changes should be guided by culture results/sensitivities; early communication with the microbiology team is recommended. Strict attention to hand hygiene and local 'bundles' of care (e.g. for arterial and venous catheters) minimizes the risk of hospital-acquired infections.

Spontaneous bacterial peritonitis is usually treated with cefotaxime (2 g iv, tds) in addition to albumin boluses, although some units may have different policies. In selected high-risk patients, prophylactic norfloxacin to prevent spontaneous bacterial peritonitis delays the development of hepatorenal syndrome (HRS) and improves survival rates. However, widespread antibiotic prophylaxis is not recommended in view of an increased incidence of multidrug-resistant bacterial infections, which carry a high mortality.

For prolonged intensive care unit (ICU) admissions, weekly swabs to test for the development of resistant organisms are recommended. Testing for *Clostridium difficile* infection should be routinely performed, especially in patients with diarrhoea, which may be overlooked in patients receiving lactulose [1].

Renal failure

Renal dysfunction in ACLF patients is characterized by increased renal sodium and solute-free water retention, leading to ascites and hyponatraemia, as well as renal vasoconstriction causing a decreased glomerular filtration rate [2]. The development of renal failure in ACLF portends a grim outcome so precipitants such as nephrotoxic drugs, e.g. non-steroidal anti-inflammatory drugs or gentamicin, intravascular volume depletion, or large-volume paracentesis without albumin replacement must be avoided [1]. Despite being the key marker of renal dysfunction in cirrhosis, serum blood creatinine commonly underestimates renal dysfunction in ACLF because of decreased creatinine production or reduced muscle mass [2]. Iothalamate clearance measurement of glomerular filtration is usually not feasible in critically-ill patients. Volume expansion with albumin (1 g/kg/day initial dose to a maximum 100 g, followed by 20–40 g/day) combined with administration of vasopressors to reduce serum creatinine to <1.2 mg/dL is recommended [1]. Vasoconstrictor choice depends on availability, with terlipressin most commonly used in the UK and Europe at 0.5–1 mg every 4–6 hours, increasing to 2 mg every 4–6 hours for up to 14 days.

Alternative regimens include norepinephrine infusion (0.5–3 mg/hour) or midodrine 7.5–12 mg orally with octreotide 100–200 μg given sc tds. In approximately 50% of patients, renal function worsens despite these measures [1]. Even in those patients whose renal function improves, this benefit may only be short-term. Good predictors of response to therapy include less severe renal impairment, an early drop in serum creatinine and an early increase in mean arterial pressure following terlipressin. Renal replacement therapy is recommended to manage severe volume overload, electrolyte abnormalities, and metabolic acidosis. Unfortunately, many patients develop adverse effects, such as hypotension, bleeding, or infection during haemodialysis, and it has not been associated with improved outcomes in HRS.

Cardiovascular dysfunction

Patients are frequently hypotensive and a hyperdynamic circulation, and cirrhotic cardiomyopathy commonly co-exists [1]. Ventricular compliance is decreased; this can be assessed by observing the change in central venous pressure (CVP) after a 200-mL colloid fluid challenge, which is more instructive than a single CVP measurement. The optimum colloid for fluid resuscitation is uncertain with hepatologists and intensivists often disagreeing over the merits of albumin in particular. Albumin is safe, but is five times more expensive than many other colloids. This author's opinion is that targeted fluid resuscitation, i.e. aimed at objectively improving cardiovascular parameters and therefore organ perfusion, is more important than the type of colloid used. Moderate–large volume ascites raises intra-abdominal pressure and results in reduced thoracic compliance which further increases the measured CVP but without an accompanying increase in ventricular preload. Echocardiography is non-invasive, and offers a more detailed and accurate assessment of ventricular function and response to volume loading. Transoesophageal echo-Doppler is not considered appropriate for most critically-ill cirrhosis patients because of the presumed increased risk of variceal bleeding following insertion (although this has never been reported). In the non-spontaneously breathing ventilated patient, the impact of phasic increases in intrathoracic pressure on venous return and cardiac output can be assessed by analysis of stroke volume or pulse pressure variation from an arterial catheter; the more volume deplete the patient is the greater the degree of variation, provided no arrhythmias are present and tidal volumes are >8 mL/kg. For patients with suspected portopulmonary hypertension, pulmonary artery catheterization should be considered to guide therapy, for example, with endothelin antagonists or sildenafil.

Raised intra-abdominal pressure with large volume ascites can cause an abdominal compartment syndrome, which is associated with renal, cardiovascular, and respiratory dysfunction. Measurement of bladder pressure via a urinary catheter is a good surrogate for intra-abdominal hypertension and should be kept <20 mmHg by large-volume paracentesis with albumin replacement (6–8 g albumin/L of ascites drained) [1].

The optimal blood pressure for ACLF is unknown. Hepatorenal syndrome (HRS) does respond to terlipressin, which acts by increasing perfusion pressure. A pragmatic approach is to give fluid challenges to restore circulating intravascular volume and, if still hypotensive, to use vasopressors such as norepinephrine to achieve mean arterial pressures of 65–70 mm Hg. Vasopressin (or terlipressin) has been used as a norepinephrine-sparing agent in sepsis and has a similar effect in cirrhosis patients [1].

Prevention and control of bleeding

Although the INR may be significantly prolonged in ACLF, routine correction of coagulation abnormalities in the absence of active bleeding is rarely necessary. Furthermore, correction prior to central venous or arterial catheter placement, paracentesis, thoracentesis, bronchoscopy, or endoscopy without biopsy is not usually required. Correction may be associated with significant complications including transfusion-associated lung injury or circulatory overload, and therefore should be performed only when there is a clear indication. Correction is recommended in the presence of active bleeding with thromboelastography (TEG), prothrombin time, complete blood count, and activated partial thromboplastin time used to guide therapy [1]. Vitamin K, 2 mg daily for 3–5 days, should be given to eliminate deficiency as a cause of coagulopathy. Massive acute haemorrhage should be managed with transfusion of red blood cells (RBCs) and fresh frozen plasma (FFP) in a 1:1 or 2:1 ratio, with transfusion of platelets and cryoprecipitate to treat consumption; early liaison with haematology is recommended. For less severe bleeding, a 4:1 RBC-to-FFP ratio may be used. Maintaining platelets with transfusion to a level of ≥50 $\times 10^9$/L is recommended; platelet dysfunction may be improved with desmopressin (DDAVP). Fibrinolysis is common and easily assessed by TEG or euglobulin lysis time. Treatment of fibrinolysis with epsilon-aminocaproic acid or tranexamic acid is indicated if bleeding persists despite thrombocytopenia and clotting factor correction, in the absence of disseminated coagulopathy. When the partial thromboplastin time is excessively prolonged, use of protamine, even without previous heparin administration, may help counteract endogenous heparin-like compounds.

For gastrointestinal bleeding, correction of coagulation abnormalities must be accompanied by antibiotic therapy, usually iv ceftriaxone or po norfloxacin, and vasoactive medications for up to 5 days. Terlipressin 2 mg 4-hourly, somatostatin 250–500 μg/hour, or octreotide 50–100 μg/hour may be used according to local protocols. Early transjugular intrahepatic portosystemic shunt (TIPSS) may be beneficial in Child–Turcotte–Pugh class C patients (>13 points) or class B with active variceal bleeding [1].

Cirrhosis patients carry a risk of venous thromboembolism, even in the presence of coagulopathy. In the absence of contraindications, cirrhosis patients in intensive care should have mechanical DVT prophylaxis, but routine pharmacological prophylaxis is not currently recommended [1].

Neurological system

Hepatic encephalopathy (HE) is treated with lactulose and non-absorbable antibiotics [1]. Titrating the lactulose dose to two or three semi-formed stools per day, while avoiding diarrhoea (and potential electrolyte abnormalities) is current practice. When advanced encephalopathy or mechanical ventilation precludes oral administration, administration should be via nasogastric tube or retention enema. The non-absorbable antibiotic rifaximin improves recurrent HE in outpatients by reducing ammonia-producing enteric bacteria, but it is unclear whether this applies to ICU patients. Furthermore, most ACLF patients will receive broad-spectrum antibiotics and rifaximin may not offer added benefit. Equally, probiotics improve minimal HE in outpatients, but are

untested in the ICU. Avoidance of sedative agents is strongly recommended. Cerebral oedema is described in ACLF; if suspected, mannitol is administered with possible invasive intracranial pressure monitoring [1]. Suggested future directions of therapy for HE include examining the effect of improving circulatory dysfunction with vasoconstrictors and albumin, or vaptans to improve hyponatremia.

Respiratory failure

Endotracheal intubation for airway control is mandatory in patients with a Glasgow coma score ≤8 and/or during active upper gastrointestinal bleeding (for safe endoscopic therapy) [1]. Lung protective ventilation strategies are recommended for respiratory failure and acute lung injury, with low tidal volumes (~6 mL/kg body weight), positive end-expiratory pressure to maintain oxygenation, and plateau pressures <30 cmH_2O to prevent further lung injury. Many patients can be managed with intermittent opiates with prompt extubation when able to protect their airway; sedatives being liver-metabolized often prolong altered consciousness or may precipitate HE. Prolonged translaryngeal intubation should be avoided, while percutaneous tracheostomy can be performed with low risk, even with coagulopathy. All patients should undergo early mobilization to prevent critical care weakness [1].

Hepatic hydrothorax may cause pulmonary or haemodynamic compromise and may therefore necessitate thoracocentesis. If the patient is not compromised, sodium restriction and diuretics may be sufficient. If refractory, TIPSS insertion should be considered. Long-duration chest drain placement carries a risk of hypovolaemia or infection and is best avoided [1].

Nutritional support

This is necessary for patients unable to maintain an adequate intake, a commonplace occurrence in ACLF. A low-protein diet neither improves outcome of HE nor the rate of recurrence so a normal intake (0.8–1.2 g/kg/day) is recommended [1]. Protein requirements may be modified on the basis of the degree of catabolism and presence of renal failure. In patients receiving continuous renal replacement therapy, the goal of protein supplementation is to prevent a negative nitrogen balance. The enteral route is preferred, but aggressive enteral feeding in patients with ileus may worsen bacterial translocation and sepsis; mixed enteral and parenteral nutrition is probably a better option. Parenteral nutrition must be administered via a dedicated line to reduce the incidence of infection.

A functioning liver is critical for glucose homeostasis. In advanced liver disease, glycogen storage may become impaired, predisposing the patient to hypoglycaemia. Nutritional support may require modification to maintain normoglycaemia [1].

Deficiencies in water-soluble vitamins (vitamin B complex and C) are common in alcoholic cirrhosis in particular, but also occur in non-alcoholic liver disease. The risks of Wernicke's encephalopathy and Korsakoff's dementia are well described in thiamine-deficient alcoholic patients, but are also seen in hepatitis C-related cirrhosis. Therefore, iv thiamine administration (100 mg daily for 3–5 days) is recommended for all cirrhotics as gut absorption may be unreliable [1].

Low levels of trace elements such as selenium and zinc are described in cirrhosis. Supplementation with zinc improves glucose disposal in cirrhotics and although deficiency is considered to precipitate HE, trials of supplementation have shown conflicting results. Nevertheless, zinc replacement at a dose of 25–50 mg elemental zinc tds is recommended, but insufficient evidence exists to recommend routine replacement of selenium.

Metabolic abnormalities

As mortality is increased in cirrhosis patients when blood glucose rose above a threshold of 146 mg/dL (8.1 mmol/L), it is recommended that blood glucose be maintained at or below this value. However, cirrhosis patients are more likely to develop hypoglycaemia and so great care must be taken with glycaemic control.

Relative adrenal insufficiency occurs in 60–80% of critically-ill cirrhosis patients. These patients may have improved cardiovascular parameters and even improved mortality following steroid therapy. However, routine administration of steroids to cirrhosis patients admitted to ICU was not beneficial in a recent controlled trial. Therefore, in the absence of adrenal insufficiency, steroid therapy is not recommended [1].

Communication

Regular, effective, and compassionate communication with the patient and family members is extremely important to update any changes in condition and provide a realistic prognosis. When multiple referring and consulting services are involved, a cohesive plan of care must be provided to avoid confusion and facilitate informed decision-making. To minimize futile care, daily reassessment of the patient's response to intensive care is needed. Given the extremely poor prognosis, if multisystem organ failure persists after several days' treatment, and especially when there is no option for liver transplantation, a change of emphasis to palliative care should be strongly considered.

Referral to a liver transplant centre

The determination of suitability for liver transplantation is beyond the scope of this chapter. All patients admitted to ICU with complications of cirrhosis warrant consultation with a transplant centre to determine whether they fulfil criteria and for expert advice. Two recent retrospective analyses of patients undergoing transplantation demonstrated that ACLF pre-transplant did not lead to worse post-transplant outcomes [1].

Liver support devices

Liver support devices based on detoxification of the patient's blood are intended to support liver function until the native liver recovers, or as a bridge to transplantation. There are two main types of liver support devices—artificial livers (acellular devices, e.g. albumin dialysis) and bioartificial devices (containing human, animal, or transformed cells) [3]. Studies have demonstrated attenuation of the systemic inflammatory response, improved cholestasis, and HE suggesting that liver support devices may improve quality of life and perhaps reduce hospital stay. However, a recent meta-analysis demonstrated no survival benefit in ACLF [4]. Liver support devices have, at this time, failed to gain US Food and Drug Administration approval. Further clinical trials are required to determine whether subsets of patients might benefit from these devices.

Conclusion

The predicted increases in the global health burden of cirrhosis due to chronic viral hepatitis, alcohol and non-alcoholic fatty liver disease will inevitably lead to increased demands for ICU admission to support organ failure. Management of these patients represents a substantial challenge in an era of liver transplantation severely limited by donor organ shortage. ACLF is associated with a very poor prognosis and early identification of the precipitating cause is essential to successfully attempt to reverse decompensation. Other management is largely supportive with close attention to renal dysfunction particularly important. Liver support devices may play a role in certain subgroups of patients in the future, but are not recommended at present. An improved understanding of pathophysiology and precipitating factors to identify who may develop ACLF, associated with aggressive early management may possibly improve outcome.

SECTION 7

Nutrition

PART 7.1

Physiology

CHAPTER 201

Normal physiology of nutrition

Annika Reintam Blaser and Adam M. Deane

Key points

- Ingested carbohydrate, glycogenolysis, and gluconeogenesis are essential for function of brain and anaerobic tissues that depend on glucose as their main energy source.
- Fat is the most energy-rich nutrient, but most of ingested lipids will be stored in adipose tissue because the oxidative capacity for lipids is low.
- During periods of inadequate energy delivery, ingested or endogenous proteins are diverted into glucose metabolism, and this provides a rationale to deliver more protein during these periods.
- Basic metabolic rate (BMR) is the largest component of total daily energy requirements, even in the case of very high physical activity or acute illness.
- Daily energy requirements range from 1800 to 2800 kcal/day or 25 to 30 kcal/kg body weight (BW)/day roughly—carbohydrates should provide 55–60%, lipids 25–30%, and proteins 10–15%.

Body composition

Water (approximately 60% in adult males and 50% in females [1]), protein, minerals, and fat are the main components of human body. Essential fat is contained in bone marrow, the heart, lungs, liver, spleen, kidneys, intestines, muscles, and central nervous system. Fat located in adipose tissue is called storage fat. The two-component model distinguishes between fat and fat-free mass (FFM), while the three-component model further divides FFM into body cell mass and extracellular mass [2]. **Lean body mass** is an indirect estimation of the weight of bones, muscles, ligaments, and internal organs, which can be calculated using various equations [3].

Direct methods of assessing body composition, such as skinfolds, bioelectrical impedance analysis, and hydrostatic weighing are not routinely used in the critically ill.

Estimation of nutritional status

Body mass index (BMI) = weight (kg)/height (m) and provides a rough estimation of nutritional status [2]. A limitation of BMI is that the calculation does not distinguish between muscle and fat mass. A BMI of 18.5–24.9 kg/m^2 is considered 'normal' regardless of age or population [1]. BMI has a U-shape relation to morbidity and mortality [2]. In persons >60 years old being slightly heavier (BMI 26–27) is associated with the longer life expectancy [2]. While being underweight is associated with poorer outcomes in the critically ill, obesity does not appear to be harmful (and may be beneficial) [4].

Estimation of the **ideal body weight** [5] is often inaccurate, but the range may be useful and can be calculated (Broca's index):

$$\left(\text{Height}\,(\text{cm}) - 100\right) \pm 15\% \text{ for women or } 10\% \text{ for men} \qquad \text{[eqn 1]}$$

Clinical examination and laboratory tests

General **clinical examination** of skin, hair, eyes, gums, tongue, bones, muscles, and thyroid gland tends only to reveal signs in cases of marked malnutrition or vitamin/mineral deficiencies.

Laboratory tests such as blood haemoglobin, total lymphocyte count, glucose, serum albumin, prealbumin, transferrin, total protein measurements, and calculation of nitrogen balance have limitations, but have been used. Nitrogen balance is considered the most dynamic nutritional indicator.

Essential nutrients: substrate and energy metabolism

Essential nutrients are substances that are not synthesized (or are synthesized in too small amounts) within the body and must, therefore, be ingested or administered. They include essential fatty acids, essential amino acids, vitamins, and dietary minerals.

Energy

Energy is derived from three major categories of macronutrient—protein, carbohydrate, and lipids—and is released by breaking down carbon–carbon bonds created in plants via photosynthesis. Energy requirements to maintain stable weight can be estimated, using calculations or measured using calorimetry.

Oxidative (burning for energy) and **non-oxidative** (storage, synthesis) substrate metabolism occur to a different extent according to the type of macronutrient and state of energy stores [2]. **Respiratory quotient (RQ)** is used to describe oxidative substrate metabolism.

Carbohydrates

Carbohydrates are compounds comprised of carbon, hydrogen, and oxygen. Depending on the composition of these molecules, carbohydrates are divided into mono-, di-, oligo-, and polysaccharides. While carbohydrates are non-essential nutrients, they comprise a substantial proportion of calories (4.1 kcal/g) in a normal diet [1]. In plants, carbohydrate is stored as starch, whereas in animals it is stored as glycogen.

Table 201.1 Nutritional requirements in adults

Nutrient	Role	Daily needs	Deficiency	Abnormalities in ICU
Macronutrients	Energy, structure, all functions	No absolute daily requirements exist	Starvation	
Carbohydrates	Major energy source, energy storage and transport, structure	55–60% of calories, max. 4 g/kg BW at rest	Hypoglycaemia, ketoacidosis	Hyperglycaemia (insulin resistance, counter-regulatory hormones)
Lipids	Energy storage, cell membrane structure, signalling molecules	25–30% of calories	Malabsorption of fat-soluble vitamins	Hyperlipidaemia with excessive parenteral nutrition and propofol
Proteins	Enzymes, structure, signalling, immune response	10–15% of calories 0.8 g/kg BW	Kwashiorkor, cachexia	Protein energy wasting occurs frequently
Vitamin	**Role**	**RDA**	**Deficiency**	**In ICU**
A (retinol)	Retinal pigment	Male 1000 µg female 800 µg	Night blindness, follicular hyperkeratosis	
B1 (thiamine)	Coenzyme in decarboxylation of pyruvate and alpha-keto acids	Male 1.5 mg, female 1.1 mg	Beriberi, Wernicke's encephalopathy	Threshold for thiamine administration should be low
B2 (riboflavin)	Coenzyme for oxidative enzymes	Male 1.7 mg, female 1.3 mg	Mouth ulcers, normocytic anaemia	
B3 (niacin) also vitamin PP or nicotinic acid	Coenzyme, precursor for NAD and NADP	Male 19 mg, female 15 mg	Pellagra, neurological symptoms	
B6 (pyridoxine)	Coenzyme in synthesis of amino acids, haeme, neurotransmitters	Male 2.0 mg, female 1.6 mg	Muscle weakness, depression, anaemia	
B12 (cobalamin)	coenzyme (deoxyribonucleotids), formation of erythrocytes, myelin	2 µg	Neurological symptoms	With pernicious anaemia (lack of intrinsic factor)
C (ascorbic acid)	Cofactor in collagen synthesis	60 mg	Scurvy	Antioxidant effect, cave oxalosis
D (1,25-cholecalciferol)	Ca^{2+} absorption and metabolism	5–10 µg	Rickets	
E (alpha-tocopherol)	Antioxidant	Male 10 mg, female 8 mg	Peripheral neuropathy	Antioxidant effect
K	Clotting, synthesis of prothrombin, factors VII,IX,X	Male 70–80 µg female 60–65 µg	Coagulopathy	
Biotin (also vitamin B7 or H, or coenzyme R)	Cofactor for several carboxylase enzymes; cell growth	30–100 µg	Neurological symptoms, alopecia, conjunctivitis, dermatitis	
Folate (vitamin B9)	Necessary for synthesis of DNA, haemopoesis	Male 200 µg female 180 µg (pregnancy 400)	Megaloblastic anaemia, peripheral neuropathy, neural tube defects	
Panthothenic acid (vitamin B5)	Synthesis of CoA. Carbohydrate, and fat metabolism	4–7 mg	Gastrointestinal and neurological symptoms	
Mineral	**Role**	**RDA**	**Deficiency**	**In ICU**
Calcium	Bone, intracellular signalling	800–1200 mg	Osteoporosis, arrhythmia hypertension	
Chromium	Cofactor	50–200 µg	Impaired glucose tolerance, peripheral neuropathy	Deficiency reported during long-term parenteral nutrition
Copper	Cofactor (oxidative phosphorylation, neurotransmitter synthesis etc.)	1.5–3 mg	Myelodysplasia, anaemia, leucopenia, neurological symptoms	Deficiency after gastric bypass. Reduce replacement in liver failure
Iron	Haemoglobin and cytochromes	Male 10 mg, female 15 mg	Microcytic anaemia, mucosal atrophy	

(*continued*)

Table 201.1 Continued

Nutrient	Role	Daily needs	Deficiency	Abnormalities in ICU
Iodine	Thyroid hormones	150 µg	Goitre, hypothyroidism	
Magnesium	Complex with ATP	Male 350 mg, female 280 mg	Muscle weakness, GI, and cardiac symptoms	Deficiency common and associated with major adverse outcomes
Manganese	Antioxidant	2–5 mg		Reduces replacement in liver failure
Molybdenum	Cofactor	75–250 µg	Liver dysfunction	
Phosphorus	Major component of the skeleton, nucleic acids, and ATP	800–1000 mg		Potentially catastrophic reduction during refeeding syndrome
Potassium	Membrane potential	At least 3510 mg (conditional recommendation by WHO)	Arrhythmias	Often life-threatening hyper- or hypo-K, narrow therapeutic/normal range
Selenium	Antioxidant	Male 70 µg, female 55 µg	Cardiomyopathy	Antioxidant effect
Zinc	Antioxidant, cofactor	Male 15 mg, female 12 mg	Skin lesions, loss of appetite	Antioxidant effect

RDA, Recommended daily allowance.

Adapted from a table published in *Medical Physiology*, Second Edition, Boron WF and Boulpaep EL, Copyright Elsevier 2012.

As an energy source, glucose is oxidized to CO_2 and water:

$$C_6H_{12}O_6 + 6O_2 + 32ADP + 32P -> 6\,CO_2 + 6H_2O + 32ATP + \text{heat} \quad (RQ = 6CO_2 / 6O_2 = 1.0) \qquad \text{[eqn 2]}$$

At rest, the maximum oxidative capacity is approximately 4 g glucose/kg BW/day [2]. If the glucose intake is greater non-oxidative metabolism occurs, resulting in glycogenesis (glycogen store is limited to 200–500 g; storing consumes about 6% of energy stored in glucose) and, after reaching the limit, in lipogenesis (storing costs 23% of energy) [6]. As an isolated energy source blood glucose covers energy needs for about 30 minutes, whereas glycogen would last for approximately one day [2]. Glycogen is stored in hydrated form, making it less energy-efficient, but easily available. Hepatic or muscle glycogenolysis occurs rapidly in response to hypoglycaemia or anaerobic demands.

Gluconeogenesis is the synthesis of glucose from non-hexose precursors (lactate, pyruvate, intermediates of the citric acid cycle, 18 of 20 amino acids and glycerol) [1]. Leucin and lysine together with fatty acids are not gluconeogenic, but ketogenic. Their breakdown-product is acetyl coenzyme A (CoA), which cannot generate pyruvate or oxalo-acetate. Gluconeogenesis is essential for the brain and anaerobic tissues (blood cells, bone marrow, renal medulla) that depend on glucose as their main energy source [1], but is energy-expensive, consuming 24% of energy contained in amino acids (AA) [6].

Lipids

Lipids are hydrophobic compounds that are soluble in organic solvents such as acetone.

Lipids contain 9.4 kcal/g of energy and can be ingested as triglycerides, sterol esters or phospholipids [1]. To generate energy, fatty acids are oxidized to CO_2 and water.

$$C_{15}H_{31}COOH\,(\text{palmitic acid}) + 23O_2 + 106ADP + 106P -> 16CO_2 + 16H_2O + 106ATP + \text{heat} \quad (RQ = 16CO_2/23O_2 = 0.70) \qquad \text{[eqn 3]}$$

In resting humans the oxidative capacity for lipids is 0.7 g/kg BW/day [2]. Greater amounts of ingested lipid will be stored as triglycerides in fat tissue. Fat constitutes approximately 20% of body weight, and the standard triglyceride store has the capacity to cover the body's energy requirements for about 2 months.

Ketone bodies are produced when accelerated oxidation of fatty acids leads to incomplete breakdown, producing acetyl CoA faster than the citric acid cycle can utilize it [1]. Ketone bodies (acetoacetate, β-hydroxybutyrate, and acetone) may serve as an alternative energy resource, e.g. during starvation up to 50% of brain energy demands might be met via ketone bodies [2].

Protein

Nitrogen differentiates protein from carbohydrates and fats. The major source of endogenous protein is muscle, which is converted into energy via complex metabolic pathways. When AA, either endogenous proteins or ingested, are metabolized to CO_2 and water, 4.3 kcal/g of energy can be released [1]. Protein metabolism in cells additionally results in the production of energy-containing metabolites (urea, ureic acid, and creatinine). The RQ for protein oxidation is 0.80–0.85 [1]. Protein stores are about 14% of body weight, but only half of it is available as an energy source, lasting for 10 days approximately. In health, protein catabolism contributes less than 5% of energy requirements, but this increases to 15% during starvation. The body constantly breaks down proteins to AAs and synthesizes other proteins according to the current needs of the body (protein turnover). Nine out of 20 AAs are essential—the body cannot synthesize them at sufficient rates for long-term survival and they must be ingested to replace the proteins oxidized during daily turnover. Excess protein is converted to glycogen or triacylglycerols [1].

To maintain nitrogen balance in an average adult individual, ingestion of 0.6–0.8 g/kg BW/day of protein is needed [2]. However, during periods of inadequate energy delivery greater amounts of protein are diverted into glucose metabolism and, in catabolic states, there is a marked increase in endogenous protein breakdown. Accordingly, more protein either ingested or administered may be beneficial during these periods [7].

Nitrogen (N) balance is the sum of protein degradation and protein synthesis, reflecting the changes in protein stores where:

$$\text{N Balance} = \text{N intake} - \text{N losses},$$

$$\text{N intake} = \text{protein intake}\ (\text{g/day})/6.25,\ \text{and}$$

$$\text{N losses} = \text{urinary urea N}\ (\text{UUN}),\ \text{g/day, determined from a 24-hour urine collection)} + 4\ \text{g miscellaneous other N losses from skin, mucosa and with faeces.} \quad \text{[eqn 4]}$$

N balance is used to estimate current protein requirements. Positive or negative N balances indicate anabolic or catabolic states respectively.

As in patients with renal replacement therapy (RRT) measurement of UUN is not applicable; the **total nitrogen appearance (TNA)** is used to express nitrogen losses [8]:

$$\text{TNA in a patient with RRT} = \left[\begin{array}{l}\text{urea nitrogen loss +}\\ \text{AA nitrogen loss during RRT}\ (\text{g})\end{array}\right] + \left[\begin{array}{l}\text{change in interdialytic blood urea}\\ \text{nitrogen}\ (\text{BUN})\ (\text{g/L}) \times \text{total body water}\ (\text{L})\end{array}\right] \quad \text{[eqn 5]}$$

Protein energy wasting [9] due to inadequate protein intake and high catabolism is thought to occur frequently in the critically ill. While preventing or limiting protein deficiency in this group is often proposed as beneficial, it is not yet established that such an approach improves outcomes.

Other

Other essential nutrients include inorganic elements like calcium, potassium, iodine, iron, trace elements (dietary minerals that are needed in very small quantities) and vitamins, which are necessary for normal functioning of the body. The role, recommended daily allowances and signs of deficiency of these essential vitamins and minerals are presented in Table 201.1.

Vitamins

Vitamins are divided into water-soluble (B,C) and fat-soluble (A, D, E and K) groups. Bonds between fat-soluble vitamins with proteins are broken by the acidity of gastric juice and proteolysis. Assimilation of fat-soluble vitamins relies on lipid absorption and their deficiency occurs in various fat malabsorption states.

Thiamine (B_1) with its phosphorylated derivatives plays a fundamental role in energy metabolism and is used in the biosynthesis of the neurotransmitters. Its best-characterized derivate thiamine pyrophosphate is a coenzyme in the catabolism of sugars and amino acids. Thiamine derivatives and thiamine-dependent enzymes are present in all cells of the body, but the nervous system and the heart are particularly sensitive to its deficiency. Thiamine deficiency may occur because of concomitant chronic disease or alcoholism and can lead to severe neurological impairment and contribute to increased mortality [10].

Vitamin K is pivotal for synthesis of coagulation factors VII, IX, X, protein C and protein S in liver, acting as a co-factor for carboxylation. Its deficiency occurs with fat malabsorption, but also during severe bleeding (disseminated intravascular coagulation). Previous treatment with vitamin K antagonists, blocking carboxylation of prothrombin (factor II), factors VII, IX and X, and making their complexes with Ca^{2+} and therefore usage for coagulation impossible, is common in hospitalized patients.

Supplementation of **vitamins E and C** has been proposed as having beneficial antioxidant effects in the critically ill [11]. This has yet to be established and particularly in patients with renal failure excessive vitamin C may lead to oxalosis.

Minerals

Calcium is necessary for the structure (calcium phosphate in bones), signalling, and enzymatic processes (co-enzyme for clotting factors, pre-synaptic release of acetylcholine) in the body.

Magnesium is essential for energy in every cell type in organism, as ATP, the main source of energy in cells, must be bound to a magnesium ion in order to be biologically active.

Supplementation of minerals such as **selenium** and **zinc** has been described in the critically ill and warrants further study [12].

Next to the essential nutrients food includes fibres and other ballast substances, carotinoides, bioflavonoids etc. considered important for health, but their functions are clarified incompletely.

Energy consumption

Estimation of energy consumption

Basal metabolic rate (BMR) is an estimation of metabolism, measured under standardized conditions in the absence of stimulation. **Resting metabolic rate (RMR)** is measured during less strict conditions and is therefore higher than BMR [1]. BMR and RMR are measured by gas analysis through either **direct** (the body is positioned in a chamber to measure the body's heat production) or **indirect** (CO_2 production is measured) **calorimetry** [13].

BMR can be estimated by a number of calculations of **Basal Energy Expenditure (BEE)** with Harris-Benedict equation being the most frequently used in critical care:

Adult males:

$$\text{BEE}\ (\text{kcal/day}) = (13.8 \times \text{weight in kg}) + (5 \times \text{height in cm}) - (6.8 \times \text{age}) + 66.5. \quad \text{[eqn 6]}$$

Adult females:

$$\text{BEE}\ (\text{kcal/day}) = (9.6 \times \text{weight in kg}) + (1.8 \times \text{height in cm}) - (4.7 \times \text{age}) + 655. \quad \text{[eqn 7]}$$

As body weight is the major factor that determines BEE, a simplified estimate of 25 kcal/kg BW/day is often used and our experience is that the latter approach is adequate for clinical purposes. The BMR is the largest component of total daily energy requirements, even in case of very high physical activity, as well as in the most hypermetabolic patients. The various estimations of stress/activity factors available to calculate the total energy expenditure (TEnE = BEE × stress/activity factor) tend to overestimate the TEnE in ICU patients, as measured TEnE is often close to calculated BEE [6].

CHAPTER 202

The metabolic and nutritional response to critical illness

Linda-Jayne Mottram and Gavin G. Lavery

Key points

- The metabolic response to critical illness is biphasic, the acute stage being accompanied by increased hypothalamic pituitary function and peripheral resistance to effector hormones.
- The acute phase has been considered adaptive, increasing the availability of glucose, free fatty acids, and amino acids as substrates for vital organs.
- Prolonged critical illness results in damped hypothalamic responses that are implicated in the critical illness wasting syndrome.
- Cytokines can stimulate the hypothalamic pituitary axis directly as part of the stress response in critical illness.
- Gastrointestinal failure may in part be a neuroendocrine phenomenon, with disordered hormonal and enteric nervous system responses.

Introduction

The metabolic response to critical illness is complex and affects every body system. The response to acute critical illness differs from the response to more prolonged states. These differences or the dynamic complexity of the neuroendocrine changes themselves, may explain the failure of pharmacological manipulation to date. The gut response to critical illness is also an example of neuroendocrine derangement. The interaction between body systems becomes apparent when gastrointestinal failure and inadequate nutrition combine to exacerbate the catabolic state. Ultimately, the consequence is to lengthen the illness, prolong intensive care stay, and hamper the recovery process.

The somatotrophic axis

Normal physiology

Human growth hormone (GH) is produced in the somatotrophic cells of the anterior pituitary in response to hypoglycaemia, exercise, sleep, high protein intake, and acute stress. This process is regulated by the stimulatory effect of growth hormone releasing hormone (GHRH) from the hypothalamus and also by the hunger-stimulating hormone, ghrelin. Inhibitory effects on GH release occur via somatostatin secretion from the hypothalamus. GH acts directly on the tissues causing lipolysis, anti-insulin effects, sodium and water retention, and immunomodulation. It also acts indirectly via hepatic production of insulin-like growth factor 1 (IGF-1) to bring about protein synthesis and thus protect lean body mass.

Acute critical illness

Serum GH levels are elevated overall and demonstrate increased pulsatility. However, IGF-1 levels are lower and GH receptor expression is reduced, which together produce a state of peripheral GH resistance. Energy-consuming anabolic processes are halted, permitting the release of amino acids for use as an energy substrate. The direct effects of lipid breakdown and antagonism of insulin are permitted, which again favourably releases energy reserves in the acute phase of critical illness [1].

Prolonged critical illness

Levels of GH are reduced with a more erratic and less pulsatile pattern of secretion, a process that is compounded by low ghrelin levels. Despite less peripheral resistance to GH, a state of relative deficiency persists and contributes to critical illness wasting [2]. The return of peripheral responsiveness to GH was thought to provide a therapeutic target for exogenous GH administration, but actually results in higher morbidity and mortality. These findings may be a function of timing of GH administration and remain under investigation. Greater abnormalities are seen in the male GH axis, which has been theorized to account for some gender differences in ICU outcome.

The thyrotropic axis

Normal physiology

In health, thyrotropin-releasing hormone (TRH) is released from the hypothalamus and in turn the anterior pituitary secretes thyroid-stimulating hormone (TSH), with negative feedback via the thyroid hormones triiodothyronine (T3) and thyroxine (T4).

Acute critical illness

The adaptive response of the thyroid to critical illness is an energy conservation strategy, reducing expenditure on metabolic processes. It is often called 'non-thyroidal illness syndrome', but may also be known as 'low T3 syndrome' or 'sick euthyroid syndrome'. Laboratory parameters include low serum T3 levels, increased reverse T, while TSH and free T4 remain largely normal [3].

Low T3 levels are partly due to reduced peripheral conversion from T4. The enzyme 5'-monodeiodinase catalyses this peripheral

conversion and accounts for 80% of free T3 in the circulation. This enzyme is inhibited during the stress response and in particular by glucocorticoids. It contains the novel amino acid selenocysteine and so may be affected by selenium deficiency.

Prolonged critical illness

As the illness progresses, free T4 decreases and is a reflection of illness severity. Those with the lowest T3 and T4 levels in critical care have the highest mortality [4]. There is dampening of the normal negative feedback loop. TSH fails to increase and loses its pulsatile secretion pattern, only doing so as the patient starts to recover.

Non-thyroidal illness syndrome is associated with prolongation of mechanical ventilation in the ICU population [5]. Despite the biological rationale for treating such a state of continued relative hypothyroidism, there is little convincing proof of efficacy. Others [6] have argued for treatment with hypothalamic releasing peptides, rather than thyroid hormone per se, but again definitive evidence to support this strategy is lacking.

The adrenocortictrophic axis

In health, corticotrophin-releasing hormone (CRH) from the paraventricular nucleus is carried in the hypophyseal-portal tract and stimulates release of adrenocorticotrophic hormone (ATCH). Cortisol is produced in the zona fasiculata of the adrenal cortex and a negative feedback loop exists to regulate secretion and synthesis.

Acute critical illness

Plasma ACTH and cortisol levels increase with loss of the normal circadian rhythm. The hypothalamus is stimulated by a direct effect of cytokines. The typical effects of glucocorticoids are manifest in order to maintain homeostasis after the stressful insult. These include use of alternative energy strategies, such as mobilization of amino acids from extrahepatic tissues, lipolysis, and subsequent utilization of glycerol, and gluconeogenesis in the liver. They have a regulatory role in the acute inflammatory response, by blocking cytokine gene expression and up-regulating specific anti-inflammatory processes. The cardiovascular effects of glucocorticoids include the maintenance of vascular responsiveness to catecholamines, endothelial integrity, and intravascular volume via their mineralocorticoid actions [7]. These anti-inflammatory and vascular effects explain the biological rationale for the use of low-dose corticosteroids in septic shock [8].

Prolonged critical illness

When critical illness is protracted, plasma cortisol levels remain high, but ACTH decreases. It is likely that this effect is mediated via peripheral mechanisms, such as substance P, atrial natriuretic peptide, endothelin, and cytokines. The adverse effects of sustained hypercortisolism, such as muscle wasting, hyperglycaemia, hypokalaemia, poor wound healing, and psychiatric sequelae become apparent and can be seen as a maladaptive response [9,10].

Sex hormones and prolactin

In health gonadotrophin-releasing hormone (GNRH) is secreted in a pulsatile pattern and stimulates the anterior pituitary to release luteinizing hormone (LH) and follicle-stimulating hormone (FSH) from the gonadotroph cells. In males, LH drives testosterone production in the Leydig cells of the testes

In the acute phase of critical illness, serum testosterone levels are low (in spite of elevated LH levels) and prolactin is high. Low testosterone switches off the anabolic processes that maintain skeletal muscle mass. High oestradiol levels are found—an adaptation that was originally thought to be beneficial as oestrogens inhibit pro-inflammatory cytokine production. Recent findings appear to contradict this and there is an association with increased mortality [11].

In prolonged critical illness there is a state of hypogonadal hypogonadism and prolactin deficiency. T- and B-lymphocytes possess prolactin receptors, requiring it for their function. Hypoprolactinaemia may play a role in the immune paralysis seen in illnesses of longer duration. The use of exogenous dopamine could theoretically suppress prolactin secretion and negatively impact immune function. Despite these concerns and a higher incidence of adverse events in shocked patients treated with dopamine, the evidence falls short of it having an adverse impact on mortality [12].

The role of the autonomic nervous system

The classical 'fight or flight' response is mediated via adrenaline and noradrenaline. A variety of physiological insults, such as pain, hypotension, hypoxia, acidosis, and hypercarbia can stimulate the sympathetic nervous system. Pre-ganglionic sympathetic fibres terminate in the adrenal medulla and cathecholamines are released rapidly from synaptic vesicles. The leukocyte itself can be an additional source of cathecholamines.

Cardiovascular responses occur via B1 receptors and include positive inotropy and chronotropy. Stimulation of the renin-angiotensoin system at the juxta-glomerular cells acts to maintain intravascular volume and tone. B2 receptor activation results in gluconeogensesis and glycongenolysis. B2 stimulation dampens the pro-inflammatory cytokine response and in sepsis it alters the balance of T helper cells from THC1 to THC2. Some regulation also occurs via α-receptors. Alpha-1-mediated vasconstriction acts to maintain blood pressure, but reduced gut perfusion and motility are adverse consequences discussed in 'Loss of Barrier Function'. The parasympathetic response to traumatic and infectious insults is largely anti-inflammatory and occurs through the activation of α7 nicotinic acetylcholine receptors. This acetylcholine-mediated reduction in cytokine production occurs, not only from a direct effect on macrophages, but also indirectly via vagal splenic innervation.

Vitamin D metabolism

Vitamin D deficiency is common in critical illness for two reasons:

- Vitamin D is lost through lack of serum binding proteins in acute illness.
- Many chronic conditions predisposing to critical illness will reduce sunlight exposure and thus synthesis of Vitamin D in the skin.

The clinical consequences of Vitamin D deficiency are bone resorption, hypercalcaemic immune dysfunction, namely reduced innate responses and heightened adaptive responses, such as prolonged hypercytokinaemia [13].

The role of cytokines

Cytokines are intercellular messenger proteins that act on various cell types to bring about pro- and anti-inflammatory responses

during critical illness. They can have local (autocrine or paracrine) or widespread (endocrine) effects.

Cytokines are produced via stimulation of Toll-like receptors (TLRs), which may be a future pharmacological target. At the cellular level, TLRs are activated not only by the presence of microbial proteins as part of the innate immune response, but also by non-infectious insults, such as tissue injury. Here, endogenous intracellular proteins released from dying cells are the trigger, and are known as 'alarmins'. The cell surface TLRs initiate the nuclear factor kappa-beta (NF-κβ) transcription pathway, which ultimately generates cytokine proteins. Note that some cytokines can be released more readily in response to catecholamines with no requirement for gene transcription. Tumour necrosis factor α (TNFα) has a positive effect on NF-κβ and is responsible for triggering further cytokine release, in what is described clinically as the 'cytokine storm'.

There are several cytokine families (Table 202.1) including the interleukins, interferons, tumour necrosis factors, chemokines, and colony-stimulating factors. Burns, tissue trauma, or infection results in a cascade of pro-inflammatory cytokines, of which the key players are TNFα, IL-1, IL-6, and IL-8. Levels of these cytokines correlate with illness severity and outcome. Cytokine gene polymorphisms and aberrant responses to TLR ligands are partly accountable for the individual response to sepsis and other insults. However, despite the wealth of research in this area, modulation of interleukins and TNFα with recombinant pharmacological agents has not been widely successful.

Table 202.1 Effects of cytokines in the inflammatory process

Cytokine	Effects
TNFα	◆ Rises early in response to sepsis and trauma ◆ Activates HPA axis ◆ Induces fever and increases insulin resistance ◆ Major trigger for other cytokine release (IL-1 and IL-6) ◆ Promotes phagocytosis and neutrophil chemotaxis
IL-1	◆ Fever ◆ T cell activation and B cell proliferation ◆ Activates HPA axis and suppresses anabolic activity
IL-6	◆ Major activator of acute phase protein synthesis ◆ B and T cell differentiation
IL-8	Neutrophil chemotaxis and activation
HMGB1	◆ Multiple effects including acting as an alarmin and cytokine ◆ Can be induced via NF-κβ and cell death ◆ Therefore, an initiator and effector of the inflammatory response ◆ Role in vascular endothelium and enterocyte permeability
Macrophage migration inhibitory factor (MIF)	◆ Key link between immune and endocrine system ◆ Expressed by leucocytes and stored intracellularly unlike other cytokines ◆ Secreted by HPA axis in response to stress or infection ◆ Antagonizes the immunosuppressive actions of endogenous steroids

Pathophysiology of the gastrointestinal tract in critical illness

The normal functions of the gastrointestinal (GI) tract extend beyond digestion, absorption, and elimination. Important immune and metabolic functions are performed by the gut, and crucially it forms a barrier between bacteria in the intestinal lumen and the sterile internal milieu.

The GI dysfunction associated with critical illness has been poorly defined and lacked universal terminology until recently [14]. A number of clinical manifestations of GI dysfunction are recognized, including stress ulceration, gastro-oesophageal reflux, intolerance of enteral nutrition, ileus, acalculous cholecystitis, abdominal compartment syndrome, intestinal ischaemia, and gastrointestinal hypermotility.

The pathophysiology of these well recognized clinical phenomena can be explained by the complex interplay between the epithelium, commensal bacteria, and the mucosal immune system [15]. The gut has been described as the 'motor' of multi-organ dysfunction syndrome and a number of key factors in its response to critical illness reinforce that status as a driver of systemic inflammation.

Loss of barrier function

Although perfusion of the gut is autoregulated, the gastrointestinal epithelium is predisposed to ischaemia for anatomical reasons. Macroscopically, endogenous cathecholamines acting on alpha-receptors constrict the splanchic circulation. Arginine vasopressin and angiotensin also contribute to this non-occlusive ischaemia. The small bowel is particularly prone to this.

Microscopically, the mucosa at the tips of the villi are most at risk of hypoxia. A countercurrent blood supply to the metabolically active villus via a central arteriole and network of venules renders it extremely supply dependent. The damaged enterocytes slough off and permit translocation of endotoxins and bacteria. In addition, ischaemia-reperfusion injury and oxidant stress are likely to further exacerbate mucosal injury.

Even in the absence of epithelial cell death, the barrier function of the intestine can be lost through disruption of cellular tight junctions. This paracellular route is another way in which endotoxin and bacteria may enter the circulation or lymphactics, resulting in sepsis or the systemic inflammatory response syndrome. Cytokines are likely to be responsible, with IL-4, interferon-gamma and HMGB-1 being implicated.

Alteration of gut microflora in critical illness can also compromise intestinal barrier function [16]. This shift from commensal bacteria to pathogenic strains can occur as a result of antibiotic use, acid suppression or the illness itself. It is likely that commensal Gram-negative anaerobes provide protection to the mucosa through promotion of mucosal repair, increased mucus production and the induction of selective bactericidal proteins, which preferentially target Gram-positive pathogens.

In the stomach, stress ulceration may be regarded as loss of barrier function and classically affects the gastric fundus. Reduced mucosal prostaglandin synthesis and lower secretion of bicarbonate-rich

mucus by goblet cells is implicated. In fact, gastric acid secretion may not be increased at all in critical illness [17].

Motility disturbances

Up to 50% of critically-ill patients suffer from gastrointestinal motility disorders, the adverse consequences of which include inadequate nutrition and aspiration of gastric contents. Common factors contribute to this problem, including electrolyte imbalance, gut oedema and drugs used in intensive care such as opioids, synthetic cathecholamines and alpha-2 agonists [18]. Although, the contribution of deranged physiology is significant.

Gastrointestinal motility in health is regulated via neural and hormonal mechanisms. Cholecystokinin (CCK), a peptide hormone that normally inhibits gastric emptying, is found at higher levels in critical illness. Peptide YY may also have a role in slowing gastric emptying and small intestine transit in these patients. Neither of these hormones has been exploited pharmacologically in clinical settings, although a CCK anatagonist does exist.

In contrast, motilin and ghrelin act to accelerate gastric emptying, but ghrelin levels are reduced in early critical illness by up to 50%. Erythromycin is a drug with agonist activity at the motilin receptor, hence the rationale for using it to treat feed intolerance. Ghrelin agonists have potential use in the treatment of gastroparesis and appetite stimulation. They may also have a wider role as ghrelin is an endogenous ligand of the GH secretagogue receptor and theoretically could reverse the catabolic state and negative nitrogen balance described previously. In summary, the gut hormone response can be considered like any other endocrine organ dysfunction in the critically ill [19].

The enteric nervous system of the gut contains the largest amount of neuronal cells outside the central nervous system. The myenteric plexus regulates motility while the submucous plexus controls secretory functions and blood flow. The migrating motility complex (MMC) is the collective term for the three phases of motility seen in the small bowel *between* meals, also known as the 'interdigestive' pattern. It has a cleansing effect, sweeping gastrointestinal debris into the colon, but is rendered defective during acute illness and contributes to ileus. The usual 'digestive' motility pattern occurs **after** a meal producing segmentation of the bowel and peristalsis. In critical illness it can be abnormally increased and promotes diarrhoea. Local and systemic factors essentially produce an imbalance between sympathetic and parasympathetic motor inputs as the single common pathway for these clinical manifestations.

PART 7.2

Nutritional failure

CHAPTER 203

Pathophysiology of nutritional failure in the critically ill

Jan Wernerman

Key points

- There is no evidence supporting nutritional supply of calories in excess of energy expenditure in critical illness.
- Early enteral nutrition in critical illness is associated with more favourable outcomes.
- In the acute phase of critical illness parenteral nutritional supplementation is not evidence based.
- The exact time-point when full nutrition should be provided in critical illness is based on individual factors, and not well defined.
- The optimal protein nutrition in critical illness remains to be established.

Background

Nutritional failure in critical illness is poorly defined. The term nutritional failure implies there is a definition of correct nutrition. This is not the case. At best, we know the energy expenditure of the patient together with whole body balance of a number of substances and nutrients. Nevertheless, optimal nutrition should be a part of optimal medical care of the critically-ill patient. There is considerable evidence that nutritional care and metabolic care makes a difference [1]. This is particularly true for overweight and underweight patients, while normally-fed patients have a larger safety margin [2].

There is a dogma that critically-ill patients should be in a positive energy balance. In current guidelines this results in recommendations of 20–25–30 kcal/kg/day [3–5]. The background is not survival advantage demonstrated by randomized controlled trials, but rather studies of nitrogen balances, where whole-body nitrogen economy is more favourable when patients are in a positive energy balance [6]. This concept has historically led to massive overfeeding, which has repeatedly been demonstrated to be harmful for critically-ill patients [1,7,8].

Overall, two extrapolations that are not validated to be true, are commonly used in guidelines for critically-ill patients:

- Findings from post-operative patients have been thought to be valid for all critically-ill patients.
- Measurements and observations made at times not related to the admission to the ICU.

This is particularly troublesome as most post-operative patients have quite different characteristics compared with patients with septic shock, with multi-organ failure, or with mechanical ventilation. Similarly, the time course for an individual patient may change rather dramatically in terms of energy expenditure during a prolonged period of critical illness.

Optimal energy supply

Measurement of energy expenditure by the use of indirect calorimetry has been used for many years. The technique is not easy to use and the availability of indirect calorimetry for critically-ill patients is often limited. Still the most important question is if actual energy expenditure should be the nutritional target calorie-wise? There is limited literature indicating that feeding in excess of energy expenditure is not a very good idea during critical illness. A pilot study with daily measurements of energy expenditure gave a signal of better outcomes compared with protocolized energy intake [9]. In the classic study by Krishnan et al., 33–67% of an arbitrary energy target of 27 kcal/kg/day (9–18 kcal/kg/day) was associated with a better outcome than 67–100% [8]. Another study demonstrated an advantage in hospital mortality when permissive hypocaloric feeding was employed and 58% of an energy target of 20–25 kcal/kg/day was compared with 71% of the energy target among the controls [10]. None of these studies properly characterized the temporal relation to ICU admission. The EPaNIC study suggests delayed parenteral nutritional supplementation shortens ICU stay and prevents infections [1]. In another classic study, Sandström et al. demonstrated full parenteral nutrition following elective surgery is a disadvantage, while parenteral nutrition may be an advantage for patients developing post-operative complications [11]. Again, in this study, the temporal relationship of extraparenteral nutrition to the course of critical illness was not well defined.

Underfeeding

In epidemiology, malnutrition is strongly associated with an unfavourable outcome. This is true also in critical illness, where the highest mortality is seen in the cohort of patients with a BMI < 20 [2,12]. The possible benefit of nutritional support in this high risk group of patients is not very strong. Observational data indicate an advantage, but again the relation between admission and treatment has been poorly characterized. Within the EPaNIC study patients with BMI < 17 were excluded, although patients with BMI > 17, but with a high nutritional risk score [13], did not benefit from early parenteral nutrition supplementation [1]. This is clearly an

area where more evidence is badly needed, as depleted underweight patients with limited physiological reserve are very vulnerable. Optimal nutrition is therefore particularly important for these patients.

Overfeeding

A caloric surplus above energy expenditure leads to fat accumulation and is well characterized in healthy individuals, as well as in critical illness [7]. The crucial question is if a marginal surplus of calories is a disadvantage as compared with hypocaloric feeding? It is probably important to differentiate between the acute phase of critical illness and the chronic phase. Indirect evidence suggests marginal overfeeding is harmful, particularly in the early phase of critical illness [1,8,10]. The positive results obtained when employing early enteral nutrition [14] may be interpreted as a beneficial effect, directly related to nutrition in the gut at an early time-point. An alternative interpretation of the results is that tolerance of early enteral nutrition selects patients with sufficient reserve to tolerate feeding in the early phase of critical illness. As success rate of enteral feeding will always have a large scatter, these questions of interpretation will always remain.

A mechanistic hypothesis concerning the harmful effects of full feeding in the early phase of critical illness is the inhibited autophagy as a result of feeding. Autophagy represents the necessary turnover of cellular structures and body proteins. Insufficient autophagy is frequently seen in muscle and liver tissue of critically-ill patients and proteins that are normally eliminated by autophagy are accumulated [15]. Early feeding and insulin therapy are potent inhibitors of autophagy [16], while blood sugar control offers a possibility to eliminate the inhibition. More research to clarify the mechanisms behind the negative effects of marginal overfeeding during the early phase of critical illness is needed.

Optimal protein supply

Available evidence concerning the protein or amino acid requirements of ICU patients is sparse and not very recent [6,17]. In summary, an amino acid supply of more than 0.2 g nitrogen/kg/day does not improve nitrogen balance if the energy provided is on the level of energy expenditure. Techniques to estimate whole-body protein content have insufficient precision and proxy measures, such as nitrogen balance or protein turnover, are not always easy to interpret [18]. The obvious increased losses associated with continuous renal replacement therapy have attained special interest [19]. This group of patients in the ICU are at particular risk to be under-fed in terms of proteins and/or amino acids.

Several authors who have reviewed this area recently recommend not less than 1.5 g of protein/kg/day for critically-ill patients [20], which is more than what is usually given today. However, the shortage of solid evidence and the poorly-understood underlying mechanisms regulating protein economy in critical illness are underlined.

Conclusion

Nutritional failure implies there may be a concept of correct or optimal nutrition. Today sufficient knowledge is not at hand to define such optimal nutrition in critical illness. Over time in longstanding critical illness malnutrition develops, which may be attenuated or delayed by nutrition therapy. On the other hand, overfeeding in the very early phase of critical illness may be detrimental for the patient. Knowledge is particularly sparse concerning the optimal protein intake during critical illness.

CHAPTER 204

Assessing nutritional status in the ICU

Pierre-Yves Egreteau and Jean-Michel Boles

Key points

- All the traditional markers of malnutrition lose their specificity in the sick adult as each may be affected by a number of non-nutritional factors.
- Nutritional assessment is required for patients presenting with clinical evidence of malnutrition, patients with chronic diseases, patients with acute conditions accompanied by a high catabolic rate, and elderly patients.
- The initial nutritional status and the extent of the disease-related catabolism are the main risk factors for nutrition related complications.
- Muscle function evaluated by hand-grip strength and serum albumin provide an objective risk assessment. Calculating a nutritional index is helpful in subsets of patients to determine complication risk and the need for nutritional support.
- A strong suspicion remains the best way of uncovering potentially harmful nutritional deficiencies.

Introduction

Normal nutritional status is a key element in the ability to overcome critical illness. Normal body composition and function are maintained in adults by a daily diet providing nutrients meeting the needs of the individual.

Why assess nutritional status?

Nutrition and disease interact in several ways. Decreased nutrient intake, increased body requirements, and/or altered nutrient utilization are frequently combined in critically-ill patients. The frequency of malnutrition in hospital in-patients has been estimated to be between 30 and 50% of both medical and surgical patients.

There is an established relationship between initial nutritional status and in-hospital morbidity and mortality [1]. Many complications are related to protein energy malnutrition (PEM): increased nosocomial infection rates due to diminished immune competence, delayed wound healing due to decreased ability to repair tissue, delayed weaning from mechanical ventilation due to altered vital functions, and frequent depression and psychological disturbances.

Assessing nutritional status pursues several goals—determination of nutritional deficiencies and evaluation of risk factors of nutrition-related complications that could affect patient outcome, evaluation of the need and potential value of nutritional support, and monitoring the efficacy of and therapeutic response to nutritional support, including tolerance.

An international committee proposed a nomenclature based on recognition of acute systemic inflammatory response [2]. The aetiology-based malnutrition definitions include 'starvation-associated malnutrition':

- When there is chronic starvation without inflammation.
- 'Chronic disease-associated malnutrition', when inflammation is chronic and of mild to moderate degree.
- 'Acute disease or injury-related malnutrition', when inflammation is acute and of severe degree [3,4].

Which patients should be assessed?

Obviously, patients with apparently normal physical build, normal diet intake, and no reason for significant increased nutrient requirements need no further investigation. Several subsets of patients require a more precise assessment:

- Patients presenting with clinical evidence of malnutrition (marasmus or the hypoalbuminaemic form of protein energy malnutrition or a mixed form).
- Patients with chronic disease, such as malignancy, alcoholism, organ dysfunction, particularly those undergoing treatment, which impairs nutrient absorption and/or utilization.
- Patients with acute conditions accompanied by a high catabolic rate, such as severe sepsis, trauma, or burns, and emergency surgery.
- **Elderly patients**: ageing is associated with a physiological anorexia, and poor dentition, economic problems, and chronic illness affect nutritional status.

How can nutritional status be assessed?

Nutritional assessment should include assessment of body composition, the presence and duration of inadequate nutrient intake, and the degree and duration of metabolic stress. The main markers of nutritional assessment in healthy adults are shown in Table 204.1. All the current criteria for objective evidence of malnutrition are non-specifically affected by many diseases and are subject to wide errors; also, disease and inactivity alone can result in the same effects as malnutrition.

Table 204.1 Markers of nutritional assessment

Anthropometric measurements	Body mass (usual, actual, ideal)	Female	19–25	Male
	BMI = BM/H^2 (kg/m^2)	16.5		12.5
	Mid-arm circumference (mid-AC) (cm)	28.5		29.3
	Triceps skinfold thickness (TSF) (mm)	23.2		25.3
	Mid-arm muscle circumference (MAMC)			
	MAMC = mid-AC – (0.314 × TSF)			
Biological tests	Plasma proteins	Normal values	23 ± 7.10^{-3}	Half-life (days)
	Albumin (g/L)	40 ± 5		21
	Transferrin (g/L)	2.8 ± 0.3		10
	Prealbumin (TTr) (mg/L)	307 ± 36		2
	Retinol-binding protein (mg/L)	62 ± 7		0.5
	IGF1	Female 18		0.08–0.16
	Urinary index			Male 23
	Creatinine height index (mg/kg ideal body weight)			
	Urinary 3 methyl histidine/urinary creatinine			
Muscle function testing	◆ Hand-grip strength			
	◆ Force-frequency curve and relaxation rate of the adductor pollicis muscle			
History	◆ Usual nutritional intake			
	◆ Impossibility of oral intake			
	◆ Physical and mental capacities			
Body composition	◆ Bioelectrical impedance analysis			
	◆ Ultrasound, CT, MRI, X-Ray absorptiometry, isotopic evaluation			

In current practice, a comprehensive assessment of nutritional status relies on a step-by-step clinically based approach and cautious interpretation of measurements and results.

Clinical assessment

Recording the patient's history and physical examination is the first stage of nutritional assessment.

History

The history includes dietary habits, nutrient intake, and interference between nutrition and the disease process itself. The latter may be responsible for either inadequate intake or excessive losses.

Physical examination

Signs of nutritional deficiency, such as muscle wasting, loss of subcutaneous fat, skin rashes, hair thinning, oedema, ascites, fingernail abnormalities, such as koilonychia, glossitis, and other mucosal lesions, should be sought. Particular signs of specific nutrient deficiencies may also be observed.

Estimation of weight loss

A loss of 10% of the usual body weight over a 6-month period or 5% over a 1-month period are indicative of a compromised nutritional status. Weight and weight variations do not reflect nutritional status or nutritional support efficacy when oedema or dehydration are or have been present.

Other anthropometric measurements

Anthropometric measurements must be interpreted with care as they may be affected by non-nutritional factors. Bed-ridden patients will lose muscle mass without malnutrition.

Measurements include weight, height, and body mass index (BMI) and mid-arm circumference (mid-AC) and triceps skinfold thickness (TSF) of the non-dominant side measured with a skin caliper. Mid-arm muscle circumference (MAMC), which is calculated from the preceding two measures, reflects skeletal muscle. TSF reflects fat stores. Mid-AC < 15th percentile defines serious malnutrition and predicts a high mortality and complication rate in critical patients [5]. High coefficients of variation between observers suggest that measurements should always be recorded by the same observer. These measurements are of no value in cases of subcutaneous emphysema or generalized oedema. Because of slow variations, they cannot be used to evaluate nutritional support efficacy.

Functional tests

Functional changes, such as a reduction in muscle power due to reduced nutrient intake, occur long before demonstrable anthropometric changes and are better predictors of complications than other anthropometric measurements (6,7). Muscle function can be considered as a specific measure of the effect of nutrient inadequate intake and refeeding. Two methods can be used in critically-ill patients.

- **Assessment of hand-grip strength** (of the non-dominant side) with a hand-grip dynamometer is reserved for co-operative patients: it has been shown to correlate with MAMC and to be the most sensitive test for predicting postoperative complications [6].
- **Measurement of the contraction of the adductor pollicis muscle** in response to an electrical ulnar nerve stimulation at the wrist can be performed in unconscious patients. The combination of an abnormal force–frequency curve and a slow relaxation rate is the

most specific and sensitive predictor of nutritionally-associated complications in surgical patients [7].

Plasma proteins

Plasma proteins reflect the visceral protein mass. They include albumin, transferrin, thyroxin-binding pre-albumin, and in patients with normal kidney function, retinol-binding protein.

Serum albumin level is the most widely used measure of plasma proteins in nutritional assessment. A fall in albumin level reflects more the severity and duration of the metabolic stress than the nutritional status itself. Sensitivity to predicting complications is better when measurements of serum albumin and transferrin are combined. Although dependent on the iron status, transferrin has a better response than albumin to nutritional repletion.

Transthyretin (TTr, called prealbumin or thyroxin-binding pre-albumin), retinol-binding protein or insulin-like growth factor 1 (IGF1), are particularly useful for following the efficacy of nutritional support [8].

Creatinine height index

The daily urinary creatinine excretion is correlated with the lean body mass. Averaged over three consecutive days, it is matched with normal controls for sex and height. Creatinine Height Index (CHI) is a reliable index of muscle mass in patients without renal failure or rhabdomyolysis.

Urinary 3 methyl-histidine also reflects muscular catabolism. Repeated measurements allow an evaluation of therapeutic response.

Immune competence

Cellular immunity is the most sensitive component of malnutrition, but reduced immune competence is not specific of malnutrition, thus making it a poor predictor of such a state in sick patients.

Subjective global assessment

Subjective global assessment (SGA) is based on history and physical examination of the patient.

- **Weight change**: loss in past 6 months, and change in past 2 weeks (in the case of recent weight gain, previous loss is not considered).
- **Dietary intake**: no change or suboptimal intake, liquid diet, or hypocaloric fluids or starvation.
- **Gastrointestinal symptoms** for more than 2 weeks (none, anorexia and nausea, vomiting, diarrhoea).
- **Functional capacity**: normal, suboptimal work, ambulatory, or bedridden.
- **Stress**: none, minimal, or high.
- **Physical signs**: loss of subcutaneous fat, muscle wasting, fluid retention, or mucosal lesions suggestive of deficiency.

The patient is classified into one of three classes.

- **Well nourished**: no or minimal restriction of food intake and/or absorption with minimal change in function and body weight.
- **Moderate malnutrition**: clear evidence of food restriction with functional changes but little evidence of any changes in body mass.
- **Severe malnutrition**: changes in both food intake and body mass with poor function.

In a critically-ill population, SGA is a reliable, easy to handle and reproducible method of nutrition assessment [9].

Nutritional indices

Several nutritional indices have been developed using mathematical and statistical methods to identify patients at risk of nutritionally-mediated complications. These indices were designed and generally validated in specific groups of patients, usually cancer or surgery.

The most widely studied is the Prognostic Nutritional Index (PNI) calculated from albumin, TSF, transferrin, and evaluation of delayed hypersensitivity reactivity. This equation correctly predicts the percentage risk of post-operative complications. Adequate nutritional support in patients with a high PNI has been shown to improve post-operative outcome [10].

The Nutritional Risk Index (NRI), using serum albumin and weight variation [11], allows identification of patients who can profit from nutrition therapy.

$$\mathrm{NRI} = [1.519 \times \mathrm{albumin(g/L)}] + (0.417 \times \%\ \text{usual body weight}) \quad \text{[eqn 1]}$$

The Pronostic Inflammatory Nutritional Index (PINI) reflects inflammation influence on plasma nutritional protein levels in critically-ill patients and discriminates risk of complications [12].

$$\mathrm{PINI} = [\mathrm{CRP\,(mg/L)} \times \mathrm{orosomucoid\ (mg/L)}] / [\mathrm{albumin\ (g/L)} \times \mathrm{TTr\ (mg/L)}]. \quad \text{[eqn 2]}$$

where CRP is C-reactive protein. Two scores associate clinical assessment and severity of disease: the Malnutrition Universal Screening Tool (MUST) [13] and the Nutritional Risk Screening tool 2002 (NRS-2002) [14]. In a study comparing NRS-2002, MUST, and the NRI to SGA, NRS-2002 was the most reliable [15].

The NUTRIC scores age, severity of disease (APACHE II, SOFA), comorbidities, days from hospital to ICU admission and serum interleukin-6. As the score increases, so does the mortality and the duration of mechanical ventilation [16].

Assessment methods of human body composition

Bioelectric impedence provides a reliable estimate of total body water, fat-free mass, and body fat in healthy individuals and in critically-injured patients. Disturbance of water distribution is frequent in critically-ill patients, making this technique irrelevant in the ICU setting [17].

Sophisticated methods measuring body composition have been developed, such as multiple isotope dilution methods, dual-photon absorption, and g-neutron activation. Because of their technical complexity, scientific limitations, and high cost, none of these methods is of clinical utility in routine critical care [17].

Computed tomography and MRI also allow for estimation of adipose tissue, skeletal muscle.

Guidelines for the assessment of nutritional status

Before initiation of nutrition, assessment of nutritional status should include evaluation of weight loss and nutrient intake before admission, level of disease severity, comorbid conditions, and function of the gastrointestinal tract [4,18,19].

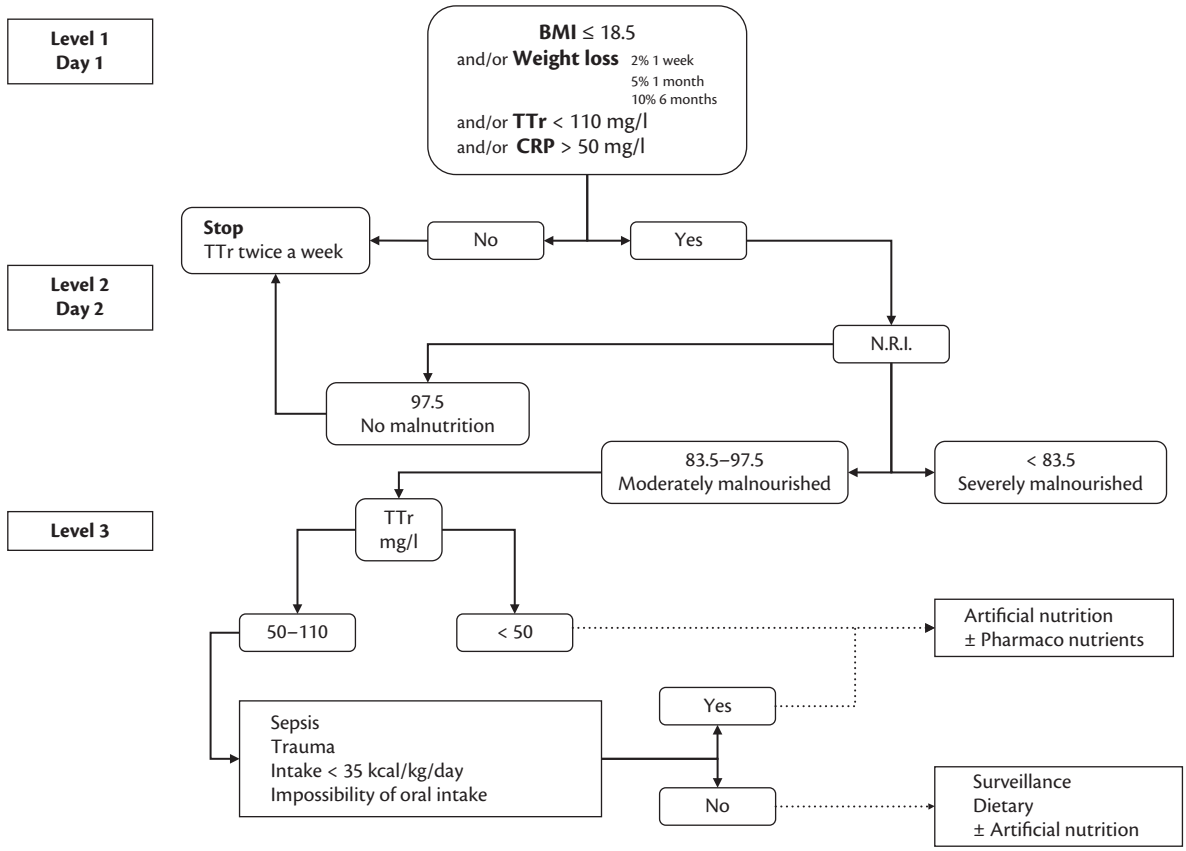

Fig. 204.1 Algorithm to screen for malnutrition.

Obese patients should be assessed similarly. Guidelines require body weight (usual, actual, and ideal) and BMI as 'vital signs'. Biomarkers of the metabolic syndrome (serum levels of triglyceride, cholesterol, and glucose) and the degree of systemic inflammatory reaction should also be assessed [20].

An algorithm to screen for malnutrition using BMI, weight loss, TTr, CRP, NRI, and critical illness severity should be performed upon admission and during the ICU stay (Fig. 204.1).

CHAPTER 205

Indirect calorimetry in the ICU

Joseph L. Nates and Sharla K. Tajchman

Key points

- Oxygen consumption can be used to determine a patient's energy expenditure.
- Indirect calorimetry is the gold standard for determining nutrition requirements in critically-ill patients.
- Interpretation of indirect calorimetry results should be performed in conjunction with the patient's clinical condition and should take into consideration any factors that may potentially alter energy expenditure.
- Despite the potential benefits of indirect calorimetry to prevent adverse effects associated with over- and underfeeding, widespread utilization is limited due to its cost and the need for trained personnel to perform gas exchange measurements.
- Aside from nutrition purposes, indirect calorimetry can assist clinicians in weaning mechanical ventilation in patients with limited respiratory reserve and increased work of breathing.

Introduction

Despite the advancement in nutrition and medicine since Antoine Lavoisier conducted the first indirect calorimetry study over 200 years ago, the assessment of energy expenditure (EE) in critically-ill patients remains a clinical challenge. The metabolic stress response, acuity of illness, and underlying comorbidities commonly present in ICU patients yield a wide variation of unpredictable metabolic derangements that are difficult, if not impossible, to quantify. Unmet metabolic demand has deleterious consequences in critically-ill patients and accurately assessing energy expenditure throughout a patient's ICU stay is vital to optimizing care and preventing adverse outcomes.

Indirect calorimetry methodology

Calorimetry is a direct measurement of heat production and usually requires 24-hour patient isolation in a hermetically-sealed room to assess temperature change. Indirect calorimetry (ICal) quantifies the amount of heat generated by the body (or resting energy expenditure (REE)) in relation to the amount of substrate used and by-product generation. Fuel substrates (carbohydrates, protein, and lipids) are oxidized to CO_2, water, and heat in the presence of O_2. By measuring the amount of O_2 consumed (VO_2) and CO_2 produced (VCO_2), ICal can be used to calculate EE. ICal was validated using direct calorimetry and is considered to be the gold standard for determining EE in the intensive care unit (ICU).

$$O_2 + \text{substrate} \rightarrow CO_2 + H_2O + \text{heat} \qquad \text{[eqn 1]}$$

Circulatory ICal (CICal) is based on a thermodilution technique that requires the insertion of a pulmonary artery catheter to measure cardiac output and mixed venous O_2 saturation. EE is calculated using measurements taken from an arterial blood gas via the Fick method (eqn 2). Catheter and arterial cannula measurements are both instantaneous and do not allow for continuous assessment of values. While CICal can provide useful results, it is an invasive technique that requires placement of a pulmonary artery catheter that may contribute to complications. This method of calorimetry is reserved for patients who already have a catheter inserted and who are not eligible for respiratory ICal due to major air leaks or other contraindications.

Fick method for determining EE

$$\text{EE}(\text{kcal/day}) = \text{CO} \times \text{Hb}(\text{SaO}_2 \times \text{SvO}_2) \times 95.18 \qquad \text{[eqn 2]}$$

where CO is cardiac output in L/min, Hb is haemoglobin concentration in mg/L, SaO_2 is the oxygen saturation of arterial blood, and SvO_2 is the oxygen saturation of mixed venous blood.

Respiratory ICal is what most clinicians refer to as 'indirect calorimetry'. By measuring VO_2 and VCO_2 via pulmonary gas exchange, EE can be calculated using the Weir equation (eqn 3). The urinary nitrogen component (uN_2) is often omitted from EE calculations (eqn 4) as it accounts for <4% of true EE in critically-ill patients and results in <2% error in the final EE calculation. The VO_2 accounts for 70–80% and the VCO_2 for 20–30% of the equation [1,2]. The Weir equation can also facilitate the identification of the substrate that is predominantly being metabolized for fuel, although it is not commonly used in this capacity.

Weir equation

$$\text{EE}\,(\text{kcal/day}) = \left[\begin{array}{l}(\text{VO}_2 \times 3.941) + (\text{VCO}_2 \times 1.11) \\ + (\text{uN}_2 \times 2.17)\end{array}\right] \times 1440 \qquad \text{[eqn 3]}$$

Simplified Weir equation

$$\text{EE}\,(\text{kcal/day}) = \left[(\text{VO}_2 \times 3.941) + (\text{VCO}_2 \times 1.11)\right] \times 1440 \qquad \text{[eqn 4]}$$

where VO_2 and VCO_2 are both measured in L/min, uN_2 is the urinary nitrogen component measured in g/day and 1440 accounts for the number of minutes in a day.

Box 205.1 Common contraindications for performing ICal

- Mechanical ventilation with $FiO_2 \geq 0.6$.
- Mechanical ventilation with positive end expiratory pressure >12 cmH_2O.
- Hyper- or hypoventilation.
- Leak in the sampling system.
- Moisture in the system, which can affect the oxygen analyser.
- Continuous flow through the system >0 L/min during exhalation.
- Inability to collect all expiratory flow.
- Unstable inspiratory FiO_2 (>± 0.01).
- Chest tube with air leak.
- Bronchopleural fistula.
- Supplemental oxygen in spontaneously breathing patients.
- Haemodialysis in progress.
- Indirect calorimeter calibration error.

Data from Branson RD and Johannigman JA, 'The measurement of energy expenditure', *Nutrition in clinical practice: official publication of the American Society for Parenteral and Enteral Nutrition*, 2004, 19, 6, pp. 622–636. Epub 2005/10/11.

ICal can be performed on mechanically-ventilated or spontaneously breathing patients. Canopies, face masks, mouthpieces, or nose pieces used to trap all gas exchange can be utilized to perform ICal in spontaneously breathing patients. Mechanical ventilators may be equipped with ICal modules to measure VO_2 and VCO_2 continuously in ventilated patients. In order to achieve the most accurate results, all patients should be screened for ICal study eligibility and only trained personnel should perform the test. Technical factors that can affect the accuracy of ICal results and are thus considered exclusion criteria for ICal are listed in Box 205.1 [3]. Many of the exclusion criteria listed can be linked to the addition or elimination of O_2 or CO_2 from the ICal study circuit, which will alter VO_2 and VCO_2 measurements. The duration of an ICal study will depend on the achievement of steady state conditions, defined as stable VO_2 and VCO_2 that vary by <10% for 5 consecutive minutes or the coefficient of variation for the two values is <5% for 5 minutes [4]. Steady state represents a period of metabolic equilibrium and ensures the reliability of the measurements obtained from the ICal study. When performed under appropriate conditions, respiratory ICal is non-invasive, reliably reproducible, and accurate. Although the use of ICal has expanded significantly over the past 25 years, its use remains limited by availability, cost, and the need for trained personnel for its correct use.

Determining energy expenditure

A patient's total daily energy expenditure is the summation of basal energy expenditure (BEE) or basal metabolic rate, diet-induced thermogenesis, and activity-related thermogenesis. The BEE is the energy required to maintain the body's basic cellular metabolic activity and organ function. Many factors may affect or alter the body's BEE and are listed in Table 205.1 [5,6]. BEE can only be measured when a person is in a deep sleep. ICal measures resting EE (REE), which has traditionally been described as the energy expended when a patient is lying in bed, awake, and aware of his or her surroundings. To measure REE, ICal should be performed under strict testing conditions including a minimum of 5 hours of fasting, at least 30 minutes to an hour of resting with no physical activity, and in the absence of any stimulants or depressants. Critically-ill patients rarely meet the previously mentioned conditions, thus the term measured energy expenditure (MEE) is more commonly used to describe EE in critically-ill patients.

Table 205.1 Factors affecting energy expenditure

Non-modifiable	Modifiable
Age	Acute or chronic respiratory distress syndrome
Body composition (e.g. obesity, ascites, oedema)	Burn
Disease processes (e.g. malignancy)	Diet
Gender	Fever/Infection
Genetics	Large or multiple open wounds
Hormonal status	Nutrition status
Limb amputation	Medications (e.g. sedatives, paralytics)
Post-operative organ transplantation	Multisystem organ failure
	Sepsis
	Systemic inflammatory response syndrome
	Trauma
	Use of paralytic agents or sedation

Data from Brandi LS et al., 'Indirect calorimetry in critically ill patients: clinical applications and practical advice', Nutrition, 1997, 13, 4, pp. 349–358. Epub 1997/04/01; McClave SA and Snider HL, 'Use of indirect calorimetry in clinical nutrition', *Nutrition in clinical practice: official publication of the American Society for Parenteral and Enteral Nutrition*, 1992, 7, 5, pp. 207–221. Epub 1992/10/01.

Clinical measurement of REE

At least four different organizations have published guidelines for the provision of nutrition support in critically-ill patients, although none of them provide specific recommendations on the use of ICal in the ICU [7–10]. Ideally, all critically-ill patients should receive ICal if their ICU length of stay is estimated to be >72 hours, especially if they are mechanically-ventilated (Fig. 205.1) However, due to cost considerations, and the availability of equipment and trained personnel, obtaining ICal may not be possible for all patients or at every institution. All factors considered, it is strongly recommended that ICU patients with any of the following conditions have an ICal study performed:

- Any clinical condition that significantly alters EE (e.g. acute or chronic respiratory distress syndrome, acute pancreatitis, burns, multiple trauma, multisystem organ failure, sepsis, systemic inflammatory response syndrome).
- Failure to respond to presumed adequate nutritional support (wound dehiscence, loss of lean body mass).
- Long-term ICU patients with multiple insults for the provision of individualized nutrition support (baseline and serial ICal measurements).

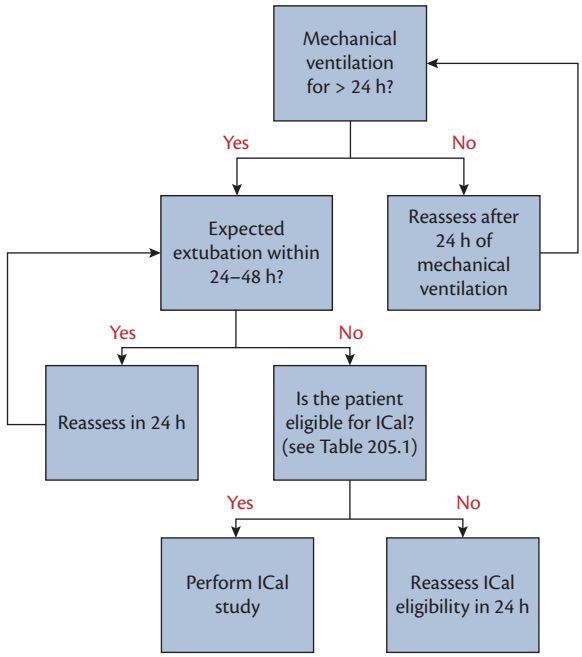

Fig. 205.1 Algorithm for performing indirect calorimetry.

Interpretation of ICal results

It is important to note the ICal study results are a MEE and may not accurately represent the BEE or REE depending on patient conditions during the study. Ideally, ICal should be measured under resting conditions. Many patient, environmental, and equipment-related factors can affect the accuracy of ICal measurements (Box 205.2) [3,6,11,12]. Keeping this in mind, ICal results give an accurate measure of the EE for the patient under the specific testing conditions. If patient conditions drastically change (discontinuation of paralytic agents, sedatives, initiation of nutrition, etc.) a follow-up ICal should be considered to evaluate the change in EE.

The MEE should serve as the daily caloric target for the provision of nutrition support in critically-ill patients. The addition of stress or activity factors to the MEE is not necessary and can increase the risk of overfeeding as the MEE has been shown to closely approximate 24-hour EE [6]. Also, since most ICU patients are receiving continuous feeding, diet-induced thermogenesis is accounted for in the MEE. However, if nutrition is intermittent, MEE should be increased by 5% to account for thermogenesis.

Another value derived from ICal is the respiratory quotient (RQ), which is defined as the ratio between VO_2 and VCO_2. The RQ value is a reflection of substrate utilization. Complete oxidation of glucose in a closed system yields an RQ value of 1. The use of protein and lipids as substrates for fuel yield different values within the physiological range of RQ values (see Fig. 205.2). It is important to remember the RQ value is a summation of whole body substrate utilization. Also, since many factors can influence the RQ, and result in false or inaccurate RQ values, the RQ value is mainly used as a measure of ICal study quality. An RQ value around 0.7 suggests underfeeding and a shift toward lipolysis for fuel substrate; alternatively, an RQ > 1 suggests overfeeding due to lipogenesis as substrate is stored as fat.

Box 205.2 Recommendations to improve the accuracy of ICal

Resting conditions

- Supine position at least 30 minutes prior to the study.
- Quiet, thermoneutral environment.
- Normal voluntary muscle movement is present during the study.
- No/minimum involuntary muscle movement is present during the study.
- Adequate pain control.
- No/minimal agitation.
- All sedatives and/or analgesics should be administered at least 30 minutes prior to the study when clinically feasible.

Nutrition considerations

- **Intermittent nutrition:**
  - If thermogenesis is to be included in the REE—perform study 1 hour after feeding.
  - If thermogenesis is **not** to be included in the REE—perform study 4 hours after feeding.
- **Continuous nutrition**: no changes to the rate and/or composition of continuous nutrition for at least 12 hours prior to the study.

Oxygen considerations

- Non-mechanically ventilated patients—no supplemental oxygen provided during the study.
- **Mechanically-ventilated patients**:
  - FIO_2 must remain constant during the study.
  - No changes in ventilatory settings for at least 90 minutes.
  - No leaks are present in the ventilation or sampling system.

Procedural considerations

- **Haemodialysis:**
  - *Intermittent*—must wait 3–4 hours after completion of haemodialysis.
  - *Continuous*—cannot perform study until continuous renal replacement therapy is discontinued.
- No general anaesthesia within 6–8 hours prior to the study.
- **Painful procedures**: wait at least 1 hour and ensure pain is adequately controlled prior to study.
- Avoid routine nursing care or procedures during the study.

Measurement considerations

- Data used to calculate EE and RQ are taken from steady state conditions.

Data from Branson RD and Johannigman JA, 'The measurement of energy expenditure', *Nutrition in clinical practice: official publication of the American Society for Parenteral and Enteral Nutrition*, 2004, 19, 6, pp. 622–636. Fig. 205.2 Interpretation of the RQ value.

Clinical benefits of ICal

Malnutrition occurs in approximately 43–88% of ICU patients and accurate determination of energy requirements is essential to avoid feeding-associated adverse effects [13]. Underfeeding may result in the development of malnutrition and associated adverse outcomes, such as decreased wound healing, increased infectious complications, increased duration of mechanical ventilation, and increased ICU length of stay [14,15]. Recent literature has suggested that a negative caloric balance in the ICU may lead to injurious consequences, including an increased ICU length of stay, duration of mechanical ventilation, overall rate of complications (pressure ulcers, acute kidney insufficiency, acute respiratory distress syndrome, and sepsis), and death [15–17]. Conversely, overfeeding critically-ill patients can lead to hyperglycaemia, hepatic dysfunction, prolonged mechanical ventilation, fluid overload including pulmonary oedema, and congestive heart failure [18]. More recently, the concept of tight caloric control has been advocated that critically-ill patients should avoid the deleterious effects of under- and overfeeding, although the studies have had conflicting results [19,20].

Weaning from mechanical ventilation

Determination of accurate daily caloric needs with ICal can also assist in the facilitation of weaning from mechanical ventilation. Overfeeding results in excessive production of CO_2 and results in increased work of breathing, which can be detrimental to weaning efforts, especially in patients with limited respiratory reserves such as those with chronic obstructive pulmonary disease and acute respiratory distress syndrome. Performing ICal allows clinicians to determine whether overfeeding is contributing to unsuccessful ventilator weaning attempts. Subsequently, decreasing caloric intake can help reduce excessive CO_2 production and decrease respiratory efforts required to successfully wean a patient from mechanical ventilation. Due to the dynamic metabolic profile of critically-ill patients, it is difficult to estimate daily caloric needs accurately.

CHAPTER 206

Enteral nutrition in the ICU

Shaul Lev and Pierre Singer

Key points

- Enteral feeding is an integral part of patient care and should be started early as soon as the patient is stabilized.
- Nasogastric or nasojejunal tubes are the main routes of enteral nutrition (EN) administration.
- Monitor gastric residual volume and follow protocols to start enteral feeding.
- Choice of feed composition should depend on the main disease—acute lung injury, diabetes, trauma, or others.
- The main complications are aspiration and diarrhoea.

Introduction

Artificial nutritional support is considered an integral part of critical care. Artificial feeding can be in the form of enteral nutrition (EN), parenteral nutrition (PN) or as a combination. The primary goal of nutrition support in the critically ill is to supply patients with macro- and micronutrients that are needed for new protein synthesis, energy production, and to sustain enzymatic function. A secondary goal is to modulate immune function in order to improve infection rates, wound healing, and to avoid non-adaptive proteolysis of vital proteins and hyper-inflammatory reactions. This field of nutrition is called immunonutrition. The intensive care unit (ICU) population is very heterogenic and the appropriate nutritional intervention should be chosen with care. First the calorie–protein targets should be defined followed by the timing for commencing EN and choice of route of feeding. EN is currently viewed as the first line of feeding for critically-ill patients who cannot be fed by mouth and has many benefits in maintaining the functionality of the intestine. The timing for starting feeding is a matter of controversy, but it is usually started in the early stages of ICU hospitalization, during the first 2 days, in order to avoid major caloric and protein deficits. The concept of commencing early nutrition for critically-ill patients is based on observation that feeding started within short time frame is associated with less gut permeability, diminished activation, and release of inflammatory cytokines and reduced systemic endotoxaemia. A meta-analysis by Heyland et al. [1] showed a trend toward reduced mortality and infectious morbidity. A systematic review by Marik and Zaloga [2] showed significant reduction in infectious morbidity and hospital stay with early EN compared with delayed feedings. While most experts agree that patients who can tolerate feeding should be nourished as soon as they are stabilized, controversy exists regarding the best management of patients who cannot tolerate EN matched to their estimated needs.

Indications

The European Society for Clinical Nutrition and Metabolism (ESPEN) recommends 'all patients who are not expected to be on a full oral diet within 3 days should receive enteral nutrition' [3]. The European [3], American [4], and Canadian [1] guidelines recommend that ventilated, haemodynamically stable patients, with a functioning digestive system, will begin enteral nutrition 24–48 hours after admission to the ICU. Bowel sounds are a poor indicator of small bowel activity, particularly in patients subject to tracheal intubation and mechanical ventilation. Their absence should not delay a trial of enteral nutrition.

Methods of administration

Enteral feeds are usually given continuously by gravity feed or pump-assisted infusion. Intermittent bolus feeds may also be given every 6 hours and may have a more positive effect on protein synthesis than the same quantity of continuous feeds. The administration set must be sterile and have connectors incompatible with intravenous infusions to minimize the risk of confusion with fluids intended for intravenous use. Enteral feeds should not be left hanging at the bedside for more than 24 hours at room temperature, since bacterial colonization of enteral feeds have been found in up to 24% of enteral feed reservoirs at 24 hours.

Routes of feeding: stomach versus small bowel

Routes of feeding include nasogastric (NG), nasoduodenal, nasojejunal (NJ), gastrostomy, and jejunostomy. Nasal tube feeding should be performed via a soft, fine-bore tube in order to avoid ulceration of the nose or oesophagus. Patients tolerate nasal tubes better than oral tubes, but the nasal route is associated with increased frequency of bleeding during insertion and with sinusitis. Nasal intubation is relatively contraindicated in patients with a fractured base of skull. Nasogastric feeding usually starts using a 12–14-French tube to allow aspiration of gastric contents to check feed absorption, and administration of viscous elixirs or crushed tablets.

The placement of nasoduodenal tubes should be considered if gastric residues are large (250–500 mL). This kind of feeding, directly to the small bowel, bypasses the stomach, enables nutritional goals to be reached faster and eliminates the need for parenteral feeding. Direct feeding to the small bowel does not cause special complications. The main disadvantage relates to the difficulty in tube placement. Fewer than 50% of fine-bore tubes pass through the pylorus spontaneously within 24 hours of insertion.

Tubes can be guided through the pylorus using fluoroscopy or endoscopy. The position of the tip of a feeding tube should be confirmed by radiography before feeding starts in order to avoid accidental tracheal intubation.

In selected patients creation of a feeding jejunostomy is considered, especially when there is a laparotomy. This procedure allows the administration of early enteral nutrition in most patients, but may be complicated by leaks, peritonitis, wound infection, and bowel obstruction.

Monitoring tolerance of enteral feeding

Up to 47% of patients in the ICU suffer from GI motility problems. Gastric residual volume (GRV) is viewed as the most common indicator of tolerance for enteral feeding, although many studies found no correlation between GRV and pneumonia rate [4]. Serial GRV measurements may decrease the amount of nutrition that is actually given. According to the American Society for Parenteral and Enteral Nutrition (ASPEN) [4], when GRV levels are 200–500 mL, and with the absence of other indicators for intolerance of feeding, enteral feeding should not be stopped [4]. One of the recommended approaches to tackle motility problems is the use of prokinetic medication. If the nasogastric aspirates are significant (i.e. more than 150 mL), prokinetic drugs such as metoclopramide (10–20 mg intravenously (iv) every 6 hours), or erythromycin (80–300 mg iv) are used to decrease gastric paresis and to assist transpyloric placement of transpyloric tube [4]. Several studies and meta-analyses have questioned the advantages of post-pyloric feeding in the ICU. A small number of studies demonstrated that post-pyloric feeding benefits by reducing gastro-oesophaegeal reflux and rate of aspirations, especially if the tip of tube is located distally in the duodenum. A meta-analysis that covered 11 studies of 637 ICU patients, did not demonstrate any advantage in the clinical outcome of patients fed directly into the small bowel, with respect to mortality, duration of hospitalization, rate of pneumonia, and aspirations [5]. A recent meta-analysis of 15 randomized clinical trials enrolling 966 participants found that post-pyloric feeding was associated with a reduction in pneumonia compared with gastric feeding (relative risk (RR) 0.63, 95% CI 0.48–0.83, $p = 0.001$; $I^2 = 0\%$) [6]. The risk of aspiration (RR, 1.11; 95% CI, 0.80–1.53, $p = 0.55$; $I^2 = 0\%$) and vomiting (RR, 0.80; 95% CI, 0.38–1.67, $p = 0.56$; $I^2 = 65.3\%$) were not significantly different between patients treated with gastric and post-pyloric feeding [6]. A recent multicentre Australian study did not find an increase in the amount of energy delivered in 181 ventilated patients with medium GRV when an early NJ tube was introduced as compared to NG tube [7].

EN composition

Many formulas are commercially available, and may differ in their caloric density, amount of proteins, and their enrichment with specific components, such as fibres, specific amino acids, fish oil, specific fatty acids, nucleotides, and other nutrients and antioxidants. Most standard formulations contain 1 kcal/mL. 'Energy dense' formulation with high fat content may contain up to 2 kcal/mL. Formulations also vary in osmolality, electrolyte, mineral, and vitamin content. All the feeds are lactose and gluten free. Carbohydrates are provided as sucrose, fructose, or glucose polymers. Proteins are provided as whole proteins. New formulations with high protein content have recently been introduced into the market. The value of a very high protein-to-energy ratio is still unproven, but allows delivery of higher amounts of proteins without fluid overload. Elemental or semi-elemental feeds contain a mix of oligopeptides and free amino acids. They are used in patients with short bowel syndrome, severe diarrhoea, radiation enteritis and pancreatic insufficiency. Fats may be provided as medium-chain fatty acids or long-chain triglycerides. Special feeds are constantly being developed, including feeds with nucleotides and arginine, and formulations enriched with fish oils. Electrolyte content varies and may affect the choice of feed when sodium or potassium restriction is important; these electrolytes can always be added to a feed when supplementation is needed. Most of the commercial formulations meet the daily recommended intake of healthy adults if given in an amount higher than 1000–1500 mL/day. The daily needs might be higher for some vitamins in settings of increased losses, such as continuous haemodiafiltration.

Specific nutrients

Some nutrients have been intensively research both in animal models and humans due to their specific biological effects, rather than their use as energy sources or substrates for protein synthesis.

Glutamine

Glutamine is a conditionally essential amino acid and is the most abundant amino acid in plasma. Glutamine is involved in many biochemical reactions in the cells. The glutamine stores in muscle tissue are depleted and low plasma glutamine concentrations are an independent prognostic factor for an unfavourable outcome in the critically-ill patient. Under catabolic conditions, such as sepsis and shock, release of glutamine from muscle tissue serves as a 'stress signal' to the organism that leads to gene activation in order to promote cellular protection and immune regulation. Glutamine serves as a precursor of nucleotides and glutathione, and is the major metabolic fuel for the enterocytes of the gut mucosa, lymphocytes, and macrophages. Several other properties are associated with glutamine, including antioxidant activity, promotion of production of heat shock proteins and protection of gut barrier functionality. In most enteral formulations glutamine is present in low concentrations and glutamine supplementation is given intravenously for burns, trauma and ICU patients.

'Immune-enhancing' enteral formulas (arginine, omega-3 fatty acids, probiotics, nucleotides)

Specific formulas designed with the aim of improving immune function and reducing the risk of infections, are called immune-enhancing enteral feeds.

These formulas are usually enhanced with omega-3, γ-linolenic acid (GLA), arginine, and/or nucleotides (low molecular weight intracellular compounds that are composed of a purine and pyridimine backbone). The effect of these feeds is controversial and might be related to a specific formula. Well-designed large clinical trials did not show improved outcome in critically-ill patients.

Arginine

Arginine-enriched formulas reduced the risk of infections and shortened the duration of hospitalization in elective surgical patients. Heyland et al. [8] suggest in a systematic review that

immune modulating formulas decrease rate of infections in elective surgical patients, but may increase mortality rates in general ICU patients, although the data to support such conclusion was weak [8]. Arginine enriched formulas might be beneficial to patients before and after major surgery and trauma, but in the meantime should not be provided to patients suffering from severe sepsis.

Omega-3 fatty acids and γ-linolenic acid

Omega-3 fatty acids help down-regulate the inflammatory response and improve overall immune function. Both eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) show benefits in membrane structure and function and gene transcription. Animal models have established the ability of fish oil solutions to reduce lung permeability in acute lung injury (ALI) compared with solutions with omega-6 or saturated fat. Preclinical data supported the concept that EPA and DHA may be beneficial in ALI/acute respiratory distress syndrome (ARDS) by reducing inflammation. Most of the animal studies have involved a pre-injury supplementation protocol and have delivered the fish oil supplementation before or soon after the insult to the lungs. Patients with ALI/ARDS have been found to have very low omega-3 levels compared with normal individuals, suggesting a potential role for omega-3 dietary supplementation in these patients [9].

Clinical data regarding the use of formulas enhanced with EPA and GLA in ALI/ARDS patients come from five randomized controlled studies. Three studies demonstrated an association between the administrations of an enteral formula enriched in EPA, GLA, and antioxidants and improved clinical outcome as compared with high-fat formula. A meta-analysis done on these three trials showed a significant reduction in the risk of mortality as well as relevant improvements in oxygenation and clinical outcomes of ventilated patients with ALI/ARDS [10]. Nevertheless, there are two recent studies that addressed the same question in patients with ALI or ARDS with mixed results. In a Spanish multicentre study [11], the EPA-GLA diet group showed a trend toward a decreased SOFA score, but it was not significant. In this study, no improvement in the gas exchange measured by the PaO_2/FiO_2 ratio was measured in the omega-3-treated group [11]. Liver function tests, glycaemia, cholesterol and triglycerides were similar in both groups [11]. The control group stayed longer in the ICU than the EPA-GLA diet group [11]. In a recent study [12], the authors used a different approach of twice-daily bolus administration of omega-3 fatty acids instead of continuous enteral infusions to deliver the supplements. In contrast to the previous studies in this study enteral supplementation of omega-3 fatty acids, GLA, and antioxidants did not improve the rate of nosocomial infections, non-pulmonary organ function, lung physiology, or clinical outcomes in patients with ALI compared with supplementation of an isocaloric control [12]. Furthermore, the study was stopped early for futility despite an 8-fold increase in plasma eicosapentaenoic acid levels [12]. The use of the omega-3 supplement resulted in increased duration of diarrhoea [12]. The study had sustained heavy criticism since the control formula contained five times more protein and the omega-3 supplements were given up to 5 days after the respiratory deterioration. Moreover, half the patients were underfed and the omega-3 fatty acids might have been catabolized as an energy source.

Fibres

Fibres are non-digestible, sugar-based, long molecules that are subject to bacterial breakdown to short-carbon molecules, such as acetate, propionate, and butyrate. These serve as important substrates for the cells of the colonic mucosa, and their uptake enhances absorption of water and electrolytes from the bowel lumen. Fibres also bind bile salts, which would otherwise be irritants to the colonic mucosa, promotes glucose absorption, and provides substrate for the normal bowel flora. The main importance of fibres is their ability to improve stool consistency. Despite concern being raised about their utility in patients who suffer from gut ischaemia, no adverse effects have been reported from including fibre in enteral feeds, and most new formulations contain a fibre source.

Probiotics

Probiotic therapy can be defined as any supplemental micro-organisms that are safe and stable and, when administered in adequate amounts, confer a health benefit to the patient. Looking at patients' microbiota profile over time in hospital reveals profound changes. These changes are due to broad spectrum antibiotics, ulcer prophylaxis, vasoactive-pressor agents, alterations in motility, and decreases in luminal nutrient delivery. These agents act by competitively inhibiting pathogenic bacterial growth, blocking epithelial attachment of invasive pathogens, eliminating pathogenic toxins, enhancing the mucosal barrier function, and favourably modulating the host inflammatory response. There is an inverse correlation between the changes in patients' microbiota and clinical outcome [13]. Unfortunately, despite the fact that the administration of probiotics agents has been shown to decrease infection rate in specific critically-ill patient populations involving transplantation, major abdominal surgery, and severe trauma [13], no recommendation has currently been made for use of probiotics in the general ICU population due to a lack of consistent outcome effect.

Many experts believe that as the ease and reliability of taxonomic classification will improve, stronger recommendations could be made for the use of specific probiotics in specific populations of critically-ill patients.

Complications

The most severe complication of EN is aspiration and is a main cause of pneumonia. Some patients have increased risk factors for aspiration, such as mechanical ventilation, old age, decreased consciousness, supine position, poor oral health, etc. In order to reduce the risk of aspiration, it is important to maintain a posture where the upper body is raised to 30–45° and to assess the tolerance for feeding. Gastrointestinal complications, especially diarrhoea, affecting up to 60%, are commonly encountered, as well as regurgitation, nausea, vomiting, constipation, abdominal pain, and bloating. Soluble fibre-enriched solutions can be used in cases of diarrhoea and in severe cases a use of a polypeptide-based formula may be tried. Metabolic complications, such as hyperglycaemia, electrolyte disturbance, especially hypokalaemia, are mainly linked to the medical condition of the patient and the content of the formula. Special attention should be given to the possible development of refeeding syndrome, a group of symptoms that appear after sudden feeding of a patient who was in a starved state. The sudden change affects insulin secretion that, in turn, causes changes in electrolytes and fluids. These changes could cause cardiac, respiratory, haematological, metabolic, and neurological disturbances and, in severe cases, a multi-organ failure and death [14]. The electrolytic

disturbances include hypophosphataemia, hypokalaemia, and hypomagnesaemia.

CHAPTER 207

Parenteral nutrition in the ICU

Jonathan Cohen and Shaul Lev

Key points

- The parenteral nutrition formula should be designed to meet nutritional needs.
- Daily writing of parenteral nutrition orders needs to include laboratory evaluation, fluid, caloric, and protein requirements.
- Calorie and protein requirements should be calculated daily.
- Laboratory assessment should be performed daily.
- Monitor drug and nutrient interactions, and their effects on laboratory variables.

Introduction

Parenteral nutrition (PN) is a technique of artificial nutrition support, which consists of the intravenous administration of macronutrients (glucose, amino acids, and triglycerides), micronutrients (vitamins and trace elements) and water. While enteral nutrition (EN) is recognized as the optimal method for providing energy and protein needs, it is not always an option in many patients and may fail to meet patient requirements. For this reason, PN has become integrated into ICU patient management with the aim of preventing energy deficits and preserving lean body mass. The addition of PN to enteral nutrition is known as supplemental PN.

Indications and modes of administration

Indications for parenteral feeding

Parenteral feeding should be considered in the following circumstances:

- **Enteral nutritional support is contraindicated**: e.g. in the presence of gut obstruction, high output fistulae, severe gut ischaemia or gut failure.
- **Enteral nutrition alone is unable to meet energy and nutrient requirements and PN is given as supplemental nutrition**: this approach may be especially relevant in high risk patients who are chronically malnourished.

Approach and clinical evidence for supplemental PN

International guidelines differ considerably regarding the indications for PN [1–3]. Thus, the European Society of Parenteral and Enteral Nutrition (ESPEN) guidelines [3] recommend initiating PN in critically-ill patients who do not meet caloric goals within 2–3 days of commencing EN. The Canadian guidelines [2] recommend PN only after extensive attempts to feed with EN have failed, while the American Society of Parenteral and Enteral Nutrition (ASPEN) guidelines [1] advocate administering PN after 8 days of attempting EN unsuccessfully.

Five randomized prospective trials have been published regarding the early use of supplemental PN [4–8]. The first trial was published in 2000, by a French group [4] and randomized 120 patients to receive either EN plus PN from day one or conventional EN given as early as possible. Despite a significant energy delivery difference between the two groups and better biochemical parameters, the only clinical improvement noted in the PN group was a decrease in the length of hospital stay. Due to these disappointing results and to a strong negative sentiment in the medical community, the use of PN was largely neglected for many years. Recently, however, there has been renewed interest in the use of PN and four randomized controlled trials (RCTs) have been published in the last 3 years [5–8]. The TICACOS study [5] was performed on 130 patients randomized to receive either EN or PN where required according to indirect calorimetry measurements and a control group targeted to 25 kcal/kg/day. The study did not find a difference in ICU mortality, but reported a significantly better hospital survival for the study group when analysing the results per protocol. The very recent bicentre Swiss trial (SPN) [6] allocated 301 patients to receive PN on the fourth day of admission if it was shown that energy delivery was less than 60% of measured EE. The study reported significantly better outcomes regarding infection rates, days of antibiotic administration and length of ventilation when analysing the results after 9 days of admission. The largest study on very early PN administration, the EPANIC study [7], recruited more than 4000 patients to receive either PN on the first 2 days of admission versus adding PN on the 8th day of admission. The study group received a low protein formulation, severely malnourished patients were excluded and most of the population comprised non-high risk patients. The study did not find any positive outcome and even suggested harm. However, the results should be interpreted with caution and the main conclusion that can be drawn is that patients who are not high risk, who are not chronically malnourished should not receive early supplemental PN. A sub-analysis of the trial also did not find any benefit in any subgroup analysed, including the patients with higher illness severity scores or patients with high malnutrition scores. A very recent multicentre Australian study prospectively randomized patients to receive complimentary PN as soon as possible if they were not expected to be orally fed for at least for 24 hours. The study did not find any significant clinical improvement except for length of ventilation, which was reduced by 1 day and a slightly improved quality of life after 1 month, which was not considered to be clinically meaningful. Interestingly, the infection rate, including blood stream infections, was not increased in the PN group [8].

Methods of administration

PN is usually delivered by programmable pumps and requires reliable vascular access. A dedicated catheter or lumen is needed.

PN should be prescribed by trained health care professionals applying validated protocols. Energy delivery should be matched to the energy target, preferably defined by indirect calorimetry or calculated by a trained dietitian. Meticulous glucose control is important, with a therapeutic goal targeting levels between 140 mg/dL to 180 mg/dL.

Choice of parenteral feeding route

Central venous

The central venous route is preferred for administration of hyperosmolar solutions (>850 mOsmol/kg) in cases where high energy intake (> 1500 kcal) is to be infused. The femoral route should not be used if possible due to a higher risk of catheter-related infections.

Peripheral venous

Parenteral nutrition via the peripheral route is possible when the prescribed solution is of low osmolality. In order to achieve this, the volume of the solution can be increased or the energy content (particularly from carbohydrate) reduced. Peripheral cannula sites should be changed every 72–96 hours.

PN composition

Carbohydrate is normally provided as concentrated glucose while 30–40% of total calories are usually given as lipids (e.g. soya bean emulsion). The nitrogen source is synthetic, crystalline L-amino acids, which should contain appropriate quantities of all essential and most non-essential amino acids. Carbohydrate, lipid, and nitrogen sources are typically mixed into a large bag in a sterile pharmacy unit. Vitamins, trace elements, and appropriate electrolyte concentrations can then be added to the infusion, thus avoiding multiple connections. Volume, protein, and calorie content of the feed should be determined on a daily basis in conjunction with the appropriate health care professional.

Stability

Commercial solutions are highly stable after preparation and can be stored for months in cool storage conditions. After opening the bag, the solution should be given within 24–48 hours depending on manufacturer's recommendations. The vitamin solutions are usually stable for up to 24 hours.

Immunonutrition

The concept of immunomodulating formulae has been extensively studied in relation to EN, but not substantiated regarding PN. In this regard, glutamine and omega-3 fatty acids have received the most attention. Glutamine is an important metabolic fuel for the cells of the gut and the immune system. It is also involved in the regulation of muscle and liver protein balance, probably mediated by an increase in cellular hydration, a triggering signal or protein anabolism. Several studies have demonstrated that parenteral glutamine supplementation may improve outcome, and the ESPEN guidelines give a grade A recommendation to the use of glutamine in critically-ill patients who receive PN. Three large multicentre trials have been published since the release of the ESPEN guidelines. The Scandinavian multicentre, double-blind, RCT of intravenous (iv) glutamine supplementation for ICU patients was recently published [9]. In this trial, patients were given supplemental iv glutamine (0.283 g/kg body weight/24 hours) for their entire ICU stay. They demonstrated a lower ICU mortality in the treatment arm compared with controls, which was not significant at 6 months. No change in the SOFA (Sequential Organ Failure Assessment) scores were noted. The SIGNET trial [10] recruited 502 patients to receive glutamine via PN, which was given as a supplement to EN. This study did not find any benefit from iv glutamine administration to unselected critically-ill patients. A trial conducted on 1223 mechanically ventilated critically-ill patients reported disappointing results and concluded that glutamine administration in this critically-ill population might in fact cause harm [11]. The harm was noted mainly in patients with multi-organ failure, haemodynamic instability, and renal failure. The doses used in this trial were higher than those recommended and glutamine was given very early in the course of hospitalization.

Studies on IV omega-3 fatty acids have yielded promising results in animal models of acute respiratory distress syndrome and proved superior to solutions with omega-6 composition. The clinical experience with the use of these solutions in critically-ill patients is not as yet proven. The discrepancy between animal models and clinical practice could be related to different time frames. Thus, while in the animal studies the fish oil solutions were given in proximity to the insults, the administration in clinical trials was much later after the primary insults.

Complications

The use or misuse of PN may be associated with many potential complications [12], which may be divided into mechanical, infectious, and metabolic complications. Most of the complication can be avoided by optimum hand hygiene, maximal barrier precautions, and close medical care by specialized total parenteral nutrition (TPN) team.

Mechanical complications

- Catheter misplacement.
- Catheter-related mechanical complications (pneumothorax, arterial injury, bleeding).
- Thrombosis or thromboembolism.

Infectious complications

- Bacteraemia.
- Fungaemia.
- Tunelitis.
- Phlebitis.
- Cellulitis.

Metabolic complications

Fluid excess

- Fatty liver and liver failure.
- Hyperosmolar, hyperglycaemic, and hypoglycaemic states.
- Hypophosphataemia and hyperphosphataemia.
- Hypercalcaemia.

- Metabolic acidosis with hyperchloraemia.
- High endogenous insulin levels.
- Vitamin deficiencies—folate, thiamine, vitamin K.
- Encephalopathy.
- Hypoprothrombinaemia.
- Vitamin excess or deficiency—vitamins A and D.
- Dermatitis.

Conclusion

Timely and adequate parenteral nutritional support administered according to guidelines recommendations, may help to achieve balanced nutritional support. Both under- and overfeeding should be avoided. In addition to energy balance, careful attention should be devoted to the adequacy of protein and micronutrient administration. Avoiding infectious complications by applying meticulous sterile techniques in catheter insertion and avoiding metabolic complications by close metabolic follow-up can be achieved as shown by studies reporting low rates of PN complications.

SECTION 8

The renal system

PART 8.1

Physiology

CHAPTER 208

Normal physiology of the renal system

Bruce Andrew Cooper

Key points

- The kidney has many important roles other than just urine production.
- The impact of kidney disease is often predictable.
- The kidney plays a critical role in fluid and electrolyte balance via many specialized trans-membrane pathways.
- The kidney is also involved in the production and modification of two key hormones and one enzyme.
- Understanding normal renal physiology can help determine clinical management.

Renal structure

General anatomy

Standard renal anatomy consists of two kidneys situated either side of the L2–5 lumbar vertebrae in a retroperitoneal position each with a single feeding artery, a single draining vein and a single ureter each connecting to the urinary bladder, which acts as a reservoir to be emptied on demand through a single urethra. Some anatomical variants include a fused or single kidney (1 in 750–1000 people), multiple renal arteries (32%) and veins (30%; usually right-sided) and duplication of the collecting system (<1%) which can be at the level of the renal pelvis, ureter, or down to the level of the bladder. Vascular duplication is usually functionally unimportant although can result in complexity at times of surgery or other invasive procedures. Ureteric duplication if often associated with obstruction or reflux. Sympathetic nerves travel within the renal artery adventitia to supply the kidney.

Internal structure

The macroscopic internal structure of the kidney can be divided into several key areas: renal cortex, renal medulla, renal pyramids, and the calyceal system including the renal pelvis. The microscopic structure of the renal parenchyma consists of between 900,000 to 1 million nephron units [1] and the renal interstitium which includes arcuate arteries, peritubular capillaries, and interstitial fibroblasts. The nephron unit begins with the renal glomerulus, a delicate tuft of capillaries supported by specialized epithelial cells (podocytes and mesangial cells) that is supplied and drained by an afferent and efferent arteriole respectively. Each glomerulus sits within a capsule (Bowman's) that is drained by a single renal tubule. Each tubule consists of a single layer of epithelial cells that have a luminal membrane (urine side) and basolateral membrane (interstitial side). The sections of the renal tubule include the proximal convoluted tubule (PxCT), the loop of Henle (LOH: consisting of the thin descending limb, thin ascending limb, and thick ascending limb), and distal convoluted tubule (DCT) several of which join together to form a collecting duct (CD). The renal cortex consists of mostly glomeruli and the PxCT and DCT, the renal medulla consists of mostly the LOH and the renal pyramids contain the CD that drain the final urine into the calyceal system. The calyceal system acts to funnel the urine via the renal pelvis into the muscular ureter that then propels the urine towards the bladder. The most metabolically active cells within the nephron unit include the PxCT and DCT, the thick ascending limb of the LOH and the glomerular podocyte. Therefore, these are the areas of the kidney that are most susceptible to toxic or ischaemic injury.

Renal function

The combined blood flow to both kidneys is in the order of 1 L/min, i.e. 20% of the entire cardiac output. The blood flow to each glomerulus is controlled by the afferent (feeder) arteriolar tone, i.e. vasodilatation will result in an increase in pressure and flow into the glomerulus and vasoconstriction will result in a decrease in pressure and flow into the glomerulus. This mechanism is under the control of prostaglandins which when present results in vasodilatation and when absent or inhibited (e.g. by non-steroidal anti-inflammatory drugs) results in vasoconstriction. The glomerular tuft is therefore subject to variable pressure loads (glomerular filtration pressure) that are not only determined by the afferent arteriolar inflow, but also the efferent arteriolar outflow. The efferent arteriolar tone is under the control of angiotensin II and vasoconstricts when present, causing an increase in the glomerular pressure and vasodilates when absent or inhibited (e.g. by angiotensin converting enzyme (ACE) inhibitors or angiotensin II receptor blockers (ARB)) resulting in a decrease in glomerular pressure. The glomerular tuft acts as a semi-permeable membrane consisting of a basement membrane that is only 330 ± 50 (SD) nm thick in the males and 305 ± 45 nm thick in the females supported on the blood side by a single layer of endothelial cells and on the urine side by a single layer of podocytes. Therefore, changes in the glomerular pressure will result in an increased or decrease in the filtration rate when the pressure is increased or decreased respectively. This filtration rate is described as the glomerular

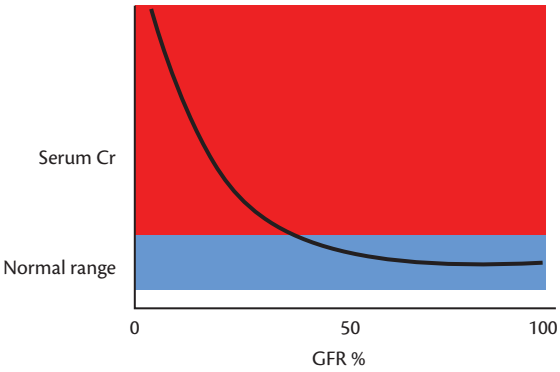

Fig. 208.1 Association between GFR and creatinine.

filtration rate (GFR) and in a normal adult male is approximately 120 mL/min or 170 L/day.

GFR is often used synonymously with 'renal function' although as described later in this chapter there are many other aspects of kidney function beyond GFR. GFR can be defined as the rate of clearance of a substance from the blood into the urine by glomerular filtration assuming that it passes through the nephron unit without undergoing any metabolism, tubular secretion, or reabsorption. As GFR can be difficult to measure accurately in a clinical setting (laboratory based settings use inulin infusions) surrogate estimates of GFR are often used. As creatinine is a continuously produced endogenous substance (muscle derived) that undergoes glomerular filtration without any subsequent reabsorption and only minimal tubular secretion it can be used as a simple measure of GFR. Creatinine clearance (CrCl) can be calculated using a timed urine collection by measuring the urinary flow rate (V) (mL/min) and urinary creatinine concentration (U) (μmol/L) with a simultaneously drawn plasma creatinine concentration (P) (μmol/L) using the simple equation: CrCl = UV/P. (**Note**: plasma creatinine should now universally be measured by the standardized isotope dilution mass spectrometry (IDMS) method, which is considered the best reference standard measure [2]). However, as creatinine production is significantly influenced by age, gender, and muscle mass and as there is often the need to compare renal function between different patient groups, various estimating equations for GFR (eGFR) have been derived (Cockcroft and Gault [3], modification of diet in renal disease (MDRD) [4], CKD Epidemiology Collaboration CKD-EPI [5]). It is important to remember that these are estimating equations derived in specific patient populations (e.g. MDRD equation was derived from patients with GFRs between 15 and 60 mL/min/1.73 m^2); they are inaccurate in patients not at steady state (i.e. during acute renal failure or its recovery) and in patients on dialysis. The units of GFR are usually millilitres per minute (mL/min) corrected for body size to an average body surface area of 1.73 m^2, i.e. mL/min/1.73 m^2. This enables the comparison of renal function in two or more individuals of different body size. Creatinine concentration can be used as a simple measure of renal function. Again assuming that creatinine production remains unchanged an increase in creatinine in a given individual reflects worsening renal function whereas a decrease reflects improving renal function. It is important to remember that the relationship between GFR and serum creatinine is inverse and non-linear (see Fig. 208.1).

From Fig. 208.1, it can also be seen that up to 50% of GFR can be lost before the serum creatinine rises outside of the normal range, and at lower levels of GFR further small reductions in GFR can result in a significant rise in the blood concentration of creatinine and other important solutes (urea and potassium).

Due to the semi-permeable nature of the glomerulus, the composition of the glomerular filtrate is effectively identical to that of the blood plasma minus the proteins which under normal circumstances are too large to cross. Given that the daily GFR is 170 L a significant recovery mechanism is needed to prevent major solute and fluid loss. This is achieved by the subsequent luminal fluid manipulation, both active and passive, that occurs in various segments of the renal tubule. The final urine produced is therefore a highly modified version of the glomerular filtrate and is so well balanced that subtle adjustments in various elements and fluid balance can be achieved.

Tubular reabsorption

The majority of the filtered solute (sodium, potassium, chloride, calcium, phosphate, and bicarbonate) is recovered in the PxCT [6] (see Table 208.1) via specific pathways driven by a sodium/potassium adenosine 5'-triphosphatase (Na^+/K^+ ATPase) found on the basolateral membrane. ATPase generates an electrochemical gradient by removing sodium from the cell and moving potassium

Table 208.1 Summary of renal handling

Element	PxCT	DL of the LOH	AL of the LOH	DCT	CD	Urine content as % of filtered load
Na^+	65–70%	0%	20–25%	5–9%	0%	<1%
K^+	65–70%	0%	25%	Secretion	0%	>20%
Ca^{2+}	55–70%	0%	20–25%	5–10%	<2%	1–3%
$PO4^{3-}$	80–95%	0%	0%	0%	0%	5–20%
HCO_3^-	80–85%	0%	10–15%	5%	0%	0%
H_2O	65–70%	15%	0%	5%	10–14%	<1%

% indicates the percentage of filtered elements reabsorbed in different part of the nephron.

PxCT, proximal convoluted tubule; DL, descending limb; AL, ascending limb; LOH, Loop of Henle; DCT, distal convoluted tubule; CD, collecting duct.

Data from Maddox DA and Gennari FJ, 'The early proximal tubule: a high-capacity delivery-responsive reabsorptive site', *American Journal of Physiology*, 1987, **252**(4 Pt 2), pp. F573–84.

into the cell. Amino acids and glucose, when at normal levels, are completely recovered by the PxCT via luminal sodium-amino acid and sodium–glucose cotransporters. Significant water recovery also occurs in parallel to this active solute uptake in the proximal tubules. The thick ascending limb of the loop of Henle selectively recovers another 20–25% sodium and chloride via a luminal sodium potassium chloride co-transporter, without any passage of water. This mechanism is blocked by frusemide. The distal convoluted tubule absorbs small amounts of sodium and chloride again utilizing a basolateral Na^+/K^- ATPase and a luminal sodium-chloride co-transporter (the latter is blocked by thiazide diuretics [7]).

Water balance

As mentioned earlier, a large volume of fluid is filtered by the glomerulus and so several mechanisms exist to prevent significant fluid losses. The majority of filtered water (65–70%) returns to the circulation along with the filtered solute in the PxCT. The second location for water reabsorption is in the thin descending limb of the LOH. This part of the LOH is permeable only to water and as it travels deeper into the renal medulla it is exposed to increasing osmotic forces, from the iso-osmolar (300 mOsm/kg) cortex through to the hyperosmolar (up to 1200 mOsm/kg) medulla. This osmotic concentration gradient is generated by the active solute exchange (counter current exchange [8]) that occurs in the LOH. Aquaporin channels selectively allow the movement of water across the cell membrane under the influence of the osmotic gradient. The solute reabsorption in the DCT also results in water reabsorption (approximately 5%). The final location for water reabsorption is in the CD. The CD again utilizes the increasing osmotic gradient as it traverses from the cortex to the medulla and water is reabsorbed via aquaporin channels under the control of anti-diuretic hormone (ADH). ADH is produced by osmoreceptors (neurosecretory neurons) in the hypothalamus under circumstances of dehydration and secreted by the posterior pituitary into the blood. ADH then travels via the blood to the kidney where it binds to a basolateral membrane receptor that initiates a cyclic AMP dependent protein kinase pathway that results in insertion of preformed aquaporin channels onto the luminal membrane of the CD [9] allowing water reabsorption. The action of ADH is to produce a reduced volume of more concentrated urine. ADH secretion is inhibited by over hydration and in the absence of ADH the CD aquaporin channels are removed from the luminal surface rendering the CD impervious to water. This absence of ADH results in the passage of a larger urine volume with a low osmolality. Through these processes serum osmolality is maintained between 285 and 295 mOsm/kg by the kidney's ability to produce urine with a concentration varying between 50 and 1200 mOsm/kg [10].

Acid balance

Normal metabolic function results in the production of acid. Some of these acids can be removed in the form of carbon dioxide via respiration. Other acids can only be removed by passage in the urine. Two areas of the nephron are critical in managing acid base balance via proximal tubular bicarbonate recovery and acid secretion in the late distal tubule/cortical collecting duct [11].

Proximal tubule

As bicarbonate is freely filtered by the glomerulus a recovery mechanism is required to prevent massive bicarbonate loss that would result in acidosis (i.e. proximal renal tubular acidosis (RTA), also known as type II RTA); the PxCT is a site of major bicarbonate recovery. The mechanism used to recover bicarbonate relies on a luminal sodium-hydrogen exchange carrier molecule (NHE-3) and luminal carbonic anhydrase (CA). Freely filtered HCO_3^- combines with actively secreted hydrogen to form H_2CO_3. In the presence of CA, H_2CO_3 dissociates to H_2O and CO_2, the latter can then diffuse into the PxCT. Within this cell and again in the presence of CA the CO_2 combines with H_2O to form H_2CO_3. This can then dissociate into H^+ and HCO_3^- of which the former can move via the NHE-3 into the luminal fluid and the latter into the blood via a basolateral Na^+/HCO_3^- co-transporter. Any defect in this system results in bicarbonate remaining within the tubule (although the distal tubule can compensate for some of these losses) resulting in a metabolic acidosis. The most common cause of this in adults is the use of a carbonic anhydrase inhibitor (acetazolamide) and in children due to a congenital tubular defect (Fanconi's syndrome which is also associated with increase urinary losses of amino acids, glucose, phosphate, and uric acid).

Distal tubule

The distal tubule is responsible for active acid secretion into the lumen via two separate mechanisms involving H^+-ATPase located on the luminal membrane (intercalated cell). This mechanism is again dependent on intracellular CA producing H_2CO_3, which then dissociates into H+ and HCO_3^-. The HCO_3^- moves across the basolateral cell membrane via a chloride-bicarbonate exchange carrier. The H^+ is actively transported into the lumen via the H^+-ATPase and then binds with either filtered HPO_4^{2-} to form $H_2PO_4^-$, or luminal ammonia (NH_3), produced by proximal tubule glutaminase from the amino acid glutamine [12], to form ammonium (NH_4^+) both of which are trapped within the lumen and excreted. This process not only results in the secretion of acid, but also generates bicarbonate and hence partly compensate for proximal losses if they occur. Significant up-regulation of acid excretion can occur through increased NH_3 production. Any defect in this distal system will result in failure of acid secretion and this usually results in a significant metabolic acidosis (distal renal tubular acidosis, also known as type I RTA). The most common causes of this condition in adults include tubular diseases seen with autoimmune diseases (Sjögrens syndrome and SLE) and drugs (lithium and amphotericin), and in children due to a congenital tubular defect (hereditary RTA).

Insulin and gluconeogenesis

The kidney has an important role in the control of blood glucose through several mechanisms. Under normal physiological conditions freely filtered glucose is completely reabsorbed by the proximal tubule leaving the resultant urine free of glucose. However, as the maximal re-absorptive capacity of filtered glucose is only 11 mM, filtered glucose loads above this level (i.e. during diabetes induced hyperglycaemia) will result in glycosuria. The process of glucose reabsorption is achieved by luminal membrane based sodium-glucose linked transporters (SGLT1/2) [13], again driven by a basolateral based Na^+/K^+ ATPase, and the passive removal of intracellular glucose via basolateral glucose transporters (GLUT1/2) [14]. The kidney is now also considered to be an important site of glucose production (up to 40%) [15], after that of the liver, through the process of gluconeogenesis. This results in

the generation of glucose from non-carbohydrate carbon substrates (principally lactate). A final factor that impacts on blood glucose control is the kidneys role in insulin clearance. Insulin is freely filtered by the glomerulus and then reabsorbed by the PxCT where it undergoes proteolytic degradation into small peptide fragments that are then returned to the circulation.

Hormonal function

Erythropoietin

Erythropoietin is a critical glycoprotein hormone that controls erythropoiesis. If the oxygen concentration of the blood passing through the kidney is low, specialized fibroblasts within the peritubular interstitium are stimulated to produce erythropoietin [16]. This erythropoietin then travels through the blood to the bone marrow where it stimulates the proliferation of erythrocyte precursors into mature red blood cells. In kidney disease erythropoietin levels can be inappropriately low or absent causing significant anaemia. This can easily be corrected by administration of synthetic erythropoietic agent [17].

Vitamin D and parathyroid hormone

Vitamin D is a critical hormone for calcium homeostasis and bone metabolism. The kidney converts 25-hydroxycholecalciferol into its activated form 1,25-dihydroxycholecalciferol [18]. In the presence of kidney disease activated vitamin D levels fall resulting in a decrease in serum calcium concentration. Decreasing calcium concentration are countered by increasing parathyroid hormone (PTH) concentration, which stimulates the release of calcium from bones in an attempt to return the serum calcium concentration to normal. PTH concentration also increases in kidney disease due to reduced phosphate clearance resulting in elevated serum phosphate concentration. PTH increases renal phosphate clearance in the attempt to return the serum phosphate to normal. This stimulation of the parathyroid gland to produce PTH is termed secondary hyperparathyroidism although if prolonged can result in the production of uncontrolled parathyroid adenomas (tertiary hyperparathyroidism) [19].

Renin

Renin is an enzyme produced by specialized cells within the afferent arteriole adjacent to the DCT (juxtaglomerular apparatus). Factors that stimulate renin production include a decrease in blood pressure, reduced sodium delivered to the DCT and increased sympathetic activity [20], i.e. situations suggesting dehydration or hypotension. Once in the blood, renin hydrolyses angiotensinogen (produced by the liver) into angiotensin I, which in turn is converted to angiotensin II by ACE within the lungs. Angiotensin II increases blood pressure through arteriolar vasoconstriction, aldosterone production, sympathetic nervous system activation, increased thirst, and direct stimulation of proximal tubular sodium reabsorption. Important factors that result in inappropriate renin production and resulting systemic hypertension include renal artery stenosis and kidney disease.

Influencing hormones

Aldosterone is an important steroid hormone that is produced in the adrenal gland (zona glomerulosa) in the presence of angiotensin II or high potassium concentration. Aldosterone acts to stimulate sodium reabsorption (via luminal epithelial sodium channels ENaC which is blocked by amiloride) and potassium secretion (via K^+ channels in the luminal membrane) in the cortical collecting duct (principal cell), again driven by a basolateral Na^+/K^- ATPase, resulting in salt and water retention.

PART 8.2

Renal monitoring and risk prediction

CHAPTER 209

Monitoring renal function in the critically ill

Paul M. Palevsky

Key points

- Renal function needs to be closely monitored in patients at high risk for acute kidney injury (AKI).
- Urine output should be monitored continuously in all patients.
- Serum creatinine should be measured at least daily, with more frequent measurement in patients at increased risk for AKI as the result of underlying susceptibilities and acute exposures.
- Calculated estimates of glomerular filtration rate (eGFR) are unreliable in critically-ill patients with unstable kidney function.
- Biomarkers of tubular injury may be helpful in the differential diagnosis of AKI and for assessment of prognosis, however, they do not have a role in routine monitoring of kidney function.

Introduction

The manifestations of kidney dysfunction in critically-ill patients range from asymptomatic laboratory abnormalities associated with early or mild disease to a constellation of symptoms including oliguria, volume overload and overt uremic manifestations accompanied by acidaemia and electrolyte derangements in patients with severe acute kidney injury (AKI). A fundamental difficulty in the assessment of kidney function is the absence of reliable bedside methods to measure glomerular filtration rate (GFR) and rapidly detect changes in kidney function. In the critical care setting, kidney function is commonly monitored based on changes in the concentration of urea and/or creatinine in the blood or as the result of sustained reduction in urine output and these are the parameters that are used for the consensus definitions and staging of AKI Tables 209.1 and 209.2 [1].

Urine volume

Although reductions in urine volume may be a manifestation of both AKI and advanced chronic kidney disease (CKD), urine volume is neither a sensitive nor specific index of kidney function. Sustained acute oliguria, which is defined as a urine output of <20 mL per hour or <400–500 mL per day, in the absence of effective intravascular volume depletion almost always indicates the presence of AKI. While oliguria is often considered to be a cardinal feature of AKI, the majority of critically-ill patients with AKI are non-oliguric. Thus, although the acute onset of sustained oliguria should prompt the evaluation for AKI, the presence of a well-maintained urine output should not be equated with the absence of impaired kidney function. Anuria (the absence of urine output) always demands prompt attention. True anuria is most often caused by complete urinary obstruction, but may also be seen with vascular catastrophes resulting in bilateral renal infarction and less commonly with severe forms of rapidly progressive glomerulonephritis. Rarely, severe intrinsic AKI due to acute tubular necrosis may result in transient anuria. In patients with CKD, urine output is generally preserved until kidney function is severely impaired and may even be sustained in occasional patients requiring chronic dialysis.

Markers of glomerular filtration rate

GFR is the primary index used to assess kidney function. While most rigorously measured from the clearance of exogenous markers

Table 209.1 Kidney Disease: Improving Global Outcomes (KDIGO) definition and staging of acute kidney injury

	Serum creatinine	Urine output
Definition	Increase by ≥26.5 µmol/L (≥0.3 mg/dL) within 48 hours; *or* Increase to ≥1.5 times baseline, which is known or presumed to have occurred within the previous 7 days	<0.5 mL/kg per hour for 6 hours
Stage 1	1.5–1.9 times baseline *or* ≥26.5 µmol/L (≥0.3 mg/dL) increase	< 0.5 mL/kg per hour for 6–12 hours
Stage 2	2.0–2.9 times baseline	<0.5 mL/kg/hour for ≥12 hours
Stage 3	≥3.0 times baseline *or* Increase to ≥353.6 µmol/L (≥4.0 mg/dL) *or* Initiation of renal replacement therapy *or* In patients <18 years, decrease in eGFR to <35 mL/min/1.73 m^2	<0.3 mL/kg/hour for ≥24 hours *or* Anuria for ≥12 hours

Either serum creatinine or urine output criteria satisfied.

Table 209.2 Comparison of RIFLE, AKIN, and KDIGO creatinine-based definitions of acute kidney injury*

	RIFLE	AKIN	KDIGO
Definition	Increase to ≥1.5 times baseline that is both abrupt (within 1–7 days) and sustained (>24 hours)	Increase of ≥26.5 μmol/L (≥0.3 mg/dL) *or* Increase to ≥1.5 times baseline within 48 hours	Increase of ≥26.5 μmol/L (≥0.3 mg/dL) within 48 hours; *or* Increase of ≥1.5 times baseline, which is known or presumed to have occurred within the prior 7 days
RIFLE –R AKIN/KDIGO Stage 1	Increase to 1.5–2 times baseline	Increase of 1.5–2 times baseline *or* Increase of ≥26.5 μmol/L (≥0.3 mg/dL)	Increase of 1.5–1.9 times baseline *or* Increase of ≥26.5 μmol/L (≥0.3 mg/dL)
RIFLE –I AKIN/KDIGO Stage 2	Increase to 2–3 times baseline	Increase of 2–3 times baseline	Increase of 2.0–2.9 times baseline
RIFLE –F AKIN/KDIGO Stage 3	Increase to >3.0 times baseline *or* Increase to >353.6 μmol/L (>4.0 mg/dL) with an acute rise >44 μmol/L (>0.5 mg/dL)	Increase of >3 times baseline *or* Increase to ≥ 353.6 μmol/L (≥4.0 mg/dL) with an acute rise >44 μmol/L (>0.5 mg/dL) *or* On RRT	Increase of ≥3.0 times baseline *or* Increase to ≥353.6 μmol/L (≥4.0 mg/dL) *or* Initiation of RRT *or* In patients <18 years, decrease in eGFR to <35 mL/min/1.73 m^2
RIFLE-L	RRT > 4 weeks		
RIFLE-E	Need for RRT for >3 months		

RIFLE, risk, injury, failure, loss, end-stage; AKIN, acute kidney injury network; KDIGO, Kidney Disease: Improving Global Outcomes; RRT, renal replacement therapy.

The urine output criteria for these three definition and classification systems for acute kidney injury are the same (see Table 209.1).

of glomerular filtration such as inulin, iothalamate, or iohexol, GFR is more commonly assessed based on the concentrations of endogenous solutes that are primarily excreted by glomerular filtration such as urea, creatinine, and less frequently cystatin C. A sudden decrease in GFR will result in rising concentrations of these solutes in the blood. However, the relationship between the GFR and the concentration of these solutes is nonlinear and may be affected by a variety of additional factors.

Urea

Urea is the major end product of nitrogen metabolism. Blood urea concentration, often assayed as blood urea nitrogen (BUN), is dependent upon the balance between synthesis in the liver and excretion by the kidneys. Although increases in urea concentration are often assumed to be due to reduced kidney excretion, increases in urea generation as a result of excessive dietary protein intake, from amino acid loading during nutritional support and from breakdown of the endogenous protein load from gastrointestinal haemorrhage as well as during the hypercatabolic states associated with fever, sepsis, or glucocorticoid administration can cause elevations in the urea concentration in the absence of significant decrease in GFR. Conversely, when hypercatabolic states are superimposed on AKI, the increase in urea may be exaggerated and exceed the increase of 4–8 mmol/L (10–20 mg/dL) per day that is typically seen in patients who are functionally anephric.

Normally, urea is freely filtered at the glomerulus and partially reabsorbed along the length of the nephron. Urea reabsorption is increased in states of low urine flow, such as volume depletion and severe heart failure, resulting in increases in urea concentration that are disproportionate to the decrease in GFR. This variability in urea generation and renal tubular reabsorption contribute to the poor performance of urea as a marker of GFR. However, the urea concentration generally correlates with symptoms of renal failure, with uremic manifestations usually absent until the urea concentration is greater than 30–35 mmol/L (85–100 mg/dL).

Creatinine

Creatinine is generated from the non-enzymatic hydrolysis of muscle creatine and is excreted primarily by glomerular filtration, although there is a variable component of tubular secretion. Creatinine generation is relatively constant, correlating with lean muscle mass, averaging 175–220 μmol/kg (20–25 mg/kg) per day in healthy young adult males and 130–175 μmol/kg (15–20 mg/kg) per day in healthy young adult females. Creatinine generation declines with age, malnutrition, and in chronic disease. Creatinine is freely filtered at the glomerulus and is not reabsorbed along the length of the nephron. In patients with normal kidney function,

less than 10% of urinary creatinine is due to tubular secretion. However, this percentage increases as GFR decreases in patients with CKD. Hence, given the relatively predictable generation rate and predominant excretion by glomerular filtration, the plasma creatinine concentration is inversely related to GFR, with increased creatinine concentration associated with decreased GFR. This has allowed the development of equations to estimate GFR based on serum creatinine with adjustments for demographic and clinical variables [2–5].

In the absence of glomerular filtration, such as during severe AKI, serum creatinine typically increases by 90–175 μmol/L (1–2 mg/dL) per day. This increase is influenced by multiple factors including the degree of decrease in GFR, the rate of creatinine production and changes in the volume of distribution of creatinine. For example, creatinine production is often reduced in sepsis [6], and may be markedly increased in rhabdomyolysis. In addition, aggressive volume resuscitation may mask an increase in serum creatinine by rapidly expanding its volume of distribution and diminishing or obscuring the rise in serum concentration [7]. Several other factors may also impair the reliability of serum creatinine as a marker of kidney function in critical illness. Some medications, most notably trimethoprim and cimetidine, block tubular secretion of creatinine, leading to an increase in serum creatinine concentration in the absence of decreased kidney function [8]. While this effect is generally minimal in patients with normal kidney function, the increase in serum creatinine may exceed 30% in patients with underlying CKD. Reported creatinine concentrations may also be increased as a result of chemical interference with some assay methods by ketone bodies or by medications, such as cefoxitin [8]. One final drawback to the use of creatinine as a marker of kidney function in patients with AKI is the inverse relationship between serum creatinine concentrations and GFR. Thus, significant reductions in GFR may occur prior to the change in serum creatinine concentration being recognized.

Cystatin C

Given the limitations of urea and creatinine as markers of kidney function, other readily available markers of glomerular filtration have been sought. Cystatin C, a cysteine protease inhibitor that is released into the bloodstream at a constant rate from all nucleated cells, has been proposed as a more sensitive endogenous marker of glomerular filtration rate, including in ICU patients. Cystatin C is filtered at the glomerulus and reabsorbed and catabolized by renal proximal tubular epithelial cells such that normally virtually no cystatin C appears in the urine. The inter-individual variability in cystatin C production appears to be less than that for creatinine. Thus, in steady-state situations cystatin C may be a more reliable marker of glomerular filtration [9]. In addition, the serum half-life of cystatin C is shorter than that of creatinine, making it a more sensitive marker for acute changes in glomerular filtration. However, cystatin C assays are not currently readily available in the acute clinical setting, and the optimal role for cystatin C in the detection of AKI in critically-ill patients remains to be determined.

Quantification of glomerular filtration rate

Precise quantification of GFR requires the measurement of clearance of endogenous or exogenous solutes that are removed primarily by glomerular filtration. Creatinine clearance may be measured by performing a timed urine collection and dividing the rate of urinary creatinine excretion by the concentration of creatinine in the blood, expressed as:

$$\text{Creatinine Clearance} = U_{creat} \times V/P_{creat} \quad \text{[eqn 1]}$$

where U_{creat} is the urine concentration of creatinine, V is the urine flow, expressed as volume per unit time, and P_{creat} is the average concentration of plasma creatinine during the urine collection [10]. When plasma creatinine is in steady state, a single measurement is sufficient. However, when creatinine concentration is changing, as is generally the case in AKI, a time averaged concentration based on serial measurements during the urine collection is necessary. Alternatively, if the timed collection is relatively brief, a mid-point serum creatinine may be sufficient [10]. Measured creatinine clearance is prone to errors in quantification of the precise duration and volume of the urine collection, small errors in quantification of these parameters, especially when collection time is shorter than 12 hours or urine volume is less than 1 litre may result in substantial error in the calculated creatinine clearance. In addition, since creatinine is excreted by tubular secretion as well as by glomerular filtration, measured creatinine clearance will generally overestimate true GFR. For these reasons, measurement of creatinine clearance is rarely used to monitor kidney function in the critically-ill patient. While the use of exogenous filtration markers such inulin, iothalamate, and iohexol provide more precise quantification of GFR, they are rarely used outside of research settings and are not practical tools for monitoring kidney function in the ICU setting. Newer techniques, using differential plasma disappearance of a large non-filterable plasma volume marker and smaller filterable reporter molecule, have been developed and may provide a means for real-time bedside measurement of GFR in the future [11].

Estimated glomerular filtration rate and creatinine clearance

Methods for estimating creatinine clearance and glomerular filtration have been developed based on serum creatinine and/or cystatin C concentrations and using demographic and clinical variables such as age, gender, race, or weight to adjust for inter-individual variability in creatinine and cystatin C generation [2–5]. These equations, including the Cockroft–Gault equation for estimated creatinine clearance and the Modification of Diet in Renal Disease (MDRD) and the CKD Epidemiology Collaboration (CKD-EPI) equations for estimated GFR can only be used when serum creatinine is in steady state. In addition, these equations were developed in cohorts of non-hospitalized patients and have not been validated in the setting of acute illness. Thus, laboratory reported estimates of GFR should not be relied upon in critically-ill patients with unstable kidney function.

Markers of tubular injury

A number of markers of tubular injury including kidney injury molecule-1 (KIM-1) [12], neutrophil gelatinase-associated lipocalin (NGAL) [13], interleukin (IL)-18 [14,15], liver fatty acid binding protein (L-FABP) [16], alpha and pi-glutathione-S-transferase (GST) [17], insulin-like growth factor-binding protein-7 (IGFBP7) [18], and tissue inhibitor of metaloprotinases-2 (TIMP-2) [18], among others, have been described. These markers have shown promise for the early diagnosis of AKI, for differentiation between

Table 209.3 Risk factors for the development of acute kidney injury

Underlying susceptibilities	Acute exposures
◆ Chronic kidney disease	◆ Sepsis
◆ Advanced age	◆ Circulatory shock
◆ Female gender	◆ Cardiac surgery/Cardiopulmonary bypass
◆ Black race	◆ Major non-cardiac surgery
◆ Volume depletion	◆ Burns
◆ Heart failure	◆ Trauma
◆ Liver failure	◆ Nephrotoxic medications (e.g. aminoglycosides, amphotericin B, cisplatin)
◆ Diabetes mellitus	◆ Radiocontrast agents
◆ Non-steroidal anti-inflammatory drugs	◆ Toxins (e.g., ethylene glycol)
◆ RAAS inhibition (e.g. ACEI, ARB)	

RAAS, renin-angiotensin-aldosterone system; ACEI, angiotensin converting enzyme inhibitor; ARB, angiotensin receptor blocker.

volume responsive (e.g. pre-renal) AKI and intrinsic tubular injury, and for prediction of the need for renal replacement therapy and hospital mortality [19]. However, the optimal marker or panel of markers and their role in the clinical care of patients at risk for AKI remains uncertain and is an active area of clinical investigation [19].

Approach to monitoring of kidney function

Monitoring kidney function in critically-ill patients should be based primarily on measurements of serum creatinine and urine output [1]. Urine output should be monitored continuously. Oliguria or anuria should be promptly evaluated for evidence of volume depletion or haemodynamic compromise. Persistent oliguria following adequate volume resuscitation should prompt further evaluation of causes of AKI, including obstruction, abdominal compartment syndrome, non-volume responsive haemodynamic compromise and intrinsic causes of AKI. Serum creatinine should be measured at least daily, with more frequent measurement in patients at increased risk for AKI as the result of underlying susceptibilities and acute exposures Table 209.3 [1].

Patients with an acute decline in kidney function should undergo a prompt, systematic evaluation to identify the specific cause, with particular attention to the identification and treatment of reversible aetiologies of AKI. Evaluation should include a careful assessment of medication and environmental exposures, ingestion of toxins, and episodes of sepsis or hypotension. Haemodynamic status, including cardiac output, preload responsiveness, and intra-abdominal pressure should be assessed as appropriate to the clinical context. Additional laboratory testing, including a comprehensive metabolic profile, complete blood count with examination of the peripheral smear, urinalysis with microscopy and urine chemistries may be helpful in elucidating the underlying cause of AKI. Renal imaging studies, particularly renal ultrasound, are also helpful in the evaluation of AKI, particularly for the assessment of acute obstruction. Biomarkers of tubular injury may be helpful in the differential diagnosis of AKI and in assessment of prognosis, although their precise role remains the subject of investigation [19].

In patients with established AKI, continued close monitoring of urine output and serum creatinine is required to stage the severity of AKI and assess the response to treatment. Just as increases in serum creatinine and urea and decreased urine output are the cardinal manifestations of AKI, spontaneous recovery of urine output and fall in blood urea and creatinine concentrations generally herald recovery of kidney function.

CHAPTER 210

Imaging the urinary tract in the critically ill

Andrew Lewington and Michael Weston

Key points

- Imaging of the urinary tract should be considered in patients with acute kidney injury if the cause is not clear.
- Ultrasound is the first choice imaging modality of the urinary tract on the ICU due to its portability and non-invasive nature.
- Contrast-enhanced ultrasound using non-nephrotoxic microbubble contrast agents allows imaging of kidney perfusion.
- Pyonephrosis is a cause of septic shock and needs urgent radiological intervention.
- If iodinated contrast is to be used then measures to prevent contrast –induced AKI must be employed.

Introduction

There are a large number of radiological techniques available to image the urinary tract. However there are limitations as to which of these imaging techniques can be used in a critically-ill patient on the intensive care unit (ICU) in terms of whether the technique can be utilized bedside or whether the patient is stable enough to be transferred to the radiology department. This chapter will therefore focus on those radiological techniques that are most commonly used to image urinary tract in critically-ill patients on the ICU. It will consider imaging of the native kidneys and also consider kidney transplants.

Imaging of the urinary tract in the critically-ill patient is predominantly required to assess renal anatomy in the clinical context of impaired kidney function and to aid diagnosis. Critically-ill patients commonly develop acute kidney injury (AKI) in association with multi-organ failure [1]. The most common cause of AKI in this setting is sepsis which results in renal hypoperfusion [2]. Initially, the AKI can be considered as pre-renal with a reduction in renal blood flow. This can be considered as a functional process. If the hypoperfusion is prolonged intrinsic AKI occurs whereby there is damage to the tubules. It is important to recognize that there are a variety of rarer disorders that should be considered if there is no clear cause. Post-renal AKI is due to urinary tract obstruction and is initially functional but will lead to structural damage if the obstruction is not relieved promptly. Pyonephrosis must be treated as an emergency and is a cause of septic shock.

Ultrasound is the most commonly used radiographic technique to image the urinary tract in critically-ill patients due to its non-invasive nature and ability to be used bedside. Gray scale ultrasound allows an assessment of kidney size (small and/or scarred kidneys implies chronic kidney disease) and the rapid exclusion of urinary tract obstruction. Doppler ultrasound of the intra-renal vasculature can be useful in the investigation of the cause of AKI. Computed tomography (CT) and vascular imaging can be performed in patients who are deemed stable enough for transfer to the radiology department. In both CT and vascular imaging of the urinary tract there should be consideration surrounding the use of iodinated contrast media and the risk of contrast-induced acute kidney injury (CI-AKI). Measures should be taken to reduce exposing patients at risk of or with AKI to nephrotoxins [3]. There is an increased awareness about the longer-term consequences of patients who have had an episode of AKI and the risk of progressive chronic kidney disease (CKD) [4]. It is important to reduce nephron loss and maintain functional reserve of the kidneys [5]. Magnetic resonance imaging (MRI) may be preferred in patients at high risk of CI-AKI but will need to be connected to specific monitoring equipment that can be safely used in the environment of MRI scanner.

Types of imaging

Ultrasound imaging

Gray scale ultrasound

Despite ultrasound findings often being non-specific gray scale and colour Doppler ultrasound are the most commonly used imaging techniques of the urinary tract in critically-ill patients because of its portability and non-invasive nature. Patients with critical illness often present with AKI as part of multi-organ failure and may have pre-existing CKD. The cause of any pre-existing CKD should always be considered and the baseline kidney function should always be sought as this is important when assessing recovery of function. However in the absence of recent biochemical tests of kidney function the demonstration of small (Fig. 210.1 and/or scarred kidneys using gray scale Doppler will favour a diagnosis of pre-existing CKD, whereas the presence of normal sized kidneys would support a diagnosis of AKI. The echogenicity and parenchymal thickness of the kidneys are usually preserved in patients with previously normal kidney function. Patients with CKD often have reduced parenchymal thickness and reduced corticomedullary differentiation. The identification of kidneys of two different sizes in patients presenting with AKI in the setting of known hypertension and treatment with angiotensin-converting enzyme

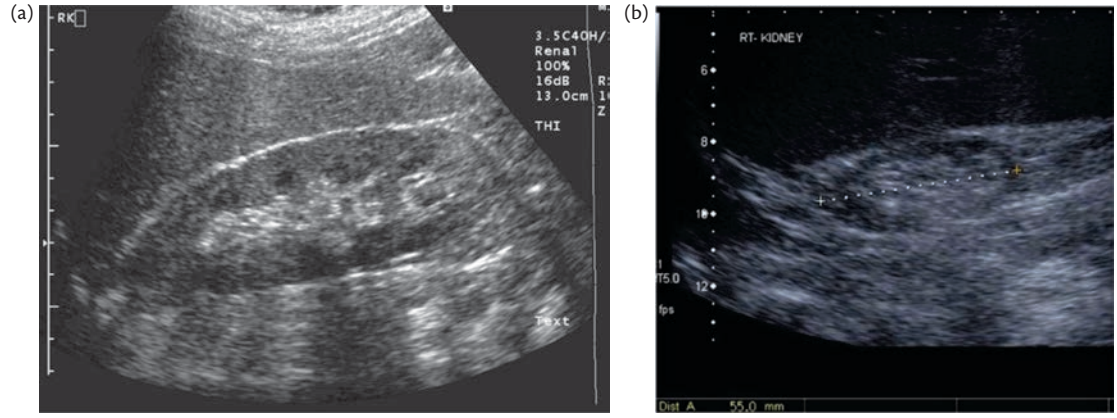

Fig 210.1 (a) Normal longitudinal ultrasound scan of right kidney. Notice the echogenic renal sinus fat, the dark evenly spaced pyramids and the even cortical echogenicity (a little darker than the adjacent liver). (b) Atrophic right kidney, 5.5 cm long. Note reduction in cortical thickness and the cortex is brighter than the adjacent liver.

(ACE) inhibitors would imply the possibility of renal artery stenosis. Further imaging of the renal arteries should be performed using colour Doppler ultrasound but may require magnetic resonance angiography (MRA) or renal arteriography for a definitive diagnosis.

The kidney size is important to assess particularly in patients presenting with AKI of unknown origin. In such patients rarer causes of AKI should be considered especially if there are features of systemic disease (e.g. uveitis, joint pains, rash, haemoptysis) and an active urinary sediment (blood and protein on urinalysis). An ultrasound demonstrating normal sized kidneys in this clinical context should prompt discussions about the utility of performing a kidney biopsy to identify rarer forms of AKI (e.g. vasculitis) and guide further management. Ultrasound guided kidney transplant biopsy maybe required in critically-ill patients to exclude the possibility of rejection as a cause of AKI.

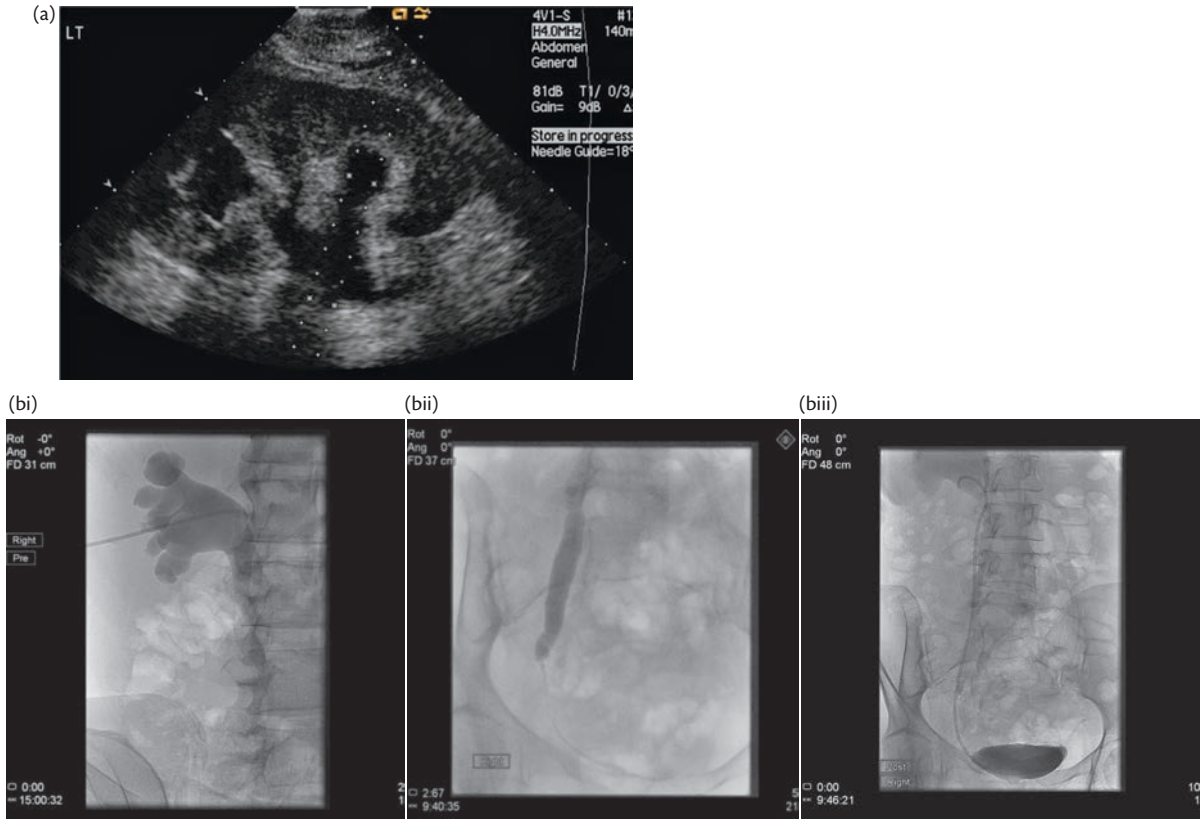

Fig 210.2 (a) Hydronephrotic kidney. The dilated pelvicalyceal system shows up as an echo-free branching structure within the renal sinus fat. Note that the guidelines for an ultrasound guided nephrostomy are aimed at the lower pole calyx. (b) Sequence of three fluoroscopic images. The first shows the dilated pelvicalyceal system is opacified by contrast medium instilled via a nephrostomy catheter. The second shows a distal extrinsic ureteric stricture that has produced the hydronephrosis. The third shows a ureteric stent in place across the stricture.

Ultrasound imaging is the technique of choice to exclude urinary tract obstruction, hydronephrosis (Fig. 210.2a). However it is recognized that in 5% of cases urinary tract obstruction may not be initially present and if it is suspected should be repeated [6]. In patients where obstruction is identified, the insertion of a nephrostomy can be performed radiologically (Fig. 210.2b). Alternatively retrograde ureteric stenting may be preferred and a urological opinion should be requested. The cause of the obstruction should always be sought and may require further imaging such as CT scanning. For obstruction of the urinary tract to cause AKI the function of both kidneys must be affected, either secondary to bilateral obstruction of the urinary tract or obstruction of a single functioning kidney. If urinary tract obstruction is suspected in patients with sepsis and AKI it is important to consider whether there could be an underlying pyonephrosis. Pus secondary to infected urine in an obstructed collecting system will appear as diffuse fine echoes on ultrasound. The associated hypotension and renal microvascular circulatory dysfunction secondary to sepsis may be of sufficient severity to result in pre-renal AKI of the other kidney. The relief of a pyonephrosis must be achieved as soon as possible to prevent the development of septic shock and irreversible damage to the renal parenchyma. Ultrasound is capable of identifying diffusely dispersed fine echoes in the obstructed collecting system which is consistent with infected urine or pus.

Contrast-enhanced ultrasonography (CEUS) of urinary tract using non-nephrotoxic microbubble contrast agents is a new technique which allows imaging of kidney perfusion. The contrast consists of microbubbles of gas stabilized in a coating of lipid, protein or polymer and has a half-life of a few minutes. Ultrasound causes the microbubbles to oscillate and resonate at an appropriate diagnostic frequency. The technique also has the advantage that the imaging is not as sensitive to movement artefacts [7]. The resolution achieved is superior to Doppler ultrasound and can be used to identify areas of non-perfusion and infarction associated with thromboembolism (e.g. trauma, vasculitis, atrial fibrillation or bacterial endocarditis). Contrast-enhanced ultrasound (CEUS) has been validated to assess and quantify the microcirculation up to capillary perfusion in several organs. A recent study utilizing CEUS 24 hours post-surgery demonstrate a decrease in renal perfusion in patients at risk of acute kidney injury [8]. It has also been shown to quantify cortical renal microcirculation in patients undergoing cardiac surgery [9]. These studies provide new possibilities for the assessment of cortical renal microcirculation in ICU patients.

Doppler ultrasonography

Duplex

Doppler ultrasonography of the renal arterial blood flow has been employed to identify patients suspected to have renal artery stenosis (RAS) [10]. Doppler ultrasonography for RAS scanning is very difficult, and is affected by the depth of the arteries, the motion imposed by respiration, and intra-abdominal gas. It has also been used to differentiate pre-renal and intrinsic AKI. Patients with pre-renal AKI generally have a normal intra-renal vascular waveform. In contrast patients with intrinsic AKI have an increased renal resistive index but this is a non-specific finding and does not distinguish the different causes of intrinsic AKI [11]. Improvements in blood flow have been described in patients prior to functional recovery. Doppler ultrasonography is useful in assessing the arterial blood flow in the critically-ill patient with a kidney transplant. Such patients developing AKI should have regular assessment of the arterial blood supply due to the increased risks of renal artery stenosis associated with the anastomotic site. Assessment of the renal transplant veins is also important to exclude renal vein thrombosis as a cause of AKI [12]. Colour Doppler ultrasound gives enhanced imaging of intra-renal blood flow and can identify focal areas of infarction.

Computed tomography

Unenhanced computed tomography

The use of computed tomography (CT) will depend upon the clinical status and stability of the patient. Critically-ill patients need continuous monitoring on transfer to the radiology department. Unenhanced CT of the urinary tract is rarely used as a first-line radiological investigation. It is usually used following ultrasonography to provide useful information on the presence of calcification if obstruction of the urinary tract has been demonstrated (Fig. 210.3) or if suspected but not identified on ultrasonography. It will also identify solid or cystic masses in the kidneys or extra renal masses causing obstruction (e.g. retroperitoneal fibrosis).

Enhanced computed tomography

Enhanced CT uses iodinated contrast media and allows imaging of the renal arteries and veins. In patients with normal kidney function the iodinated contrast is excreted through the urinary tract. However in patients with AKI contrast media will not be excreted and so is not of any clinical utility in assessing the flow through the urinary tract (Fig. 210.4). The contrast will remain in the kidney tubules for up to 24–48 hours. Iodinated contrast media is nephrotoxic and therefore contrast enhanced CT scanning to image the urinary tract system must be approached cautiously in critically-ill patients at risk of AKI. Computed tomography angiography can be used to investigate suspected renal artery stenosis or identify potential sites of active haemorrhage following kidney biopsy (Fig. 210.5).

Magnetic resonance imaging

Magnetic resonance imagining (MRI) allows assessment of both morphological (Fig. 210.6a, b) and functional changes of the urinary tract system. It is an attractive alternative to CT to visualize the renal arteries as it does not require iodinated contrast

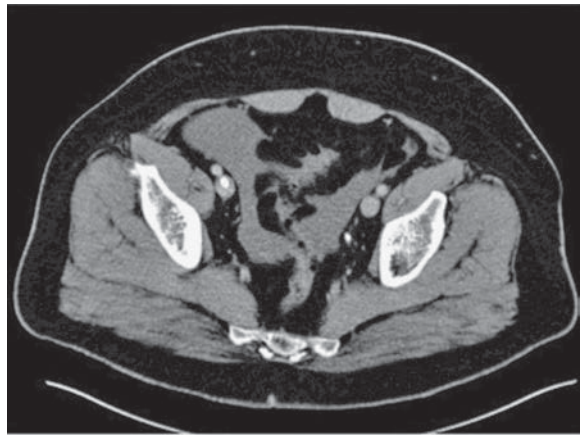

Fig 210.3 Axial CT scan in the lower abdomen. The calculus in the left ureter is visible as a high density focus. There is also free fluid in the peritoneal cavity.

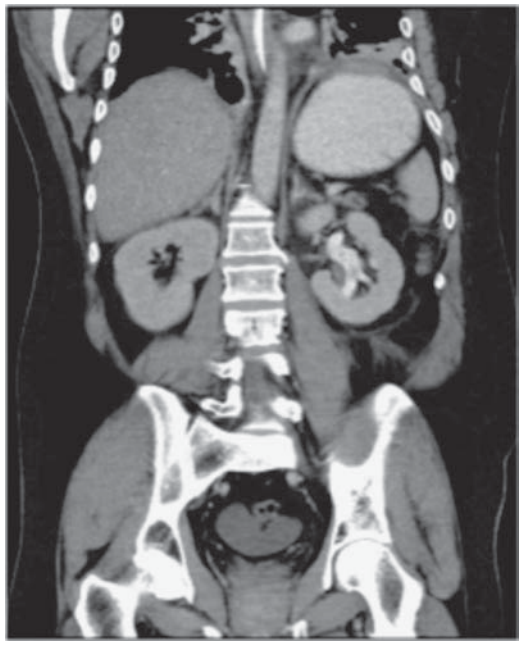

Fig. 210.4 Coronal reformatted CT image. This shows the left kidney has mild distension of the pelvicalyceal system and has retained excreted contrast medium. The right kidney has cleared of contrast medium. One of the typical features of an obstructed system is delayed excretion and persistence of the enhancement. Note that acutely obstructed systems may not be very dilated.

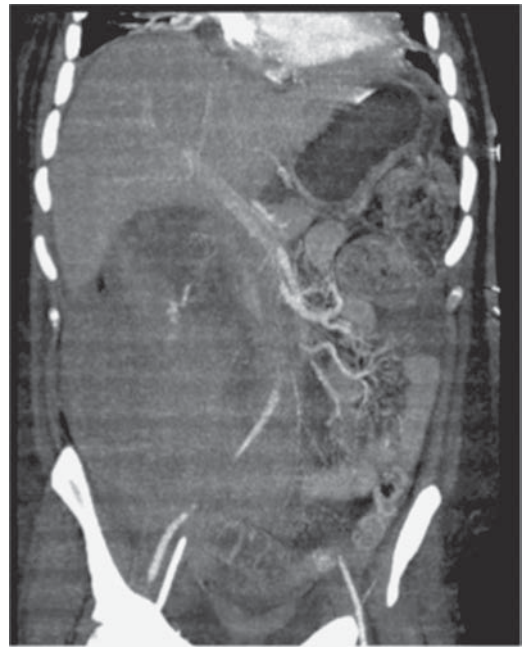

Fig. 210.5 Coronal reformatted CT image in the arterial phase following intravenous contrast medium enhancement. The site of arterial blood leak into the perinephric haematoma is shown.

media and is therefore not associated with CI-AKI (Fig. 210.6c). Magnetic resonance angiography (MRA) should be considered in patients with AKI that is suspected to be the secondary to renal artery stenosis. Demonstration of renal artery stenosis using MRA reduces the subsequent exposure to iodinated contrast which will be required to confirm the findings using renal angiography prior to intervention. Critically-ill patients that require MRI will need to be transferred to non-magnetic life support equipment. Magnetic resonance imaging uses gadolinium (Gd) which is non-nephrotoxic but has rarely been associated with the risk of developing Nephrogenic Systemic Fibrosis (NSF) [13]. Nephrogenic systemic fibrosis is a severe fibrosis of the skin resulting in extensive limitation in mobility.

Renal angiography

Renal angiography is used less often due to the availability and improved resolution of CTA and MRA. Is most often performed for therapeutic interventions such as angioplasty and stenting of confirmed renal artery stenosis or complications from such procedures (Fig. 210.7a) and embolization of sites of renal haemorrhage (Fig. 210.7b).

Iodinated contrast agents

Contrast–induced AKI (CI-AKI) is the third most common cause of AKI in hospital after renal hypoperfusion and nephrotoxic medication [3]. The risk of CI-AKI has been reported to be as high as 25% in patients with a combination of chronic kidney disease (CKD) and diabetes, cardiac failure, older age and exposure to nephrotoxic drugs. The CI-AKI Consensus Working Panel has recommended that the risk of CI-AKI becomes clinically important with an eGFR < 60 mL/min/1.73 m^2 [14]. Critically-ill patients with sepsis and/or hypotension are particularly vulnerable to injury following iodinated contrast exposure. There is currently no validated CI-AKI risk assessment available to recommend for routine use.

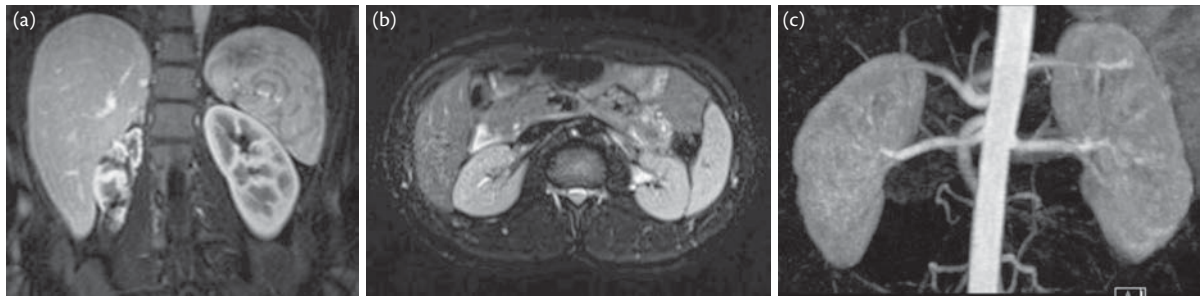

Fig 210.6 Normal magnetic resonance image (MRI) of the kidneys: coronal gadolinium-enhanced magnetic resonance image of the kidneys, scarred atrophic right kidney and normal left kidney (a), axial pyelographic phase image of kidneys (b), coronal maximum intensity projection of an magnetic resonance angiogram (MRA) (c).

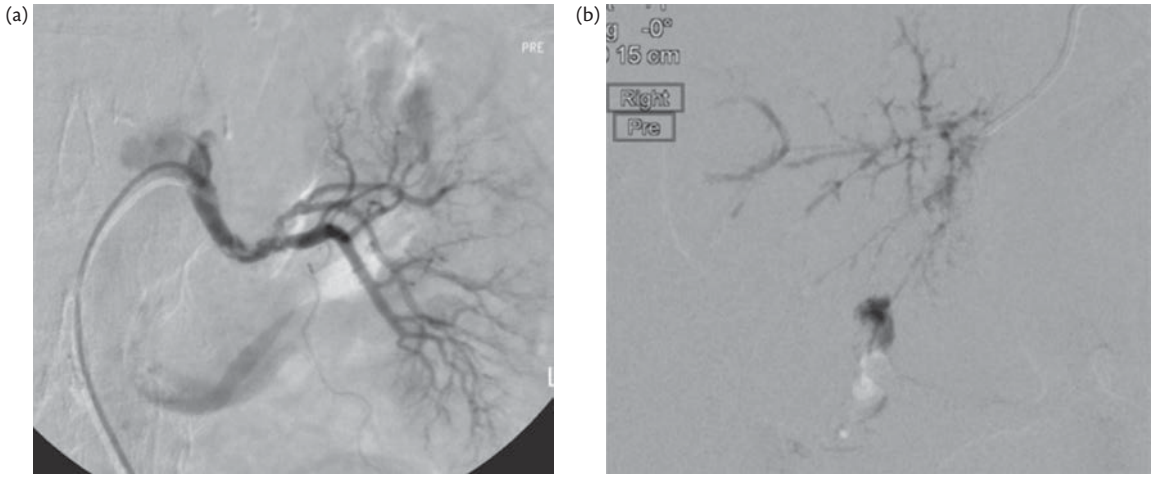

Fig 210.7 Left renal angiogram. The catheter is in the aorta with its tip lying in the ostium of the left renal artery. A spiral lucency corresponding to a dissection flap can be seen within the main renal artery (a). Subtraction renal angiogram technique showing the site of bleeding in the lower pole of the right kidney (b). This was subsequently successfully embolized to stop the bleeding.

Prevention of CI-AKI is important as there is no specific treatment and involves identification of patients at increased risk of CI-AKI. It should also be considered whether alternative imaging could be utilized such as ultrasound or whether carbon dioxide can be used to reduce the amount of iodinated contrast agent required.

Acutely ill patients and patients who are identified at high risk of CI-AKI should have an assessment of their volume status and receive appropriate volume expansion prior to the procedure. It is currently recommended that either intravenous 0.9% sodium chloride or isotonic sodium bicarbonate should be used for volume expansion in patients at risk of CI-AKI. Potentially nephrotoxic medications such as non-steroidal anti-inflammatory drugs and aminoglycosides should be withheld or avoided.

More controversial is the debate regarding whether iso-osmolar contrast media is safer than low-osmolar contrast media in patients at risk of CI-AKI. Currently, there is only one type of iso-osmolar media which has failed to demonstrate any clear benefit compared to different low-osmolar media in preventing CI-AKI. The volume of contrast media should be minimized and further exposure to contrast media should be delayed until full recovery of renal function unless absolutely necessary. Currently there is no compelling evidence for the routine use of N-acetylcysteine to prevent CI-AKI [3].

Table 210.1 summarizes the preferred imaging for common renal conditions.

Box 210.1 Risk factors for patients developing contrast–induced AKI

- Chronic kidney disease (CKD) eGFR < 60 mL/min/1.73m^2.
- Age > 75 years old.
- Cardiac failure.
- Nephrotoxic medication.
  - Aminoglycosides.
  - NSAIDs.
  - Amphotericin B.
- Hypovolaemia.
- Sepsis.
- Volume (dose) of contrast.
- Intra-arterial administration.

Table 210.1 Preferred mode of imaging the renal tract on the ICU

Clinical condition	Preferred radiological investigation on ICU
AKI or CKD	Ultrasound (size and shape of kidneys)
Renal artery stenosis	Doppler ultrasound/CT angiography or MR Angiography
Renal vein thrombosis	Doppler ultrasound
Renal infarction	Contrast-enhanced ultrasound
Pyelonephritis	Ultrasound
Obstruction	Ultrasound
Renal calculus	CT scan
Retroperitoneal Fibrosis	CT scan
Haematuria	Ultrasound/renal arteriography

PART 8.3

Oliguria and acute kidney injury

CHAPTER 211

Pathophysiology of oliguria and acute kidney injury

Rinaldo Bellomo and John R. Prowle

Key points

- The concept that global renal ischaemia accounts for the development of acute kidney injury (AKI) in critically-ill patients in general and patients with sepsis in particular is flawed.
- In patients with severe sepsis, septic shock, and increased cardiac index, global renal blood flow is most likely also either normal or increased.
- In animals and patients with sepsis global renal blood flow is dissociated from glomerular filtration rate.
- Even in the presence of adequate global renal blood flow, there can be tissue ischaemia, especially in the medulla, a finding that suggests intra-renal shunting.
- Inflammation and microvascular changes are likely major contributors to tubular injury and loss of renal excretory function.

Introduction

The term acute kidney injury (AKI) has replaced acute renal failure [1] to emphasize that there is a continuum of kidney injury that begins long before loss of excretory kidney function can be detected with standard laboratory tests. In ICU patients, several conditions trigger and/or predispose to AKI: severe sepsis/septic shock, major surgery (especially open heart surgery), severe liver disease, cardiogenic shock, pre-morbid chronic kidney disease (CKD), and the presence of rhabdomyolysis [2]. As the clinical syndrome common to all of these conditions AKI has conventionally been treated as a single pathophysiological entity. However, much evidence now suggests that the pathophysiology of AKI differs in clinical situations and that septic AKI (S-AKI), in particular, is profoundly different form other forms of AKI.

Key concepts and problems with current paradigms

Most clinicians are familiar with two key AKI-related terms. The first is 'acute tubular necrosis' (ATN). In classic teaching, ATN describes a form of 'intrinsic' (structural) AKI which follows severe and persistent 'pre-renal AKI'. The assumption that ATN results from continued hypoperfusion is widely accepted in textbooks and by clinicians, but may in fact be false. ATN conflates a histological diagnosis (tubular necrosis) that is rarely confirmed by biopsy with a complex clinical syndrome. In both animal experiments and human disease the clinical syndrome is commonly *not* linked with the specific histopathological appearance of ATN [3].

A second concern is that ATN is believed to represent the consequence of sustained or severe 'pre-renal azotemia' which, in contrast to ATN, is considered free of histopathological changes. 'Pre-renal azotemia' is typically expected to resolve over, at most, two to three days. Again, 'pre-renal azotemia', like ATN, is conceptually flawed [4], because it implies that clinicians can know by taking a history, examining the patient and performing urine and blood tests, that there is no histopathological injury.

The third concern is that such concepts are biologically flawed because they imply that AKI does not represent (like all other diseases known to man) a continuum of injury [5].

Pathophysiology

The pathophysiology of inflammatory diseases of the kidney parenchyma (glomerulonephritis and/or vasculitis) is complex. Detailed discussion of these mechanisms is outside the scope of this chapter and can be found in dedicated reviews [6,7]. The same principle applies to acute (but uncommon) vascular events which can cause parenchymal injury and to obstructive disease of urinary tract. In this review, we will mostly focus on AKI secondary to pre-renal factors because it is by far the most common form of AKI in ICU patients.

Animal models of acute kidney injury

The majority of our conceptions of the pathophysiology of AKI due to pre-renal causes are derived from animal models [8]. Most animal models involve the induction of 30–45 minutes of ischaemia by the acute and complete occlusion of the vascular pedicle of the kidney. The associated injury then causes increased organ oedema, decreased renal blood flow (RBF), ATN, and apoptosis, loss of glomerular filtration rate (GFR), evidence of tubular casts with tubular obstruction, and back-leak of tubular solutes and solvent.

However, the clinical relevance of such models is limited, possibly even negligible to conditions like sepsis (the most common form of AKI in ICU patients). Their relevance even to periods of decreased perfusion (e.g. during major surgery) is also limited, given that 80% renal artery occlusion for 2 hours leads to no sustained renal dysfunction.

Unfortunately, animal models of septic AKI which fully resemble the human phenotype are difficult to develop. In small animals endotoxin bolus often induces a hypodynamic (low cardiac output)

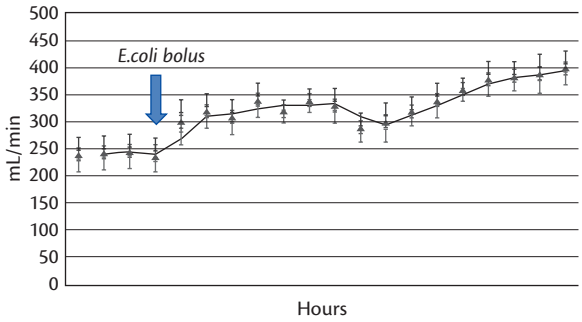

Fig. 211.1 Changes in renal blood flow (with moving average line fit) measured by transit-time flow probe placed around the renal artery in sheep after the induction of Gram negative bacteraemia through intravenous bolus of *E. coli*. Renal blood increases by almost 60% over several hours (values are shown hourly).

[9] shock state resembling more cardiogenic shock, than the human sepsis phenotype. In septic patients a hyperdynamic state (high cardiac output, low blood pressure) is most common. When a hyperdynamic sepsis phenotype of septic AKI is produced in large animals, RBF actually increases to supranormal levels (Fig. 211.1) and renal histopathology is normal.

If experimental septic AKI can occur in the setting of increased RBF, it is impossible to know for sure that such hyperaemia does not also happen in man (RBF cannot be measured continuously and non-invasively in man). Also, if loss of GFR can occur in the absence of histopathological changes in septic animals and humans, it is impossible to assume that ATN occurs due to sepsis in man.

Human studies

Given the uncertainties mentioned previously, it would seem logical to pursue pathophysiological investigations in man. However, renal biopsy is dangerous and ethically unwarranted in critically-ill patients and no accurate, non-invasive, reproducible bedside techniques exist to measure RBF in man. Urinary analysis is similarly of limited pathophysiological value.

The challenge of assessing perfusion

While complete renal ischaemia and reperfusion is associated with AKI both experimentally and clinically, in patients surviving cardiac arrest (a clinically relevant cause of global ischaemia), AKI is uncommon in the absence of post-resuscitation cardiogenic shock. Thus, a major, but relatively short lived (20–30 minutes) reduction in global RBF **alone** appears insufficient to initiate AKI. Conversely, there is considerable historical and recent clinical data to suggest that **established AKI** is associated with reduction in RBF **as a proportion of cardiac output** [10]. To reconcile these seemingly contradictory observations, we need to know how clinical conditions like sepsis and major surgery affect not only global RBF, but also blood flow distribution within the kidney and renal oxygenation in the cortex and medulla, how these changes are related to renal injury (histological and/or functional), and whether reductions in RBF seen in man during established AKI are a cause or a consequence of AKI.

The complexity of renal blood flow

Auto-regulation of RBF is impaired in critical illness prior to and during AKI so that global RBF varies with cardiac output which may be normal, elevated or depressed in different clinical contexts. Renal vasodilatation in experimental sepsis may be due to nitric oxide derived from the endothelial and neural isoforms of nitric oxide synthase (NOS). However, reversal of renal vasodilation by non-selective NOS-blockade does not restore renal function. Furthermore, GFR decreases even during mild hyperdynamic sepsis not associated with systemic hypotension. These observations suggest that an imbalance in pre- and post-glomerular resistance or the development of intra-renal shunting or both account for a fall in glomerular filtration. Thus, outside of extreme situations, what matters to GFR and AKI is not global RBF, but intra-renal blood flow. To confirm these concerns, recent studies have shown that increased renal capillary permeability occurs prior to falls in RBF and that alterations in global renal blood flow are accompanied by changes in cortical microcirculatory hypoperfusion [11], peri-tubular capillary leakage and reactive nitrogen species [11]. In this setting, increased renal blood flow can hide medullary hypoxia due to shunting (Fig. 211.2).

The possible role of bioenergetic failure

Recently experimental studies of septic shock showed that, despite shock, renal hypoperfusion and AKI, tissue hypoxia does not appear to a major pathophysiological issue; mitochondrial respiration remained normal and the gradient between microvascular PO_2 and tissue oxygen tension remained unchanged in both the renal cortex and outer medulla.

Experimental studies have used magnetic resonance technology to measure ATP in the kidney during mammalian hyperdynamic sepsis with or without the infusion of a vasopressor drug. Under both circumstances global renal ATP was preserved. Observations like these undermine the hypothesis that tissue ischaemia is an initiating event in S-AKI [12].

The role of inflammation

Collectively, much evidence suggests that inflammatory responses and inflammatory alterations in the microcirculation are responsible for the progression and maintenance of S-AKI. Toll-like receptors (TLR) recognize molecules that are broadly shared by common pathogens and play a key role in triggering inflammatory responses. In an ovine model of hyperdynamic S-AKI, a TLR-4 antagonist improved renal function during lipopolysaccharide infusion and attenuated renal tubular injury [13]. Thus, in a model of AKI associated with renal hyperaemia, blockade of an early inflammatory pathway prevented biochemical AKI and tubular injury.

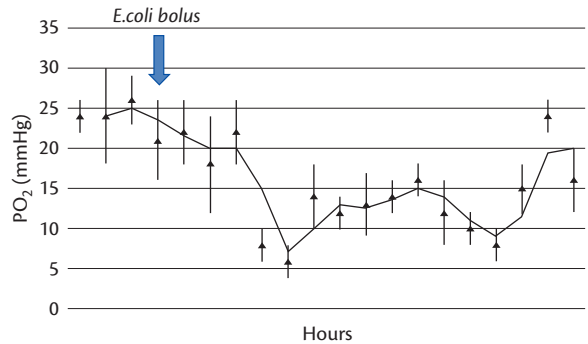

Fig. 211.2 Changes in tissue oxygen pressure in the renal medulla during experimental sepsis in sheep with moving average line fit. In animals that have increased renal blood flow as displayed in Fig. 211.1, there can be substantial undetected medullary hypoxia (values shown hourly).

The reduction in RBF during sustained AKI may occur as a consequence of inflammatory tubular injury contributing to sustained reduction in GFR.

Given that most renal oxygen consumption is related to active sodium reabsorption, the kidney might be relatively protected against ischaemia when GFR is lost. However, recent data for post-cardiac surgery patients also found that sodium reabsorption is inefficient in post-operative AKI compared with no AKI, suggesting that renal oxygenation may remain impaired, despite decreased GFR. This raises the concern that recurrent ischaemia and inflammation may cause repeated renal injury during AKI, leading to delayed recovery and/or non-recovery of renal function. Specific pathways for cellular regeneration or fibrosis may be involved in these processes.

The lessons from attempts to increase global renal blood flow

Treatment choices to optimize renal perfusion during AKI are not clear-cut. For instance prevention of endotoxaemia-induced systemic hypotension by immediate fluid resuscitation in a rat model reduced renal inflammation, but did not prevent reduced renal microvascular oxygenation. In humans, administration of un-buffered isotonic saline solutions has been shown to cause renal vasoconstriction suggesting buffered crystalloids should be used in patients with or at risk of AKI. Conversely, use of vasopressors to raise mean blood pressure from 60 to 75 mmHg has been shown to raise global RBF in humans with AKI after cardiac surgery [14], suggesting renal perfusion pressure is important in determining RBF in AKI. However, use of vasopressors to restore blood pressure will not affect the inflammatory pathogenesis of S-AKI.

An integrated view

A new renal blood flow related paradigm and working hypothesis for the development of AKI is emerging from the accumulating data. Transient alterations in glomerular filtration pressure gradient may cause reversible reduction GFR. Depending on circumstances, this may be associated with reduced, unchanged or elevated RBF. However, sustained AKI likely occurs as a result of tubular injury, which may or may not be preceded by haemodynamic alterations in GFR. If haemodynamic alterations occur, they may be related to intra-renal haemodynamics. If microvascular events occur, global renal blood flow may be maintained or even increased and yet GFR can be markedly decreased. This dissociation between global renal blood flow and function has been recently shown in critically-ill patients by cine phase contrast magnetic resonance [10]. In such patients RBF is related to cardiac index (Fig. 211.3), but not to GFR. Once established tubular injury may then be associated with reduction in RBF secondary to oedema and inflammatory congestion.

Neurohormonal mechanisms

Despite all of the observations mentioned previously, it seems likely that sympathetic system activation and neuro-hormonal responses unique to the kidney are activated in the setting of AKI (Fig. 211.4). They include activation of the renin-angiotensin system (RAAS), activation of the renal sympathetic system, and activation of the tubuloglomerular feedback (TGF) system. Such paradigms, however, do not provide information on which particular pathway of injury has primacy in terms of importance or timing or both. As such, these paradigms do not yet guide the development of novel

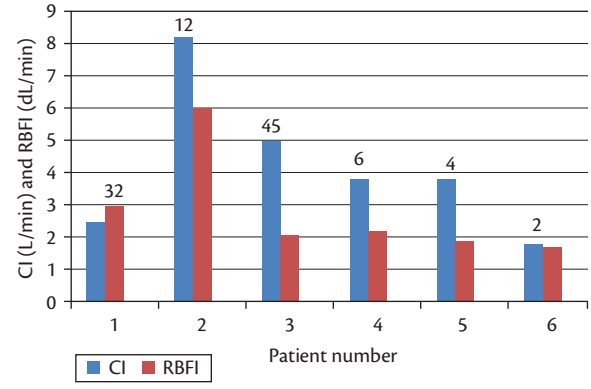

Fig. 211.3 Histogram showing the cardiac index (CI, L/min) and renal blood flow index (RBFI, dL/min) in a cohort of critically-ill patients with AKI. In these patients, CI and RBFI were closely related as shown, although GFR (presented as mL/min above each bar) did not show any correlation with RBFI.

interventions aimed at preventing or attenuating AKI. Finally, it remains unknown whether neurohormonal changes are fundamental to specific forms of AKI like the so-called hepatorenal syndrome (HRS) [15].

In the HRS, like in experimental sepsis, AKI appears to occur in the absence of histopathological and, therefore, is essentially 'functional' in nature. The characteristic finding of intense renal vascular vasoconstriction associated with high levels of RAAS activation suggests that neuro-hormonal cause the HRS. Although the mechanisms for such activation are debated, decreased systemic blood pressure secondary to splanchnic vasodilatation is considered a key event. As a consequence the renal circulation may suffer. Whether this eventually occurs in other states of hypotension and systemic vasodilatation (inflammation or sepsis) remains unknown, but is theoretically possible. Thus, elevations in norepinephrine, renin, and angiotensin II levels may participate in other forms of AKI suggesting that, in some situations, neurohormonal renal vasoconstriction may be a fundamental mechanism of loss of excretory function.

Other forms of acute kidney injury

In large observational studies, rhabdomyolysis-associated AKI accounts for close to 5–10% of cases of AKI in ICUs depending on the setting. Its pathogenesis likely involves pre-renal (hypovolaemia), renal (neurohormonal vasoconstriction, and myoglobin cast formation) and post-renal factors (intra-abdominal hypertension) [16].

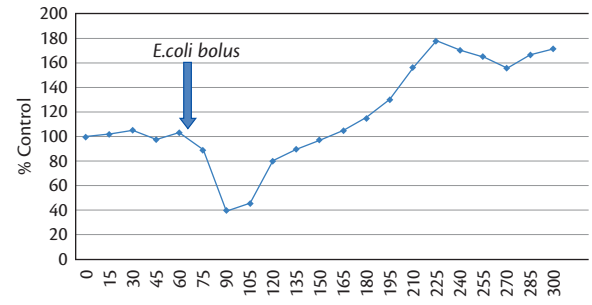

Fig. 211.4 Renal sympathetic nerve activity (RSNA) after the induction of sepsis in sheep. After the initial fall, there is a progressive increase in RSNA.

The changing demographics of patients in developed countries and the increasing incidence of both chronic heart failure and CKD have seen the emergence of more and more patients who combine the presence of heart disease with AKI, often superimposed on CKD and frequently triggered by an acute decompensation of heart failure 'cardiorenal syndromes'. Although focused work in this field is only in its inception, initial insights are emerging that organ congestion may be more important to the pathogenesis of AKI in this setting than low blood pressure and cardiac output [17].

Cardiac surgery associated AKI is increasingly common as older patients undergo such surgery. Its pathophysiology is complex and likely involves multiple mechanisms of injury (cardiopulmonary bypass [CPB]-induced inflammation and haemolysis, low cardiac output states, organ oedema, renin-angiotensin system activation, sympathetic system activation, cholesterol embolism, etc.). These mechanisms likely interact and carry different weight in different patients [18]. With the exclusion of CPB-derived events, similar mechanisms likely play a role in other forms of **major surgery** (another common cause of AKI in critically-ill patients).

Finally, drug- induced AKI accounts for or significantly contributes to 10–15% of AKI in the ICU [19]. The pathophysiology is dependent on the drug in question and varies from direct tubular toxicity from accumulation with aminoglycosides to profound afferent arteriolar vasoconstriction with calcineurin inhibitors [19]. Whatever the mechanism, no effective therapies allow toxic drug therapy to be safely continued; drug withdrawal, lesser dosage or avoidance remain the only therapeutic options.

Oliguria

Our limited understanding of the pathophysiology of AKI in critically-ill patients is reflected in our similarly limited understanding of the pathophysiology of oliguria. Although urine output is the only real time signal that clinicians have to assess what might be happening in the kidney, it is a profoundly flawed biomarker of developing AKI. Several prospective studies show that even several hours of oliguria have limited specificity in diagnosing subsequent AKI [20]. Moreover, clinicians seek to increase such urine output by means of intravenous fluid loading or diuretic therapy or both either in a sequence or together. The pathophysiological basis for such interventions is weak and the potential for harm is real. Whether such interventions are useful in critically-ill patients with adequate mean arterial pressure, intravascular filling, and cardiac output is doubtful.

Conclusion

Although we refer to AKI as if it were a single condition, it represents multiple different aetiologies. Accordingly, its pathophysiology differs depending on the disease or clinical event triggering its development. For the most common type of AKI (S-AKI) in critically-ill patients, novel insights suggest that intra-renal haemodynamic events coupled with/or triggered by inflammation and neurohormonal responses are responsible for loss of kidney function. Establishing, the timing, hierarchy, and links that govern these events will provide a challenge for decades to come. Until such pathophysiological mechanisms are better understood, the development of effective therapies will continue to prove elusive.

CHAPTER 212

Diagnosis of oliguria and acute kidney injury

John A. Kellum

Key points

- Acute kidney injury or impairment (AKI) may be defined as an abrupt reduction in kidney function to a level that is insufficient to meet the needs of the patient.
- Urine output is both a reasonably sensitive functional index for the kidney as well as a biomarker of tubular injury. However, the relationship between urine output and renal function/injury is complex.
- Neither oliguria nor azotaemia alone provide sufficient sensitivity, specificity, or time responsiveness to be useful to define AKI.
- The KDIGO criteria, based on changes in serum creatinine or low urine output represent a broad international consensus for diagnosing and staging AKI.
- Sepsis is the most common cause of AKI in the intensive care unit; although AKI is often multifactorial it is important to rule out or treat preventable causes.

Introduction

For practical purposes acute kidney injury (AKI) is conceptualized entirely through changes in glomerular function even though there are other important functions of the kidney (e.g. tubular, hormonal) that are not considered and even though **injury** to the kidney may not manifest as a change in glomerular function. Also for practical purposes the definition of AKI is based on changes in serum creatinine and urine output—in the near future this is likely to change with the introduction of specific biomarkers of renal cell damage. Unlike other vital organs, the kidney reduces its function when it senses that there is insufficient circulating blood volume, either because blood volume is indeed reduced (e.g. haemorrhage, dehydration) or because other pathologic conditions make it appear that way by reducing renal perfusion (e.g. acute decompensated left heart failure, renal artery stenosis). Much confusion can result when AKI is thought of only as an intrinsic disease of the kidney when factors external to the kidney frequently cause injury or impair function. Similar to the concept that a cardiac arrest is still a cardiac arrest even when the heart is empty and the myocardium is normal; AKI is still AKI when the kidney itself is structurally normal. Finally, when the opposite occurs and there is damage to the kidney without clinical signs, a subclinical form of AKI is said to exist.

Definitions

Oliguria

Although urine output is a reasonably sensitive functional index for the kidney as well as a biomarker of tubular injury, the relationship between urine output and renal function/injury is complex. For example oliguria may be more profound when tubules are patent, but tubular reabsorbtive function is preserved. Volume depletion and hypotension are profound stimuli for vasopressin secretion, as a consequence the distal tubules and collecting ducts become fully permeable to water and thus, urine volume is minimized and urine concentration maximized (>500 mOsm/kg). Conversely, when the tubules are injured, maximal concentrating ability is impaired and urine volume may even be normal (i.e. non-oliguric renal failure). Analysis of the urine to determine tubular function has a long history in clinical medicine. Indeed, a high urine osmolality coupled with a low urine sodium concentration in the face of oliguria and azotemia is strong evidence of intact tubular function. However, this should not be interpreted as 'benign' or even 'pre-renal'. Intact tubular function, particularly early on, may be seen with various forms of renal disease (e.g. glomerulonephritis). Sepsis, the most common condition associated with acute renal failure in the ICU [1], may alter renal function without any characteristic changes in urine indices [2,3]. Finally, although severe oliguria and even anuria may result from renal tubular damage, it can also be caused by urinary tract obstruction and by total arterial or venous occlusion. These conditions will result in rapid and irreversible damage to the kidney and require prompt recognition and management.

Azotaemia

Classically, high blood nitrogen levels, in the form of urea nitrogen, are referred to as azotaemia. The upper limits of the normal ranges for serum urea or blood urea nitrogen (BUN) vary by age, race, and sex (due in part to differences in muscle mass) and by diet (vegetarians will have lower levels), but in general are less than 8.5 mmol/L and 24 mg/dL, respectively. In more recent years, the term is azotaemia is often used for a reduction in GFR regardless of the cause and is manifest by elevations in, but while creatinine is only slighted reabsorbed (with also some tubular secretion), urea is reabsorbed in a manner that is flow dependent. Thus, as flow through the tubules decreases, urea reabsorption, and hence the serum concentration, increases. This difference in renal physiology for urea and creatinine can be exploited to help delineate the aetiology of azotaemia, though important limitations apply.

Acute kidney injury or impairment

Neither oliguria nor azotaemia alone provide sufficient sensitivity, specificity, or time responsiveness to be useful to define acute kidney disease.

The term AKI has been proposed to encompass the entire spectrum of renal impairment from minor changes in renal function to the requirement for renal replacement therapy. Thus, the concept of AKI creates a new paradigm. AKI is not synonymous with acute tubular necrosis (ATN), nor with 'renal failure'. Instead, it encompasses both and also includes less severe conditions (even pre-renal azotaemia). Indeed, AKI can really be thought of as including all forms of **injury** to the kidney as well as **impairment** of function regardless of the cause. This is important because rather than focusing exclusively on patients with renal failure or on those who receive dialysis or on those that have a clinical syndrome defined by pathology that is rarely confirmed (e.g. ATN), the strong association of AKI with hospital mortality demands that we change the way we think about this disorder. In a study by Hoste et al. [4], only 14% of patients reaching RIFLE 'F' received renal replacement therapy yet these patients experienced hospital mortality more than 5 times that of the same ICU population without AKI.

Damage, sub-clinical acute kidney injury, and renal reserve

Damage to the kidney may precede, follow or occur simultaneously with functional decline. This is because reductions in renal function may be adaptive, for example in response to a decrease in circulating blood volume. While the concept of AKI is intended to include damage without loss of function, common forms of AKI (e.g. sepsis) do not produce structural changes that are easily detected with existing imaging techniques. Histopathology does reveal evidence of damage, though often very mild and patchy, but kidney biopsies are rarely obtained from patients with AKI. Studies using sensitive biomarkers of renal damage (e.g. neutrophil gelatinase-associated lipocalin, and kidney injury molecule-1) suggest that some patients have functional decline without evidence of damage while others have biomarker evidence of damage without manifesting functional decline [4]. This second group may be thought off as having a form of AKI that is 'sub-clinical' meaning that it is below our ability to detect clinically [5]. It is important to appreciate that subclinical does not equate to 'mild' or 'unimportant'. This is because the healthy kidney can suffer significant loss of nephrons before there is a change in renal function under normal conditions. A young, healthy individual has significant renal reserve and can sustain significant renal damage without manifesting AKI, while a much smaller degree of injury to a patient with chronic kidney disease (CKD) will result in clinical AKI. The biological consequences of subclinical AKI are currently unknown. The damage may heal or there may be some permanent loss of functional renal reserve. The outcome may be determined by the characteristics of the patient (especially age, but possibly also genetic factors determining recovery), as well as the type and duration of the renal insult.

Diagnosis and staging

Rifle criteria

In order to standardize the definition of AKI, the Acute Dialysis Quality Initiative (ADQI) proposed the RIFLE criteria through a broad consensus of experts [5]. The acronym RIFLE stands for the increasing severity classes Risk, Injury and Failure, and the 2 outcome classes loss and end-stage kidney disease. The three severity grades were defined on the basis of the changes in serum creatinine or urine output where the worst of each criterion is used. The two outcome criteria, loss and end-stage kidney disease, are defined by the duration of loss of kidney function. Since the RIFLE criteria were initially proposed, they have been widely adopted and have ushered in a new era of precision for the diagnosis, treatment, and study of AKI. However, almost from the beginning, there was a concern that using a relative change in serum creatinine to define AKI would mean that patients with pre-existing CKD (and elevated baseline creatinine) would have to incur a larger absolute increase in serum creatinine to fulfil the diagnosis. For example a patient with a serum creatinine of 70 mmol/L (0.8 mg/dL) would meet the criteria for AKI once the serum creatinine reached 105 mmol/L (1.2 mg/dL) or a 35 mmol/L absolute increase. Conversely a patient with serum creatinine of 200 mmol/L (2.26 mg/dL) would not meet the criteria for AKI until the serum creatinine reached 300 mmol/L (3.39 mg/dL) or an absolute increase of 100 mmol/L. Although relative changes in serum creatinine can be equated across different patients because they relate to relative changes in GFR (a doubling of serum creatinine corresponds to a 50% decline in GFR regardless of the baseline creatinine), it is likely that an increase in serum creatinine <100 mmol/L is still clinically significant. Furthermore, compared to patients with normal renal function, patients with CKD will require a much longer time in order to observe a relative change (e.g. 50%) than will be required to observe a fixed increase (e.g. 35 mmol/L).

Beyond rifle: acute kidney injury network and kidney disease improving global outcomes

The Acute Kidney Injury Network (AKIN), an international, interdisciplinary group proposed to modify the RIFLE criteria to include a small (26.5 mmol/L) absolute increase in serum creatinine as an alternative criterion for AKI as long as it was observed to occur within 48 hours [6]. In 2012, Kidney Disease Improving Global Outcomes (KDIGO) adopted the modified RIFLE criteria proposed by AKIN and also included modifications proposed for paediatric patients Table 212.1 [7]. The KDIGO AKI clinical practice guideline emphasizes the need to begin management of AKI in high risk patients even before evidence of AKI is apparent. This approach is predicated on the assumption that AKI is preventable in some proportion of patients. Evidence that this is indeed the case is available only for some forms AKI (most notably nephrotoxic). Nevertheless, the expectation that AKI can only be avoided or attenuated if it can be either predicted or detected early seems reasonable.

Finally, there is hope that the use of functional makers (urine output and serum creatinine) will be replaced or augmented in the near future by injury biomarkers. Several potential serum and urinary markers have been identified Table 212.2 [8]. In the future, markers of cellular injury in the kidney will likely define AKI and offer the potential to diagnose the disorder before functional decline. Until then, the 'tried and true' markers of urine output and serum creatinine, disciplined by (modified) RIFLE criteria, will be the best we can provide.

Risk stratification

Given the risks associated with AKI and the likelihood that early intervention will result in better outcome, it is important to

Table 212.1 Definition and staging of acute kidney injury. Based on the original RIFLE criteria and the modification to include a small absolute increase in serum creatinine for stage 1 as proposed by AKIN, the KDIGO definition of AKI is shown. For staging of AKI, the worse criterion (creatinine or urine output) is used

AKI is defined as any of the following:

- Increase in SCr by ≥ ≥26.5 μmol/L (0.3 mg/dL) within 48 hours; or
- Increase in SCr to ≥1.5 times baseline, which is known or presumed to have occurred within the prior 7 days; or
- Urine volume <0.5 mL/kg/hour for 6 hours.

AKI is staged for severity according to the following criteria

Stage	Serum creatinine	Urine output
1	1.5–1.9 times baseline OR >0.3 mg/dL (>26.5 μmol/L) increase	<0.5 mL/kg/hour for 6–12 hours
2	2.0–2.9 times baseline	<0.5 mL/kg/hour for >12 hours
3	3.0 times baseline *or* Increase in serum creatinine to >4.0mg/dL (>353.6μmol/L) *or* Initiation of renal replacement therapy *or* in patients <18 years, decrease in eGFR to <35 mL/min/1.73 m^2	<0.3 mL/kg/hour for >24 hours *or* Anuria for >12 hours

determine a patient's risk for AKI. The general concept of risk for AKI can be thought of as comprising both the patient's susceptibilities and their exposures [7]. Table 212.2 provides a list of common susceptibilities and exposures. Intuition would suggest that the presence of multiple susceptibilities and exposures would lead to greater risk. Indeed most patients with AKI have more than one susceptibility and/or exposure; many have multiple. However, there is no reliable way to risk stratify patients based on clinical or laboratory criteria. Lack of adequate risk stratification can result in over or under utilization of resources or 'renal sparing' therapies (e.g. admitting a low risk patient to hospital because of concern for AKI; not stopping a nephrotoxic drug for failure to appreciate a high risk patient). Neither is desirable and efforts are under way to develop better risk prediction tools.

Table 212.2 Causes of AKI: exposures and susceptibilities for non-specific AKI

Exposures	Susceptibilities
Sepsis	Dehydration or volume depletion
Critical illness	Advanced age
Circulatory shock	Female gender
Burns	Black race
Trauma	CKD
Cardiac surgery (especially with CPB)	Chronic diseases (heart, lung, liver)
Major non-cardiac surgery	Diabetes mellitus
Nephrotoxic drugs	Cancer
Radiocontrast agents	Anaemia
Poisonous plants and animals	

CKD, chronic kidney disease; CPB, cardiopulmonary bypass.

Aetiology

Acute tubular necrosis

When mammalian kidneys are subjected to prolonged (most studies use more than one hour) warm ischaemia followed by reperfusion there is extensive necrosis destroying the proximal convoluted tubules and the proximal tubules of the outer stripe of the medulla. Distal nephron involvement in these animal experiments is minimal, unless medullary oxygenation is specifically targeted. Although these animals develop severe acute renal failure, not much else resembles the clinical syndrome in humans [6] and the term ATN does not accurately reflect the morphological changes in AKI [6]. Instead, ATN describes a clinical situation in which there is adequate renal perfusion to largely maintain tubular integrity, but not to sustain glomerular filtration. Renal biopsies in patients with ATN dating back to the 1950s [7] confirm the limited parenchymal compromise in spite of severe organ dysfunction [6]. Thus, the syndrome of ATN has very little to do with the animal models traditionally used to study it. More recently, investigators have emphasized the role of endothelial dysfunction, coagulation abnormalities, systemic inflammation, and oxidative stress in causing renal injury, particularly in sepsis [9,10]. True ATN does, in fact, occur. Patients with arterial catastrophes (ruptured aneurysms, acute dissection) can suffer prolonged periods of warm ischaemia just like animal models. However, these cases comprise <1% of AKIs and ironically, these patients are often excluded from

studies seeking to enrol patients with the more common clinical syndrome known as ATN.

Pre-renal azotaemia

At the other end of the spectrum from ATN is the condition that occurs when the kidneys are structurally normal, but something extrinsic is impairing their function. While the causes of AKI are traditionally classified as prerenal, renal, and post-renal, the imprecision of this approach leads to diagnostic and therapeutic confusion. For instance, the treatment of intravascular dehydration, often cited as the classic example of pre-renal azotemia, includes rapid rehydration. However, other 'pre-renal' conditions, including nephrotic, hepatorenal, and cardiorenal syndromes can present with similar laboratory findings, yet the management for these conditions requires fluid restriction. Unfortunately, for many clinicians, the statement that a patient is 'pre-renal' has become synonymous with being dehydrated.

Similarly, reversibility of renal dysfunction does not define 'pre-renal' nor the absence of harm. Several large cohort studies and the prospective EARLYARF study [11] identified that transient (less than 48 hour) AKI was associated with increased need for dialysis and risk of death, even when AKI resolved within 24 hours. The concept of purely functional loss is also challenged by recent studies providing evidence that some, albeit less, damage is actually present in patients with transient AKI. If 'pre-renal' AKI is defined as transient AKI combined with evidence of preservation of renal tubular function (e.g. with a fractional sodium excretion less than 1%), then biomarkers of damage are increased above that observed in 'No-AKI' patients [11]. Even the earliest studies of reversible azotaemia induced in volunteers by water deprivation noted kidney damage as shown by the development of haematuria and proteinuria, which reversed after rehydration [12]. On the other hand, there is good evidence, that when AKI biomarkers are positive, even in the absence of apparent change in function, patients have worse hospital survival and even increased need for dialysis than patients without AKI [4]. Of course the biomarkers may simply predict changes in function that would manifest later except that competing endpoints such as death or dialysis occur first.

Differential diagnosis for AKI

Thus, like many other syndromes, AKI is caused by multiple diseases and should be viewed from the perspective of the disease or diseases causing it, rather than as syndrome comprised of pre-renal, renal, and post-renal conditions. Furthermore, AKI occurring in critically ill patients is frequently multi-factorial. Table 212.2 lists common causes of AKI. It is important to determine the cause of AKI when possible, and in particular, to determine reversible causes. Fig. 212.1 provides a diagnostic flow diagram for patients at risk of or diagnosed with AKI. The longer the AKI condition persists the more likely the injury will become irreversible.

Clinical judgement

While the definitions and classification system discussed above provide a framework for the clinical diagnosis of AKI, they should not be interpreted to replace or to exclude clinical judgment. While the vast majority of cases will fit both AKI diagnostic criteria as well as clinical judgment, AKI is still a clinical diagnosis—not all cases of AKI will fit within the proposed definition and not all cases fitting the

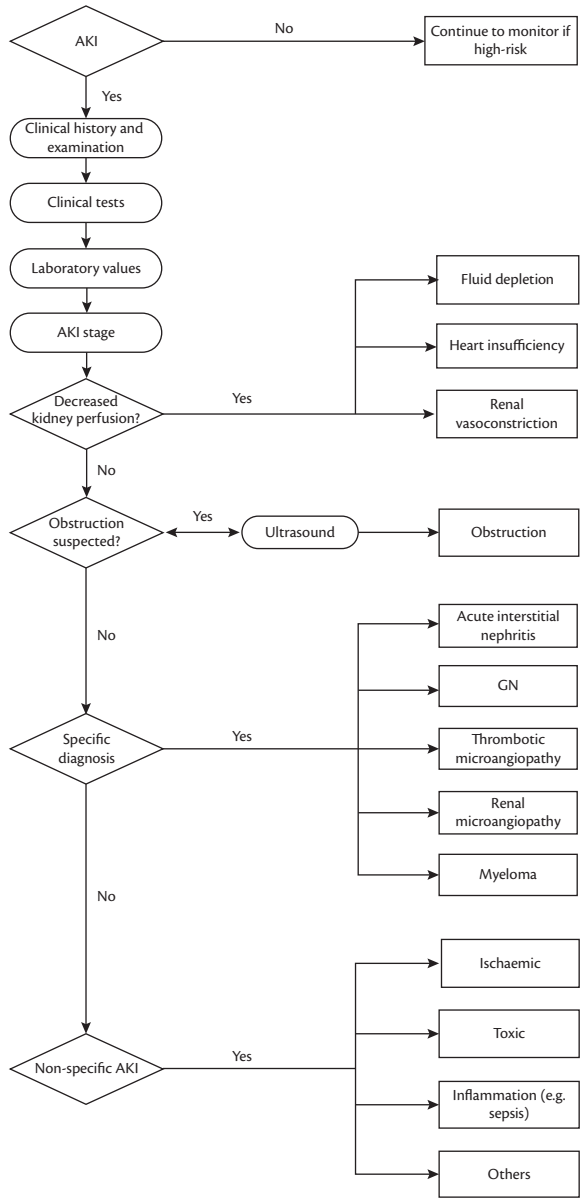

Fig. 212.1 Diagnostic flow diagram for patients at risk of or diagnosed with AKI.

definition should be diagnosed as AKI. However, exceptions should, in general, be very rare. For example, endogenous chromogens (e.g. bilirubin, ascorbic acid, uric acid) and various drugs (e.g. cephalosporins, trimethoprim, cimetidine) may interfere with the creatinine assay, which it could impact the diagnosis of AKI. A similar problem exists with urine output. Particularly outside the ICU, urine output is not often reported and urine collections may be inaccurate, especially in non-catheterized patients. Finally, a weight-based criterion for urine output will mean that some very obese patients will fulfil the definition of AKI without any kidney abnormality. Clinical judgment should always be exercised in interpreting such data.

Conversely, there are situations where a case of AKI fails to meet the definition. These cases should be distinguished from conditions in which data are simply missing and refer to situations in which existing data are unreliable. For example, a patient might receive very large quantities of intravascular fluids such that SCr is falsely

lowered. Similarly, massive blood transfusions will result in the SCr more closely reflecting the kidney function of the blood donors than the patient. It is unusual for these cases not to result in oliguria and, thus, most patients will be diagnosed with AKI even if SCr is not increased. Nevertheless, the clinician should be cognizant of possibility that SCr may be falsely lowered by large-volume fluid resuscitation or transfusion. Changes in creatinine production are also well known in conditions such as muscle breakdown where production increases and in muscle wasting (including advanced liver disease) where production is decreased. Creatinine production may also be decreased in sepsis possibly due to decreased muscle perfusion.

Conclusion

Small changes in kidney function in hospitalized patients are important and associated with significant changes in short and possibly long-term outcomes. The shift of terminology from ATN and acute renal failure to AKI has been well received by the research and clinical communities. AKI severity grades represent patient groups with increasing severity of illness as illustrated by an increasing proportion of patients treated with RRT, and increasing mortality. Like CKD stages AKI stages have now been linked to specific treatment recommendations [7].

CHAPTER 213

Management of oliguria and acute kidney injury in the critically ill

Mohammed Ahmed and Sean M. Bagshaw

Key points

- Acute kidney injury (AKI) is common and increasingly encountered in critically-ill patients and portends a greater risk of morbidity, mortality, and resource utilization.
- Identification of those at highest risk and intensive monitoring for early intervention of AKI can reduce risk of developing severe or worsening AKI.
- There are generally no 'magic bullets' to prevent or treat AKI once established, rather management for ALL critically-ill patients should ideally focus on restoration of systemic and renal haemodynamics; along with discontinuing, dose-adjusting or avoiding potentially nephrotoxin exposures.
- Fluid therapy remains the cornerstone for prevention and management of early AKI; however, fluid resuscitation with potentially nephrotoxin solutions should be avoided, and fluid accumulation and overload should be limited.
- Selected clinical contexts, such as contrast media-associated AKI (CA-AKI), hepatorenal syndrome (HRS), rhabdomyolysis, and sepsis, may involve specific interventions to reduce risk of AKI.

Introduction

Acute kidney injury (AKI) is exceedingly common and increasingly encountered amongst hospitalized patients with critical illness. Those with AKI suffer worse clinical outcomes, including overt kidney failure and need for renal replacement therapy (RRT), higher mortality, prolonged hospitalization, and amongst survivors, non-recovery of kidney function, and chronic kidney disease (CKD). AKI often occurs in association with clearly identifiable patient- and/or intervention-related risks and can be anticipated as a consequence or complication of critical illness. Intensivists are often the key care providers for these critically-ill patients who are at high risk of AKI. Accordingly, working knowledge of the scope, complexity, and general principals of prevention and management of AKI are indispensable in the care of these patients.

It is important to recognize these patients are often exposed to multiple discrete risks that may accumulate (i.e. multiple insults) over their course and exert an important modifying influence on the duration and severity of AKI, along with the probability of recovery of kidney function. Evidence has consistently shown that timely identification for those at high risk of or who have developed milder forms of AKI can afford opportunity for earlier intervention. The implementation of a real-time electronic alert system (i.e. 'AKI sniffer') to an ICU was found to contribute to earlier identification and more aggressive intervention in those with worsening AKI, including fluid therapy, diuretics and/or vasoactive support, along with a higher likelihood of resolution of AKI within 8 hours [1].

Multiple different therapies have been investigated over the last several decades that while showing benefit in experimental studies for preventing or mitigating damage after an acute kidney insult, these have not translated into effective interventions in humans. In essence, there is essentially no specific therapeutic intervention for the vast majority of critically-ill patients developing AKI. Accordingly, strategies to prevent or mitigate AKI should be individualized, while avoiding further exposure to kidney insults, and mitigating the complications associated with kidney failure. In general, the over-arching tenets for **all** potentially susceptible patients are shown in Box 213.1. Selected examples of acute physiology and interventions with the potential for negative effects on kidney function are shown in Table 213.1.

Specific interventions for acute kidney injury

Fluid therapy

Type of fluid therapy

Fluid therapy represents the cornerstone for the prevention and management of AKI. Of the numerous strategies evaluated for prevention of AKI, only fluid therapy has been shown to be consistently effective. There are a variety of fluid types available for resuscitation. These are broadly categorized as crystalloid solutions (i.e. 0.9% saline or balanced Ringer's Lactate), and colloid solutions (i.e. hydroxyethylstarch [HES], dextran, gelatin, albumin, blood products). There remains controversy, along with conflicting data, about which type of fluid (i.e. crystalloid vs. colloid) should ideally be used during resuscitation. The most common resuscitation fluid administered worldwide is synthetic colloid (i.e. HES); however, it

Box 213.1 Summary of approach to management and intervention in AKI

Approach to management and interventions

- Restore/optimize arterial filling.*

- Monitor/maintain fluid and electrolyte homeostasis.
- Remove/avoid all non-essential nephrotoxins or performed appropriate therapeutic monitoring/dose-adjustment when necessary.
- Consider context-specific interventions (i.e. contrast-media; hepatorenal syndrome; rhabdomyolysis; sepsis).
- Monitor for/avoid excess fluid accumulation.
- Monitor for/avoid complications of overt kidney failure (i.e. hyperkalaemia; metabolic acidosis; intravascular volume overload) and, when appropriate, plan for RRT.

*There should be early use of invasive/functional haemodynamic monitoring (i.e. arterial catheter, central venous pressure, echocardiography, pulmonary artery catheter, or methods to measure stroke or pulse pressure variation) to guide timely and appropriate resuscitation.

is likely the majority of critically-ill patients receive some combination of crystalloids, colloids, and/or blood products.

Recent data have suggested HES contributes to or exacerbates AKI, in particular in sepsis. Three multi-centre, randomized trials comparing HES to control resuscitation fluids (3% modified gelatin; 0.9% saline; Ringer's acetate) in critically ill septic patients have found HES results in worse clinical outcomes, including increased risk of AKI, greater rate of RRT use, and higher mortality [2–4]. These data of potential harm, coupled with no improvement in outcomes and excessive cost compared with crystalloids, have led to consensus guideline recommendations that HES not be used in patients with severe sepsis or at risk of AKI [5].

Resuscitation with saline solution (i.e. 0.9% saline) compared with balanced crystalloid solution (i.e. Ringer's lactate; Plasmalyte) may predispose to metabolic acidosis and AKI in peri-operative and critically-ill patients. Observational data have suggested the use of balanced crystalloids, when compared with 0.9% saline, for peri-operative resuscitation in patients undergoing major abdominal surgery reduced post-operative complications, including need for RRT [6]. In a small non-randomized study, balanced crystalloid resuscitation in patients with diabetic ketoacidosis resulted in more rapid correction of base deficit when compared to 0.9% saline [7]. Similarly, in a non-randomized before-and-after study, the restriction of chloride-rich solutions in critically-ill patients can decrease the incidence of severe metabolic acidosis and contribute to lower adjusted-rates of AKI and RRT [8].

Fluid volume and accumulation

It is important to recognize there is currently no evidence that fluid therapy will reverse AKI once established. In fact, AKI patients, whether oliguric or not, require judicious monitoring of volume status, not only to correct preload deficits, but also because of the adverse consequences of fluid accumulation. The unnecessary accumulation of fluid can negatively impact clinical outcomes, in particular in oliguric patients with established AKI [9,10]. For example, observational data in patients with septic shock have shown higher mortality in those not achieving a negative fluid balance in at least one of the first three days after ICU admission. The impact of a maintaining a neutral or negative fluid balance has been shown to improve outcomes in acute lung injury (ALI) [9], pulmonary oedema and is predictive of successful weaning from mechanical ventilation. In patients with sepsis and AKI, excessive fluid therapy, despite optimal systemic haemodynamics and a high rate of diuretic use, does not necessarily improve kidney function, but may worsen gas exchange. Observational data of fluid accumulation in critically ill children with AKI has consistently been identified as a predictor of mortality [11]. Similarly, in adult critically-ill patients with septic AKI, fluid accumulation predicted 60-day mortality. In AKI patients, fluid overload independently predicts higher likelihood of RRT requirement and mortality [10]. These observations highlight the importance for monitoring of fluid balance in critical illness, in particular after the initial phase of resuscitation, where obligatory fluid intake (i.e. medications, nutrition) may greatly exceed output (i.e. relative oliguria) leading to rapid fluid accumulation, in particular in AKI, where water and solute excretion in impaired.

Vasodilator therapy

The use of vasodilators is theoretically attractive to restore renal blood flow (RBF) and mitigate renal vasoconstriction in AKI. Dopamine (DA), via the DA receptors present in renal tissue, can reduce renal vascular resistance and has long been used to mitigate AKI; however, evidence from a large randomized trial failed to show any benefit for 'renal-dose' DA in critically-ill patients with early AKI [12]. Moreover, DA has been associated with arrhythmic complications. Additional therapies, including the DA_1 receptor agonist fenoldopam; atrial natriuretic peptide (ANP); and B-type natriuretic peptide (i.e. nesiritide) merit further investigation; however, have not yet conclusively been proven effective.

Diuretic therapy

The role of diuretic therapy in the management of AKI remains controversial. Yet, diuretics are extensively used in critically-ill patients despite a lack of definitive evidence of effectiveness for improved clinical outcomes and concern for harm [13]. There has long been the hypothesis that the oliguria and reduced glomerular filtration rate (GFR) observed with AKI, mediated largely by glomerulotubular feedback (TFG), is an adaptive physiological response for kidney protection. However, this has recently been challenged. In a prospective observational study, Redfors et al. evaluated the renal oxygen supply/demand relationship in 49 post-cardiac surgery patients with and without AKI. In those with AKI, GFR, RBF, sodium reabsorption was reduced, but also associated with a significant increase in rVO2, such that for each unit of reabsorbed sodium, there was a 2.4-fold higher utilization of oxygen for those with AKI compared with those who did not have AKI. These data challenge the hypothesis that oliguria and reduced GFR in AKI are simply adaptive/protective mechanisms. These data further indirectly support a potential 'renal protective' role for furosemide, to attenuate and/or reduce the severity of kidney injury, when administered in the early phases of AKI. Diuretics also have an important role for managing fluid accumulation and

Table 213.1 Selected examples of acute physiology and interventions with the potential for negative effects on kidney function

Intervention	Example	Action
Altered systemic haemodynamics		
Reduced arterial filling	Diuretics	Discontinue
Negative inotropic therapy	β-blockers	Discontinue
Anti-hypertensive therapy	CCB	Discontinue
Altered renal haemodynamics		
Afferent arteriolar vasoconstrictors	NSAIDs	Discontinue
Efferent arteriolar vasodilators	ACEi/ARB*	Discontinue
Altered renal venous pressure		
Elevated intra-abdominal pressure	Excess fluid accumulation	Avoid
Nephrotoxins		
Antibiotics	Aminoglycosides; vancomycin; colistin; sulfamethoxezole; foscarnet	Discontinue, monitor or dose-adjust
Antifungals	Amphotericin	Discontinue, monitor or dose-adjust
Antivirals	Acyclovir; HAART	Discontinue, monitor or dose-adjust
Immunosuppression	Tacrolimus; cyclosporin	Discontinue, monitor or dose-adjust
Fluid therapy	Dextrans; hydroxyethyl starch	Avoid
Diagnostic imaging	Radio-contrast media	Avoid
Cytotoxic chemotherapy	Cisplatin; methotrexate	Discontinue, monitor or dose-adjust

*ACEi and ARB lead to reduction in glomerular blood flow, which has beneficial effects for kidney survival in chronic kidney disease patients but may lead to worsening kidney function in patients with AKI.

CCB, calcium channel blockers; NSAID, non-steroidal anti-inflammatory drugs; ACE, angiotensin enzyme converting; ARB, angiotensin receptor blocker; HAART, highly active anti-retroviral therapy; IAP, intra-abdominal pressure.

in the delivery of optimal nutritional support. Numerous studies have evaluated loop diuretics in the treatment of AKI; however, most have failed to find consistent clinical benefit and some have suggested worse clinical outcome. Additional small trials have suggested that diuretics might reduce the severity of kidney injury by converting 'oliguric' to 'non-oliguric' AKI, shorten the duration of AKI, improve renal recovery, and perhaps delay or ameliorate need for RRT. Importantly; however, improved survival or renal recovery has yet to be confirmed by high-quality evidence. Recent data from a large randomized trial of fluid strategies in critically-ill patients with acute lung injury (ALI) have suggested potential improved outcome with furosemide use. In the subgroup with AKI, those received greater cumulative furosemide were observed to have lower mortality, while greater fluid balance was associated with higher mortality. Importantly, there was no observed threshold of furosemide dose above which mortality was observed to increase [9]. These data imply the selective use of furosemide is likely effective and safe in most patients with AKI; however, further randomized trials are needed.

Cytoprotective and antioxidant therapy

Additional 'cytoprotective' interventions for prevention of AKI, such as remote ischaemic preconditioning, hypothermia, thyroxine, erythropoietin, statins, ascorbic acid (vitamin C), and insulin-like growth factor are theoretically attractive. However, they have not yet been proven consistently beneficial in randomized trials. Tight glycaemic control with intensive insulin therapy has been shown to reduce the incidence of severe AKI requiring RRT in single centre trials, however, this was not replicated in a large multi-centre trial.

Specific syndromes

Contrast media-associated acute kidney injury

Contrast media-associated AKI (CA-AKI) is a leading cause of iatrogenic kidney injury following diagnostic and interventional procedures. The pathophysiology of CA-AKI remains incompletely understood; however, is believed to involve a combination of renal vasoconstriction, corticomedullary ischaemia, direct tubular toxicity, and tubular cast formation/obstruction. An estimated 16.3% of critically-ill patients receiving contrast media with imaging procedures develop CA-AKI [14]. Those developing CA-AKI were more likely to need RRT, less likely to recovery kidney function, had longer durations of hospitalization and higher mortality. Approaches to preventing CA-AKI are largely categorized into three strategies based on our current understanding of its pathophysiology:

- Interventions to induce a forced diuresis and high urine flow rates.
- Interventions to induce renal vasodilatation.
- Interventions to attenuate oxidative stress and inflammation in the kidney.

Most interventions to date, with the exception of fluid hydration, have proven either ineffective or inconsistent, including forced diuresis, N-acetylcysteine, sodium bicarbonate, and prophylactic haemofiltration. Pragmatically, in critically-ill patients, the perceived benefits and risks of undergoing a diagnostic/therapeutic procedure involving contrast media must be carefully explored and strategies to mitigate the risk, such as alternative modalities of imaging in those at increased risk, or alternatively, if proceeding with the procedure, ensuring volume repletion, avoiding the use of concomitant nephrotoxins, and minimizing the volume of contrast media administered. In those at high risk, a plan for potential need for RRT should be considered.

Hepatorenal syndrome

Hepatorenal syndrome (HRS) refers to the development of functional AKI in advanced cirrhosis. HRS develops in nearly 40% of patients with advanced cirrhosis by 5 years. HRS may be associated with a precipitating event, such as spontaneous bacterial peritonitis (SBP), gastrointestinal bleeding, or volume depletion due to diuretic therapy or large volume paracentesis or may follow a more indolent path whereby kidney function may deteriorate over a period of weeks to months, often in association with refractory

ascites. Strategies to prevent HRS should focus on directed treatment of precipitants such as rapid restoration of effective circulation volume with albumin, haemodynamic support with vasoactive therapy as indicated, antimicrobials, and albumin for SPB, and strict avoidance of nephrotoxins. While in established HRS, liver transplantation (LT) is the only definitive intervention; additional bridging therapies are available. Vasoconstrictor therapy, to mitigate splanchnic vasodilatation and restore mean arterial pressure and renal perfusion, can reverse HRS and improve outcome. Evidence from randomized trials supports the use of the synthetic vasopressin-analogue terlipressin, when administered with albumin, to restore of kidney function and improve patients survival to transplantation [15]. Terlipressin has been associated with secondary organ ischaemia, including cardiac arrhythmias and splanchnic ischaemia, therefore, this therapy is contraindicated in those with significant coronary, cerebral and/or peripheral artery disease. If terlipressin is unavailable or too costly, alternative vasopressors to reverse of HRS may be used including intravenous infusions of arginine vasopressin and norepinephrine or oral therapy with the α-adrenergic agonist midodrine coupled with subcutaneous octreotide. For refractory ascites and progressive HRS, small clinical studies have found transjugular portosystemic intrahepatic shunting (TIPS) may attenuate or improve kidney function over several weeks to months.

Rhabdomyolysis and myoglobinuric acute kidney injury

Rhabdomyolysis is a syndrome characterized by the breakdown of striated muscle, resulting in the release of myoglobin and other muscle constituents into the extracellular fluid. The cornerstone for prevention and treatment of myoglobinuric AKI remains aggressive volume resuscitation to expand the vascular compartment to restore and maintain kidney perfusion. This is primarily achieved initially with isotonic crystalloid solutions (10–15 mL/kg/hour) titrated to physiologic endpoints such as central venous pressure and urine output (target 200–300 mL/hour for persisting myoglobinuria). In the context of crush syndrome associated with disaster, fluid resuscitation should be initiated prior to evacuation. Following initial resuscitation, bicarbonate (50–100 mEq/L) may be added, titrated to achieve a urine pH >6.5, to increase the solubility and renal excretion of tubular myoglobin and uric acid casts, along with attenuation of concomitant acidosis, hyperkalaemia, and release of free iron from myoglobin. Importantly, if urinary alkalization is unsuccessful or symptomatic hypocalcaemia ensues, bicarbonate-containing solutions should be discontinued. There are theoretical benefits for the use of mannitol (1–2 g/kg over 24 hours) including provoking an osmotic diuresis to flush intra-tubular myoglobin deposition and cast formation, remove sequestered water from injury muscle and mitigate compartment syndrome; and potentially acting as a free radical scavenger; however, these benefits are currently not supported by evidence from randomized trials. Further augmentation of urine output with loop diuretics may be beneficial for patients with relative oliguria and excessive fluid accumulation. While controversial, myoglobin clearance can be augmented by haemofiltration with high-flux haemofilters (molecular weight cut-off 30–60 kDa). Additional controversial strategies have been hypothesized, including allopurinol to reduce uric acid production, improving microcirculatory blood flow with pentoxyifylline, attenuating oxidant injury with glutathione, chelation of circulating free iron with deferoxamine and dantrolene to reduce intracellular calcium; however, all lack robust data to support recommending. Unfortunately, in patients with myoglobinuria and overt kidney failure, no specific therapy is available and patients should be supported early by initiation of RRT.

Sepsis-associated acute kidney injury

Sepsis is a key contributing factor for AKI in critically-ill patients that portends higher risk of poor clinical outcome. Yet, our understanding of its pathophysiology remains incomplete. Recent experimental data in hyperdynamic septic AKI have shown GFR and urine output can be restored by infusion of the potent efferent arteriolar vasoconstrictor angiotensin II (ATII) [16]. Experimental models have also suggested mitigation of the immune response with dexamethasone may improve kidney function [17]. While restoration of systemic haemodynamics is a principal mechanism to prevent and treat AKI, supraphysiological augmentation of mean arterial pressure has not been shown to improve kidney function and may contribute harm. More recently, the addition of arginine vasopressin to norepinephrine in septic shock was shown to reduce the incidence of worsening AKI in those at risk [18]. Several studies have suggested fluid resuscitation with albumin may be associated with improve survival in septic shock; however, improvements in kidney function have not been assessed and further confirmatory trials are ongoing. Alternatively, fluid resuscitation with HES in septic shock and in those at risk for AKI has consistently been associated with worse clinical outcome and recently practice guidelines have recommended against their use in these settings [2,3,5]. The administration of alkaline phosphatase (AP) may reduce renal tubular expression of inducible nitric oxide synthase and mitigate AKI. A recent phase II randomized trial of a continuous 48 hour AP infusion started early after AKI onset found greater reduction in systemic and kidney-injury specific mediators and improvement in creatinine clearance at 28 days [19]. Observational data have also suggested that delay to effective antimicrobial therapy in septic shock is an important independent factor for AKI [20]. Finally, following the acute resuscitative phase, excessive fluid accumulation has been associated with worse clinical outcome. In these circumstances, there should be concerted effort to minimize or avoid non-essential fluid administration.

Conclusion

AKI remains a challenging clinical problem in the care of critically-ill patients due largely to the paucity of specific therapeutic interventions aimed at reducing poor outcome. Those patients most at risk for the development of AKI can often be identified by an assessment of demographic, clinical, diagnostic and procedure-related factors couple with early and intensive bedside monitoring. All critically-ill patients at risk of or with milder forms of AKI should have their support individualized with a particular focus on: restoring systemic and renal haemodynamics; avoidance of potentially exacerbating nephrotoxin exposures; opportunities for context-specific therapies in selected circumstances, and prevention monitoring for life-threatening complications of kidney failure with RRT planning if necessary.

PART 8.4

Renal replacement techniques

CHAPTER 214

Continuous haemofiltration techniques in the critically ill

Zaccaria Ricci and Claudio Ronco

Key points

- Critically-ill patients with severe acute kidney injury (AKI) should be supported with extracorporeal renal replacement therapy. Timely and correctly prescribed treatments produce the best outcomes.
- Intermittent techniques are reserved for haemodynamically stable patients, and are less commonly used in critical care.
- Continuous veno-venous haemofiltration/haemodialysis/haemodiafiltration may all be used in critically-ill patients. Each modality has advantages and pitfalls. Haemodiafiltration possibly combines the best of both purification techniques.
- A continuous renal replacement therapy dose of at least 25 mL/kg/hour should be delivered. Due to machines inaccuracies and downtime, a prescription of 30–35 mL/kg/hour may be needed to achieve a dose of 25 mL/kg/hour.
- Heparin remains the gold standard for circuit anticoagulation. Alternatives to heparin are available, and should be considered if there is particular concerns about haemorrhage or if heparin induced thrombocytopaenia is suspected.

Introduction

The mainstay of severe acute kidney injury (AKI) treatment is extracorporeal renal support. Advances in modern technology have provided different modalities to perform renal replacement therapies (RRT), but the optimal time to start and stop RRT is not yet established.

Indications to start renal replacement therapies

Renal replacement is indicated when renal dysfunction leads to one or more of the following:

- Oligo/anuria (0–0.2 mL/kg/hour).
- Severe fluid overload.
- Pulmonary oedema.
- Hyperkalaemia.
- Metabolic acidosis.

However, recent greater ease of use, novel so called 'extra-renal indications' and a relatively low associated morbidity has brought clinicians to standardize treatment timing and explore new indications (i.e. severe sepsis and multi organ dysfunction syndrome). As a matter of fact, indication to start RRT remains a matter of debate and no clear recommendations have been provided. As a general rule, early RRT is considered beneficial, in a clinical state where renal dysfunction is clearly worsening, but before one of the above-mentioned indications has been reached. However, this hypothesis has not been definitively proven [1–3].

Indications to stop renal replacement therapies

There is no hard evidence on how and when RRT should be stopped. It is generally accepted, however, that re-appearance of urine output (>500 mL/day) in a previously anuric patient is a signal that the kidneys are improving. RRT might also be weaned to lighter forms (i.e. from intense to less intense treatments, or from continuous to semi-continuous or intermittent therapies) if the patient demonstrates haemodynamic stability and improving severity of critical illness.

Principles of renal replacement

The glomeruli filter the blood to remove excess water and waste products. Renal replacement uses semi-permeable membranes to achieve a similar result. The membrane may be artificial, as in a filter, or autologous, as in the peritoneum. Many molecules, including water, urea, and solutes of various molecular weights, are transported across the membrane by variable combinations of the processes of diffusion (dialysis) and convection (ultrafiltration).

During diffusion the movement of solutes depends on their tendency to reach the same concentration (equilibrium) on each side of the membrane: this results in the passage of solutes from the compartment with the higher concentration to the compartment with the lower concentration. Diffusion is affected by characteristics of the semi-permeable membrane including thickness, surface area, temperature, and diffusion coefficient. Diffusion is provided by dialysis, in which a solution (the dialysate) flows on the other side of the membrane, counter-current to blood flow, in order to maintain a solute gradient.

In convection, the movement of solute across a semi permeable membrane is a result of transfer of water across the membrane. In other words, as the solvent (plasma water) crosses the membrane, solutes are carried with it if the pore size of the membrane allows such passage. Convection can be achieved by ultrafiltration (UF),

which creates a transmembrane pressure (TMP) gradient. UF depends on the rate of flow (Qf), the membrane coefficient (Km) and the TMP gradient between the pressures on both sides of the membrane:

$$Qf = Km * TMP \quad \text{[eqn 1]}$$

The TMP gradient is the difference between the pressure in the blood compartment which is directly related to blood flow (Qb), and filtrate compartment pressure which is modulated by a pump in modern RRT machines. The machines are designed to maintain a constant filtration rate (Qf): when the filter is 'fresh' and highly permeable, the pumps retard UF production, generating a positive pressure in the filtrate compartment (TMP is initially dependent only on blood flow). As the membrane fibres become degraded, a negative pressure on the filtrate side is necessary to achieve a constant Qf. With time, TMP progressively increases up to a maximum level at which solute clearance is compromised and clotting of the filter or membrane rupture is possible.

The size of molecules cleared during convection and UF exceeds that during diffusion, because they are physically dragged to the UF side, however, this gradually becomes limited by the protein layer that progressively closes filter pores during convective treatments. In addition, the membrane itself can adsorb molecules, and this is important for higher molecular weight toxins. The membrane adsorptive capacity is generally saturated in the first few hours of filter use and has a relatively minor impact on mass separation processes. During UF, plasma water and solutes are filtered from blood, leading to a decrease in blood hydrostatic pressure and increase in blood oncotic pressure. The fraction of plasma water that is removed from blood during UF is called filtration fraction and should be kept in the range of 20–25% to prevent excessive haemoconcentration within the filtering membrane. Otherwise, the oncotic pressure gradient could neutralize the TMP gradient resulting in equilibrium.

Replacing plasma water with a substitute solution completes the haemofiltration (HF) process. The replacement fluid can be administered after the filter (post- filter dilution HF, often called simply 'post-dilution'), before (pre- filter dilution HF, often called simply 'pre-dilution'), or both. Post-filter dilution leads to a higher urea clearance, but pre-filter dilution may prolong circuit life by reducing haemoconcentration and protein build-up in the filter fibres. Conventional haemofiltration is performed with a highly permeable, steam-sterilized membrane with a surface area of about 1–2 m^2. The addition of convection to the diffusion process allows haemodiafiltration: dialysis and replacement solutions run simultaneously within the same filter to obtain additional solute removal.

Choice of mode

The ideal renal replacement treatment should include:

- Efficient solute removal.
- Low impact on haemodynamics.
- Low anticoagulant needs.
- Minimal interference with patient mobility.

Continuous RRT (CRRT) exhibits many of these features. Advantages of CRRT include using a low UF rate and slowing solutes exchanges which reduces the risk of as solute disequilibrium which can give rise to neurological symptoms and cerebral oedema, and the ability to adjust the CRRT prescriptions to individual patient's needs on an hour to hour basis. Different CRRT modalities are shown in Fig. 214.1.

Practical CRRT prescription

During CRRT, clearance (K) depends on circuit blood flow (Qb), haemofiltration flow (Qf), or dialysis flow (Qd), molecular weight of solutes, and filter type, and size. Circuit blood flow is mainly dependent on vascular access and operational characteristics of the individual RRT machine.

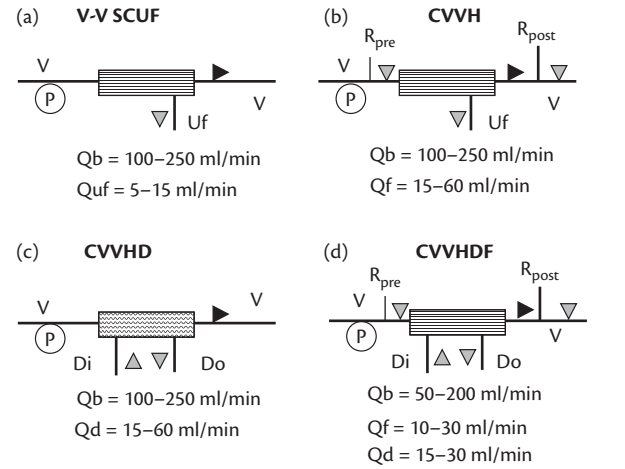

Fig. 214.1 Techniques of CRRT. (a) Slow continuous ultrafiltration (SCUF): blood is driven by a pump (P) through a highly permeable filter via an extracorporeal circuit, using veno-venous (V) access. The ultrafiltrate produced during membrane transit is not replaced and it corresponds to weight loss. It is used only for fluid removal in overloaded patients. Circuit blood flow: (Qb) 100–250 mL/min; ultrafiltrate flow (QUF): 5–15 mL/min. (b) Continuous veno-venous haemofiltration (CVVH): CVVH is similar to SCUF above except that the ultrafiltrate produced during membrane transit is partly or completely replaced (R) to maintain intravascular volume. Replacement fluid may be delivered before (R PRE), after (R POST) or both sides of the filter (pre- or post-dilution). Clearance for all solutes is convective and equals UF rate. Qb: 100–250 mL/min; QR: 15–60 mL/min; QUF: QR+ 5–15 mL/min. A variant of CVVH is high volume haemofiltration (HVHF): this treatment uses highly permeable membranes and haemofiltration with a high volume setting: Qb >200 mL/min and QUF> 35 mL/kg/hour in order to increase removal of high molecular weight solutes (e.g. inflammatory mediators). It is currently reserved to research purposes and experimental studies, as evidence for its use in the treatment of human sepsis is limited to small and inconclusive trials. (c) Continuous veno-venous haemodialysis (CVVHD): In CVVHD, blood is driven through a low permeability dialyser via an extracorporeal circuit in veno-venous mode and a countercurrent flow of dialysate (Di-Do) is delivered on the dialysate compartment. The ultrafiltrate produced during membrane transit corresponds to patient's weight loss. Solute clearance is mainly diffusive and efficiency is limited to small solutes only. Qb: 100–250 mL/min; QDi: 15–60 mL/min; QDo: QDi + QUF. (d) Continuous veno-venous haemodiafiltration (CVVHDF): Technique where blood is driven through a highly permeable dialyser via an extracorporeal circuit in veno-venous mode and a countercurrent flow of dialysate is delivered on the dialysate compartment. The ultrafiltrate produced during membrane transit is in excess of the patient's desired weight loss and replacement solution is needed to maintain fluid balance. Solute clearance is both convective and diffusive. CVVHDF has the main advantage of getting the most solute clearance with the lowest blood flow rate and should be reserved to heavier adult patients. Qb: 100–250 mL/min; QDi: 15–60 mL/min; Do: Di + QR + QUF.

Table 214.1 Different anticoagulation types

	Indication	Contra-indication	Advantages	Disadvantages
Unfractionated Heparin	Standard treatments	Heparin induced thrombocytopenia, high risk of bleeding	Relatively easy to manage, easy to reverse	Relative high risk of bleeding, relative low efficacy
No Anticoagulation	Post-operative patients with high risk of bleeding; critically-ill patients with severe coagulopathy	Standard treatments	Reduced adjunctive bleeding risk	Potentially reduced circuit lifespan
Regional heparinization	Patients at high risk of bleeding with excessively low circuit lifespan	Heparin induced thrombocytopenia	Easy to manage	Relative low efficacy
Low molecular weight heparin	Need for alternatives to continuous heparin infusion	Heparin induced thrombocytopenia	No need for continuous infusion	Difficult to reverse
Bivalirudine	Heparin induced thrombocytopenia	Blood stagnation	Fair anticoagulant efficacy	Scarce clinical experience, cost
Argatroban	Heparin induced thrombocytopenia	Liver insufficiency	Reliable anticoagulant efficacy	Scarce clinical experience, cost
Prostacycline	Heparin induced thrombocytopenia	Haemodynamic instability	Short half-life, no effect on coagulation cascade	Relative low efficacy
Epoprostenol	Heparin induced thrombocytopenia; standard treatment in experienced centres	Liver insufficiency	Significantly prolonged circuit patency	Metabolic alkalosis, cumbersome technique in non-experienced centres
Non-thrombogenic surfaces	High risk of bleeding	High risk of circuit clotting	Prolonged filter patency	Costly, scarce clinical validation

In haemofiltration, Qf is strictly linked to Qb by filtration fraction. In dialysis however, even if Qd is not limited by filtration fraction, still Qd/Qb ratio should not exceed 0.3, in order to optimize dialysis efficiency.

Urea and creatinine concentrations are generally used as reference solutes and their serum concentrations used to monitor the effectiveness of the RRT prescription; because their clearance has a 1:1 correlation with Qd/Qf rate (e.g. urea clearance of 10 mL/min corresponds to a Qf –or Qd- of 10 mL/min). However, it is important to be aware that serum urea and creatinine (typically and rapidly decreasing during the first CRRT days) are determined by the effectiveness of RRT and are not indicative of underlying renal function or eventual AKI outcome. The role of RRT is to maintain the patient's homeostasis in the period of AKI, providing the time necessary for the kidneys to recovery. RRT is used as a therapy, for example in patients with severe sepsis, to remove inflammatory mediators, but the effectiveness of such use has not yet been proven.

During continuous treatments, a standard initial therapy prescription should target a minimum urea clearance of 25–35 mL/kg /hr (1.7–2.5 l/hr of Qf/Qd in a 70 kg patient): this recommendation derives from the results of two recent large trials (RENAL and ATN trials) that reported no improvement in outcomes when CRRT doses higher than this were used. As yet there has been no prospective trial comparing same doses of different modalities (i.e. continuous haemodialysis vs. haemofiltration) and choice of modality generally relies on personal and institutional expertise and protocols. Current recommendations are to provide a CRRT dose that is not lower than 25 mL/kg/hour [4–6].

A negative fluid balance has recently been identified as having a strong association with outcome in critically-ill patients with AKI: it is possible that a negative fluid balance should be targeted in haemodynamically stable patients being treated with CRRT. However, the link between fluid balance and outcome has reported from observational data only and currently we recommend the net UF rate should be tailored to the individual patient's needs [7–12].

Anticoagulation

During RRT blood comes into contact with the artificial surfaces and in most patients some form of anticoagulation is needed Table 214.1. To reduce the risk of filter clotting, vascular access should to be of adequate size, and blood flow rate should exceed 100 mL/min. Pump flow fluctuations should be prevented (in modern machines this is mainly due to increased circuit resistances rather than flow rate inaccuracies). Venous bubble traps, where air/blood contact occurs, are used to prevent systemic air embolus, and the machine will alarm if bubbles are detected.

There is evidence that, when set-up is perfectly optimized, anticoagulants contribute little to the maintenance of circuit patency. When anticoagulants are relatively contra-indicated (risk of bleeding, pre-existing coagulopathy, thrombocytopaenia) RRT can still be performed safely and filter life may not be compromised.

Unfractionated heparin is the most commonly used anticoagulant. The dose ranges from 5 to 10 IU/kg/hour. In patients in whom systemic anticoagulation is to be avoided, heparin can be used in combination with post-filter administration of protamine (regional anticoagulation); with a 1 to 1 ratio (1mg of protamine per 150 IU of unfractionated heparin) and monitoring of activated partial thromboplastin time (aPTT). The response to heparin administration can be unpredictable due to altered bioavailability, antithrombin III (ATIII) depletion and the risk of heparin induced thrombocytopenia (HIT).

Low molecular weight heparins (LMWH) may also be used, but prospective studies have not yet shown them to be superior in prolonging circuit life. Bioavailability is more reliable than with

unfractionated heparin and the risk of HIT is lower. However, the anticoagulant effect cannot be reversed and there may be a higher risk of haemorrhage.

Epoprostenol is potentially useful for RRT anticoagulation, being a potent inhibitor of platelet aggregation with a short half-life. It is infused at a dose of 4–8 ng/kg/hour with or without the adjunct of low dose heparin. Hypotension may be induced by higher doses. High cost and the risk of hypotension may limit its use to short-term treatment.

Citrate chelates calcium to prevent clot formation and can be used to produce regional anticoagulation. The effect of citrate is reversed by post-filter administration of calcium chloride to maintain systemic normocalcaemia. This approach is effective in maintaining filter patency and compares favourably with heparin. It also avoids the risk of HIT and does not lead to systemic anticoagulation. However, the risk of potentially fatal hypocalcaemia, metabolic alkalosis, and the need for special fluids and the increased complexity of circuit set-up currently limit its use.

Finally direct thrombin inhibitors (bivalirudine, argatroban) have been proposed as alternative anticoagulants in cases where unfractionated heparin is contraindicated, but clinical experience is still limited to case series [13].

CHAPTER 215

Haemodialysis in the critically ill

Rolando Claure-Del Granado and Ravindra L. Mehta

Key points

- Several new methods of dialysis are now available to treat critically ill patients with acute kidney injury (AKI). Haemodialysis remains an important technique to treat these patients.
- Rational use of haemodialysis requires an understanding of its operational factors and appreciation of the advantages and disadvantages of this technique.
- Delivered dose of dialysis needs to be measured and dose assessment should be a continuous process.
- Intermittent Haemodialysis should be preferred over slow low-efficiency dialysis (SLED) or Continuous renal replacement therapy (CRRT) in the case of severe hyperkalaemia or metabolic acidosis where rapid correction is required; for pulmonary oedema with fluid overload in patients without severe haemodynamic impairment; when high risk of bleeding and when anticoagulation is contraindicated; and to treat poisoning.
- IHD, SLED and CRRT are complementary methods that can be used in critically ill patients with AKI. They can be used at different times in the same patient as the patient's condition changes.

Introduction

Haemodialysis is used worldwide to manage patients with acute kidney injury (AKI). In recent years, there have been many advances in haemodialysis technology including biocompatible synthetic membranes, bicarbonate buffers, adjustments in blood, and dialysate flow rates, and improved monitoring of patient parameters. These have facilitated the widespread use of haemodialysis in the intensive care unit (ICU) despite which considerable controversy exists regarding the optimal use of haemodialysis in this setting. In this chapter we provide a brief review of the current status of haemodialysis to treat AKI in critically-ill patients.

Operational characteristics of haemodialysis techniques

Haemodialysis techniques utilize diffusion for solute removal by developing a concentration gradient between the vascular and dialysis compartments in the dialysis filter. This gradient facilitates bidirectional transport of solutes across a highly permeable membrane to allow effective removal of waste products (e.g. urea and creatinine) while replenishing the blood with base and electrolytes. Three main factors govern the rate of solute and fluid removal; blood and dialysate flow rates, membrane permeability and therapy duration.

In most haemodialysis sessions solute and fluid removal are optimized by having the blood flow rate (Qb) set at 200–400 mL/min based on the desired clearance for metabolic control. The site and type of access (femoral vs. jugular, tunnelled versus non-tunnelled catheter) contribute significantly to getting an adequate Qb particularly in hypotensive patients. Dialysate flow rate (Qd) usually is set at 500–800 mL/min to run countercurrent to blood flow and results in a solute saturation of approximately 40%. Ultrafiltration (UF) rate is set depending on patient's volume status and haemodynamic variables. Standard therapy for IHD is a treatment length of 3 to 4 hours, and treatment frequency ranges from 3 to 6 days per week [1].

Anticoagulation

Using an anticoagulant; most commonly heparin, helps to ensure membrane permeability, and to maintain circuit patency. Clotting of the filter reduces its longevity, and more importantly, reduces the efficiency of solute clearance and is a major barrier to delivery of effective dialysis [2]. Inefficient anticoagulation reduces dialyzer performance by diminishing the surface of the membrane available for diffusion or convection. The mainstay of anticoagulation for intermittent haemodialysis (IHD) is heparin, which is usually administrated as a bolus, followed by a continuous infusion into the arterial line. The target is to maintain a partial thromboplastin time of 1.5–2 times the normal level.

In patients with thrombocytopenia and coagulation disorders, systemic anticoagulation should be avoided; and regional citrate anticoagulation can be performed with calcium-containing or calcium-free dialysate, preferred for short and long sessions, respectively. The citrate infusion rate depends on the blood flow; therefore, during IHD with a blood flow ≥300 mL/min a citrate infusion of 50–60 mmol/hour would be appropriate. A common approach is to adjust the citrate infusion to maintain a post-filter calcium concentration of 0.25–0.35 mmol/L [3]; the patients serum ionized calcium must be maintained within the normal range through calcium administration on the return side of the filter. Regional citrate anticoagulation is increasingly used for CRRT and some studies have shown increased filter life, fewer bleeding complications, and in one study, increased survival [4]. Anticoagulation-free strategies postpone clotting by intermittent flushing of the arterial line of the circuit every 15–30 minutes with saline [5]. While successful, the saline volume administered must be included in the net ultrafiltration.

These operational parameters are used in the majority of IHD procedures and in most instances are effective in achieving reductions in solute levels and in maintaining fluid balance. However,

Table 215.1 Some operational characteristics of different renal replacement therapies

	CVVH	CVVHD	CVVHDF	IHD	SLED	EDD
Access	VV	VV	VV	VV	VV	VV
Blood flow (mL/min)	150–200	150–200	150–200	300–350	100–150	100–150
Dialysate flow (mL/min)	0	1000	1000	500	100–200	100–200
Replacement fluid (mL/min)	15–60	0	10–30	0	0	0
Ultrafiltration rate (L/h)	1	0.3	0.8	0.5	1	1
Urea Clearance (mL/min)	16.7	21.7	30	150–180	78	78

VV, venous-venous; CVVH, continuous venous-venous haemofiltration; CVVHD, continuous venous-venous haemodialysis; CVVHDF, continuous venous-venous haemodiafiltration; IHD, intermittent haemodialysis; SLED, slow low-efficiency dialysis; EDD, extended daily dialysis.

Reproduced from Mehta RL, 'Renal replacement therapy for acute renal failure: matching the method to the patient', *Seminars in Dialysis*, 1993, **6**(4), pp. 253–9, copyright 1993, with permission from John Wiley and Sons and American Society of Diagnostic and Interventional Nephrology.

the resulting high clearance (>200 mL/min for urea) causes a rapid decrease in the concentration gradient, which reduces the removal rate, limiting the total amount of solute removed. Additionally, critically-ill patients with AKI are generally fluid overloaded and hypoperfused and urea refilling from the interstitium to the blood results in compartmentalization that reduces operational efficiency. To counteract these limitations, strategies have emerged to reduce the Qb and Qd to 100 and 300 mL/min respectively and prolong the duration to 6–12 hours. These slow low-efficiency dialysis (SLED) or extended daily dialysis (EDD) techniques improve haemodynamic stability, provide adequate solute and fluid balance and are being utilized in some ICUs in lieu of CRRT Table 215.1. These hybrid modalities can be performed for 6–12 hours at night using ICU staff, thereby eliminating interruption of therapy, reducing staff requirements, and avoiding scheduling conflicts. Studies comparing EDD/SLED to CRRT have revealed favourable haemodynamic tolerance in critically-ill patients while achieving dialysis adequacy and ultrafiltration targets, since fluid removal and solute clearance are more gradual [6].

As shown in Table 215.2 haemodialysis techniques have some advantages and disadvantages in comparison with CRRT [7]. However, since dialysis techniques depend on diffusive clearance, they are subject to losses of key components (e.g. phosphorus and amino acids) and are limited in removing larger molecules. The rapid rate of solute and fluid removal may also contribute to haemodynamic instability and reduce plasma osmolality promoting osmotic water movement into cells and therefore reducing plasma volume. Osmolality changes may also induce or worsen cellular oedema, including cerebral oedema [8]. Several technological advancements in recent years have focused on features that could help physicians to optimize patient's volume status while avoiding haemodynamic instability and further kidney insults. Some of these features include: UF profiling, sodium profiling, blood volume monitoring, and blood temperature monitoring. In a prospective, randomized, crossover stratified study, Paganini et al. [9] compared a fixed dialysate sodium (140 mEq/L) and fixed UF rate (Protocol A), or a variable sodium dialysate (160–140 mEq/L) and variable UF (50% UF during the first third of treatment time, 50% UF over the last two thirds treatment time) (Protocol B). They found greater haemodynamic stability, significantly less need of interventions, and relative less blood volume changes with Protocol B [9]. Two small-randomized control trials have compared haemodynamic parameters between SLED and CRRT; in both studies no significant differences were found in all measured haemodynamic parameters [10,11].

Timing of initiation of haemodialysis

The optimal timing of dialysis for AKI is not defined. The initiation of dialysis for critically-ill patients with AKI is largely empirical and is subject to wide variation. In most instances, physicians start therapy based on a number of patients and process of care factors, e.g. blood concentrations of potassium, bicarbonate, sodium, and urea, liver function, bleeding risk, clinical parameters like body weight and arterial blood pressure, and finally the availability of equipment and staff, logistical considerations, and departmental protocols need also to be considered.

Table 215.2 Advantages and disadvantages of intermittent haemodialysis, sustained low-efficiency dialysis, extended daily dialysis, and continuous renal replacement therapies

	IHD	SLED/EDD	CRRT
Haemodynamic stability	++	+++	++++
Treatment duration	++	+++	++++
Patient mobility	++++	++	+
Fluid control	+	++	++++
Low osmolality variations	+	++	++++
No anticoagulation	++++	++	+
Small solute clearance	++++	+++	+++
Removal of medium molecular weight solutes	+	++	+++
Need of water production	+	+	-
1 machine several patients per day	++++	++	-
Continuous and adaptable therapy	+	++	++++
Cost	++	+++	++++
Nurse training	++++	++	+
Nurse workload	++	++	+

IHD, intermittent haemodialysis; SLED, slow low-efficiency dialysis; EDD, extended daily dialysis; CRRT, continuous renal replacement therapies.

Studies suggest that the decision when to start renal replacement therapy (RRT) should be individualized and based on trends in the patient's severity of illness, the presence of oliguria and fluid overload trying to minimize and avoid the complications of uraemia and volume overload rather than specific serum creatinine or urea values [12]. In a recent study Ostermann et al. evaluated optimal triggers for RRT in critically-ill patients with AKI. They examined data from 2 randomized controlled trials, 2 prospective studies and 13 retrospective trials and found large variation in the different parameters and cut-offs for RRT initiation. They found that no single biochemical parameter was able to define the optimal indication and time to start RRT. They also concluded that the degree of fluid overload, oliguria, and associated non-renal organ failure were more appropriate parameters for RRT initiation [13]. These data highlight the need to develop evidence-based and patient-specific indications for dialysis initiation in AKI.

Haemodialysis prescription and dose for acute kidney injury

Haemodialysis prescription for critically-ill patients with AKI is also largely empirical and is influenced by desired blood concentrations of solutes (e.g. serum urea, potassium, bicarbonate), fluid balance and haemodynamic stability. It is often influenced by logistic considerations including the availability of equipment and staff, and departmental protocols. As with timing of RRT, haemodialysis prescription should be individualized and operational characteristics of IHD/SLED must be considered before selecting different machine settings (i.e. Qb, Qd, ultrafiltration rate), choosing the type of anticoagulation (heparin versus regional citrate versus no anticoagulation), treatment time, and treatment frequency.

Haemodialysis prescription must also incorporate an assessment of the delivered dialysis dose. Traditionally Kt/V_{urea} has been employed as dialysis dose measurement in patients with end stage renal disease (ESRD). Kt/V_{urea} is defined as the dialyzer clearance of urea (K, obtained from manufacturer in mL/min) multiplied by the duration of the dialysis treatment (t, in minutes) and divided by the urea volume of distribution in the body (V, in mL), which is approximately equal to the total body water distribution. Based on studies in patients with ESRD that showed the influence of dose expressed as Kt/V_{urea} on outcomes, the same dose method has been employed for assessing delivered dose in acute haemodialysis. Nonetheless, some assumptions needed for calculating Kt/V_{urea} in chronic dialysis cannot be applied in patients with AKI. Routine measures of Kt/V_{urea} are unsuitable for quantifying haemodialysis regimens that vary in frequency because cumulative Kt/V_{urea} does not change proportionally to cumulative solute removal [14]. Another problem is that there is no standard method for assessing dose of dialysis in AKI; studies that have explored dose-outcomes relationships and prescribed vs. delivered dose of dialysis have used several different dose expressions (single-pool Kt/V, equilibrated Kt/V, frequency of dialysis per week, etc.).

The concept of providing higher dialysis doses in order to improve patients' outcomes has also been applied to critically-ill patients with AKI. However, recent trials did not confirm this benefit. The acute tubular necrosis (ATN) study, a randomized multicenter trial in 1124 critically-ill AKI patients compared intensive dosage (defined in IHD/SLED as 6 times per week) and less-intensive dosage (as IHD/SLED 3 times per week) [15]. There were no differences in day 60 all-cause mortality, duration of RRT, recovery rate of kidney function, or non-renal organ failure between the groups.

However, dose is still an important factor in the care of patients with AKI, and the actual delivered dose should be continuously assessed to ensure that operational characteristics of the treatment (e.g. filter function) do not preclude the delivery of a prescribed dose [14]. Dialysis dose should also consider fluid balance as an additional parameter as emerging evidence strongly support the influence of fluid overload as a major factor influencing outcomes [16]. Current dialysis machines incorporate on-line measurements of solute clearances and provide information on the delivered Kt/V making this a versatile tool for managing patients [17].

Effect of haemodialysis on outcomes

There is still an ongoing debate of which dialysis modality is better for critically-ill patients with AKI. Several studies have compared IHD and CRRT; most have found no significant differences in terms of mortality, as well as no differences in secondary outcomes such as renal recovery, RRT dependence, or haemodynamic tolerance. Even if CRRT confers a haemodynamic benefit; it is unclear whether this translates into improvements in the patient-relevant outcomes of survival and renal recovery [18]. There are few studies that have compared SLED vs. CRRT, those studies have found no significant differences in all measured haemodynamic parameters (mean arterial pressure, systemic vascular resistance, cardiac output) and fluid removal, with comparable removal of small solutes (e.g. creatinine and urea) [10,11].

Current evidence suggests that there is no superior method of RRT for critically-ill patients with AKI, since the three methods seem to provide similar outcomes. The choice between different modalities should consider the operational characteristics of each method with its advantages and limitations, patients' characteristics and clinical scenario, making sure that an adequate dose of dialysis is delivered and haemodynamic stability is maintained. Examples of situations where IHD may be preferred include severe hyperkalaemia, severe metabolic acidosis, pulmonary oedema with fluid overload in oliguric patients without severe haemodynamic impairment, high bleeding risk and when anticoagulation is contraindicated, and to treat poisoning with a substance of low molecular weight (<500 Da), high water solubility, low protein bound fraction, and low volume of distribution (<1.5 L/kg). On the other hand, in patients with severe haemodynamic instability with fluid overload and when risk of cerebral oedema is present CRRT or SLED should be chosen over IHD.

Van Berendoncks et al. found no difference in 2-year survival when conservative treatment, IHD, and CRRT where compared. Separate survival analysis comparing the conservative treated AKI with the total group of RRT; and sub analysis comparing the two types of RRT did not show a significant difference in long-term outcome. Of patients with chronic kidney disease, one half of the patients stayed in the same category, one quarter decreased, and one quarter increased. Mean serum creatinine did not differ between discharge and follow-up [19].

Finally, the question of the overall effect of RRT vs. conservative management of AKI has not been tested in an RCT. An observational study of Elseviers et al. noted increased mortality in patients treated with RRT vs. conservative management and this difference persisted even after adjustment of disease severity

using the SHARF score [20]. As with other aspects we have previously discussed (timing, type of RRT, and dose) the decision to start RRT requires an integrated and individualized approach, considering conservative management as well as different RRT options in each patient.

Conclusion

Haemodialysis constitutes an important technique to treat critically-ill patients with AKI. The choice of dialysis over conservative treatment, deciding when to start dialysis, and which modality to use, should be based on the operational characteristics of each method with due regard for its advantages and limitations. Haemodialysis techniques should be considered as part of an arsenal for RRT that can be used in critically-ill patients with AKI and based on the individual patient's need at any given time.

CHAPTER 216

Peritoneal dialysis in the critically ill

Jeffrey C. Sirota and Isaac Teitelbaum

Key points

- Peritoneal dialysis (PD), the first modality of renal replacement therapy (RRT) used in the acute setting, dates back nearly 100 years. However, haemodialysis has now largely replaced PD in the treatment of acute kidney injury.
- PD is technically simpler to perform than haemodialysis, requiring simple, inexpensive, and widely available equipment and less specialized staff. As such, acute PD may be particularly important in resource-deprived areas or when natural disasters render haemodialysis impossible.
- Acute PD should be considered when haemodialysis is not available; when central venous access cannot be obtained or should be avoided; when AKI is accompanied by hypothermia or hyperthermia; and in patients with acute haemorrhagic pancreatitis, diuretic-refractory heart failure, or increased intracranial pressure.
- Close monitoring for various infectious, mechanical, pulmonary, and metabolic complications must be performed when acute PD is chosen, but these potential issues should not dissuade clinicians from considering this modality.
- Small observational studies have shown that PD can achieve favourable outcomes in non-hypercatabolic AKI, but there is a paucity of data comparing acute PD to acute haemodialytic techniques.

Introduction: the advantages of peritoneal dialysis

Acute kidney injury (AKI) is a widespread problem with increasing incidence, occurring in up to 20% of critically-ill patients and requiring renal replacement therapy (RRT) in approximately 0.5% of those affected [1]. Initially explored in the 1920s and made commonplace by the 1970s, peritoneal dialysis (PD) was the first modality of RRT used in AKI [2]. However, the emergence of haemodialysis (HD) has resulted in a significantly diminished role for PD; in a recent multinational survey PD was used in less than 5% patients who required RRT in an intensive care unit (ICU) [3].

However, despite its decline in popularity, PD still boasts a number of potential advantages over extracorporeal blood purification techniques, chief among which is the technical ease with which it can be performed. In comparison to HD, PD involves simpler access as well as inexpensive and widely available materials. Additionally, PD can be performed by nurses without specialized HD training in resource-deprived settings that may even lack electricity [4].

Some evidence has also suggested faster renal recovery with PD than with HD [5]. Despite these advantages, however, contemporary use of PD in AKI has been confined to resource-poor settings, following natural disasters when resources and capacity for HD may be exceeded, and to use in children, where its relatively gentle nature and its ease of dosing make it particularly attractive [6,7].

This chapter will review the indications and contraindications for PD in AKI, technical considerations, the available data on outcomes, and possible complications.

Indications and contraindications for peritoneal dialysis in acute kidney injury

Indications

Advances in extracorporeal RRT have led to a paradigm in which the only absolute indication for PD during AKI is the need for RRT when extracorporeal RRT cannot be performed, either due to resource limitations or technical constraints. In addition to this single absolute indication, relative indications also exist in which PD may be considered.

First, PD should be considered when central venous access cannot be obtained or should be avoided. Second, because PD does not require anticoagulation, patients with haemorrhagic conditions may benefit from PD instead of HD, although this advantage is lessened by the emergence of HD approaches that minimize systemic anticoagulation. Thirdly, PD can be beneficial when AKI is accompanied by hypothermia or hyperthermia, as the dialysate temperature can be manipulated to normalize body temperature [8,9]. PD may also have particular benefit in acute haemorrhagic pancreatitis where it may remove active inflammatory mediators [10]. PD can also achieve gentle volume removal without causing significant haemodynamic instability and so may be beneficial in patients requiring ultrafiltration (UF), such as those with diuretic-refractory heart failure [11]. Finally, PD's gentle solute removal may be safer than HD in patients with increased intracranial pressure in whom rapid solute removal may precipitate cerebral oedema.

Contraindications

Contraindications to acute PD are those related to the limitations of the dialytic modality and those related to mechanical concerns.

The former involves potentially inadequate therapy related to the gradual nature of fluid and solute clearance in PD. For example, although life-threatening hyperkalaemia can be treated with acute PD, HD is preferred if available. Similarly, hypercatabolic patients with emergent complications of high solute burden are better suited for HD modalities that provide more rapid solute clearance. Finally, patients who require more precise control of fluid removal might be better treated with HD.

The second category of relative contraindications involves mechanical issues. Instillation of PD fluid may increase intra-abdominal pressure and cause restrictive pulmonary physiology; therefore, caution should be used in patients with respiratory compromise. Certain post-operative conditions may also limit the use of PD, including the presence of new abdominal wall incisions, paralytic ileus, or presence of peritoneal drains (although PD can be performed successfully following abdominal surgery [12]). PD is also relatively contra-indicated in patients with anatomical conditions that preclude adequate filling of the peritoneal cavity (e.g. abdominal adhesions, hernias). Finally, infections such as abdominal wall cellulitis and peritonitis are relative contraindications PD.

Technical considerations

While a variety of different PD modalities exist, they affect solute and fluid clearance by the same principles. Sterile, potassium-free dialysate is instilled through a catheter into the peritoneal cavity and allowed to 'dwell', permeable solutes with a higher concentration in blood than dialysate (such as urea) move down the concentration gradients into the fluid. Additionally, the high dialysate glucose concentration draws water out of the blood, producing net UF. The dwell is followed by fluid drainage, and the instill–dwell–drain cycle is repeated. Cycling of PD fluid bags can be performed manually or automatically by a cycler machine. If available, the latter option is technically easier and requires less supervision.

Peritoneal access

The first step in initiating PD is placement of a peritoneal catheter, of which there are two types. The semi-rigid acute catheter can be placed at the bedside by a trained proceduralist without general anaesthesia. However, semi-rigid catheters carry risks of discomfort, peritonitis, and a risk of bowel perforation which increases with duration of catheter placement [13]. Placing a softer cuffed catheter is a surgical procedure that often requires general anaesthesia with its attendant risks. Laparascopic placement using less anaesthesia is also possible. Cuffed catheters carry less risk of bowel perforation and infection and are more comfortable, they do not require frequent replacement (as semi-rigid catheters do) and are less likely to trigger cycler alarms that cause dialysis interruptions [14,15].

Peritoneal dialysis modalities

High volume PD (HVPD), accomplished through a large number of daily exchanges, is the modality best suited for critically-ill patients who require high solute clearance. Another option for critically ill, hypercatabolic patients is continuous flow PD (CFPD), which involves one peritoneal access for instilling dialysate and another for draining; this arrangement allows higher dialysate flow rates and solute clearances.

Acute intermittent PD is a simpler technique that involves two or three 24-hour sessions per week of rapid cycling fluid into the peritoneal cavity (20–30 exchanges per day) [16]. This approach may not provide adequate small solute clearance in hypercatabolic critically-ill patients [2] and is better suited for maintenance therapy of AKI. Similarly, chronic equilibrated PD (CEPD), which involves an average of four exchanges daily with longer dwells, is also better-suited for patients following resolution of life-threatening AKI.

Finally, tidal PD involves leaving a residual volume of fluid (10–50% of the instilled volume) in the peritoneal cavity after each drain. Tidal PD should theoretically allow for improved solute clearance because fresh dialysate is instilled more frequently and faster [16], but as yet studies have not proven this to be the case [17].

Peritoneal dialysis prescription

PD requires orders for the following variables, all of which require frequent re-evaluation due to the dynamic nature of AKI:

- **PD fluid glucose concentration**: dialysate tonicity (and therefore fluid removal) can be varied by choosing different glucose concentrations. Three standard glucose concentrations are available—1.36, 2.25, and 3.86 g/dL; these correspond to 1.5, 2.5, and 4.25% dextrose, with an osmolarity of 346, 396 and 485 mOsm/L, respectively. Glucose concentration is chosen based on desired fluid removal with a more concentrated glucose solution being chosen when greater fluid removal is desirable.
- **PD fluid volume**: the volume of dialysate infused per exchange is largely determined by patient size. A typical adult can tolerate 2 L, while children are often prescribed 30 mL/kg of body weight. Smaller volumes may be warranted in the first few days after PD catheter insertion (to minimize leaks from the catheter site) and in patients with respiratory compromise or abdominal wall hernias.
- **Times**: 'inflow time' (i.e. time required to instill dialysate) should be minimized in order to maximize dialysis efficiency; if it exceeds 15 minutes, then increased catheter resistance should be suspected (e.g. from catheter kinking or reduced abdominal compliance). 'Dwell time' depends on the PD modality, but should be at least 30 minutes to allow for adequate solute clearance. 'Outflow time' (i.e. time required to drain the peritoneal cavity), like inflow time, should be kept to a minimum to improve overall dialysis efficiency.
- **Dialysate additives**: PD fluid is commonly supplemented with additives. Insulin may be added in diabetic or critically-ill patients who can become hyperglycaemic from the PD fluid's glucose load. Potassium can be added to avoid hypokalaemia. If fibrin clots cause catheter obstruction, heparin can be added (there is no risk of systemic anticoagulation as heparin is not absorbed). Finally, antibiotics can be administered via the PD fluid.

Outcomes using peritoneal dialysis in the treatment of acute kidney injury

Adequate control of metabolic derangements and favourable outcomes can be achieved using various modes of PD in non-hypercatabolic AKI. A limited number of prospective trials are available as well.

In a randomized trial comparing PD with continuous veno-venous haemofiltration (CVVH) in 70 adults with AKI due to malaria [18], outcomes were better in the CVVH group; metabolic abnormalities resolved faster, duration of treatment with RRT was shorter and the mortality was lower. However, as PD practices in the trial were not optimal, the external validity of the results is unclear. In addition, patients with AKI due to malaria may benefit from specific non-dialytic aspects of haemodialysis such as the use of heparin, which may have rheologic benefits to the red blood cells. Another randomized trial assigned 120 patients with AKI, mostly due to sepsis, to either daily HD or HVPD [5]. Mortality in the two groups was similar, but renal recovery occurred significantly earlier in the PD group. These seemingly contradictory results emphasize that in the absence of large, robust clinical trials the relative effects of PD and other forms of RRT in patients with AKI remain unclear.

Complications of peritoneal dialysis

Infectious complications

Peritonitis is the most important infectious complication during acute PD, with a reported incidence of 12% [19]. Typically resulting from contamination of the peritoneal cavity with Gram-positive or Gram-negative organisms, peritonitis usually arises in the first two days of acute PD. Cloudy drain fluid should prompt fluid analysis for cell count, Gram stain and culture, and initiation of empiric antibiotic treatment. Local skin and soft tissue infections can also occur at the PD catheter insertion site.

Mechanical complications

A variety of mechanical complications may occur with acute PD. The most dangerous is bowel perforation, which can present with pain and blood or faecal material in the peritoneal fluid. Bladder perforation is less common and can present with urine leakage into the PD effluent. Perforation requires prompt antibiotic and surgical care. Acute PD can also cause abdominal discomfort, usually from catheter placement and the distension of the peritoneal cavity with dialysate.

Pulmonary complications

The increase in intra-abdominal pressure caused by PD fluid can restrict diaphragmatic excursion resulting in impaired secretion clearance and basal atelectasis. Increased intra-abdominal pressure can promote gastro-oesophageal reflux predisposing to aspiration. Respiratory impairment can also occur if PD fluid enters the thorax through congenital or iatrogenic defects in the diaphragm which occurs in up to 1% of patients starting PD [20] and should be suspected if pleural fluid glucose concentration is significantly higher than that of serum.

Metabolic complications

The glucose load of PD fluid may cause or worsen hyperglycaemia particularly in patients with diabetes mellitus. Cessation of PD can result in hypoglycaemia in critically-ill patients being treated with insulin infusions if the insulin infusion rate is not decreased at the same time. Hypernatraemia can result from free water losses in the hypotonic ultrafiltrate and prolonged PD can result in hypokalaemia. PD can contribute to malnourishment in critically-ill patients due to the protein loss through the dialysate.

Conclusion

RRT in patients with AKI has long been achieved with PD, and available evidence suggests that this approach is reasonable and safe in many circumstances. By virtue of its technical simplicity, PD remains an important modality for RRT in resource-deprived areas and may be life-saving when no alternative exists. In addition, it should also be considered in all settings when its advantages over HD may be particularly beneficial.

PART 8.5

Established renal failure

CHAPTER 217

The effect of renal failure on drug handling in critical illness

Myrna Y. Munar and Ali J. Olyaei

Key points

- Acute and chronic kidney injury alters the pharmacokinetic of most commonly used drugs.
- For most agents, the dose or dosing interval should be adjusted to be appropriate for the individual patient's renal function.
- For drugs with narrow therapeutic window, plasma concentration should be monitored and dosage adjusted accordingly.
- For most patients with kidney disease, exposure to nephrotoxins should be avoided as much as possible.
- It is important to accurately estimate renal function to improve drug dosing in patients with chronic kidney disease (CKD).

Introduction

The kidneys play an important role in the elimination of many drugs as well as their pharmacologically active metabolites. Chronic kidney disease (CKD) affects not only glomerular blood flow and filtration, but also tubular secretion and reabsorption, and renal metabolism. Several pharmacokinetic processes such as drug absorption, bioavailability, protein binding, volume of distribution, and non-renal clearance are also affected. Patients with CKD require medication dosing appropriate for their level of kidney function to avoid adverse drug events, to prevent further renal injury, and to optimize outcomes.

Many medications are frequently administered orally. Oral bioavailability, defined as the fraction of an oral dose that actually reaches systemic circulation, is determined by the fraction of the dose that undergoes absorption, the fraction that escapes gut metabolism and drug transport from the intestinal wall back into the gut lumen, and the fraction that escapes hepatic metabolism. Drug absorption may be altered in patients with CKD as a result of vomiting secondary to azotemia or uraemia, delays in gastric emptying, changes in gastric pH, and the presence of gastrointestinal tract oedema.

Absorption is characterized by the maximum drug concentration (C_{max}), the time it was achieved (T_{max}), and area-under-the plasma concentration-time curve (AUC). Delays in gastric emptying and sluggish gastrointestinal (GI) motility may result from diabetic or uremic gastroparesis, or both. The result is delayed absorption with a prolonged T_{max} and a lower C_{max}. Eventually the administered dose is absorbed; therefore, the overall extent of absorption (AUC) is unaffected. Delayed drug absorption becomes clinically significant for medications in which a rapid onset of pharmacologic effect is needed.

Several medications taken by patients with CKD can alter gastric pH and, to a lesser extent, gut motility including: histamine-2 receptor blockers, proton-pump inhibitors, and antacids. Ammonia formation in the gut can also contribute to an increase in gastric pH. Elevated blood urea nitrogen in CKD can be converted by gastric urease enzymes to ammonia, resulting in an increase in gastric pH. Regardless of aetiology, an increase in gastric pH can result in either an increase or a decrease in drug absorption. For example, some imidazole antifungals (e.g. itraconazole) are dependent upon a low gastric pH for disintegration and dissolution. Gastric alkalinization reduces drug disintegration and dissolution, resulting in reduced absorption and bioavailability [1]. Conversely, the oral bioavailability of weakly acidic medications such as NSAIDS or oral hypoglycaemics (e.g. glipizide) can be enhanced in an alkaline gastric environment by increasing drug dissolution and subsequent absorption [1].

Drug interactions involving antacids, which are used to treat gastrointestinal symptoms or as dietary phosphate binders to treat the hyperphosphataemia of chronic renal disease, can occur through various mechanisms: alterations in drug dissolution by changing gastric pH, alterations in gastric motility, complexing with certain medications reducing absorption, alterations in drug ionization whereby weak acids are more ionized and less absorbed and weak bases are less ionized and more likely to be absorbed, and alterations in drug elimination by changing urinary pH [1]. Aluminum-, magnesium- and calcium-containing antacids, can form insoluble complexes with co-administered medications leading to reduced absorption. These medications can also interfere with oral iron absorption by two mechanisms: decreasing iron solubility by increasing gastric pH, and formation of non-absorbable insoluble complexes [2]. Two classes of antibiotics, tetracyclines and fluoroquinolones, are also susceptible to these absorption interactions [1]. Other phosphate binders, such as sevelamer and lanthanum have also been reported to decrease the absorption of fluoroquinolones [3,4]

Another factor that can affect drug absorption is gastrointestinal tract oedema caused by congestive heart failure or by hypoalbuminaemia due to liver cirrhosis or nephrotic syndrome. Acidic drugs such as penicillins, cephalosporins, salicylates, phenytoin, valproic acid, and furosemide mainly bind to albumin, while basic drugs, such as propranolol, morphine, disopyramide, and oxazepam, bind mainly to alpha 1-acid glycoprotein (AAG). AAG is an acute-phase

protein whose serum concentration is increased in CKD. Although the binding of most basic drugs to AAG is unaffected in CKD, the binding of certain drugs, such as disopyramide, may be increased.

The decrease in protein binding of acidic drugs in patients with renal impairment may be caused by:

- Hypoalbuminaemia which may occur in association with uraemia and in nephrotic syndrome.
- Accumulation of competitive endogenous substances (e.g. organic acids in uraemia, drugs, and/or drug metabolites) that can compete with the acidic drugs for protein binding sites.
- Conformational or structural changes in the binding site in uraemia resulting in decreased affinity of binding sites for the acidic drug.

Total plasma drug concentrations represent both drug bound to plasma proteins and unbound or free drug. Only free drug is pharmacologically active and capable of crossing membranes. The decrease in protein binding results in a greater fraction of unbound drug available for distribution as well as drug elimination by hepatic metabolism, or in patients with end-stage renal disease, by dialysis. Therefore, an increase in the apparent volume of distribution and an increase in total body clearance may be observed. The overall effect is no change in the unbound or active drug concentration, but a reduction in the total plasma concentration. The classic example of this effect is with the acidic drug, phenytoin. Total phenytoin concentrations may be misinterpreted in patients with renal impairment and hypoalbuminaemia, resulting in erroneous upward dose titration in response to low measured total phenytoin concentrations. Therefore, it is recommended to monitor unbound or free phenytoin concentrations instead.

Tissue binding is reduced in uremic states resulting in an increase in the fraction of drug unbound in tissues. Changes in tissue binding are not clinically significant for most drugs, with the exception of digoxin. The volume of distribution of digoxin is reduced in patients with end stage renal disease (ESRD) [5]. Decreased tissue uptake combined with impaired renal excretion may result in increased digoxin serum concentrations if loading doses are not reduced.

Drug metabolism is classified as either phase I or phase II reactions. Phase I reactions consist of oxidation, hydrolysis, and reduction mediated by cytochrome P-450 isoenzymes, while phase II reactions involve conjugation via glucuronidation, sulphation, acetylation, methylation, and glutathione conjugation. Both phase I and phase II reactions are slowed in renal impairment [2], which can result in increased serum drug concentrations. Phase I and phase II metabolism result in the formation of water soluble metabolites that are subsequently excreted by the kidney. Thus, pharmacologically active and toxic metabolites can accumulate in renal impairment. A notable example is the narcotic analgesic, pethidine. Pethidine is metabolized to norpethidine, a toxic metabolite with little analgesic activity, but with the propensity to lower the seizure threshold [6]. It should not be used in patients with severe kidney disease and renal failure.

Last of all, metabolic enzymes found in the liver are also found in the kidney within the renal cortex. However, the total weight of the kidneys are less than the total weight of the liver, therefore the contribution of renal metabolism to overall drug clearance is probably low in comparison to liver metabolism.

The effect of CKD on renal drug metabolism could be clinically important for two medications: vitamin D and insulin. The kidneys play an important role in the activation of vitamin D to calcitriol. Therefore, patients with severe kidney disease should receive the active form of vitamin D as calcitriol, paricalcitol, or doxercalciferol. The kidneys, in addition to the liver and muscle, are important sites for insulin degradation and clearance. CKD can have variable effects on insulin and glucose homeostasis. On one hand, impaired renal insulin degradation and clearance, malnutrition from gastroparesis or anorexia, and deficient renal gluconeogenesis lower the threshold for hypoglycaemia [7,8]. On the other hand, increased insulin resistance may mitigate these effects.

Renal clearance represents the sum of three processes that control the movements of drugs between plasma and urine: glomerular filtration, tubular secretion, and tubular reabsorption. Drug clearance by glomerular filtration (CL_{GFR}) is dependent on the patient's glomerular filtration rate (GFR) and the fraction of drug not bound to plasma proteins. Drugs that are highly protein bound are not readily filtered at the glomerulus for two reasons: plasma proteins, such as albumin carry an anionic charge that is repelled by anionic sites within the glomerulus, and protein bound drugs are too large to be filtered. However, highly protein bound drugs are actively secreted into the proximal convoluted tubules. However, tubular secretion is a transport-mediated process that can be saturated, thus, with high drug concentrations tubular secretion can reach a limit resulting in a longer elimination half-life. Other drugs can also compete for tubular secretion (e.g. penicillin and probenecid). Finally, CKD can reduce tubular reabsorption resulting in higher urinary concentrations and increased elimination of drugs. Caution should be exercised when prescribing drugs that are potentially nephrotoxic and undergo tubular reabsorption (e.g. methotrexate and lithium).

It is vital to accurately estimate renal function to improve drug dosing in patients with CKD. GFR is a high-quality estimate of renal index in both healthy and diseased kidneys. Inappropriate drug dosing in CKD may adversely affect patient outcomes. Overexposure and underexposure are major concerns in CKD. To reduce potential toxicities or sub-therapeutic exposures, a number of biomarkers and mathematical models have been developed to accurately estimate GFR [9].

Serum creatinine

Creatinine is a product of muscle metabolism. Creatinine is unbound and is filtered through the glomerulus with minimal tubular secretion. These properties make serum creatinine a good marker for measuring GFR. However, since creatinine is a function of muscle breakdown, it is affected by differences in muscle mass, age, gender, race, diet, and certain drugs. Additionally, since serum creatinine (SCr) accumulation is time dependent, it does not adequately reflect the change in GFR due to an acute kidney injury (AKI). Likewise when resolution of kidney injury occurs, SCr levels may 'lag' behind kidney recovery. Lastly, creatinine secretion from the proximal tubules depends on GFR so for patients with renal insufficiencies, may have an inaccurate lower creatinine [10].

Cockcroft–Gault

The most common method to estimate renal function is use of the Cockcroft-Gault (CG) equation. The CG formula was developed in 1976, and today is the most widely used formula for assessment of

kidney function [11]. Variables in the equation include age, body weight, and SCr. For females, the equation is multiplied by 0.85.

$$\text{CrCl} = (140 - \text{age}) \times \text{Wt (kg)} \times (0.85 \text{ for females})/72 \times \text{SCr} \quad \text{[eqn 1]}$$

It is important to note that the CG method estimates creatinine clearance (CrCl) not GFR. However, CrCl is recommended by the FDA for drug dosing adjustment in CKD. The CG formula places heavy emphasis on age, weight, and muscle mass. As such, it is not an accurate measure of renal function in obese or malnourished patients or patients with muscle disease, or advanced or unstable renal function.

Modification of diet in renal disease

The Modification of Diet in Renal Disease (MDRD) equation was developed in 1999 in an attempt to improve accuracy compared to the CG formula. It was derived from the MDRD study involving 1628 patients who were assessed to determine the most accurate measure of GFR [12]. Compared to the CG formula, the MDRD includes additional variables that may affect SCr. In total, four

Table 217.1 Therapeutic drug monitoring in chronic kidney disease

Drug name	When to draw sample	Therapeutic range	How often to draw levels
Aminoglycosides (conventional dosing): gentamicin, tobramycin, amikacin	*Trough*: immediately prior to dose *Peak*: 30 minutes after a 30–45-minute infusion	**Gentamicin and tobramycin** *Trough*: 0.5–2 mg/L *Peak*: 5–8 mg/L **Amikacin** *Trough*: < 10 mg/L *Peak*: 20–30 mg/L	Check peak and trough with 3rd dose For therapy less than 72 hours, levels not necessary. Repeat drug levels weekly or if renal function changes
Aminoglycosides (24-h dosing): gentamicin, tobramycin, amikacin	Obtain random drug level 12 hours after dose	0.5–3 mg/L	After initial dose, repeat drug level in 1 week or if renal function changes
Carbamazepine	*Trough*: immediately prior to dosing	4–12 μg/mL	Check 2–4 days after first dose or change in dose
Ciclosporin	*Trough*: immediately prior to dosing	150–400 ng/mL	Daily for first week, then weekly
Digoxin	12 hours after maintenance dose	0.8–2.0 ng/mL	5–7 days after first dose for patients with normal renal and hepatic function; 15–20 days in anephric patients
Enoxaprin	4 hours after 2nd or 3rd dose	0.7–1.1	Weekly and as needed
Lidocaine	8 hours after iv infusion started or changed	1–5 μg/mL	As needed
Lithium	*Trough*: before a.m. dose, at least 12 hours after last dose	*Acute*: 0.8–1.2 mmol/L *Chronic*: 0.6–0.8 mmol/L	As needed
Phenobarbital	*Trough*: immediately prior to dosing	15–40 mcg/mL	Check 2 weeks after first dose or change in dose. Follow-up level in 1–2 months
Phenytoin: free phenytoin	*Trough*: immediately prior to dosing	10–20 mcg/mL 1–2 mcg/mL	5–7 day after first dose or after change in dose
Procainamide **NAPA** (n-acetyl procainamide): a procainamide metabolite	*Trough*: immediately prior to next dose or 12–18 hours after starting or changing an infusion. Draw with procainamide sample	4–10 μg/mL *Trough*: 4 μg/mL *Peak*: 8 μg/mL 10–30 μg/mL	As needed
Sirolimus	*Trough*: immediately prior to next dose	10–20 ng/dL	Weekly for first month, then as needed
Tacrolimus	*Trough*: immediately prior to next dose	5–10 ng/mL	Daily for first week, then weekly
Valproic acid (valproate semisodium)	*Trough*: immediately prior to next dose	40–100 mcg/mL	Check 2–4 days after first dose or change in dose
Vancomycin	*Trough*: immediately prior to dose *Peak*: 60 minutes after a 60-minute infusion	*Trough*: 10–20 mg/L *Peak*: 25–40 mg/L	With 3rd dose (when initially starting therapy, or after each dosage adjustment). For therapy less than 72 hours, levels not necessary. Repeat drug levels if renal function changes

Data from: Olyaei AJ and Steffl JL, 'A quantitative approach to drug dosing in chronic kidney disease', *Blood Purification*, 2011, **31**(1–3), pp. 138–145; Olyaei AJ and Bennett WM, 'Drug dosing in the elderly patients with chronic kidney disease', *Clinics in Geriatric Medicine*, 2009, **25**(3), pp. 459–527.

variables are included: age, SCr, race, and gender (6-variable equation (MDRD6) includes BUN and albumin).

$$\text{GFR} = 175 \times \text{SCr}^{-1.154} \times \text{age}^{-0.203} \times 1.212\,(\text{if black}) \times 0.742\,(\text{if female}) \quad \text{[eqn 2]}$$

MDRD has been validated in a number of patient populations and most importantly does not require body weight. This allows for reporting of eGFR along with the routine chemistries. Recently, this method was adopted by the National Kidney Foundation as the primary equation for determining estimated GFR and CKD staging. The MDRD can significantly underestimate the GFR in patients with good kidney function (GFR >90 mL/min/17.3 m^2). Additionally, its accuracy has not been established in paediatrics, elderly, hospitalized, and other ethnic origins (only blacks). Most important MDRD does not address the patient's weight and obesity factor.

Chronic kidney disease epidemiology collaboration equation

CKD Epidemiology Collaboration Equation (CKD-EPI) was developed in 2009 to match the accuracy of the MDRD equation at GFR < 60 mL/min/1.73 m^2 and to offer greater accuracy at GFR >90 mL/min/1.73 m^2.

$$\text{eGFR} = 141 \times \min(\text{SCr}/\text{k},1)^{\text{a}} \times \max(\text{SCr}/\text{k},1)^{-1.209} \times 0.993^{\text{age}} \times 1.159\,(\text{if black}) \times 1.018\,(\text{if female}) \quad \text{[eqn 3]}$$

CKD-EPI has shown to be as accurate as MDRD in patients with GFR<60 and substantially more accurate in the subgroup with GFR >90 [13]. In a recent review paper and recommendation, CKD-EPI was more accurate and the least biased when compared to CG and MDRD [14]. However, it has not been validated for most drugs and there is a lack of information in older patients [15].

Today, the CG method is the most commonly used formula to assess kidney function. It has been around the longest, has been well validated, is easy to remember, and is fairly accurate in estimating kidney function. Also, most drugs are dosed based on the patient's weight (mg/kg) which makes the CG method easier to use for most estimates. In some circumstances all three formula should be utilized to improve patient outcomes while reducing adverse drug reactions related to overexposure. A patient's renal function should always be estimated based on the best available evidence for that specific patient [16].

Drug dosing in chronic kidney disease

Many drugs require loading doses to rapidly achieve therapeutic plasma concentrations. This is particularly true for antimicrobial and cardiovascular agents. For most drugs no renal dose adjustment is required for the loading dose. However, maintenance doses should be adjusted for drugs that are excreted primarily unchanged through the urine. The maintenance doses can be adjusted in two different ways, 1) reduce each dose, but maintain the same dosing interval to avoid the risks of toxicity due to drug accumulation, or 2) maintain the same dose, but lengthen the dosing interval to decrease the risk of sub-therapeutic dosing for concentration dependent drugs. In addition, for drugs with proven therapeutic drug monitoring (TDM), measuring plasma or whole blood concentrations can optimize therapeutic regimens while reducing toxicities (Table 217.1) [17,18].

However, hypoalbuminaemia may affect TDM for drugs that are highly protein bound, such as phenytoin, and the results of TDM should be interpreted with caution. Although the total drug concentration may be low, active unbound drug concentrations are high and the patients are at risk for drug toxicity. Therefore, hypoalbuminaemia should be considered in the interpretation of measured total drug concentrations. Finally patients with CKD are at great risk of developing kidney injury from drugs or diagnostic agents. Exposure to nephrotoxins should be avoided as much as possible [19].

CHAPTER 218

The effect of chronic renal failure on critical illness

Sinead Kinsella and John Holian

Key points

- The prevalence of chronic and end stage kidney disease (CKD and ESKD) is increasing and these patients are frequently admitted to Intensive Care Units (ICU).
- Sepsis and cardiovascular events are the most frequent causes of ICU admission in patients with CKD and ESKD.
- Patients with ESKD and CKD requiring ICU admission have better ICU and in-hospital survival than patients with acute kidney injury (AKI) requiring renal replacement therapy (RRT).
- ESKD patients who survive an episode of critical illness have higher ICU re-admission rates and may benefit from closer monitoring following ICU discharge.
- Mortality in critically-ill ESKD patients is related to their co-morbid conditions rather than to ESKD status, therefore appropriately selected ESKD patients benefit from ICU admission.

Introduction

The incidence and prevalence of chronic and end stage kidney disease (CKD and ESKD) are increasing world-wide, reflecting an increase in Type 2 diabetes, hypertension, and an ageing population. Patients with ESKD treated with dialysis have significant co-morbidities due both to their underlying disease and specific to their ESKD. These patients are more likely to become critically ill and require admission to an ICU. It is reported that between 1.3 and 11% of ICU admissions are patients with dialysis-dependent ESKD [1–4]. It is estimated that the risk of requiring ICU admission in the ESKD population is 4-fold higher than that of the general population [1]. Cardiovascular events including sudden death, myocardial infarction, cardiac arrest, and malignant arrhythmias are the major cause of death accounting for 43% of all-cause mortality among haemodialysis patients [5]. Cardiovascular events and infectious complications are the leading causes of hospitalizations in patients with ESKD [6] and account for approximately 24 and 20.5% of ICU admissions respectively [7]. In addition, patients with ESKD are almost twice as likely to have received cardio-pulmonary resuscitation prior to ICU admission, compared to patients without ESKD [1].

Outcomes

Despite their chronic co-morbidities, several studies have reported lower ICU mortality for patients with ESKD than for patients with Acute Kidney Injury (AKI) requiring Renal Replacement Therapy (RRT). Clermont et al. in a study of 1530 ICU admissions reported that patients with ESKD had intermediate mortality (11%), compared with patients with AKI (23%) and those without renal failure, (5%) [2]. Unchino et al. found that ICU mortality matched for illness severity score was similar for patients with ESKD and AKI [3]. Similarly in a systematic review of 16 studies including 6591 patients, Arulkumaran et al. report an ICU mortality of 21.4% and an in-hospital mortality of 34.5% for patients with ESKD. In-hospital mortality for patients with AKI requiring RRT was significantly higher compared to patients with ESKD, (55 versus 24%, $p < 0.0001$). The 90-day mortality among patients with AKI requiring RRT was also higher compared to ESKD, (56% versus 38%, $p = 0.0007$). In most studies, the unadjusted in-hospital mortality of patients with ESKD is significantly less than for patients with de novo AKI requiring RRT, however, following adjustment for confounders, these studies consistently show that mortality in critically-ill patients with ESKD is largely related to their co-morbid conditions rather than to ESKD status [1,2,4]. Similarly while pre-existing non-dialysis requiring CKD is a risk factor for the development of acute kidney injury in the ICU, Mehta et al. observed in the PICARD study that patients with CKD and super-imposed AKI had lower mortality rates than those with new-onset AKI (31 versus 41%, $p = 0.03$) [8].

While critical illness associated with AKI requiring RRT has a less favourable ICU outcome compared to patients with ESKD admitted to the ICU, re-admission rates to the ICU are reportedly higher in the patients with ESKD and patients with ESKD have significantly longer hospital stays [1,4].

Data on long-term survival of patients with ESKD following an episode of critical illness is limited. Bell et al. observed that the risk of death was 2.86-fold higher during the first year and 1.95-fold higher during the second year following ICU admission when compared to patients with ESKD not admitted to the ICU. Conversely, Chapman et al. found that once patients who died within a month of ICU discharge were excluded; there was no difference in 2-year survival between patients with ESKD admitted to the ICU and a comparator group of patients with ESKD without a history of critical illness [9].

Outcome predictors

Illness severity scores and non-renal organ failure are important predictors of outcome in critically-ill patients with ESKD in the ICU. However, the accuracy of outcome prediction scoring systems such as Sequential Organ Failure Assessment (SOFA) score, Simplified Acute Physiology Score (SAPS) and the Acute Physiology and Chronic Health Evaluation (APACHE) score in patients with ESKD is controversial. In most studies the predicted ICU and in-hospital mortality based on illness severity scores over-estimate the actual mortality in patients with ESKD [1–4]. One potential explanation for the over-estimation of mortality in ESKD patients may be that illness severity scoring systems allocate high points for renal variables such as oliguria, and elevated urea and creatinine. These variables, which may be indicative of systemic inflammatory response syndrome (SIRS), haemodynamic instability and systemic vasodilatation in patients with AKI, are baseline characteristics of the patient with ESKD. As such, unmeasured changes in acute physiology which result in AKI, along with non-renal organ responses to AKI may account for the observed difference in mortality in patients with AKI vs. those with ESKD, despite similar illness severity scores. It has also been suggested that patients with ESKD respond differently to critical illness compared to patients without kidney disease. Unchino et al. found that even after matching for diagnosis and illness severity score, patients with ESKD required less vasoactive drugs, required mechanical ventilation for shorter periods of time and had a lower incidence of SIRS compared to patients with AKI [3]. Plasma levels of pro and anti-inflammatory cytokines which are associated with SIRS are predictive of mortality in patients with AKI and plasma cytokine levels have been shown to be significantly higher in critically-ill patients with AKI compared with patients with ESKD and CKD [10]. It has been suggested that the state of immunosuppression inherent to CKD [11] is responsible for the differences in cytokine production, development of SIRS and response to critical illness and may contribute to the observed differences in mortality [3]. The development of novel sensitive serum and urinary biomarkers to detect AKI, such as neutrophil gelatinase-associated lipocalin (NGAL), kidney injury molecule-1 (KIM-1), and interleukin 18 may allow the detection of super-imposed AKI in patients with CKD or ESKD who have residual renal function and help distinguish between the effects of loss of organ function and acute physiological responses on outcomes of critical illness [12].

The reason for admission to the ICU is an important predictor of outcome for patients with ESKD, as it is for other patients. The relative risk of death for patients with ESKD admitted to ICU with a medical diagnosis is twice that of patients with ESKD admitted with a surgical diagnosis [9]. This may reflect an appropriately low threshold for admitting patients with ESKD patients to ICU following surgery, given their co-morbidities and increased mortality after major surgery.

Practical considerations

Cardiovascular disease

Cardiovascular disease accounts for up to 50% of mortality in patients with ESKD. In addition, the majority of patients with CKD die of cardiovascular events before progressing to ESKD. Atherosclerotic coronary artery disease is highly prevalent in both CKD and ESKD patients and is frequently asymptomatic. Left Ventricular Hypertrophy (LVH) is also highly prevalent in patients with CKD and ESKD, with over 70% of incident dialysis patients demonstrating evidence of LVH [13]. Both eccentric LVH, due to volume overload and concentric LVH, due to hypertension and exacerbated by anaemia, hyperparathyroidism and elevated angiotensin II, occur. The predominant effect of these changes in patients with ESKD is diastolic dysfunction, often with preserved ejection fraction. Modest increases in Left Ventricular volume in these patients results in a large increase in LV pressure, pre-disposing to acute pulmonary oedema. In addition, relatively small volume ultrafiltration on dialysis can result in an abrupt fall in LV diastolic pressure, predisposing to hypotension and haemodynamic instability.

Given the prevalence of LVH and diastolic dysfunction, acute pulmonary oedema is a frequent cause of admission to the ICU in the dialysis population and has been associated with respiratory infection, excessive interdialytic weight gain and inappropriate dry weight. Admissions to the ICU with pulmonary oedema are also more likely to occur towards the end of the 2-day weekend dialysis gap [14]. Patients with dialysis-dependent ESKD are frequently anuric and more likely to develop pulmonary oedema and hypertension due to volume overload and salt excess. These patients demonstrate resistance to diuretic therapy and require ultrafiltration to restore salt and water balance. Similarly patients with CKD and residual urine output may require higher diuretic doses in order to achieve a response.

Cardiac arrhythmias and sudden cardiac death are also more common in patients with renal disease due to abnormalities in coronary micro-circulation, impaired coronary reserve, myocardial fibrosis, impaired vascular compliance, and increased sympathetic nervous system activity. Fluxes in electrolytes such as potassium, calcium, and magnesium which occur during dialysis also increase the risk of arrhythmia.

Sepsis

Infectious complications are the most common cause of hospitalization in patients with ESKD. Factors resulting in increased susceptibility to infection include immunocompromise related to chronic disease [11], increased exposure to nosocomial infection, hypoalbuminaemia, anaemia, malnutrition [15] and widespread use of in-dwelling dialysis catheters. It is estimated that half of all catheter related blood stream infections in dialysis patients are due to Gram positive cocci, one third due to Gram negative organisms and approximately 20–30% are polymicrobial [16]. In addition the risk of Meticillin-resistant Staphylococcus aureus (MRSA) bacteraemia is substantially higher in the dialysis population compared to the general population as up to 9.5% of haemodialysis patients are carriers of MRSA [17]. It is therefore prudent to administer empiric antibiotic treatment which includes MRSA and Gram negative cover to the ESKD patient with sepsis until causative organisms have been identified. In addition, in the case of catheter–related sepsis, dialysis patients often improve dramatically on removal of the source.

Vascular access

The use of arteriovenous fistulae for continuous haemofiltration should be avoided as lower pump speeds may predispose to thrombosis of the fistulae and prolonged needle placement predisposes to infection. The insertion of a dedicated haemodialysis catheter

is preferred for continuous RRT, but insertion of catheters into the subclavian vein should be avoided due to the increased risk of central vein stenosis. Catheters should be placed contralateral to any existing permanent dialysis access and catheter placement may be difficult due to multiple previous venous access procedures.

Anti-coagulation and bleeding risk

Renal failure is associated with an increased risk of bleeding with the most common manifestations being gastro-intestinal bleeding and prolonged bleeding from needle and venous access insertion sites. Bleeding diathesis in uraemia is due to dysfunctional platelet adherence, abnormal von Willebrand factor metabolism and anaemia.

Anti-coagulation is required to maintain patency of the extra-corporeal dialysis circuit both during intermittent and continuous dialysis therapies. While low molecular weight heparin is frequently used in chronic stable haemodialysis patients, the use of unfractionated heparin is preferred in the acute or critically-ill patient as it is easily monitored and readily reversible. Haemodialysis catheters are routinely 'locked' with heparin to maintain patency when not in use and care should be taken to withdraw the instilled heparin volume prior to catheter use to avoid systemic anticoagulation. Regional citrate anticoagulation is an increasingly popular alternative to heparin as it restricts anticoagulation to the extracorporeal circuit, where it acts by chelating ionized calcium. Calcium is then replaced by infusion at the end of the extracorporeal circuit. Use of citrate anticoagulation requires monitoring for hypocalcaemia and the development of metabolic alkalosis, as citrate is metabolized by the liver to bicarbonate. Other anticoagulation strategies for RRT include thrombin antagonists (lepirudin, argatroban), platelet inhibiting agents (epoprostenol) and Factor Xa inhibitors (fondaparinux).

Anaemia

CKD and ESKD patients are frequently anaemic due to erythropoietin and iron deficiency and are often prescribed Erythropoiesis Stimulating Agents (ESA's) to maintain haemoglobin levels. Anaemia is a common complication in critical illness due to blood loss, reduced red cell production, increased red cell destruction, decreased erythropoietin production and hyporesponsiveness of the bone marrow to erythropoietin. The use of erythropoietin in critically-ill patients has not been shown to reduce red blood cell transfusions in the ICU and has been associated with an increased incidence of thrombotic events. The benefit of continuing ESA's in critically ill ESKD patients has not been evaluated [18].

Peritoneal dialysis

Peritoneal dialysis has several advantages over haemodialysis based modalities including non-vascular access, greater haemodynamic stability, and no requirement for systemic anticoagulation. It is also less expensive. Contra-indications to PD include recent intra-abdominal surgery, peritonitis, and respiratory compromise, as intra-peritoneal fluid may further impair lung function and gas-exchange. PD is the modality of choice for RRT in critically ill paediatric patients. Despite the advantages of PD, it is ineffective in the management of life-threatening hyperkalaemia and it is less effective than haemodialysis based modalities in severe acute illness, pulmonary oedema, drug overdose, and hypercatabolic states. As such, PD is not commonly used in the ICU setting. If PD is used in this setting, care should be taken to monitor venous blood glucose levels, as icodextrin containing PD fluid may interfere with point-of-care blood sugar monitoring resulting in overestimation of capillary glucose and severe undetected hypoglycaemia [19].

In patients with ESKD treated with chronic PD, peritonitis is a significant cause of morbidity and mortality and such patients may require admission to the ICU. Clinical presentations of PD peritonitis include abdominal pain, fever, nausea and vomiting, and cloudy peritoneal effluent. If PD peritonitis is suspected, empiric antibiotic treatment should be initiated promptly. Peritoneal effluent should be sent for cell count and differential, Gram stain and culture. A diagnosis of PD peritonitis is confirmed if two or more of the following criteria are met:

- Signs and symptoms.
- PD effluent white cell count >100/μL (after a dwell time of at least 2 hours) with at least 50% neutrophils.
- A positive culture of an organism from the PD effluent.

PD peritonitis is usually caused by a single organism. Culture of multiple Gram negative or mixed Gram negative and positive organisms from the PD effluent should raise immediate concern for presence of a perforated viscus and prompt appropriate investigations for 'surgical' peritonitis.

Intra-peritoneal administration of antibiotics is superior to intravenous administration for treating PD peritonitis and should be initiated without delay. Empiric antibiotics must cover both Gram positive and Gram negative organisms and the selection of empiric antibiotics is based on the centre-specific history of sensitivities of peritonitis associated organisms. Gram positive organisms can be covered by vancomycin or a cephalosporin, Gram negative organisms by a third-generation cephalosporin, aminoglycoside or ciprofloxacin. Failure of the effluent to clear after 5 days of appropriate antibiotic therapy or identification of fungal infection by microscopy or culture should prompt removal of the PD catheter [20].

Drug dosing

Drug dosing in CKD and ESKD can be particularly challenging as care must be taken to ensure therapeutic drug levels while avoiding toxicity or inadequate plasma levels. Correct dosing of drugs in these patients requires consideration of drug-protein binding, volume of distribution and residual renal function. In addition extracorporeal drug clearance differs depending on the modality of RRT used.

Conclusion

The incidence of CKD and ESKD is increasing and these patients with CKD or ESKD frequently require treatment in an ICU. Mortality in critically-ill patients with ESKD is frequently related to their co-morbid conditions rather than their ESKD status, therefore appropriately selected patients benefit from ICU admission. Cardiovascular disease and sepsis account for the majority of ICU admissions in this population and the aetiology of these conditions differs from that in patients without kidney disease. Optimal critical care management of patients with ESKD and CKD requires that these differences are recognized.

SECTION 9

The neurological system

PART 9.1

Anatomy and physiology

CHAPTER 219

Normal anatomy and physiology of the brain

Simona Ferioli and Lori Shutter

Key points

- Central nervous system dynamics such as blood flow, cerebrospinal fluid circulation, and intracranial pressure are tightly regulated by its different compartments. Knowledge of basic physiological mechanisms is essential in understanding how the brain can be affected by systemic diseases encountered in the intensive care unit.
- The cerebral cortex attends complex functions including memory, language, abstraction, judgment, emotion, attention, and synthesis of movements. These can be selectively impaired in patients with primary central nervous system pathologies depending on their location.
- Consciousness is commonly affected in critically-ill patients. Its integrity depends on arousal and content, which are regulated by distinct structures within the central nervous system.
- Ventilation is controlled by a multi-level network of peripheral and central nervous structures that are crucial in diagnosis and treatment of respiratory failure.
- Motor and sensory systems are hierarchically organized along tracts involving nerves, muscles spinal cord, and central structures. Identification of their localization and function is important for diagnosis of different patterns of weakness and sensory loss that occur in critically-ill subjects.

Meninges, cerebral spinal fluid, and the blood–brain barrier

The brain is protected from mechanical trauma within the skull by three meningeal layers and the cerebral spinal fluid (CSF). The outer meningeal layer is the dura, which is attached to the inner surface of the skull and extends caudally around the spinal cord to form the dural sac. The two layers that constitute the dura separate to form the intracranial walls of the venous sinuses where cerebral spinal fluid gets reabsorbed. The epidural space (between the inner skull and dura) contains the middle meningeal artery, a branch of the external carotid artery. The subdural space (between the inner side of the dura and subarachnoid) is traversed by bridging veins that drain into the dural sinuses which continue into the jugular veins. The middle meningeal layer is the arachnoid, which adheres loosely to the inner dura, defines the subarachnoid space and is filled by CSF (Table 219.1). The inner meningeal layer is the pia, a thin epithelial layer that tightly covers the parenchyma. All these spaces can become sites for life-threatening haemorrhages, particularly in the setting of trauma (epidural and subdural haematomas) or aneurysm rupture (subarachnoid space). CSF is produced by the choroid plexus, which is a vascular structure lying within the ventricles. CSF circulates through the ventricular system, enters the subarachnoid space, surrounds the spinal cord and is ultimately reabsorbed by the arachnoid granulations into dural venous sinuses. The total volume of CSF is about 150 cm^3, with a production of approximately 500 cm^3 every 24 hours. The blood–CSF barrier maintains osmolality, electrolytes, proteins, and glucose content of CSF within constant limits. Substances in serum typically can only move into CSF by active transportation across the blood–brain barrier, a highly selective filter made up of tight junctions around capillaries (Fig. 219.1), but inflammation can produce a breakdown of this barrier and allow direct CSF penetration. Bacteraemia is the most common example of meningeal colonization and paramenin-geal spread [1,2]. Once in the CSF, substances can freely diffuse to the brain parenchyma.

Cerebral blood flow

Cerebral blood flow (CBF) is dependent on cerebral perfusion pressure (CPP) and cerebral vasculature resistance. According to the Kelly–Monroe doctrine, due to the rigid skull compartment, CPP is calculated by subtracting the intracranial pressure (ICP)

Table 219.1 Normal CSF composition

Proteins	Glucose	White blood cells	Red blood cells	Appearance
15–40 g/L	2.7–4.7 mmol/L (2/3 plasma glucose concentration)	0–3 (Lymphocytes)	None	Clear

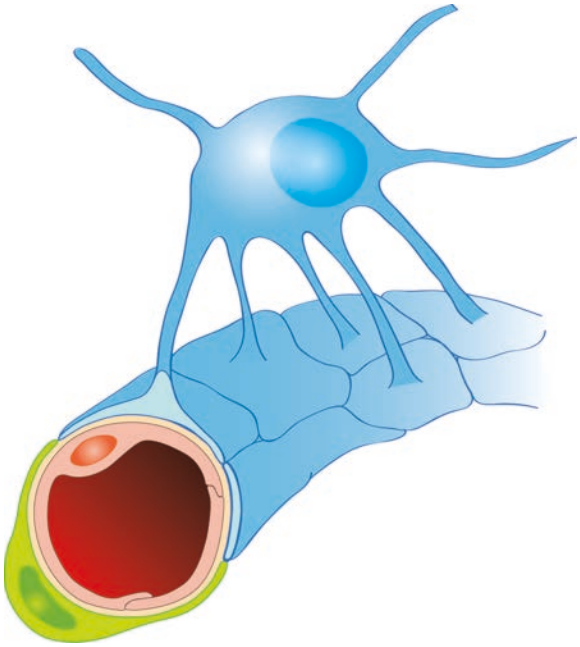

Fig. 219.1 The blood–brain barrier. Brain capillary endothelial cells are connected by tight junctions and most of the capillary is covered by astrocytes foot processes.

from the mean arterial pressure (MAP) according to the formula: CPP = MAP – ICP. Normal ICP is less than 20 cmH_2O (or less than 15mmHg), but physiological variations occur with Valsalva manoeuvres, sneezing, or coughing. Any space-occupying lesion can increase ICP. This is initially compensated by reduction in CSF and cerebral blood volume (CBV). Severely elevated ICP ultimately affects CBF causing ischaemia and may lead to cerebral herniation. CBF is maintained at a constant level in normal brain by the intrinsic process of autoregulation through myogenic and metabolic mechanisms that allow adjustments in arterial calibre in response to many different parameters, including arterial blood pressure, $PaCO_2$, PaO_2, and several pharmacological agents. Any increase in $PaCO_2$ results in cerebral vasodilation. In contrast, variation of PaO_2 does not affect cerebral blood flow until it decreases below 50 mmHg (6.7 kPa). Autoregulation normally maintains constant blood flow between a MAP of 50 and 150 mmHg, but MAPs below this range can allow a drop in cerebral perfusion, which can lead to ischaemia. Conversely, MAPs above this range may cause damage to the blood–brain barrier, leading to oedema and hemorrhagic events. Autoregulation is also impaired in primary brain pathologies where the blood–brain barrier is damaged and CBF becomes linearly dependent on MAP [3].

Functional cortical regions

The cerebral cortex provides the necessary substrate for several sophisticated intellectual and cognitive functions that determine behaviour, motor planning, and sensory processing. The dominant hemisphere (usually the left hemisphere) controls language which is primarily localized in the inferior frontal lobe (Broca's area), temporal lobe (Wernicke's area), and the interconnecting parietal lobe area. Lesions to these areas cause problems generating and understanding spoken and written language, depending on the precise location.

The non-dominant hemisphere is involved in mechanisms of attention and visual-spatial analysis, which are localized primarily in parietal frontal areas. Bilateral frontal lobes are responsible for inhibition of inappropriate behaviours, motivation, judgment, and working memory. In addition, the frontal eye fields control horizontal conjugate eyes movements; a damage to one of these areas generates a gaze deviation ipsilateral to the lesion typically seen, for example, after hemispheric strokes. The visual area lies in the occipital lobes where each hemisphere receives information from the contralateral halves of both visual fields. Damage to this region is responsible for visual field deficits (quadrantianopia, hemianopia) or cortical blindness. Motor and somatosensory cortex are represented in the frontal and parietal lobes respectively, and are somatotopically-organized so the size of each body region is related to its sensory or motor importance (see Fig. 219.2) [1].

Consciousness

Consciousness refers to a state of awareness of self and environment that depends on intact arousal and content [4]. Arousal is clinically related to the level of alertness or wakefulness. It is mediated through a core of nuclei that extend through the brainstem (known as reticular formation) and project to the cortex bilaterally through the diencephalon (thalamus and hypothalamus). The content of consciousness includes sensory, motor, emotional, executive, and mnemonic systems, localized throughout multiple levels of both cortical hemispheres. Coma is usually caused by lesions of the upper brainstem or diffuse bilateral cortical areas, but could also result from mass effect of lesions above the brainstem compressing the reticular formation and thalamus. The arousal system can also be affected by metabolic abnormalities that impair the state of consciousness and resemble coma in the absence of a structural lesion (encephalopathy). The major neurotransmitters released by the arousal system that regulate the level of alertness are norepinephrine, dopamine, serotonin, histamine, orexin and acetylcholine (see Fig. 219.3) [5].

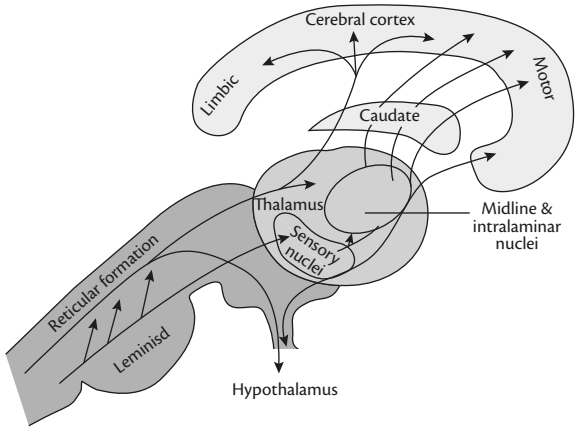

Fig. 219.3 The ascending reticular system and its projections. This diagram depicts the brainstem, containing the reticular formation and the ascending sensory pathways (lemnisci), the thalamus, the caudate nucleus, and the higher structures (limbic system, motor areas, and cerebral cortex). Projections to the hyopthalamus are also shown.

Respiration

Breathing occurs automatically under control of a network of neurons in the lower medulla. Afferent inputs, including chemoreceptors for oxygen, carbon dioxide, and lung stretch receptors, project to the cardiorespiratory centre of the nucleus solitarius and modulate the respiratory pattern. The central nervous system can also stimulate breathing via medullary serotoninergic neurons or temporarily regulate ventilation through voluntary cortical control. The medullary breathing centres project via the lateral columns of the spinal cord and modulates the phrenic nerve control of the diaphgram and the (cervical nerve roots C3–C5), intercostal nerves that innervate thoracic inspiratory and expiratory muscles. Distinct abnormal respiratory patterns can be associated with central nervous system pathologies. Extensive bilateral medullary lesions lead to respiratory arrest, whereas partial damage may produce ataxic breathing (disorganized breathing pattern with random periods of apnoea). Higher pontine lesions can cause apneustic respiration, which is marked by prolonged end-inspiratory pauses. Central neurogenic hyperventilation (sustained tachypnoea) is encountered with damage at different brainstem levels and can lead to metabolic derangements (alkalosis). Cheyne–Stokes respiration, which is generally not harmful, consists of cyclic phases of incremental hyperventilation followed by hypoventilation to the point of apnoea. It has been associated with left ventricular dysfunction, as well as bilateral upper pons or higher cerebral lesions [6].

Autonomic control

The nervous system is directly responsible for maintenance of homeostasis through a complex network of interactions among hypothalamus, limbic system, midbrain nuclei, and peripheral autonomic nervous system. It regulates intravascular volume, regional blood flow, thermoregulation, motility and secretions of gastrointestinal and respiratory tracts, micturition, and reproduction. The hypothalamus integrates emotional input from the limbic system with autonomic responses, and regulates endocrine function through control of pituitary hormones. It activates mechanisms of heat dissipation or conservation in response to variations in body temperature, and regulates food intake and thirst. Heart rate and blood pressure control are mediated through the nucleus solitarius in the medulla, which receives input from carotid and aortic arch baroreceptors, and projects to brainstem and spinal cord autonomic neurons. The peripheral autonomic system regulates involuntary control of visceral functions and consists of three subdivisions—sympathetic, parasympathetic, and enteric nervous systems. The sympathetic is involved in 'fight or flight' functions, such as increasing heart rate, blood pressure, bronchodilation, and pupil size. In contrast, the parasympathetic slows heart rate, decreases pupil size, and promotes peristalsis and gastric secretions. Acetylcholine is the neurotransmitter that activates all preganglionic autonomic neurons, and is the final neurotransmitter of parasympathetic and sweat glands neurons. Norepinephrine is the sympathetic system post-ganglionic neurotransmitter. Other substances such as vasoactive intestinal peptide (VIP), substance P, and neuropeptide Y have also been found to have a role in autonomic modulation [7].

Motor control

The motor cortex follows a somatotopic pattern, where parts of the body responsible for elaborate movements have a larger representation than those responsible for gross movements. It projects to contralateral lower motor neurons that innervate specific muscle groups through peripheral nerves. The cranial nerves lower motor neurons are located at different levels throughout the brainstem, and integrate vestibular, visual, and somatosensory inputs to eye movements and postural control. The anterior horns of the spinal cord contain lower motor neurons for skeletal muscles, with each spinal cord segment corresponding to specific muscles group and receiving sensory inputs from related dermatomes. The cerebellum and basal ganglia connect to the motor cortex through complex feedback loops that regulate coordination and motor planning. Pathological posturing reflexes can be seen in extensive lesions interrupting upper motor neuron pathways, with flexor posturing seen after damage at the midbrain or higher, and extensor posturing seen with lesions of the lower brainstem. Reflex responses, such as pupil light reflex or deep tendon reflexes are motor responses to external stimuli that depend only on brainstem or spinal cord pathways, and do not require conscious participation. Weakness caused by an upper motor neuron lesion is characterized by increased tone and hyper-reflexia (secondary to loss of cortical modulation of the reflex response and tone), whereas lower motor neuron weakness is characterized by hypotonia and hyporeflexia [8].

Peripheral nervous system

Cranial and spinal peripheral nerves are responsible for somatosensory afferents to the central nervous system, motor output, and autonomic regulation to target organs. The majority of peripheral nerves are mixed, containing axons that carry both sensory input of a specific skin region (dermatome) and others that innervate distinct muscle groups (myotome). Autonomic fibres also travel along the peripheral nerves and synapse at paravertebral ganglia (sympathetic ganglia) or near end organs (parasympathetic ganglia). Nerve roots that exit the cervical and lumbosacral region are organized in bundles (brachial plexus and lumbosacral plexus) that provide somatosensory innervation of the upper and lower extremities.

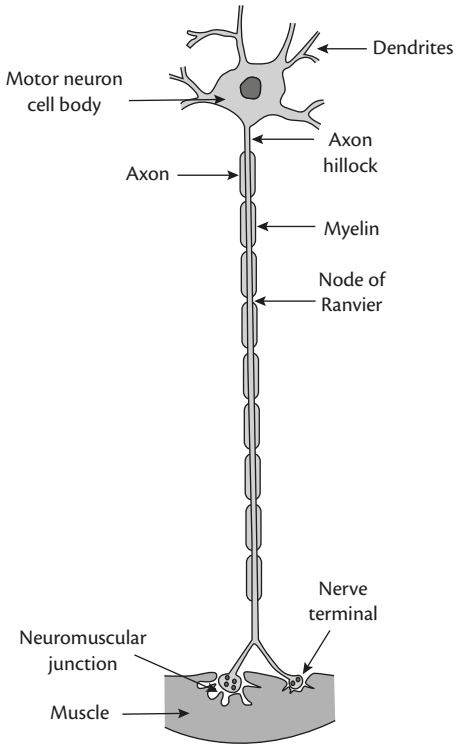

Fig. 219.4 Schematic diagram of the motor neuron and its components, the neuromuscular junction, and muscle.

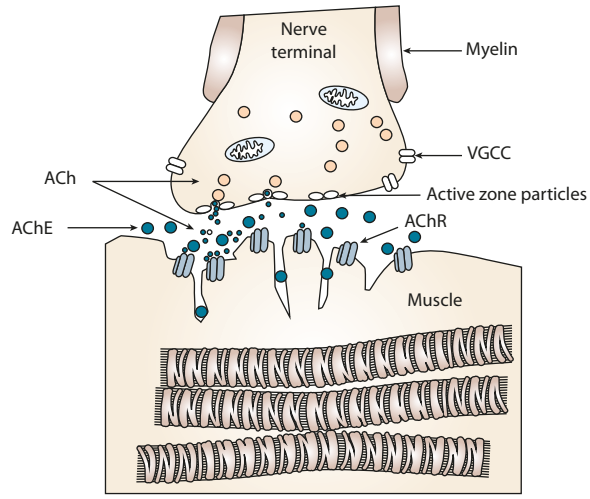

Fig. 219.5 The neuromuscular junction.
The nerve terminal synaptic cleft, and muscle endplate are shown: Ach, acetylcholine; AChE, acetylcholinesterase; VGCC, voltage-gated Ca2+ channels; AChR, acetylcholine receptors.

Sensory fibres begin with receptors in cutaneous or visceral muscles and tendon receptors, and then travel to the cell body in the dorsal root ganglia. Its central process enters the spinal cord in the region of the dorsal horns and travels centrally. Motor fibres start at the motor neuron cell body in the anterior horns of the spinal cord, and the axon travels within the peripheral nerve to the neuromuscular junction. Compression neuropathies or 'plexopathies' can be encountered in the ICU as consequence of prolonged positioning or from initial injuries. Critical illness polyneuropathies have also been documented in ICU patients, and may present with difficult ventilator weaning or evidence of diffuse usually symmetric weakness and sensory loss (see Fig. 219.4).

Neuromuscular transmission

Motor and sensory stimuli travel along nerves through generation of action potentials. Conduction velocity is determined by fibre size and myelination. Myelin is a protein-lipid complex produced by Schwann cells that insulates axons, leaving gaps of exposed axons (nodes of Ranvier) where action potential conduction occurs through voltage gate sodium channels. Unmyelinated sensory fibres (pain and temperature) have a smaller diameter and conduction is slower when compared with myelinated larger fibres for motor and sensory (proprioception and joint position) transmission. Demyelination of peripheral nerves, as seen in acute inflammatory demyelinating syndrome (AIDP or Guillain–Barré), may slow and block nerve conduction, causing respiratory muscle weakness and autonomic instability, which often requires treatment in an intensive care unit. Muscle contraction initiates when depolarization opens calcium channels concentrated in the nerve terminal membrane and stimulates release of acetylcholine at the neuromuscular junction level. Acetylcholine acts on post-synaptic muscle receptors and allows sodium into muscle fibres, which then implements muscle contraction by release of intracellular calcium. The action of acetylcholine is terminated by hydrolysis by acetylcholinesterases. Antibodies against acetylcholine receptors results in the classic form of myasthenia gravis, which can lead to diffuse weakness and respiratory failure. Muscles can also be severely compromised in critically-ill patients (critical illness myopathy) or develop wasting and muscle necrosis (necrotizing myopathy of intensive care). Both are distinguished by profound weakness with spared sensation (see Fig. 219.5) [9].

CHAPTER 220

Normal anatomy and physiology of the spinal cord and peripheral nerves

Steve Casha and Philippe Mercier

Key points

- The spinal cord contains efferent and afferent sensory, motor, and autonomic pathways connecting the body with the cerebrum.
- A cross-section of the spinal cord reveals a very organized structure containing ascending, descending and bidirectional tracts.
- Each mixed spinal nerve innervates a particular area of skin called a dermatome and a discrete set of muscles called a myotome.
- Neurological problems affecting the spine and peripheral nerves are frequently encountered in the intensive care unit.
- A basic understanding of the anatomy of the spine and peripheral nerves is essential to localize pathology.

Introduction

Pathology of the spine and peripheral nerves is common in the intensive care unit. Critical care specialists may be asked to provide supportive care to patients already under the care of a neurologist or neurosurgeon, provide the care and management of patients from initial presentation such as in trauma or may consult neurologists and neurosurgeons regarding secondary neurological complications occurring in patients with other medical or surgical diseases. Regardless, the critical care specialist must have a working knowledge of the anatomy of the spine and peripheral nerves in order to localize pathology, formulate a differential diagnosis and initiate treatment of a diverse group of disease states.

The spinal cord

Gross anatomy

The spinal cord is the major conduction pathway for both afferent and efferent pathways between the brain and the body and is a component of the reflex centre. It is a cylindrical structure slightly flattened in the anterior–posterior plane beginning as an extension of the medulla and ending as the conus medularis [1]. During development the spinal cord extends to the end of the dural sac that is attached at the level of the second sacral vertebrae. The spine and dura grow more rapidly than the spinal cord such that at birth the conus medularis lies at the level of the third lumbar vertebrae and eventually it is located at the level of first or second lumbar vertebrae [1].

The spinal cord is contained within the vertebral canal and protected throughout its length by the vertebral column. The spinal cord is surrounded by the pia mater, the arachnoid membrane and a single layer of dura mater that is a continuation of the inner dural layer of the brain [1]. The spinal cord is bathed in cerebrospinal fluid (CSF) that is continuous with cerebral CSF and it is also protected by a layer of epidural fat [1].

The spinal cord, like the vertebral column, is organized in a segmental fashion. There are eight cervical, 12 thoracic, five lumbar, five sacral, and one coccygeal spinal segments [1]. The cord is enlarged in two regions corresponding to upper and lower extremities. The cervical enlargement extends between spinal cord segments C4–T1 and its spinal roots form the brachial plexus. The lumbosacral enlargement extends from T11 to S3 gives rise to spinal roots that form the lumbosacral plexus (Fig. 220.1) [1].

Spinal nerves for each segment are formed from a merger of anterior and posterior roots formed from a series of rootlets that emerge from each segment of the spinal cord [1]. The posterior nerve roots form a ganglion (dorsal root ganglion) in the intervertebral foramen before the anterior and posterior roots evaginate the dura separately and unite to form a mixed spinal nerve [1]. Each spinal nerve divides into a posterior primary and anterior primary ramus almost immediately. The anterior roots of the spinal nerve carry efferent (motor) fibres to skeletal muscle and many contain presynaptic autonomic fibres [1]. The cell bodies of the somatic axons contributing to the ventral roots are contained within the anterior horns of the grey matter of the spinal cord [1]. The posterior roots contain afferent (sensory) fibres from the skin, subcutaneous and deep tissues, and the viscera. The cell bodies of the posterior fibres are found within the dorsal root ganglia and synapse within the dorsal aspect of the grey matter of the spinal cord [1].

Internal structure of the spinal cord

The spinal cord in cross-section consists of central grey matter in the shape of a butterfly. Within the grey matter can be divided

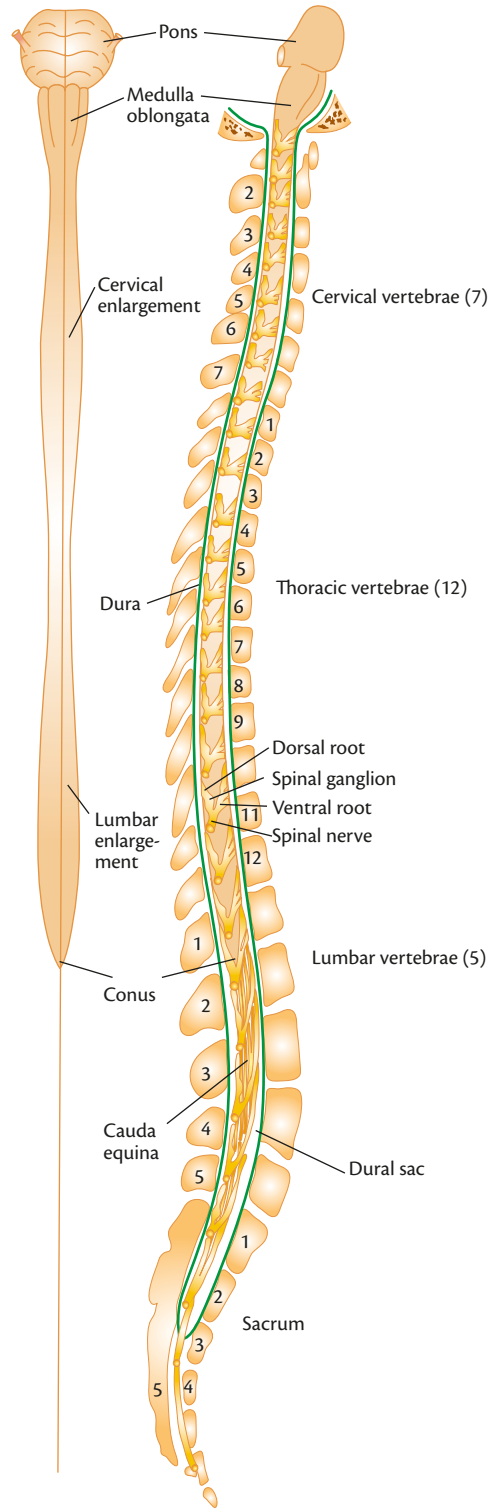

Fig. 220.1 Sagittal view of the spinal cord. Spinal nerve roots exit through the bilateral neuroforamina (not shown) and are named for each vertebral level. The spinal cord typically ends as the conus medullaris between the L1 and L2 levels in the adult.

Reproduced from Brodal P (editor), *The Central Nervous System*, Fourth Edition, 2010, Figure 6.3, by permission of Oxford University Press, USA.

into rexed laminae that have different specific roles [1]. A number of afferent or ascending tracts, efferent or descending tracts, and bidirectional tracts can be identified and are summarized in Fig. 220.2.

Autonomic nervous system

Sympathetic efferents arise from the interomediolateral nucleus of the grey matter of the spinal cord and exit through the ventral roots forming paired paravertebral ganglia that form a continuous

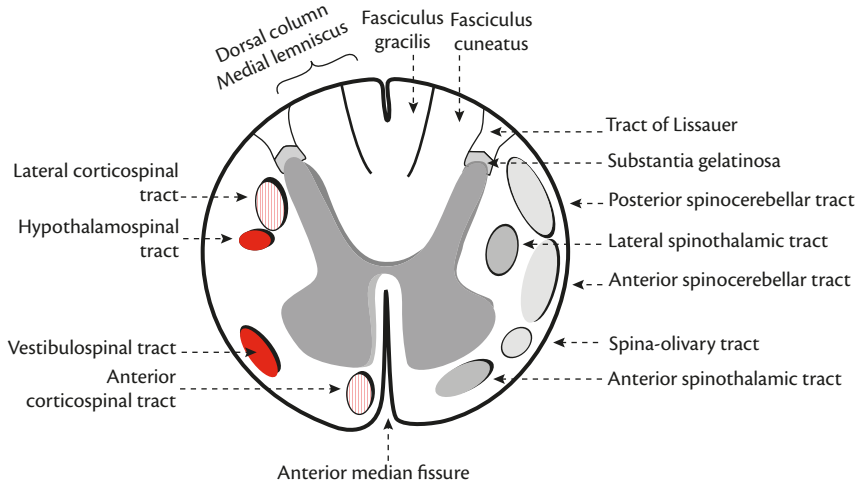

Fig. 220.2 Cross-section of the cervical spinal cord. Descending white matter motor tracts (red) include the anterior corticospinal tract involved in skilled movement, the vestibulospinal tract that facilitates extensor muscle tone, and the lateral corticospinal tract that is involved in skilled movement. The hypothalamospinal tract carries autonomic efferents to the thoracic spine. Bi-directional white matter tracts include the dorsolateral fasciculus of lissauer and the fasciculus proprius that contains short spinospinal connections. Ascending white matter sensory tracts (grey) include the fasciculus gracilis and cuneatus that are involved in joint position, fine touch and vibration for lower and upper limbs, respectively, the posterior spinocerebellar tracts that carries stretch receptor innervation, the lateral spinothalamic tract that conveys pain and temperature sense, anterior spinocerebellar tracts, which convey whole limb position, spinotectal tract and the anterior spinothalamic tract that convey light touch, and spino-olivary tract, which carries information from muscles, tendons, and cutaneous impulses.
Reproduced from Samandouras G (editor), *The Neurosurgeon's Handbook*, 2010, figure 6.21, with permission from Oxford University Press.

chain from contributions from T1 to L2 or L3 called the sympathetic trunk [1]. The head and neck sympathetic efferents are supplied by three sympathetic chain ganglia called the superior, middle, and inferior stellate cervical ganglia [1]. The sympathetic chain supplies sympathetic efferents to the body. Presynaptic neurons either enter or synapse with a paravertebral ganglion at that level, ascend or descend in the sympathetic trunk to synapse with a post-synaptic neuron in a higher or lower paravertebral ganglion or pass through the sympathetic trunk without synapsing [1]. Sympathetic post-ganglionic neurons release predominately norepinephrine activating noradrenergic receptors resulting in 'fight or flight' responses, including pupil dilatation, inhibition of salivation and lacrimation, airway dilatation, accelerated heartbeat, sweating, pilo-erection, hepatic glucose production and release, inhibition of digestion, adrenal secretion of adrenaline and noradrenaline, relaxation of the urinary bladder, and stimulation of ejaculation [1].

Parasympathetic efferents arise from cranial nerve parasympathetic nuclei (CN III, VII, IX, and X) and from sacral parasympathetic nuclei located in the lateral grey matter of levels S2–S4 [1]. Preganglionic nerve fibres travel longer distances to terminal ganglia that are typically located close to the effector organs [1]. Parasympathetic post-ganglial neurons release predominantly acetylcholine activating muscarinic cholinergic receptors on end organs resulting in a 'rest and digest' response opposite to the sympathetic response [1].

Vascular supply

The vascular supply to the spinal cord includes a single anterior spinal artery, as well as paired posterior spinal arteries running longitudinally. The anterior spinal artery is a midline vessel that is formed by a union of branches from both vertebral arteries [2]. The paired posterior spinal arteries also arise directly from the vertebral arteries or the posterior inferior cerebellar arteries. All three vessels run from the level of the foramen magnum to the conus medularis within the subarachnoid space [2]. The anterior spinal artery supplies the whole spinal cord anterior to the posterior grey columns, whereas the posterior spinal arteries supply the grey and white posterior columns [2]. The spinal arteries also form anastomoses with a number of segmental medullary arteries that form the more important vascular supply of the distal cord [2]. The medullary arteries enter the spinal canal through the intervertebral foramina as branches of the vertebral, costocervical, posterior intercostal, lumbar, and lateral sacral arteries [1]. The largest medullary artery is named the artery of Adamkiewicz that accompanies a nerve root between T8 and L1. It forms the major vascular supply of the distal two thirds of the cord including the lumbosacral enlargement [1]. A few radicular arteries that perfuse a small portion of the spinal cord do not form anastomoses with the anterior and posterior spinal arteries [1].

Anterior and posterior spinal veins communicate freely with each other and 12 anterior and posterior medullary and radicular veins. The spinal veins join the internal vertebral venous plexus in the extradural space that is continuous with the draining veins and sinuses of the cranium as well as communicating with the external venous plexus on the surface of the vertebrae [2].

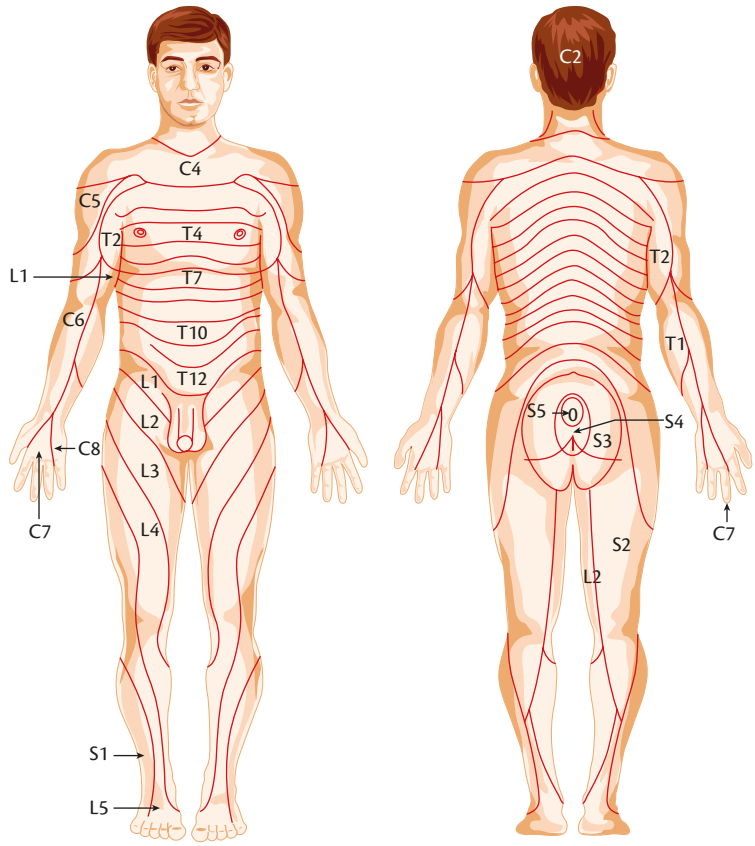
The peripheral nervous system

Nerve fibres can be either myelinated or unmyelinated. Peripheral nerves are myelinated by Schwann cells along their length. Myelinated segments are separated by small gaps (Nodes of Ranvier) [1]. This arrangement permits more efficient salutatory conduction increasing the conduction velocity 5–50 fold [1].

Nerve fibres can be classified in relation to their function. Group A fibres include alpha fibres (Ia and Ib) involved in motor function and proprioception, beta fibres that transmit touch, pressure

and proprioception, gamma fibres that innervate muscle spindles and delta fibres that response to touch, pain, and temperature. Group B fibres are myelinated preganglionic autonomic neurons and Group C are small unmyelinated fibres that can mediate either postganglionic autonomic function, touch sensation or pain [1].

The skin supplied by a single spinal nerve is called a dermatome [2]. The dermatomes of the spinal nerves are reliable (Fig. 220.3), but it is important to note that overlap exists, especially in the thoracic dermatomes [2].



Myotomes

Muscle group	*Nerve supply*	**Reflexes**
Diaphragm	C(3), 4 (5)

The muscles innervated by a single spinal nerve are called a myotome [1]. In general most muscles are supplied by two adjacent segments of the spinal cord [1].

The upper and lower limb muscles and skin are innervated by the brachial, lumbar, sacral, and coccygeal plexuses [2]. The brachial plexus is formed by the anterior rami (roots) of the C5–T1 nerves [2]. The roots go on to form three trunks, three ventral, and three dorsal divisions followed by three cords before becoming terminal nerves including the musculocutaneous, accessory, radial, median, and ulnar nerves [2]. Several peripheral nerves are given off the roots, trunks and cords (Fig. 220.4).

The lumbar plexus is formed from the anterior rami of the L1–L4 spinal nerves. The L1 and L2 roots form the iliohypogastric nerve, ilio-inguinal, and genitofemoral nerves (Fig. 220.5).

The L2–L4 roots form the lateral cutaneous nerve of the thigh, femoral, and obturator nerves [2]. The sacral and coccygeal plexus are formed from the L4–S5 roots [2]. The major branches include the superior and inferior gluteal nerves, the posterior femoral cutaneous nerve, the sciatic nerve that divides into tibial and peroneal nerves, and the pudendal nerve (Fig. 220.6).

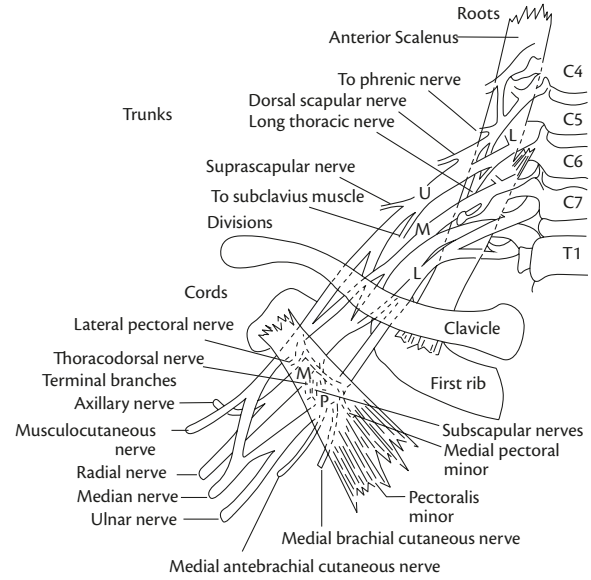

Fig. 220.4 Organization of the brachial plexus as the five cervical roots give rise to three trunks, three anterior, and three posterior divisions, three cords and the terminal branches that give rise to the major nerves of the arm, forearm, and hand.

Conclusion

The spinal cord, together with the peripheral nervous system, forms a predictable organized network that allows localization of disease through the distribution of symptoms and signs, both at a gross anatomical level and at the level of specific tracts and nerve fibres.

PART 9.2

Neurological monitoring

CHAPTER 221

Electroencephalogram monitoring in the critically ill

Paul M. Vespa

Key points

- Electroencephalography (EEG) monitoring produces a large quantity of data over a long time period and expertise is required for its interpretation.
- EEG monitoring can assist in detecting brain ischaemia and seizures, monitoring depth of sedation, and in improving prognostication.
- The use of cEEG in critically-ill patients with non-traumatic or traumatic brain haemorrhage may be considered the standard of care, given the high incidence of seizures and the marked adverse effects of seizures in this clinical scenario.
- Commercially available software packages that process EEG data can simplify EEG monitoring, but often the raw EEG data must be inspected to ensure accurate interpretation.

Introduction

The critical care of patients with acute neurological injury is frequently dependent on neurological monitoring of the brain. Soon after a brain injury, the brain experiences increased vulnerability to secondary insults. These insults include cytotoxic brain oedema, repeat ischaemia, fever-related injury, and seizures. Monitoring intracranial pressure and cerebral oxygenation have become common in recent years, but ideally the fundamental concept is to monitor brain function. Brain monitoring can detect important changes in brain physiology and function that can be affected by direct medical or surgical intervention. Electroencephalography (EEG) monitoring, conventionally known as continuous EEG monitoring (cEEG), is the predominant monitor of brain function. This chapter considers the fundamentals of cEEG monitoring, and will focus on these points:

- The fundamentals of EEG for the intensivist.
- Seizures detection after haemorrhagic brain injury and coma.
- The pathophysiological response of seizures after brain injury.
- The detection of seizures by visual inspection of the raw EEG and/or processed EEG.
- Treatment of status epilepticus by rapid identification and abolition of seizures using cEEG.
- The use of quantitative EEG to detect brain ischaemia and seizures, to monitor sedation, and to aid prognosis.

The fundamentals of EEG for the intensivist

EEG is a well-established method of monitoring brain electrical activity that is conceptually similar to electrocardiography. The brain has a fundamental rhythm much like the heart's normal sinus rhythm. In contrast to the heart, the brain's rhythm is variable and much faster than the normal heart beat, and usually has a frequency range of 4–20 cycles/second (Hertz). The normal brain rhythm looks much like ventricular fibrillation. The EEG usually speeds up when the patient is more alert, and slows down and has lower amplitude when the patient is more somnolent. When the patient is sedated, there is a lot of low amplitude activity in the 13–30 Hertz range, or beta activity. This beta activity is a sign that the brain is healthy and responding to the sedatives. Sleep activity occurs under normal conditions and the classic sign of sleep is the sleep spindle. In contrast to normal EEG rhythms, a seizure looks like ventricular tachycardia. Fig. 221.1a–e shows the main predominant features of EEG. Fundamentally, an EEG that has symmetry between right and left hemispheres, and is spontaneously variable over time and reactive to stimulation is considered to be normal. Epileptic seizures are repetitive discharges of spikes, which evolve over a short period of time, usually 1–2 minutes. A spike looks much like a paroxysmal atrial or ventricular complex from the ECG with a triphasic appearance (Fig. 221.1e).

Methods for cEEG monitoring in the ICU

cEEG is analogous to continuous ECG monitoring. cEEG is continuously displayed at the bedside, 24 hours per day, for moment-to-moment online observation by physicians and nurses (see Fig. 221.2). A physician trained in the interpretation of EEG reviews the ongoing EEG activity at the bedside at least three times each day and additionally, when requested, the bedside nurse observes suspicious EEG activity. Seizures are detected in one of three ways:

- On-line identification of seizures by the neuro-ICU nurse or neurointensivist.
- By the total power trend seizure detection method.
- By detection during regularly scheduled EEG segment review.

The date and time of the seizure, and the clinical behaviour noted by the bedside nurse or neurointensivist are recorded.

Commercial software packages for automated seizure detection exist. These methods make use of a processed EEG that provides

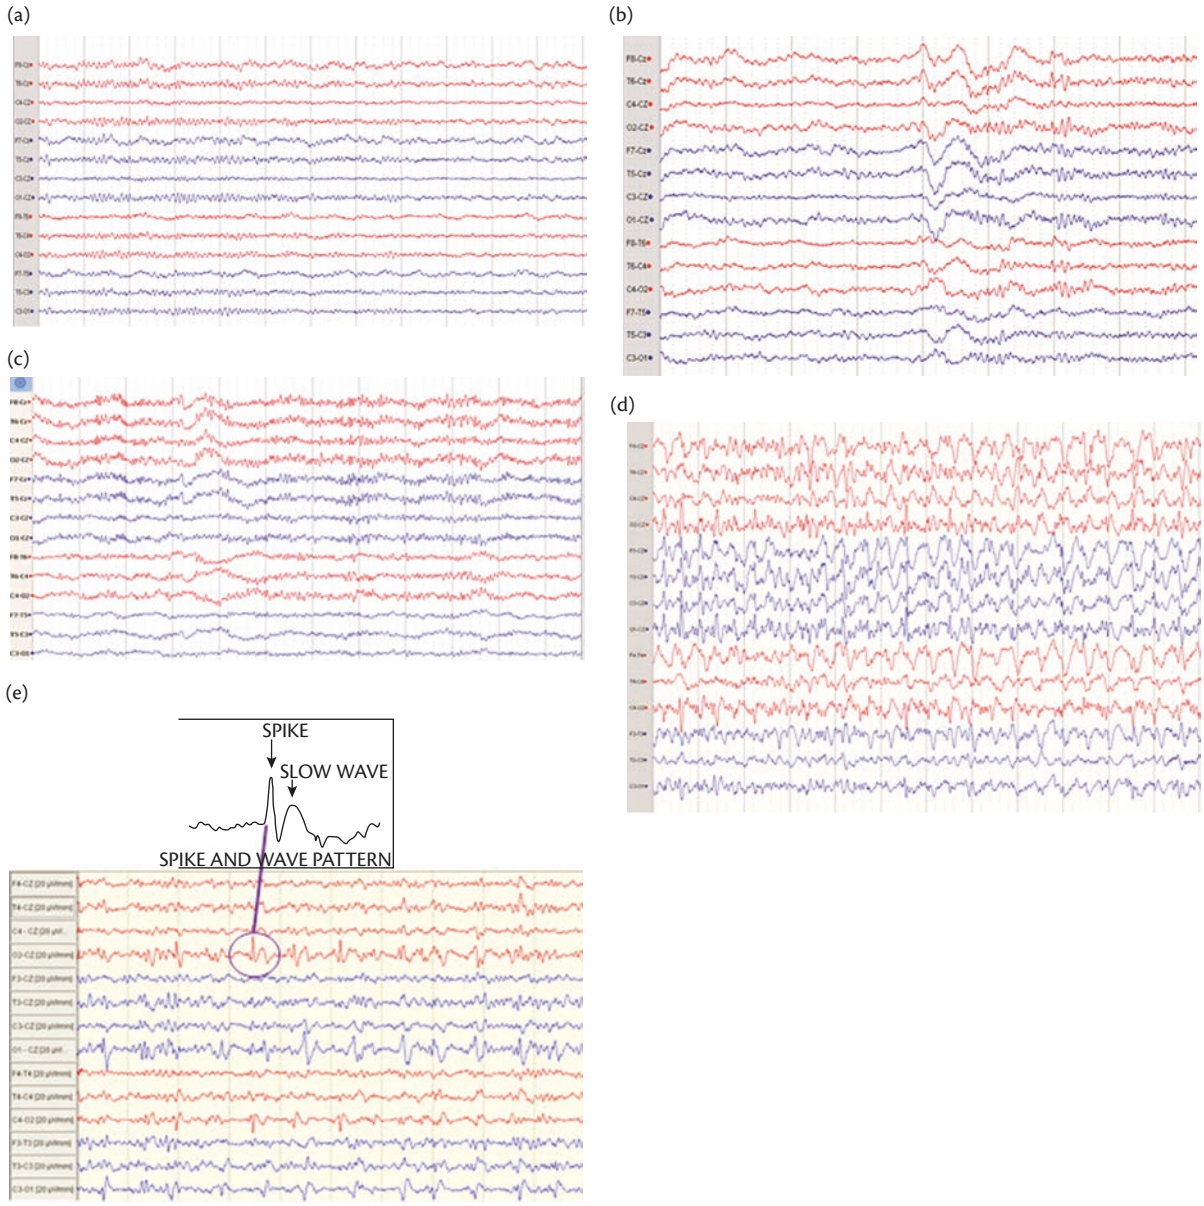

Fig. 221.1 Examples of basic EEG patterns. (a) An example 14-channel EEG segment demonstrating normal alpha rhythm in all electrodes. (b) An example of normal stage II sleep with sleep spindles shown across all electrodes. (c) The typical example of diffuse beta that occurs with deep sedation using propofol. (d) An example of a generalized non-convulsive seizure seen on cEEG. (e) A highlight showing the details of example spike and wave morphology that is seen with seizures. Red lines indicate the right side of the brain and blue lines indicated the left side of the brain.

trends of the waveforms, but most still require human interpretation of the raw EEG.

Seizure detection is based on the inspection of the raw EEG or the processed EEG. The seizure has a spike and wave morphology, which repeats over time and grows in amplitude and/or speed.

Quantitative EEG in the ICU

EEG is very labour intensive because it produces a lot of data that is collected over a long period of time. For most intensive care units (ICUs), there is a need for a summary of the EEG data over time, and a summary for non-experts to understand the current state of the brain with respect to several important questions:

- Is the brain ischaemic?
- Are seizures occurring?
- Is the patient sedated?
- Is the patient neurologically viable?

Quantitative EEG (qEEG) is generically a process to compress the EEG, and display the EEG in a temporal and spatial distribution along a timeline. The basic qEEG parameter is a compressed spectral

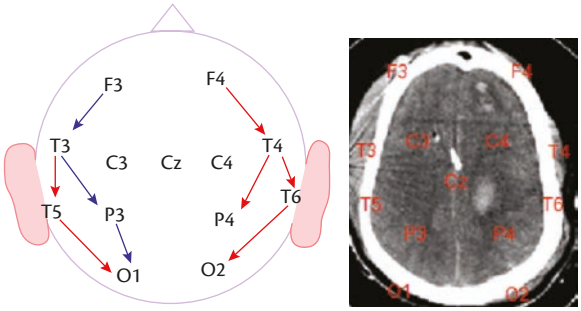

Fig. 221.2 An example of the nomenclature and localization of the electrodes used in ICU continuous EEG monitoring. The left scalp electrodes have odd numbers and the right scalp electrodes have even numbers. An example of a brain CT showing minimal artefact from scalp subdermal needle electrodes.

array (CSA), in which short EEG segments are separated into frequency bins and displayed as a function of the relative amount (or power) of each frequency. The CSA is then displayed in multiple formats by various manufacturers. Fig. 221.3 outlines the basic concept of converting EEG to CSA. In the most basic form, qEEG becomes a single number that represents an overall simplification of the EEG rhythms; this is the method used by the Bispectral Index (BIS) monitor. In the most complex methods, 5 or more qEEG parameters are presented simultaneously in a time series.

Quantitative EEG in brain ischaemia

Classically, the analog EEG becomes abnormal when cerebral blood flow falls below 20–25 cm^3/100 g/min. However, subtler signs of ischaemia at higher blood flows have been seen using raw EEG. These signs include, in order of appearance:

- A loss of fast beta frequencies (12–30 Hz).
- Slowing of background into 5–7 Hz theta frequencies.
- Slowing into the delta range (1–4 Hz).
- Flattening of the EEG with burst-suppression or continuous suppression.

Jordan and Stringer [1] found that hemispheric EEG slowing correlated with moderate to severe reductions in cerebral blood flow as determined by stable Xenon CT cerebral blood flow measurements.

qEEG measures, such as CSA and frequency analysis trending have proven more useful in acute ischaemic disease. CSA has an appeal to the non-neurologist since it requires less expertise to interpret and can convey large amounts of neurophysiological data in a concise manner.

Several studies of continuous or extended EEG monitoring in the acute phases of stroke have been performed. In patients with aneurysmal subarachnoid haemorrhage the ratio of alpha/(theta + delta) activity and alterations in total power were very sensitive to transient ischaemia caused by vasospasm. In patients following stroke, the percentage of alpha and delta activity correlates with reductions in CBF and cerebral metabolic rate for oxygen in the acute and subacute stages of stroke.

The percentage alpha activity trend variability may be a useful measure of the adequacy of blood flow in patients with aneurysmal subarachnoid haemorrhage. In asymptomatic patients with adequate blood flow, a variability (or fluctuation) of the trend is very evident. However, the percentage alpha trend variability decreases acutely with the onset of vasospasm-induced decreases in cerebral blood flow. With treatment and resolution of vasospasm, the percentage alpha trend variability returns to normal (Fig. 221.4). A comparison of the temporal changes in transcranial Doppler (TCD) velocities and the qEEG variables suggest that the increased TCD flow velocity that occurs in vasospasm can be predicted in advance by reductions in percentage alpha variability. Thus, the acute EEG and qEEG provide insightful information that can be integrated with other information to determine the state of cerebral blood flow and metabolism in the acutely-ill neurological patient.

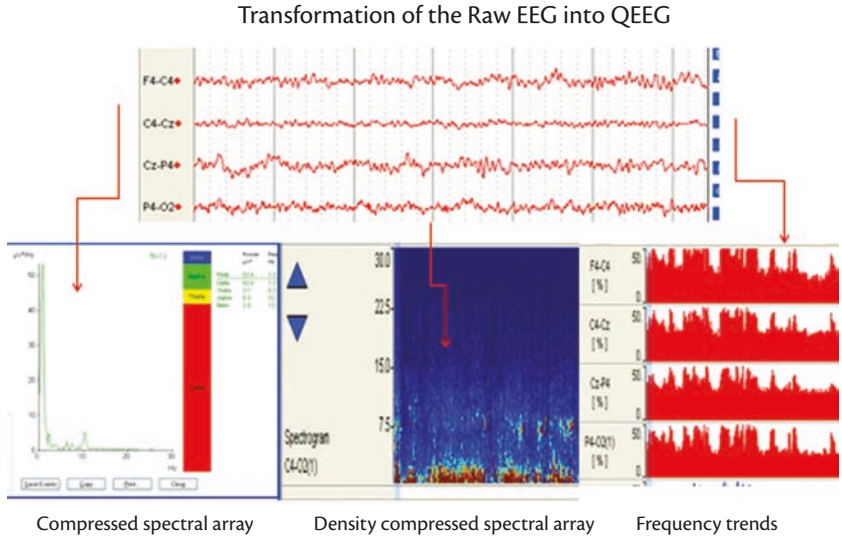

Fig. 221.3 A conceptual montage of images demonstrating how short segments of raw EEG (top) are automatically and periodically transformed using computer algorithms into quantitative EEG displays (bottom). Three potential quantitative displays are shown including: (bottom left) compressed spectral array [with a short duration of data from one electrode displayed as an integral based on frequency]; (bottom middle) compressed density spectral array [with long duration of data displayed as a function of time across the abscissa, frequency domain along the ordinate, and the power of each frequency conveyed as colour, with red indicating the highest power]; (bottom right) Frequency trends [with a single frequency band (alpha bandwidth) displayed as function of time across the abscissa and power across the ordinate.

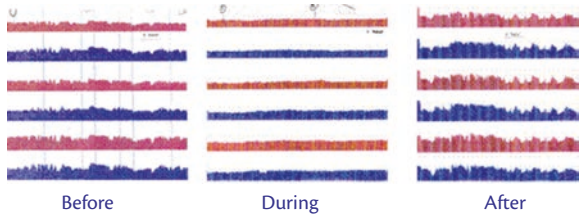

Fig. 221.4 An example of the percent alpha frequency trend changing over time as a function of cerebral vasospasm-related delayed cerebral ischaemia. Each segment shows an 8-hour trend of percent alpha. During spasm (middle) the percent alpha becomes invariant and indicates cerebral ischaemia. After spasm resolves, the percent alpha once again becomes variant (right) similar to baseline (left).

Reprinted from Electroencephalography and Clinical Neurophysiology, Vespa PM et al., 'Early detection of vasospasm after acute subarachnoid hemorrhage using continuous EEG ICU monitoring', 103, 6, pp. 607–615, Copyright 1997, with permission from Elsevier.

Similar findings have been reported by [2] for the alpha–delta ratio. The alpha–delta ratio appeared to be even more sensitive for the detection of delayed cerebral ischaemia.

Detection of seizures using qEEG

Seizures occur with relatively high frequency in comatose ICU patients, with estimates from between 8–12 % of patients with general medical critical illness, and 20–40% of patients with neurocritical illness. Automated seizure detection algorithms have been created to detect seizures, but most of these algorithms do not perform reliably in the ICU setting. Hence, qEEG is often used to enhance the ability to identify and detect seizures. Several qEEG methods have been used to detect seizures. The qEEG trends permit one to determine the timing, duration, repetition rate, and total duration of the seizures. However, each of the qEEG parameters is subject to contamination by artefact from muscle or high frequency non-seizure activity. Hence, it is critical to verify the seizure by examination of the raw EEG waveform. It is unclear which qEEG parameter is best for the detection of seizures. However, what is clear is that within a single subject, seizures usually have a typical morphology on the raw EEG and a typical qEEG appearance. This permits one to operationalize a particular qEEG pattern that can be monitored by the non-expert and treatment can be gauged according to the incidence of that qEEG marker.

Non-convulsive seizures in ICU patients

In an initial study of continuous EEG monitoring in a neuroscience ICU population in 124 patients with ICU admission diagnoses that included stroke, intracerebral haemorrhage, seizures, metabolic coma, brain tumours, and brain trauma, seizures occurred in 35% of the patients during the ICU course. Over 75% demonstrated non-convulsive seizures or non-convulsive status epilepticus. Seizures were not readily clinically diagnosed by obvious motor manifestations and the diagnosis required EEG evaluation. The duration of monitoring was determined by the incidence of epileptiform activity. The impact of the cEEG on clinical decision making was determined using the available EEG information in making the following decisions:

- Initiating or modifying anticonvulsants.
- Obtaining a CT or MRI scan.
- Adjusting cerebral perfusion or mean arterial blood pressure.

Overall, the cEEG was decisive in these decisions in 51% of patients, and made a significant contribution in the remaining 31% of patients. Thus, cEEG monitoring detected abnormal subclinical pathophysiology that could be treated and contributed directly to patient care in a large number (82%) of patients.

The incidence of non-convulsive seizures after traumatic brain injury has been recently established. In a seminal study Vespa et al. [3,4] used cEEG monitoring in patients with moderate and severe traumatic brain injury (GCS 3–12). Monitoring was performed for 7–10 days after injury, beginning at the time of admission to the intensive care unit. Electrographic seizures without clinical signs of convulsions were the most common form of seizure; 22% of 91 patients were found to have seizures, with a majority (57%) demonstrating non-convulsive seizure activity. Most seizures occurred within the initial week after the brain injury and the incidence of seizures was not affected by therapeutic phenytoin levels or by the withdrawal of ethanol, nor by the type of brain injury.

The incidence of seizures after brain ischaemia has relied upon studies of clinical signs of seizure activity. The incidence of clinically-defined seizures after bland ischaemia stroke varies from 5 to 17% The incidence of seizures after stroke increases with large territory ischaemic injury and with cardioembolic stroke. The use of cEEG after ischaemic stroke suggests that the incidence of non-convulsive seizures is much higher than detected in the previous studies, which are based on clinical signs of seizures.

The incidence of seizures after intracerebral haemorrhage has been noted to be higher than after ischaemic stroke. Immediate and early seizures occur in 2.8–18.7% of patients with the status epilepticus occurring in 1.1–2% of patients. In a recent study [5,6] the incidence of seizures detected by cEEG after intracerebral haemorrhage was 28% compared with 6% after ischaemic stroke. Using similar cEEG methods, Claassen [2] detected an 18% incidence rate of seizures in a mixed population of intracerebral haemorrhage, subarachnoid haemorrhage, and ischaemic stroke. Again, most seizures occurred within the first week after injury. Oddo et al. [7] have found a high incidence of seizures in septic patients in general ICUs. Hence, across many ICU populations, seizures are common neurological insults.

Seizures have been seen increasingly after cardiac arrest, especially in the era of more intensive treatment of these patients using therapeutic hypothermia. Once considered a hopeless condition, therapeutic hypothermia is being routinely applied to cardiac arrest patients. Several groups have performed continuous EEG monitoring during and after therapeutic hypothermia. The incidence rate of seizures ranges between 12 and 23% in recent studies and tend to occur during rewarming. Table 221.1 summarizes available studies on the incidence of seizures in selected neurocritical care populations.

Continuous EEG in prognosis

Prognosis remains one of the most significant questions for most comatose patients and methods to determine prognosis, such as brain imaging, neurological examination, and evaluation of serum biomarkers often are insufficient to render meaningful prognosis.

Table 221.1 This table lists available studies on the incidence of seizures in selected neurocritical care populations

Study on ICU cEEG	Number of patients	Seizure incidence (%)	Diagnostic groups
Jordan 1995 [9]	124	35	Coma from variety of diagnoses
Vespa 1999 [3]	94	22	TBI
Vespa 1999b [4]	300	21	TBI, SAH, I-C haemorrhage
Vespa 2003 [6]	63	28	I-C haemorrhage
Claassen (2004) [2]	204	17	SAH
Pandian (2004) [10]	105	42	Coma from variety of diagnoses
Young 2006 [11]	55	20	Coma from variety of diagnoses
Ronne-Engstrom (2006) [12]	70	33	TBI
Claassen (2007) [13]	102	28	I-C haemorrhage
Oddo (2009) [7]	201	22	Sepsis and medical ICU diagnoses
Vespa (1999) [3]	140	23	TBI
Rittenberger (2012) [14]	101	12	Cardiac arrest
Mani (2012) [15]	38	23	Cardiac arrest
Wusthoff (2011) [16]	26	65	Cardiac arrest

TBI, traumatic brain injury; SAH, subarachnoid haemorrhage; I-C haemorrhage, intracranial haemorrhage.

Data from various studies (see references).

EEG has a long track record of being useful for the determination of prognosis. Selected characteristics of raw EEG, such as the background rhythm and Synek scale, spontaneous variability and responsiveness stimulation have been used to assist in prognosis [8], but remain somewhat arbitrary and difficult to use due to a lack in inter-reader reliability and qualitative interpretation. qEEG is more objective, since it uses derived measures, and uses a larger amount of data that has been trended over time. Lack of variability in the CSA of comatose patients is a powerful predictive indicator of persistent unresponsiveness and lack of recovery after traumatic brain injury. More recently, the lack of variability over time of the percent alpha trend (PAV) during the initial 3 days after severe traumatic brain injury was found to have a high predictive value for clinical outcome at 1 month [17] and 6 months [18]. The PAV is very low in those patients who are destined to have a poor outcome, and the lack of improvement in the PAV over a few days also predicts a poor outcome. PAV trends are automatically created by modern EEG software, and can be useful in tracking improvement or lack of improvement in real time. A caveat in using PAV, as well as the other qEEG parameters, is that deep sedation can artificially reduce the variability in the PAV, and thus create a falsely poor PAV. Several other forms of qEEG may also be useful for prognosis.

Use of qEEG for sedation monitoring

qEEG may be used to monitor sedation in the ICU. The most commonly used modality is the BIS [19]. BIS is an algorithm-derived number that roughly indicates the degree of EEG activity when patients are under general anaesthesia. BIS ranges from 0 (brain dead) to 100 (normal brain function) and a value of <60 indicates general anaesthesia, and <30 indicating burst suppression. BIS has been used intra-operatively to monitor the effects of general anaesthesia, and has been specifically designed to detect the effects of inhalational anaesthetics. The application of BIS to ICU monitoring has been more controversial due to the inability of BIS to monitor non-inhalational sedatives and several case reports questioning its reliability in the ICU due to muscle artefact, machine interference, and lack of ability to detect seizures [20].

Apart from sedation monitoring, qEEG has been used to assist in deep sedation and barbiturate-induced coma. The burst suppression index is an example qEEG parameter that can be useful in titrating barbiturates.

Goal-directed treatment of seizures based on cEEG

Patients with seizures after brain haemorrhage or cerebral injury are prone to increased brain oedema, shift and elevated intracranial pressure [5,6]. These events occur during the initial week after injury, which overlaps with the peak incidence of post-traumatic seizures. Several principals of goal directed seizure treatment can be derived from the current literature:

- cEEG should be started immediately upon presentation of the brain injury or haemorrhage.
- Brain haemorrhage patients (traumatic or non-traumatic) have a higher risk than ischaemic stroke patients and should have priority for monitoring if resources are limited.
- Monitoring should continue for at least 5 days.
- The lack of clinical seizure activity is not an indication to avoid cEEG since the most seizures are non-convulsive.
- cEEG is a useful monitor for titration of anti-epileptic medications.

Conclusion

Anticonvulsants are typically quite effective at stopping the seizure activity when used as continuous infusions. However, the goal

for the duration of continuous infusion is not clear and recurrent seizures can occur when the continuous infusion is stopped, even when continued routine anticonvulsants are used. Goal-directed treatment using cEEG as a clinical guide has been reported to be effective in stopping seizures and led to an overall improvement in clinical outcome in a case-controlled cohort study [3,4]. The net effect on patient care was to improvement outcome, while decreasing length of stay and being cost neutral in the process.

CHAPTER 222

Cerebral blood flow and perfusion monitoring in the critically ill

Samson Sujit Kumar Gaddam and Claudia S. Robertson

Key points

- Prevention of secondary cerebral ischaemic insults is an important strategy in the management of acute neurological conditions. Monitoring of cerebral perfusion may aid in early identification of ischaemic insults and help in the management.
- Cerebral perfusion pressure (CPP) is a simple way of assessing cerebral perfusion, but in some cases ischaemia can be present even with a normal CPP.
- CBF imaging, either with stable xenon CT or other CT and MRI techniques, can provide quantitative regional cerebral blood flow (CBF) measurement, but only at a single instance in time and are difficult to use in managing critically-ill patients.
- CBF can be measured in the intensive care setting, either directly or indirectly, through measurement of cerebral oxygenation.
- Some of the tools monitor global perfusion and some assess only regional perfusion in a local area of brain surrounding the monitor. With these local monitors, the location of the probe is important in interpretation of the findings.

Introduction

Cerebral pathological conditions such as traumatic brain injury (TBI) and stroke can result in significant morbidity and mortality. The various biochemical cascades that follow primary brain injury lead to secondary brain injury resulting in raised intracranial pressure and decreased cerebral perfusion. Current critical care management of TBI and stroke involves monitoring of cerebral physiological parameters such as cerebral blood flow (CBF) and cerebral oxygenation, which may help in early recognition and treatment of secondary brain injury.

Cerebral blood flow and perfusion

Knowledge of the characteristics of cerebral circulation in normal individuals is pivotal to the understanding of CBF and cerebral metabolism in pathological states. CBF can be represented by one of the following formulas:

$$CBF = CPP/CVR \quad \text{[eqn 1]}$$

$$CBF = (k \times CPP \times d^4)/(8 \times l \times v) \quad \text{[eqn 2]}$$

where CPP is cerebral perfusion pressure, which is equal to mean arterial pressure (MAP) minus intracranial pressure (ICP), CVR is cerebral vascular resistance, k is a constant, d is the diameter of the vessel, l is length of the vessel, and v is blood viscosity. CBF is normally regulated by cerebral metabolic rate and is also affected by CPP and arterial PCO_2. Normal CBF is 55 mL/100 g/min (gray matter = 75–80 mL/100 g/min, white matter = 20–30 mL/100 g/min).

Cerebral metabolism is entirely dependent on the oxidation of glucose and requires a constant supply of oxygen. Cerebral metabolic rate of oxygen ($CMRO_2$) is given by the following formula:

$$CMRO_2 = CBF \times AVDO_2 \quad \text{[eqn 3]}$$

where $AVDO_2$ is the arteriojugular venous difference of oxygen content. $CMRO_2$ is kept constant under most conditions at an average 3.2 mL/100 g/min (1.5 μmol/g/min). In normal states CBF is tightly coupled to $CMRO_2$ and CBF increases or decreases based upon the local metabolic requirements of brain tissue. This coupling is mediated by metabolic variables like PO_2, PCO_2, extracellular pH, adenosine, extracellular potassium ion concentration, and nitric oxide. However, in pathological states such as TBI and stroke, there can be uncoupling of CBF and $CMRO_2$.

Cerebral blood flow and perfusion monitoring

The available monitoring techniques for CBF measure flow directly or indirectly by assessing the relative adequacy of CBF through estimation of cerebral oxygenation. Measurement of CPP is the most widely used method to assess CBF. It involves continuous invasive monitoring of arterial blood pressure and ICP. An increase in ICP or a decrease in MAP can result in reduction in CBF causing ischaemia of the injured brain. The guidelines for management of severe head injury recommend CPP to be maintained at a minimum of 60 mmHg [1]. However, in states of impaired autoregulation such as TBI, cerebral perfusion may be inadequate despite a CPP of 60 mmHg, and other monitoring techniques may be useful to supplement assessment of cerebral perfusion.

Other available methods of measuring CBF, including stable xenon-enhanced computed tomography (CT), single photon emission computed tomography (SPECT), perfusion CT, perfusion

magnetic resonance imaging (MRI), and positron emission tomography (PET) provide intermittent measurements of flow. Although PET provides accurate and valuable quantification of physiological and metabolic parameters like CBF, $CMRO_2$, and oxygen extraction fraction after intravenous ^{15}O-radioisotope administration, cost-effectiveness, radiation-exposure, and the need to transport the patient are major impediments to its clinical usefulness [2]. Perfusion CT uses infusion of iodinated contrast and collection of serial sequences of images using a helical CT scanner. Each image is then subtracted from a baseline image to develop a time-enhancement curve. In addition to providing quantification of both global and regional CBF, it allows determination of vasomotor reactivity. Perfusion-weighted MRI is helpful in identifying ischaemic regions, but it can be time-consuming and challenging to scan critically-ill patients in an MRI suite. SPECT provides semi-quantitative data on CBF by measuring the localization of ^{99m}Tc radioisotope in the brain tissue. Abnormal areas are compared with the contralateral side or the cerebellum, and relative CBF is calculated. It is useful in the management of patients with acute stroke, vasospasm, and occlusive vascular disease. Measurement of both global and regional CBF with stable xenon CT imaging (inhalation of 28–33% xenon) is also feasible, but these techniques provide only intermittent data, are inaccurate in pulmonary disorders, and are not widely available except for research purposes [2,3]. Like PET all imaging studies require transportation of the patient to the imaging suite.

Thermal diffusion flowmetry (TDF) and laser Doppler flow (LDF)

These allow continuous monitoring of CBF at the bedside. These methods are invasive and require placement of a probe on the surface of or within the brain. Attention to the placement of probes in the region of interest is crucial as these devices detect only the changes occurring in the surrounding brain tissue. TDF measures regional blood flow by calculating the temperature difference between a neutral plate and a heated element (two gold disks or two bands). TDF correlates well with stable xenon CT results and has been reported to help in early detection of neurological deterioration [4]. LDF measures erythrocyte flux and then calculates CBF [5]. It has been used in monitoring of patients with ischaemic insults and is also useful in assessing autoregulation. Potential risks of invasive techniques include complications such as bleeding, infection, and displacement of the probe.

Transcranial Doppler (TCD) ultrasonography

This provides a non-invasive means of real time bedside measurement of flow velocity (FV) from the major intracerebral vessels such as the middle cerebral artery (MCA). FV is directly proportional to flow and inversely proportional to cross-sectional area of the vessel, and can be used as an indicator of CBF as long as vessel diameter does not change [6]. Some studies have shown close correlation between changes in MCA flow velocities and stable xenon CT CBF values [7]. However, an increase in FV could be due to a decrease in vessel diameter (such as that which occurs with cerebral arterial vasospasm) or to an increase in CBF (hyperaemia). The MCA to extracranial internal carotid artery flow velocity ratio (known as the Lindegaard ratio or hemispheric index) is used to differentiate between these two conditions [8]. Normal hemispheric index is 1.76 ± 0.1 and values above 3 are suggestive of vasospasm. TCD is also used to assess cerebral autoregulation and confirm brain death [9]. One limitation is that the temporal ultrasonic window that is normally used for TCD study is absent in 5–10% of patients.

Monitoring of CBF alone may not be sufficient in a critical care setting as the relative adequacy of blood flow cannot be determined based on absolute values of CPP or CBF. For example, when CBF is low (25–30 mL/100 g/min), the brain is either hypoperfused or there is a reduced cerebral metabolic requirement. Which of these two conditions exists can be determined by measurement of cerebral oxygenation using techniques such as measurement of jugular venous oxygen saturation ($SjvO_2$) or brain tissue oxygenation ($PbtO_2$).

Global cerebral oxygenation

This can be monitored by insertion of a fibre optic $SjvO_2$ catheter into the jugular vein and positioning the tip of the catheter in the jugular bulb. In normal young males, $SjvO_2$ ranges from 55 to 71% (mean 61.8%). In patients with brain injury, $SjvO_2$ is typically higher than normal and averaged $68.1 \pm 9.7\%$ in large series [10–12]. Current guidelines for the management of TBI recommend maintaining a $SjvO_2$ of at least 50% [1]. There is some controversy over optimal placement of the $SjvO_2$ catheter since jugular venous blood is incompletely mixed. Stocchetti et al. [13] found differences between the values of $SjvO_2$ measured from right and left jugular bulbs. Metz et al. [14] based on their study of bilateral $SjvO_2$ in 22 patients recommended that the catheter should be placed on the dominant side in diffuse injury and on the ipsilateral side when the injury is focal. The potential complications with $SjvO_2$ monitoring include carotid puncture, injury to nerves in the neck, pneumothorax, infection, and venous thrombosis. Although $SjvO_2$ is useful as a measure of global cerebral oxygenation, it cannot identify regional cerebral ischaemia and has low sensitivity. PET studies have shown that approximately 13% of brain tissue must be affected before $SjvO_2$ levels drop below 50% [15].

Local cerebral oxygenation

This can be measured with two techniques, brain tissue PO_2 ($PbtO_2$) and near infrared spectroscopy (NIRS). $PbtO_2$ is measured by a catheter (Clark electrode) placed into the brain tissue. Normal values for $PbtO_2$ are 20–40 mmHg. As the brain tissue oxygenation is measured only in the tissue directly surrounding the tip of the catheter, the placement of the catheter is very important. When the probe is placed in normal brain tissue, the values closely parallel global oxygenation, but when the probe is positioned in injured tissue, the values reflect local oxygenation and can vary substantially from global oxygenation. Current guidelines for the management of TBI recommend treatment of $PbtO_2$ values less than 15mm Hg [1]. Clinical studies have shown increased mortality and morbidity in TBI patients with low $PbtO_2$ [16]. Spiotta et al. [17] found improvement in outcome and mortality with $PbtO_2$-guided therapy when compared with conventional ICP/CPP management in patients with severe TBI.

Near infrared spectroscopy

NIRS is a bedside, real-time transcranial method used for continuous monitoring of local cerebral oxygenation [18]. It measures near infrared light (650–1100 nm) reflected from haemoglobin

molecules based on the oxygenation state and calculates regional oxygen saturation (rSO_2) from the attenuation of the light. The probe is usually placed over the forehead and needs to be in contact with the scalp for optimal reading. NIRS readings are influenced by ambient light, thickness of scalp and bone, presence of blood, and amount of melanin in the skin. It has been shown to be a useful modality in monitoring patients undergoing cardiopulmonary bypass surgery [19], carotid endarterectomy and in cerebral autoregulation assessment. Various studies have evaluated the use of NIRS in patients with brain trauma and subarachnoid haemorrhage. NIRS oxygen saturation (rSO_2) has been shown to correlate well with $SjvO_2$ in some TBI studies. Dunham et al. [20] observed that rSO_2 greater than 75% suggested an adequate CPP and rSO_2 less than 55% suggested an inadequate CPP.

Intracerebral microdialysis

This is used to monitor the metabolic products in brain. Biochemical parameters, such as energy substrates (glucose and pyruvate), metabolic products (lactate), neurotransmitters, glycerol, and potassium can be measured. Elevated lactate/pyruvate ratio is associated with fatal outcome after TBI. Glycerol levels are elevated in severe TBI. Neurotransmitters such as glutamate are elevated following TBI and seizures. As with $PbtO_2$ catheters, microdialysis probes only measure metabolic products in the tissue immediately around the catheter tip, and require knowledge of the position of the catheter for correct interpretation of the findings.

CHAPTER 223

Intracranial pressure monitoring in the ICU

Jonathan K. J. Rhodes and Peter J. D. Andrews

Key points

- Intracranial pressure (ICP) monitoring is an established monitoring modality in intensive care unit.
- It can aid prognostication after severe brain injury.
- Measurement of ICP can warn of life-threatening deterioration.
- Control of ICP and management of CPP can help maintain oxygen delivery to the brain.
- Further research into the efficacy of ICP monitoring, including defining treatment thresholds (ICP and CPP) and effectiveness of associated reduction therapies is urgently required.

Monro–Kellie doctrine

Alexander Monro (1733–1817), professor of Anatomy at the University of Edinburgh Medical School, and his former pupil George Kelly of Leith (1758–1829), initiated the doctrine that now bears their names. This states that the sum of the volumes of brain tissue, cerebrospinal fluid (CSF) and intracranial blood is constant. An increase in one should cause a decrease in one or both of the remaining two [1].

This doctrine predicts that in the presence of a space-occupying lesion in or around the brain, such as a haematoma, contusion, swelling around an area of infarction or the presence of diffuse swelling of the brain itself, blood, and CSF volume will reduce, and a pressure rise within the rigid skull will be prevented.

The significance of the Monro–Kellie doctrine is that in practice the volume compensation possible due to blood and CSF redistribution can be extremely limited. Prior to the exhaustion of this compensation an increase in volume results in a very limited increase in intracranial pressure (ICP) and, compliance (Δ volume/Δ pressure) is high. However, once this is exhausted, marked increases in ICP occur after volume changes of only a few cubic centimetres. Compliance is then said to be low (Fig. 223.1).

Normal ICP is position dependent. For a subject in the horizontal position, ICP can be 10–15 mmHg. When the subject is upright it decreases and can have a negative value (–5 mmHg) relative to the foramen of Monro. Following brain injury, swelling may obstruct the normal CSF pathways within and surrounding the brain, preventing even redistribution of pressure within the intracranial compartment. With increasing ICP a pressure gradient can then develop within the skull, causing brain contents to shift or herniate from high to low pressure areas, either within the supporting dura or down through the foramen magnum. This can cause irreversible structural brain damage and is a common cause of brain death. Increased ICP can also compromise cerebral perfusion, leading to ischaemia, further swelling due to oedema, and a cycle of increasing ICP.

In many centres, the measurement and monitoring of intracranial pressure has therefore become an integral part of the early management of patients with acute brain injury. A continuous display of ICP can providing an early warning of evolving pathology, allowing urgent control measures to prevent herniation. The calculation of cerebral perfusion pressure (CPP, calculated as the mean arterial pressure (MAP) minus the ICP) is also fundamental to the maintenance of cerebral blood flow and prevention of secondary ischaemic insults, which can adversely affect outcome.

Techniques for ICP measurement

ICP can be measured by a variety of methods. In 2007, the Brain Trauma Foundation concluded that, 'the ventricular catheter connected to an external strain gauge is the most accurate low-cost and reliable method for monitoring intracranial pressure' [2]. However the economic comparisons of devices, including disposables and bedside monitors, is unlikely to have included the costs associated with placement in an operating room, which is mandatory for ventricular devices. The measurement of ICP through a ventricular catheter coupled via a fluid-filled line to an external strain gauge is analogous to the more familiar transduction of arterial or central venous pressure. Intraventricular catheter systems allow treatment of ICP by draining CSF, sampling of CSF for diagnosis or research, and these systems can be recalibrated after insertion. However, if ventricular blood load is heavy they can become occluded with clot. Furthermore, if the ventricles are effaced or collapsed due to intracranial pathology placement might not be possible.

Microstrain gauge, pneumatic, and fibre optic devices also exist that can be placed either into the ventricular system or brain parenchyma. Parenchymal placement is technically simpler and may be performed by non-surgical specialists, outside the operating room environment. However microstain gauge and fibre optic systems cannot be recalibrated without removal making drift from a zero (atmospheric pressure) baseline not assessable. Another consideration is that of MRI compatibility, as not all available systems are specified MRI safe.

Haematoma formation associated with ICP monitoring is described with an incidence of 11% in one series [3]. However,

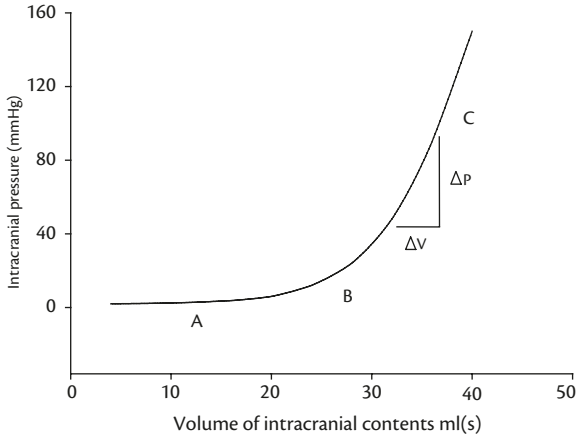

Fig. 223.1 Intracranial pressure–volume relationship. In health, when ICP is normal, an increase in the volume of the intracranial contents can be accommodated without an increase in ICP, region A. However, this accommodation is limited and soon a point of decompensation is reached, point B. Thereafter, further increases in volume result in large increases in ICP, region C. In region A compliance (ΔV/ΔP) is high. In region C compliance is low. The inverse of compliance is elastance (ΔP/ΔV).

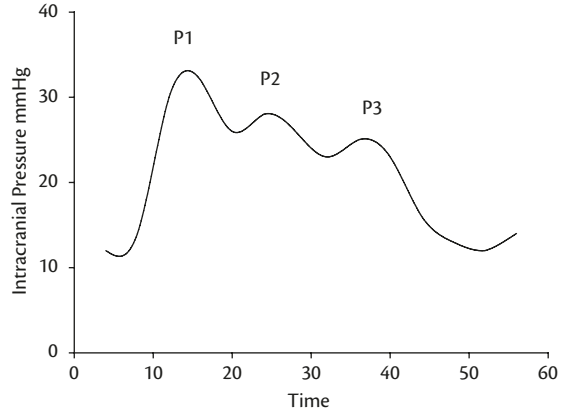

Fig. 223.2 Component parts of an ICP wave. The first (P1) reflects the arterial pressure wave transmitted into the CNS through the choroid plexus. The second peak (P2) is due to mass transport of blood with each cardiac cycle. The final peak is the dicrotic notch and represents the closing of the aortic valve. With reducing intracranial compliance the amplitude of P2 increases to match and then exceed that of P1.

clinically significant bleeding requiring surgical intervention is much less common, with a published incidence of 0.5% [2]. Correction of coagulation defects is an essential prerequisite to the placement of an ICP monitor. The risk of infection should also be considered and thorough asepsis at placement is essential. Culture positive probe tips have been reported in up to 17% of cases [4]. However, clinically significant infection is much rarer, and was only seen in patients with ventricular placement where ventriculitis was a risk [4]. This risk is thought to increase with duration of catheter placement and for intraventricular systems, repeated CSF sampling. The frequency of regular CSF culture for infection surveillance needs to be balanced against the risk of repeated CSF access. In clinical practice, CSF surveillance varies from none to, every 48 hours or daily if infection is suspected.

ICP waves

In addition to the determination of a value for ICP at any single moment, in order to avoid herniation and reduced CBF, the display and analysis of the ICP waveform, and its trends with time can add further valuable information.

The normal ICP wave contains three component parts (Fig. 223.2). As intracranial pressure increases the amplitude of the ICP wave form also increases. With each cardiac cycle there is a transient increase in CBV. When ICP increases and the compliance of the volume–pressure relationship is low, this increase in volume causes an increasingly large pressure change with each left ventricular systole. The amplitude of the ICP wave therefore increases. Ultimately at the upper inflection point of the volume pressure relationship the amplitude of the ICP wave is reduced. At this point ICP approximates to mean arterial pressure (MAP) and so CPP is very low. Further increases in ICP collapse the cerebral arterial bed limiting the increase in blood volume and so amplitude falls [5].

In 1964 Nils Lundberg, using a ventricular cannula attached to an external strain gauge, recorded the changes in ICP with time in non-ventilated patients with chronic pathologies. He also observed that following TBI increases in ICP were associated with clinical deterioration, that ICP recording could be used to rationalize management and he described a series of characteristic waves present in the ICP trends [6]. Lundberg 'A' waves or 'plateau waves' have an amplitude of 50–100mmHg and last 5–20 minutes. The generation of these waves is thought to be due to an exaggerated attempt to maintain CBF in the presence of reduced intracranial compliance or may be due to vasomotor centre instability. A spontaneous reduction in cerebral perfusion pressure will lead to vasodilatation to maintain CBF. The increase in CBV will increase ICP and so lower CPP once more. This cycle continues until vasodilatory capacity is exhausted. If a Cushing's response due to brain stem ischaemia increases MAP or treatment is given to lower ICP, CPP can be restored and the plateau can be terminated. With restoration of CPP cerebral blood flow improves, followed by vasoconstriction, reduced CBV and lowering of ICP and therefore further improvement in CPP (Fig. 223.3). 'B' waves are oscillating waves with an amplitude up to 50 mmHg and a frequency of 0.5–2/min. At low amplitude (<30 mmHg) they are thought to represent physiological cyclical oscillations in CBF due to respiratory cycling altering cardiac output. A fall in cardiac output reduce CBF leading to vasodilatation as part of physiological autoregulation. CBV will increase and ICP will increase. As cardiac output and CBF increase the cycle reverses with vasoconstriction reducing CBV and, hence, ICP again. Thus, CBF is maintained about a mean with small oscillations and corresponding changes in ICP. An alternative explanation is that these oscillations are primarily driven by tissue metabolism regulating cerebral blood flow. Accumulation of metabolic products at a tissue level will increase CBF due to vasodilatation, and so CBV and ICP increase. As the metabolic load is 'washed out' vasoconstriction occurs, and CBF, CBV, and hence ICP decreases. Whatever the exact cause of these waves, in the presence of reduced intracranial compliance the amplitude of the ICP oscillations can be increased, and so they indicate intracranial pathology. Lundberg 'C' waves are also oscillating waves with an amplitude up to <20 mmHg and a frequency of 4–8/min. These waves occur in health and their significance is uncertain [6,7].

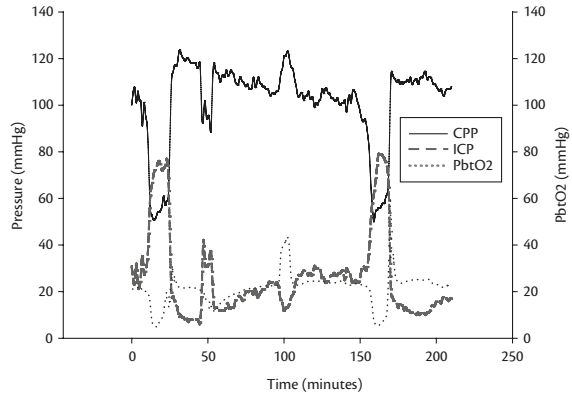

Fig. 223.3 Characteristic Lundberg A waves. Cerebral perfusion pressure (CPP), intracranial pressure (ICP) and brain tissue oxygen tension ($PbtO_2$) are plotted continuously. The large amplitude ICP waves lead to a reduction in CPP. The resulting ischaemia is suggested by the associated fall in $PbtO_2$.

Indications

Determination and continuous measurement of ICP may be useful in a variety of acute brain pathologies. The use of ICP monitoring is incorporated into international guidelines for traumatic brain injury management [2]. In addition, ICP monitoring is employed in severely-ill patients with reduced level of consciousness following subarachnoid haemorrhage (SAH), intracerebral haematoma, ischaemic stroke, meningo-encephalitis, hypoxic brain injury and other conditions associated with diffuse cerebral oedema such as fulminant liver failure.

The use of ICP monitoring or protocol driven management of raised ICP has been associated with improved outcomes after acute brain injury. Therefore, although ICP monitoring cannot be recommended with a high degree of certainty, it is recommended with moderate certainty for those patients following TBI who are likely to be at risk of intracranial hypertension. These are patients whose post resuscitation GCS is 3–8 and who have an abnormal cranial CT scan [2]. In patients with a normal scan the guidelines are less clear. Many of these patients will not suffer raised ICP, but if the patient has two additional adverse features (Age over 40, unilateral/bilateral motor posturing or systolic BP < 90 mmHg) the risk of intracranial hypertension is increased [8] and ICP monitoring is recommended [2]. A minority of patients whose initial cranial CT scan is normal will have evolving lesions, which may not be apparent in the absence of ICP monitoring. In such circumstances follow-up CT scanning should be performed.

Prognostication and intracranial pressure-guided management

ICP measurement can be helpful in determining prognosis. An ICP greater than 20 mmHg, despite interventions in critical care, is predictive of poor outcome following TBI [9]. Furthermore in clinical series interventions that were able to control ICP are associated with improved outcome [10,11].

The rationale for monitoring ICP and maintaining CPP come from observations that uncontrolled ICP can lead to secondary brain damage by reducing CPP and causing herniation. Hypotension is associated with worsened outcome after TBI [9] and secondary injuries are often ischaemic in nature.

Whether treating increased ICP improves outcome in brain-injured patients is an obvious question, and has only been tested in one randomized controlled trial conducted in South America, in which ICP-guided management was not superior to management guided by clinical examination and repeated imaging [12], ICP monitoring was associated with less use of potentially harmful ICP reducing interventions. Supporting data that the control of ICP improves outcome currently comes from observational data or studies using historical controls. Marmarou et al. reported in an observational study of patients in the Traumatic Coma Data bank, when ICP was measured for at least 48 hours after injury, that the proportion of ICP readings greater than 20 mmHg was predictive of poor outcome [9]. Eisenberg and colleagues conducted a trial designed to test the efficacy of barbiturate infusion in controlling ICP resistant to stranded measures. Post hoc analysis of outcome at 1 month found that survival was significantly better in patients in whom ICP could be controlled, in both the treatment and control groups [10]. Similarly, Saul and Ducker published a retrospective analysis of two sequential series of similar patients in which ICP treatment was started at differing thresholds. In the first series ICP treatment was initiated at an ICP >25 mmHg, with mannitol and CSF drainage. In the later series, the lower threshold of 15 mmHg was used, treatments guided by a protocol and escalating through mannitol, CSF drainage, and barbiturate infusion. In the later protocol, there were significantly fewer patients with an ICP >25 mmHg. This was associated with a significant reduction in mortality [11]. The ability to control ICP or the association of better outcome with ICP <20 mmHg could simply reflect less severe pathology or the prognostic relationship between ICP and outcome. Data suggesting ICP monitoring does not improve outcome comes from a more contemporary report. Cremer et al. [13] compared outcomes in severe TBI patients admitted to two different trauma centres. One provided supportive intensive care with therapy guided by clinical signs and serial CT scans. The second centre used an ICP/CPP targeted approach. The probability of favourable outcome was no different in the two centres.

Many of these studies are now quite dated as clinical management is constantly changing. Better availability and resolution of modern CT scanning, driving early surgical intervention, changing sedation regimes, ventilation practices and the development of protocol driven treatment in specialist centres are some of the probable confounders influencing outcomes today. In several of the studies cited, hyperventilation and systemic steroids were standard therapies; these treatments are no longer advocated in the management of TBI [10,11,14]. The Eurotherm3235 trial showed that titrated hypothermia was effective at reducing ICP after TBI when used as the primary stage II intervention, but resulted in a higher mortality and poorer outcomes [15].

Further developments in ICP measurement

Pressure reactivity

Although CPP-guided management of patients with brain injuries is standard practice in many units there is significant uncertainty as to the optimum CPP target. The widely accepted value of a minimum CPP of 60 mmHg is a guideline only [2]. It is based on cohorts of patients who had improved outcomes or better surrogate markers of cerebral perfusion compared with case controls. This guideline may be appropriate for populations of patients, but for individuals there may be considerable variation.

The pressure reactivity index (PRx) is a continuously derived variable, which essentially indicates if cerebrovascular autoregulation is intact or not. Study of PRx suggests that in individual patients there is a CPP at which PRx is optimal and where autoregulation is best preserved. In retrospective analysis deviation of mean CPP from a PRx defined $CPP_{optimal}$ correlated with adverse outcome [16]. Although guidelines suggest that CPP should not be allowed to fall below 60mmHg, for an individual patient, calculated $CPP_{optimal}$ can be considerably higher [2,16], but whether routine use of this technique improves outcome is not currently known.

Brain tissue oxygen monitoring

The management of ICP and CPP aims to maintain cerebral blood flow and, hence, oxygen delivery. Evidence from studies in which brain oxygenation has been measured would suggest that these parameters alone are not sufficient to guarantee this delivery [17]. Brain parenchymal oxygen tension monitoring, in addition to ICP monitoring, is an option in some commercial clinical systems. Oxygen and associated temperature electrodes can be either inserted through the same craniotomy as the ICP monitor or they can be incorporated into a single catheter.

Measurement of parenchymal oxygen can be used to guide patient management. Brain oxygen tension ($PbtO_2$) can be improved by treating raised ICP, optimizing arterial carbon dioxide tensions, correcting anaemia or increasing CPP. Much like PRx, brain oxygen tension can be used to set an individual patient's CPP. It has been demonstrated that below $CPP_{optimal}$, defined by PRx, $PbtO_2$ decreases linearly. Above $CPP_{optimal}$ $PbtO_2$ plateaus, so increasing CPP further does not improve oxygenation [18], these data provide indirect support for the concept of targeting a derived $CPP_{optimal}$.

Conclusion

ICP measurement is an established monitoring modality in ICU and can aid prognostication after acute brain injury. ICP monitoring is recommended in all patients with severe TBI and an abnormal cranial CT scan. The ability to control ICP is associated with improved outcome after TBI. The lessons from TBI studies can also be applied to other acute pathologies of the CNS where ICP can be increased. ICP measurement can warn of impending disaster and allow intervention. Furthermore, maintenance of CPP may help to ensure adequate cerebral oxygen delivery, although this might not be sufficient without measuring brain oxygenation as well. Although a recent trial in two South American countries suggested that ICP-guided management and management guided by clinical examination and repeated imaging produced equivalent outcomes, the external validity and generalizability of these results remains to be confirmed.

CHAPTER 224

Imaging the central nervous system in the critically ill

Olivier Bodart and Steven Laureys

Key points

- Computed tomography (CT) scan is still preferred to magnetic resonance imaging (MRI) in the acute management of traumatic brain injury (TBI) due to its sensitivity to lesion that requires immediate surgery, its accessibility, and the speed of the acquisition.
- Recent studies show the prognostic value of MRI sequences, such as diffusion tensor imaging (DTI) in coma following TBI or anoxia.
- CT remains the gold standard to detect acute haemorrhage.
- CT and CT angiography are suited to detect acute ischaemic stroke and major arterial occlusions, which is useful to aid the thrombolytic versus interventional therapy. However, MRI is more sensitive in the very first hours and can detect contraindications to IV thrombolysis.
- In traumatic spine injuries CT is used for the evaluation of bony structures and MRI for the evaluation of ligamentous injuries and the spinal cord.

Introduction

Signs and symptoms of central nervous system dysfunctions are frequently seen in the critical care setting, either in patients who are admitted primarily for a brain or spine lesion or for any other reason. There are many conditions that can lead to neurological impairment and it is beyond the scope of the present chapter to detail the imaging characteristics of them all. We will focus on some key primary brain and spines injuries. We will do so by discussing when it is important to obtain neurological imaging, which modality to use, what one can expect to find, and what are the main implications for determining prognosis.

Imaging of the brain

Traumatic brain injury

Patients admitted for a major traumatic brain injury (TBI) require emergency imaging of the head and brain primarily to identify lesions that may require urgent neurosurgery or special monitoring. The technique of choice is usually Computed tomography (CT) however, in cases of **mild** TBI (of which the definition may vary) it is not always necessary. Among the scales developed to avoid excessive use of health resources, the Canadian computed tomography head rule scale is highly sensitive and among the most specific to determine which patients with minor/mild head injury require CT scanning [1]. CT is preferred to magnetic resonance imaging (MRI) in the emergency set-up as it is faster in acquiring the data, more widely available, and more accessible to patients dependent on life-supporting equipment. MRI has the advantage of an absence of radiation for the patient. However, the presence of a pacemaker and/or metallic foreign bodies are contraindications. MRI is increasingly used for the initial assessment of patients with TBI, but it remains to be shown whether the extra findings do change patients' management [2]. CT is highly sensitive to skull fractures and acute intracranial bleeding, especially to lesions that would require immediate surgery, such as epidural or subdural haematomas. When performed with contrast enhancement, it also provides a whole brain and neck angiogram, and is thus able to demonstrate vascular injuries (such as blunt injuries, traumatic dissections, aneurysms, etc.). However, digital subtraction angiography remains the technique of choice for these latter lesions. MRI is more sensitive to lesions of the brainstem and the posterior fossa, and has a better tissue contrast, hence a better spatial resolution. It is thus able to detect more subtle (but still clinically relevant) brain injuries, such as 'diffuse axonal injury' and cortical contusions [3].

Some neuroimaging techniques can provide the caregiver valuable information on the prognosis of their patient. For example, some specific MRI sequences, such as diffusion tensor imaging (DTI), provide prognostic information that is often more accurate than clinical or CT scores [4].

Stroke

Strokes can be classified into two major categories: ischaemic and haemorrhagic. Ischaemic strokes are caused by interruption of the blood supply (caused by thrombosis, arterial embolism, etc.), while haemorrhagic strokes result from rupture of a blood vessel or an abnormal vascular structure. About 87% of strokes are caused by ischaemia and the remainder by haemorrhage. Some haemorrhages can develop inside areas of ischaemia (termed 'haemorrhagic transformation'). Such haemorrhagic strokes are associated with higher mortality rates than ischaemic strokes. In acute cerebrovascular accidents (CVA), neuroimaging is needed in an emergency setting to determine the ischaemic or haemorrhagic nature of the lesion and, hence, to direct the patient's further therapeutic management. Due to the wide availability of a CT scanner in emergency departments, this technique is often performed first in stroke patients. CT is excellent to demonstrate acute haemorrhagic lesions (Fig. 224.1a), whilst

MRI is more sensitive in following the progression of the haemorrhage and in searching for the possible underlying causes. Both techniques may identify complications of haemorrhagic stroke, such as intraventricular haemorrhage, brain oedema, and hydrocephalus. In ischaemic stroke, the sensitivity of the CT scan in the first 6 hours is low. However, some early signs may still be seen, such as loss of gray matter–white matter differentiation, swelling of the circumvolutions, and (less frequently) spontaneous hyperdensity in the middle cerebral artery (Fig. 224.1b). Nonetheless, CT and CT angiography are able to detect acute ischaemic stroke and major arterial occlusions, which is useful in guiding thrombolytic or interventional therapy. In comparison, MRI is far more sensitive in detecting acute ischaemic lesions (Fig. 224.1c); diffusion-weighted imaging (DWI) can show ischaemic impairment (cytotoxic oedema) within 3 minutes of the event. It can also better demonstrate the exact extent of the ischaemic lesion and is able to show smaller lesions, as well differentiate acute ischaemic lesions from old ones (Fig. 224.1d). MRI perfusion imaging can be useful to study penumbra and other zones at risk of lesion extension.

Prognosis in stroke depends of many factors among which the localization and the size of the ischaemic and/or haemorrhagic lesion are assessable by neuroimaging techniques.

Subarachnoid haemorrhage

Patients presenting with excruciating headache, and even more if associated with focal neurological deficit, should be scanned as soon as possible to exclude subarachnoid haemorrhage (SAH). The spontaneous hyperdensity of blood on CT makes it a very sensitive tool for diagnosis of this condition (Fig. 224.1e). Many cases of SAH are related to trauma and up to 85% of the non-traumatic cases are caused by a ruptured aneurysm that must be treated to prevent recurrence. Some MRI sequences such as FLAIR (fluid attenuated inversion recovery) can demonstrate SAH as hyperintensities in sulci or cisterns, but this finding has many other possible diagnoses and is thus less specific than CT. It can, however, be useful in demonstrating an underlying tumour in intraparenchymal bleeding, and is able to detect small SAH after a few days. Vasospasm is a frequent complication of SAH, which can be assessed via transcranial Doppler ultrasonography, MR and CT angiography, and digital subtraction angiography. Risk of clinically significant vasospasm can be estimated using the modified Fischer scale, which stratifies the risk by the appearance of the SAH on the initial CT [5]. CT or MRI can assess hydrocephalus, another possible complication of SAH. Angiography remains the gold standard for detecting even smaller aneurysms, and is one of the therapeutic options for these,

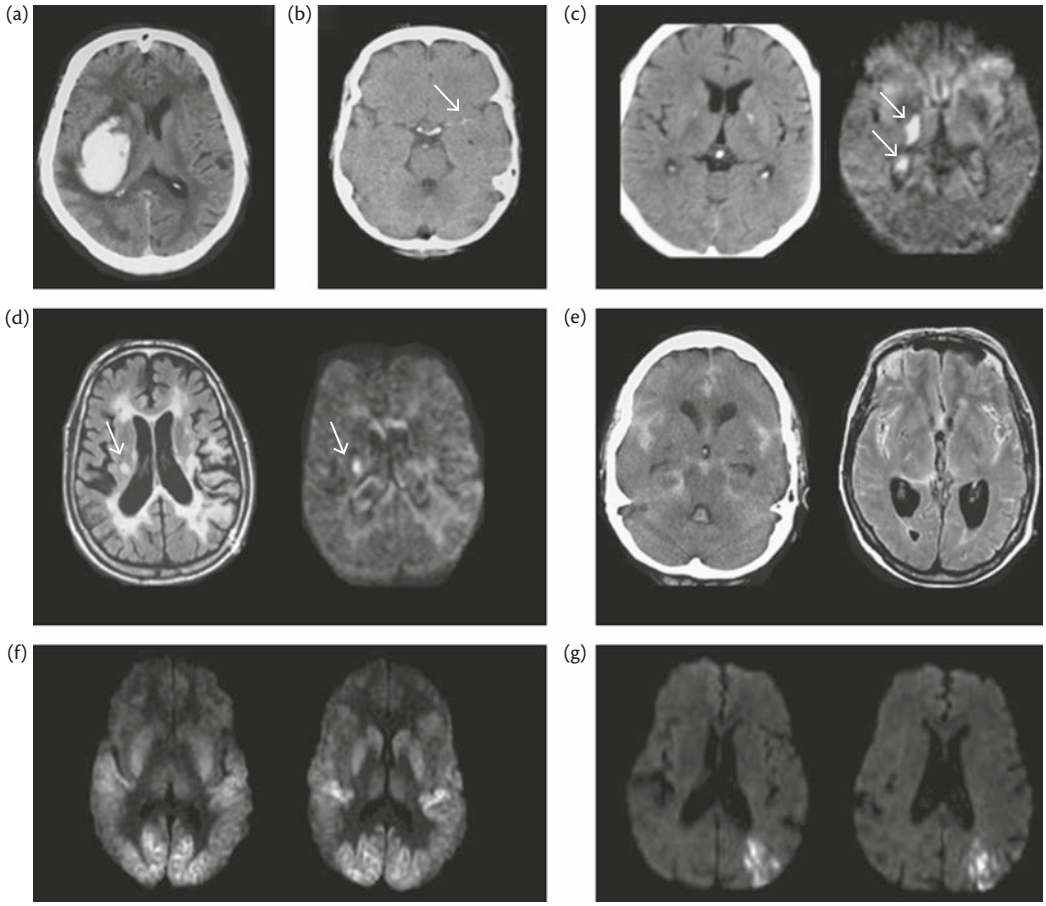

Fig. 224.1 (a) CT scan of acute intracranial haemorrhage. The CT image shows hyperdense acute haemorrhage in the basal nuclei-corona radiata on the right, along with surrounding hypodense oedema. (b) Early hyperdensity on a CT scan of the left middle cerebral artery (indicated by arrow). (c) CT scan (left) and MRI (right) of acute ischaemia. The image on the right shows high sensitivity of MRI DWI in the acute phase of ischaemia (visible as hyperintensity in DWI sequences); the acute ischaemia is not evident on the CT scan (left). (d) DWI sequence is useful to differentiate new ischaemic lesions (arrow—more evident on right image), not easily discernable on a FLAIR image (left image). (e) Acute SAH is better seen on a CT scan (left) than MRI (right). (f) Widespread hyperintensity on DWI in hypoxia (most affected are the cortex and basal nuclei). (g) Boundary zone hyperintensity on DWI in hypoperfusion.

CT, computed tomography; DWI, diffusion-weighted imaging; FLAIR, fluid attenuated inversion recovery; SAH, subarachnoid haemorrhage.

depending of their location, size, and other factors. If an aneurysm is suspected, digital suppression angiography should be done as soon as the condition of the patient allows.

Anoxic brain injuries

Following a cardiac arrest or a prolonged hypoxic state (also often encountered in TBI), patients may have significant neurological deficits and a depressed level of consciouness. Neuroimaging techniques can be used, even early, to assess the extent of the anoxic-ischaemic lesions. In the first 2 days, CT may reveal diffuse swelling with consequent effacement of the sulci, ventricles, and cisterns, hypodensities of the cortical and basal ganglia gray matter, and an attenuation of the gray–white matter interface (also termed loss of gray–white differentiation). MRI, for the reasons previously explained (related to the incompatibility of life-supporting equipment and the time required to perform the scan), is often difficult to obtain immediately. When performed early, DWI and FLAIR may show widespread hyperintensities, which classically first affect the basal ganglia and the thalamus, and next the cortex, the subcortical white matter, the cerebellum and the hippocampus (Fig. 224.1f) (while MRI T1 and T2 sequences can be normal or near normal). In the subacute phase, there is usually a resolution of the brain oedema and of the hyperintensities evident on DWI. FLAIR and T2 sequences may show extensive changes in the gray matter and the development of white matter lesions. In case of hypoperfusion (i.e. without blood flow cessation), the lesions tend to be situated in the watershed territories (Fig. 224.1g). In case of a pure hypoxic event, lesions in DWI tend to be restricted to the thalamus and some cortical regions. Prolonged coma (other than caused by sedation) of more than 6 hours is of poor prognosis. The better outcome can be expected in young patients who had a cardiac arrest due to a primary cardiac arrhythmia, and in who the blood flow was restored in less than 6 minutes. Hypoxic events also tend to have a better prognosis. In the acute phase, the presence of bilateral hippocampal hyperintensities in DWI and in FLAIR sequences is a marker of poor prognosis [6], as is diffuse hyperintensities on these sequences [7] or a decrease in fractional anisotropy (a DWI measure reflecting brain water diffusion measured in three directions with a lower number indicating less restricted diffusion due to impaired white matter integrity) in selected regions of the white matter [8].

Other conditions

In a general context, CT should be performed as an emergency in cases of a new focal neurological deficit, persistent altered mental status, or partial-seizure onset for adults above 40 years old. This is especially so in the presence of fever, recent trauma, history of cancer, anticoagulant use, or suspicion of AIDS. MRI should be performed first if a cerebellar, brainstem, or internal auditory canal lesion is suspected. It is also an excellent technique to search for intra- or extra-axial mass lesions. MRI is also very good in diagnosing inflammatory and infectious diseases, such as abscesses, empyema, and encephalitis. It can show the extent of the lesion, and its potential communication with the ventricles, vessels, and sinuses.

Imaging the spine

Traumatic lesions

If spine trauma is suspected, neuroimaging should be performed as soon as possible as urgent surgical realignment and fixation may be necessary. In asymptomatic traumatic patients, imaging of the cervical spine is not necessary if the neurological examination is strictly normal, if the patient is not intoxicated, if there are no complains of cervical pain or midline tenderness, and if there are no other major injuries related to the trauma that might distract the patient [9]. In the emergency department, although the plain radiographies may rule out major cervical spine injuries [10], patients with major trauma should usually undergo whole body CT, as the cervical, thoracic, and lumbar spine can thus be imaged at the same time. CT scanning is highly effective and superior to MRI for studying bone structures. MRI is better to study the soft tissues around the spine and, more importantly, allows a high-resolution study of the spinal cord, which is of paramount importance in cases of compression (especially if caused by intraspinal haematomas, ligament damage, or a prolapsed disc—all conditions in which plain radiography and CT scan can be near-normal). The indications for spine CT scan in the traumatic setting are a history of major trauma, especially in the presence of impaired consciousness, physical signs of spine trauma, a history of distracting mechanism of injury and the presence of neurological signs and symptoms. Spine fractures are often complex and may require surgical stabilization. The extent of spinal cord damage and oedema on MRI is correlated with functional outcome.

Non-traumatic lesions

In the setting of non-traumatic spinal cord lesions, MRI is the most informative imaging technique, as it allows a good evaluation of the spinal cord. It should be performed early, as compressive lesions require urgent surgery. Specific appearance of the lesions on different MRI sequences, potential enhancement, and location will help in differentiating aetiologies, from inflammatory demyelinating and infectious processes to ischaemia and vitamin deficiency. A practical diagnostic work-up algorithm using spinal cord MRI has recently been proposed [11]. The prognosis will mainly be related to the etiology, and in the case of non-traumatic compression of the spinal cord, to the rapidity of the neurosurgical management.

PART 9.3

Sleep disturbance

CHAPTER 225

Pathophysiology and therapeutic strategy for sleep disturbance in the ICU

Louise Harder and Atul Malhotra

Key points

- Sleep is an essential homeostatic function.
- Sleep disturbance can lead to impaired neurocognitive and cardiometabolic function.
- Sleep apnoea is a common condition which can affect pharmacological and airway management in the ICU.
- Sleep disturbance in the ICU may contribute to delirium.
- Patient ventilator dyssynchrony may contribute to sleep disruption in the intensive care unit.

Introduction

The topic of sleep in the intensive care unit has been receiving increasing attention in recent years, but remains poorly studied. Robust data support the impact of sleep deprivation and sleep fragmentation on various health outcomes in outpatient populations [1]. However, the relevance of these data to critically-ill patients remains unknown. This review summarizes the currently available literature, recognizing that some of the information provided is extrapolated from best available evidence [2].

Sleep is an essential function of the body, which when disrupted has health consequences. Sleep can be disturbed in a variety of ways including insufficient sleep duration (sleep deprivation) and sleep fragmentation, e.g. as seen in obstructive sleep apnoea (OSA) or with repetitive environmental stimuli. Sleep deprivation in outpatients has well established neurocognitive and cardiometabolic sequelae. For example, sleep deprivation is an important risk factor for motor vehicle accidents, memory impairment, and mood disturbances. In addition, rigorous data have defined an important impact of sleep deprivation on glucose tolerance [3]. Physiological studies have also shown impairment in function of other hormones, such as leptin and ghrelin, both hormones which change in a direction that stimulates appetite [4]. As such, epidemiological studies have shown increased incidence of hypertension, myocardial infarction, obesity, and all cause mortality [1]. Thus, one could reasonably hypothesize that inadequate sleep duration could have important biological effects in critically-ill patients.

Sleep disorders

Many sleep disorders have important health effects, but respiratory abnormalities, e.g. OSA are the most relevant for the intensivist. OSA is a very common condition characterized by repetitive collapse of the pharyngeal airway, resulting in sleep fragmentation, recurrent desaturations, and catecholamine surges [5]. The condition is estimated to affect roughly 5% of the USA population and is likely increasing in prevalence due to increasing obesity and the ageing population. OSA has important consequences, including risk of motor vehicle collisions and incident cardiovascular disease. Although randomized trial data are still evolving, nasal continuous positive airway pressure (CPAP) is the treatment of choice as it has been shown to reduce daytime sleepiness and blood pressure, and probably also reduces the risk of motor vehicle collisions and cardiovascular events [6].

Despite the high prevalence, OSA remains underappreciated, with estimates of 80–90% of disease remaining undiagnosed [7]. Given the associated comorbidities of OSA, including diabetes, obesity, and hypertension, patients with OSA are at risk of critical illness and thus knowledge of OSA is important to the intensivist. The following concepts should be emphasized:

- Patients with OSA are at increased risk of peri-operative complications [8], including an increased risk of respiratory failure, prolonged intubation, and delayed discharge. A large study assessing patients undergoing bariatric surgery found that OSA was an independent risk factor for post-operative complications [9]. As patients with OSA are particularly sensitive to hypnotics and analgesics, careful attention to pharmacology is required to avoid hypoventilation and respiratory compromise. At present, the data fall short of showing a definitive reduction in peri-operative risk with CPAP therapy in patients with OSA, although investigative efforts are ongoing in this area.
- Patients with OSA frequently have difficult airways, which can complicate intubation and lead to failure of extubation. Many risk factors for difficult intubation traditionally used by anaesthesiologists (such as Mallampati score, retrognathia, and neck circumference) are also predictive of OSA. As such, experienced anaesthesiologists frequently recognize patients as challenging,

even if a formal diagnosis of OSA has not been made. Following extubation, it is likely that upper airway dysfunction contributes to recurrent respiratory failure. Thus, one mechanism underlying the well-established benefit of non-invasive ventilation post-extubation in high risk patients may be via distending the upper airway by raising its transmural pressure [10].

- Obesity hypoventilation syndrome (OHS) occurs in roughly 10% of patients with OSA. Almost half of patients with OHS present with acute hypercapnic respiratory failure, emphasizing the role of the intensivist in managing such patients. Appropriate initial diagnosis and management followed by long-term non-invasive ventilation or CPAP generally results in good outcomes.
- Sleep apnoea can be important in patients with acute congestive heart failure (CHF). OSA has been observed in more than 50% of patients with acute CHF and treatment with nasal CPAP has been shown to improve left ventricular ejection fraction both in the acute setting and in the longer term [11].
- Patients with OSA are at greater risk of cardiovascular complications particularly during the night with an increased propensity for sudden cardiac death and myocardial infarction during the night time, as compared to the usual 10.00 hours peak seen in patients without OSA [12]. Patients with OSA are also at risk of atrial and ventricular tachyarrhythmias often in temporal association with breathing abnormalities. However, the link of OSA to bradyarrhythmias and complete heart block is more controversial. Data suggest that treatment of OSA can decrease cardiovascular risk, including the risk of arrhythmias. Given that CPAP compliance is quite variable, we recommend that treatment, in addition to CPAP, address cardiac issues directly for optimal patient care.

Sleep fragmentation in the ICU

Although OSA is characterized by sleep fragmentation, its consequences are also probably related to recurrent desaturations and catecholamine surges. As such, sleep fragmentation, which can occur in critically-ill patients, may or may not have similar sequelae to OSA. Indeed, there are a variety of issues underlying sleep disturbances in ICU patients (see Table 225.1).

Studies of sleep in the ICU have documented poor sleep quality characterized by minimal slow wave sleep and rapid eye movement (REM) sleep and recurrent arousals from sleep [13]. However, standard EEG criteria for sleep staging may be hard to implement in the critically ill. For example, sleep spindles (one of the hallmark findings of stage 2 non-REM sleep) can be induced with benzodiazepines. Thus, a distinction between sedation and sleep can be quite challenging. Similarly, delta wave activity is used to define slow wave sleep (or N3 non-REM sleep), but can also be seen in encephalopathy. The discussion of sedation versus sleep becomes quite complex due to these issues around defining accurate stages of sleep. We would emphasize that a sedated patient may not receive the beneficial effects associated with natural sleep. While some data support reduced sleep drive following propofol anaesthesia in sleep-deprived animals, the clinical relevance of these data is unclear [13].

Insights into the sleep versus sedation controversy have been provided through basic neurobiology. The ventrolateral pre-optic area (VLPO) of the hypothalamus is thought to be the critical centre for the control of sleep. Lesions to the VLPO can produce insomnia [14]. Various anaesthetic agents, therefore, can be tested in VLPO-lesioned animals to understand the potential role of sleep pathways in determining the response to medications. For example, dexmedetomidine is thought to work through sleep centres, and thus is considered by some to be inducing pharmacological sleep, rather than sedation. In contrast, other anaesthetic agents probably work through non-specific GABA inhibition of neurons and exert their effects via pathways independent of VLPO. Indeed, some randomized trial data have suggested that dexmedetomidine may improve clinical outcome compared with benzodiazepine infusions, although the role of sleep homeostasis in determining these findings is unknown [15].

Delirium

The importance of delirium in the ICU has recently been emphasized based on data showing an association with increased mortality.

Table 225.1 Causes of sleep disturbance in ICU patients

Factor	Issue	Solution
Excessive noise	Disrupts sleep, particularly with changes in noise levels	Silence unnecessary alarms Minimize conversations, etc., during night time Consider earplugs
Bright light	Disrupts circadian rhythms, suppresses melatonin	Maintain light/dark cycle Consider melatonin supplementation
Reduced total sleep time	May affect metabolic and immune function	Provide adequate dark time Discharge from ICU as soon as possible
REM suppression	May be risk factor for delirium	Unclear
Patient/ventilator asynchrony	Can fragment sleep, increase respiratory efforts/dyspnoea	Careful bedside assessment Provide optimal flow delivery, triggering sensitivity Consider proportional assist ventilation
Air leak during non-invasive ventilation	Can fragment sleep	Optimize interface

The mechanisms underlying delirium are complex, but may relate at least in part to disruption of sleep. Trompeo has shown that severe suppression of REM sleep is associated with increased incidence of delirium [16]. However, as yet, there are no convincing data demonstrating that interventions to improve sleep yield a reduction in delirium in the ICU. Indeed, benzodiazepines are a risk factor for delirium [15], emphasizing the need for alternative medications and non-pharmacological approaches to optimizing sleep. Randomized trials are ongoing to study optimized treatment of delirium and to assess its impact on longer term outcomes, such as neurocognitive performance, sleep, and post-traumatic stress disorder. Such data will be critical to defining the causal pathways in ICU patients.

Mechanical ventilation

Patient–ventilator dyssynchrony can be a source of discomfort and recurrent awakenings. Pleural pressure is thought to be the trigger for arousal from sleep based on observations that individuals wake from sleep at a particular oesophageal pressure threshold, regardless of the respiratory stimulus [17]. Thus, high respiratory drive or patient efforts against high resistance can generate markedly negative pleural pressures, which may generate arousals from sleep. Optimizing ventilator triggering, positive end-expiratory pressure, and inspiratory flow profile can improve synchrony. We have chosen three findings to emphasize:

- A randomized trial has shown improvement in sleep quality with the use of proportional assist ventilation compared with standard pressure support ventilation. The mechanism underlying this observation is unclear, but ostensibly ventilatory support commensurate with patient demands can improve synchrony [18].
- During non-invasive ventilation, air leak has been shown to disrupt sleep. The mechanism underlying this finding may relate to disruption of respiratory pattern or may simply involve facial or oral mechanoreceptors [19].
- Central apnoeas are observed when $PaCO_2$ falls below the so-called chemical apnoea threshold. Improvements in breathing patterns are observed with reductions in pressure support levels or with the addition of dead space. Thus, central apnoeas in patients being assessed for liberation from mechanical ventilation do not necessarily require return to passive mechanical ventilation with full support.

Immune function

Sleep disruption has been shown to affect immune function. Antibody titre responses following influenza vaccine are impaired in people who are sleep deprived as compared to controls. In epidemiological studies, reduced sleep duration is associated with an increased incidence of community acquired pneumonia [20]. One study in which investigators innoculated rhinovirus into healthy volunteers found an increased susceptibility to clinical infection among those who were sleep-deprived compared with controls. Furthermore, some experimental work regarding natural killer cell and T cell function has also shown important deleterious influences of sleep deprivation. At present there is a paucity of data regarding whether sleep disturbance in the ICU can contribute to ventilator associated pneumonia or other nosocomial infections.

Conclusion

Well-established therapies for sleep disorders have shown improved outcomes in the acute setting. Despite widespread recognition of the importance of natural sleep and its disturbance on well-being, there remains a paucity of information regarding the causes, effects, and effective treatment of sleep disorders in critically-ill patients. Basic questions about sleep in the ICU remain. For example, how should sleep be quantified in critically-ill patients? Does sleep disturbance in the ICU yield important consequences on clinical outcomes? Does treating sleep disruption contribute to improved outcomes in patients treated in the ICU? Some existing data support simple sleep-related interventions to improve surrogate outcome measures in critically-ill patients. The impact of interventions to improve sleep on hard clinical outcomes requires further study.

PART 9.4

Agitation, confusion, and delirium

CHAPTER 226

Causes and epidemiology of agitation, confusion, and delirium in the ICU

Eduard E. Vasilevskis and E. Wesley Ely

Key points

- Delirium is extremely common in the intensive care unit (ICU), occurring in 60–80% of mechanically-ventilated patients at some point during their ICU stay.
- Hypoactive delirium (without agitation) is far more common that hyperactive delirium (with agitation), and often goes unrecognized unless actively sought with validated delirium measurement instruments.
- The onset of delirium should prompt an investigation into underlying causative and potentially reversible factors. These include medications, untreated pain, and untreated infections.
- Benzodiazepines are a common risk factor predisposing to and prolonging delirium in the ICU. Alternative analgesic and sedative agents should be considered prior to the use of benzodiazepines.
- Early mobility is a process of care that is protective against delirium. Successful mobility protocols include standard safety parameters, begin therapy as early as 24 hours following ICU admission, and include mechanically-ventilated patients.

Introduction

The presence of agitation, confusion, and/or delirium is common in the intensive care unit (ICU), occurring in 60–80% of mechanically-ventilated patients, and 40–60% of non-ventilated patients. Often their presence signifies evidence of acute end organ injury and is precipitated by a variety of underlying aetiologies. The vulnerability of the patient and the severity of the predisposing insult impact both the epidemiology, as well as the causes of agitation, confusion, and delirium.

Definitions

Agitation, confusion, and delirium are separate yet related conditions that are best understood when viewing through the lens of clear definitions as follows:

- **Agitation**: a disorder of excessive psychomotor activity that may include disorientation, pressured speech, labile affect, and potentially dangerous behaviours in the ICU that could lead to removal of vascular access lines, pulling at endotracheal tubes, and ventilator dyssynchrony [1].
- **Confusion**: an abnormality in orientation, memory, and/or thought process. Confusion by itself may be acute or chronic. A confused patient may be agitated, sedated, or have a normal level of consciousness.
- **Delirium**: a form of acute brain dysfunction that is characterized by inattention, cognitive impairment, and alterations in consciousness [2]. Additional, although less common, features of delirium include hallucinations, delusions, and labile affect. Depending upon the level of consciousness, delirium can be either hyperactive (with agitation), hypoactive (with sedation), or mixed [3], with the latter two categories occurring most frequently in the intensive care unit.

The conditions listed above are not mutually exclusive (Fig. 226.1). Agitated patients may or may not be delirious, although all should be formally assessed for the presence of delirium. Alternatively, agitation may be a patient response to pain, anxiety, drug withdrawal, or psychosis. Importantly, delirious patients may not be agitated, with a majority being sedated or only intermittently agitated.

The remainder of this chapter will focus on delirium since it includes a significant proportion of agitated patients, is commonly missed by practitioners when validated measurement instruments are not used (this is particularly true for hypoactive delirium) [4], and is associated with increased health care utilization, and increased risk of both death and long-term cognitive impairment [5,6].

Pathophysiology of delirium

Just as hypotension reflects cardiovascular system dysfunction and decreasing urine output reflects renal system dysfunction, ICU delirium reflects acute dysfunction of the nervous system. Delirium is the end product of a sequence of insults and injury that lead to a common measurable manifestation of end-organ brain injury. Delirium does not have a single aetiology, but rather has multiple different and potentially interacting aetiologies. Recent studies have implicated inflammation [7] and metabolic derangements of neurotransmitters [8] in the development of delirium. Other factors may include abnormalities in cerebral blood flow, endothelial dysfunction, pain, and toxic effects of medications.

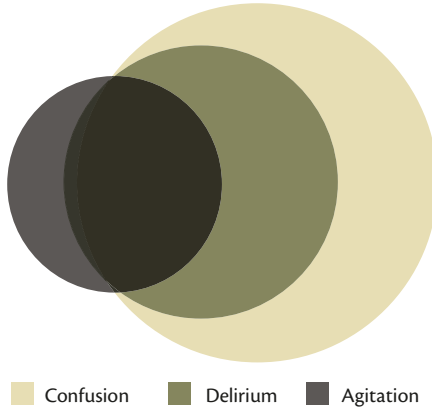

Fig. 226.1 Agitation, confusion, and delirium.

Epidemiology of delirium

Delirium can be assessed in a variety of different ways. The most common method is to report the period prevalence of ICU delirium, which is the frequency at which patients experience at least one day of delirium during their entire ICU stay. When period prevalence is considered, it is estimated that between 60 and 80% [6,9] of mechanically-ventilated, and between 40 and 60% of non-ventilated patients will experience at least one day of delirium during their ICU stay. When one considers only the first 24 hours of ICU admission, the point prevalence is between 20 and 40% [10]. The cumulative incidence of delirium depends upon the inclusion or exclusion of patients identified with delirium in the first 24 hours, and therefore may be equivalent to the period prevalence reduced by 20–40%, respectively.

The epidemiology of ICU delirium is also population dependent, and leads to variable reports of prevalence and incidence. For example, the consideration of coma is an important factor. Coma incidence is mutually exclusive from delirium, and is one of the strongest risk factors for subsequent development of delirium [11]. Studies, therefore, that exclude patients admitted with coma lead to reduced reports of prevalence and incidence of delirium [12]. In addition, studies with a higher proportion of patients with persistent coma (i.e. delirium could not be measured during the patient's entire ICU stay), will likely under-represent the degree of acute brain dysfunction among the studied cohort of patients. Populations with increased burden in other risk-factors (e.g. mechanically-ventilated patients with sepsis), will similarly report increased measures of both prevalence and incidence of delirium [6]. In addition, delirium epidemiology may be less accurate among populations in whom accurate assessments of delirium is difficult (e.g. those with sensory impairment, language barriers, or neurological deficits) or who have clinical features that may also be present among delirious patients (e.g. psychomotor retardation in patients with depression or dementia).

A final consideration of ICU delirium epidemiology includes whether validated screening instruments were used, the instrument selected, and the training received by those using the instrument. Each instrument (e.g. CAM-ICU or ICDSC) has unique test characteristics and minimum training requirements for reliable measurements.

Regardless of the population, it is critical to understand that the prevalence and incidence of hypoactive delirium, or mixed hypo/hyperactive delirium far exceeds that of hyperactive (e.g. agitated) delirium alone [3]. This is why the use of validated instruments for measurement is critical in the ICU, because without such instruments up to 70% of cases of delirium are not recognized [4]. The high false negative clinical diagnosis of delirium is in large part due to the high prevalence of hypoactive delirium.

Causes of delirium

Delirium is a syndrome, and reflects end organ dysfunction that results from a variety of unique and likely interacting pathways. Currently, it is felt that the development of delirium depends upon a combination of host vulnerability, regarded as predisposing factors combined with the severity of a specific insult. A highly vulnerable patient may require a minimal insult, whereas a resilient patient requires a severe insult to precipitate delirium.

Non-modifiable risk factors for ICU delirium

A patient's given vulnerability is described by their predisposing (i.e. non-modifiable) risk factors. These include prior comorbidities, demographic factors, genetic factors, as well as the specific acute illness for which the patient was admitted. Among comorbidities, prior cognitive impairment is among the most important [12,13]. Age is an important demographic factor, although less consistently associated with ICU delirium [14]. Both dementia and age will become increasingly important risk factors as the number of elderly patients and patients with dementia cared for in ICUs grows worldwide. Few genetic factors have been investigated, although apolipoprotein E4 is a genetic marker that has been associated with incident delirium [15]. Finally, the severity of the presenting illness plays an important role in predisposing patients to delirium. A patient that presents with higher severity of illness (e.g. sepsis or coma) is at far greater risk for the development of delirium [11,14]. For example, over 80% of patients that are admitted to the ICU in a comatose state and are discharged alive will at some point transition from a comatose state into a delirious one [6,10].

Modifiable risk factors for ICU delirium

Whereas the predisposing factors are largely non-modifiable, other factors may be more directly influenced by the clinical decision making and processes of care in the ICU. Attention to these factors may potentially prevent or decease the duration of delirium among ICU patients.

The most consistently described risk factor for incident and prolonged delirium is the choice of sedative, and most notably the use of benzodiazepines [9,13,14,16,17]. Importantly, the risk of ICU delirium is dose dependent, with up to 100% of patient that receive daily lorazepam equivalents of 20 mg or more experiencing delirium [14]. Similar relationships have been seen with midazolam. Dexmedetomidine is a newer sedative therapy, that when compared with benzodiazepines, reduces the risk for incident delirium [16,17]. This either supports a beneficial effect of dexmedetomidine, and/or supports the previously described harmful effect of benzodiazepines. There are limited data regarding the

effects of propofol on incident delirium. Opiate medications are another medication class that has been implicated in some investigations, but results have been inconsistent, and may depend upon the patient population studied (e.g. trauma, surgical, or medical) [9,14]. The role of opiates is complicated because under-treatment of pain is recognized as a risk factor for delirium, and should be treated when identified. Antipsychotics, both typical and atypical, have not been shown consistently to be either protective or harmful for incident delirium in the ICU despite their common use for treatment of delirium [18].

Non-pharmacological factors play an equally important role in impacting the risk for ICU delirium. Early mobilization is an important example of a practice that demonstrates great potential in the prevention of delirium, reducing the duration of delirium by a median of 2 days [19]. The mechanism of protection is unclear, but may include reduction of sedative agents by means of scheduled interruption of sedation, cognitive activation during exercise, and direct neuroprotective benefits associated with exercise. Additional non-pharmacological practices that deserve the ongoing attention include the removal of unnecessary lines and catheters [12] and interventions that improve the quantity and quality of sleep in the ICU, such as the use of earplugs [20].

Overall, when approaching a patient with ICU delirium, it is important to first recognize that there is a new acute end organ injury that signifies a new or worsening process. Clinicians may use the mnemonic '**THINK**' to exclude or treat possible underlying causes (see Chapter 227, 'Assessment and Therapeutic Strategy for Agitation, Confusion, and Delirium in the ICU', for an explanation of this). This should lead to a focused physical exam including neurological assessment, laboratory and medication review, and investigation of any underlying infectious or other acute medical condition.

Conclusion

Confusion is a non-specific, and non-diagnostic term to describe a patient with a wide range of symptoms, from memory impairment to disorientation. Agitation embodies an increased level of psychomotor activity and anxious or aggressive behaviour. Many agitated patients may also be delirious, yet they represent a minority of all delirious patients. Both predisposing and precipitating risk factors play important roles in the development of delirium. Cognitive impairment and age are among the most important predisposing risk factors, whereas benzodiazepine use and immobility are common modifiable factors. Recent trials suggest that dexmedetomidine may reduce the risk of delirium when compared to benzodiazepines. Promising non-pharmacological protective factors include early mobilization and sleep protocols. The onset of delirium should prompt the physician to THINK and investigate for the underlying cause(s).

CHAPTER 227

Assessment and therapeutic strategy for agitation, confusion, and delirium in the ICU

Michele C. Balas and E. Wesley Ely

Key points

- Without routine monitoring, delirium often goes unrecognized in the critical care setting.
- A number of easily-administered, valid, and reliable agitation/sedation and delirium screening tools are available for use in critically-ill adults.
- The treatment of agitation and delirium in the intensive care unit (ICU) setting begins with prompt recognition and removal of the underlying cause of the disorder.
- Delirium most often occurs as a direct physiological consequence of a new medical condition or substance intoxication, withdrawal, or side effect.
- The role antipsychotic medications play in the prevention and treatment of ICU delirium has yet to be determined. In terms of pharmacological management of ICU delirium, the question is not necessarily what medication to give, but which to discontinue.

Introduction

During their time in an intensive care unit (ICU), critically-ill patients frequently experience fluctuations in their level of consciousness, experience various emotions, such as fear, isolation pain, and anxiety, and display a variety of psychomotor behaviours including both hypo- and hyperactivity. Without routine monitoring using valid and reliable pain, sedation/agitation, and delirium screening tools, it is often impossible for clinicians to determine the exact aetiology of their patient's mental status change or behaviour. The first step in the assessment and management of agitation, confusion, and delirium, therefore, is accurately determining which condition or syndrome the patient is experiencing.

Agitation, confusion, and delirium assessment

Agitation, a psychomotor disturbance characterized by a marked increase in both motor and psychological activities, occurs frequently in ICU patients and is believed to be caused by a number of factors, including pain, the inability to communicate, anxiety, drug withdrawal, and delirium [1]. Confusion is a very general term often used to describe people experiencing problems with coherent thinking. Since confusion is such a non-specific term, we will not refer to it in this chapter. The American Psychiatric Association's *Diagnostic and Statistical Manual*, 5th edn (DSM-5) [2] diagnostic criteria for delirium include:

- **Criterion A**: a disturbance in **attention** (i.e. reduced ability to focus, sustain, or shift attention) and awareness.
- **Criterion B:** the disturbance develops over a short period of time (usually hours to days), represents a change from baseline attention and awareness, and tends to fluctuate in severity during the course of the day.
- **Criterion C:** an additional disturbance in **cognition** (e.g. memory deficit, disorientation, language).
- **Criterion D**: the disturbances in Criteria A and C are not explained better by another pre-existing established or evolving neurocognitive disorder, and do not occur in the context of a severely reduced level of arousal (e.g. coma)
- **Criterion E:** there is evidence from the history, physical examination, or laboratory findings that the disturbance is a direct physiological consequence of another medical condition, substance intoxication or withdrawal, or exposure to a toxin, or is due to multiple aetiologies.

The treatment of agitation and delirium in the ICU setting historically involved the administration of high dose, often continuously infused, sedatives and narcotics, the application of physical restraints to prevent patients from harming themselves or others, and as needed (prn) intravenous antipsychotics. Numerous studies conducted over the last 20 years, indicate that this is a potentially harmful management strategy. The current, more patient-centred, focus is to use sedation/agitation and delirium assessment tools and management protocols aimed at achieving 'light' levels of sedation. Beneficial outcomes linked to the use of such protocols in controlled studies include shorter duration of mechanical ventilation, lower mortality rates, more 'on-target' sedation, less pain and agitation, reduced direct drug costs, lower tracheostomy rates, and decreased incidence of ventilator associated pneumonia, with few negative outcomes reported [3].

Sedation/agitation screening tools

A necessary component of protocol-directed sedative administration, and mental status examination in general, is the use of appropriate sedation/agitation rating scales. While a number of these scales have been developed for use with critically-ill patients, the two most widely used include the Richmond Agitation-Sedation Scale (RASS) [4] and the Sedation Agitation Scale (SAS) [5]. The RASS consists of a 10-point scale, with four levels of anxiety or agitation (+1 to +4 with a higher score indicating greater anxiety or agitation), one level to denote a calm and alert state (0), and five levels of sedation (–1 to –5 with a more negative score indicating deeper sedation). The SAS consists of a 7-point scale, with three levels of agitation (5–7 again with a higher score indicating greater agitation), one level to denote a calm and co-operative state (4), and three levels of sedation (3–1 with the lower score indicating deeper sedation). Each tool requires administrators to first observe the patient's behaviour, assess their responsiveness to verbal commands, and if not responsive, to assess their response to a physical stimulus. Both scales are quickly and easily administered, demonstrate good reliability and validity, and have been used with patients in a variety of critical care settings.

ICU delirium screening tools

In addition to disturbances in consciousness and cognition, critically-ill patients experiencing delirium often present with a variety of other signs and symptoms (Box 227.1). This variability in presentation makes accurate diagnosis challenging, particularly in mechanically-ventilated patients who cannot speak. While psychiatric evaluation remains the 'gold standard' for delirium diagnosis, this approach is often impractical in critical care settings due to the large number of patients at risk for developing this syndrome.

To address these issues, the use of standardized delirium screening tools is advised by several international organizations. While a number of tools have been developed for use in mechanically-ventilated and non-ventilated patients in ICU, the two most widely used, easily administered, valid, and reliable tools include the Confusion Assessment Method-ICU (CAM-ICU) [6] and the Intensive Care Delirium Screening Checklist (ICDSC) [7]. The CAM-ICU defines delirium in terms of the four DSM-V diagnostic features. Delirium is deemed present when a patient displays an acute change or fluctuating course of mental status (Feature 1), inattention (Feature 2), and **either** an altered level of consciousness (Feature 3), **or** disorganized thinking (Feature 4). Attention is assessed with either visual or auditory components, including picture recognition or hand squeezing to a series of letters. A current RASS score of anything other than 0 is considered evidence of an altered level of consciousness. Finally, disorganized thinking is assessed by having the patient respond to a series of 4 yes/no questions and performing a simple command. Patients unresponsive to verbal stimulation (i.e. RASS score of –4 or –5) cannot be screened for delirium with the CAM-ICU.

The ICDSC contains eight items based on DSM criteria and features of delirium including altered level of consciousness, inattention, disorientation, hallucination or delusion, psychomotor agitation or retardation, inappropriate mood or speech, sleep/wake cycle disturbance, and symptom fluctuation. The scale is completed based on information collected from an entire 8-hour period or from the previous 24 hours. Each item is scored as either 1 (present) or 0 (absent). A total score of 4 or greater is considered to indicate the presence of delirium.

Box 227.1 Additional manifestations and associated features of delirium

- **Disturbance of consciousness:**
  - Reduced clarity and awareness of environment.
  - Distracted by irrelevant stimuli.
  - Engagement in conversation difficult.
- **Changes in cognition:**
  - Impairment in memory (most commonly recent).
  - Disorientation (usually time or place).
  - Language disturbances (e.g. dysarthria, dysgraphia, rambling or irrelevant speech).
- **Perceptual disturbances** (e.g. hallucinations, illusions, misinterpretations, or delusions).
- **Associated features**:
  - Disturbance in sleep/wake cycle.
  - Disturbed psychomotor behaviour (both hypo- and hyperactivity).
  - Emotional disturbances (e.g. fear, depression, anxiety, irritability, anger, euphoria, or apathy).
  - Situation inappropriate behaviour (e.g. calling out, screaming, or cursing).
  - Non-specific neurological findings (e.g. tremor, myoclonus, asterixis).

Implementation strategies

Without the use of valid and reliable screening tools, ICU nurses and physicians are notoriously poor at detecting delirium, at times missing the diagnosis in 75% of cases [8]. This under-recognition is significant in that it can seriously hamper early treatment and reversal of the underlying cause of delirium. Fortunately, studies, have shown that it is possible to implement delirium screening tools into everyday clinical care [9]. Interprofessional educational strategies that have been used to increase the ICU provider's knowledge of delirium assessment tools include the use on on-line, on-demand education videos, lectures, case-based scenarios, and spot checking by expert raters.

Therapeutic strategies

Identify and remove cause of delirium/agitation

The next step in the assessment and management of agitation and delirium is to determine and promptly remove the underlying cause of the disorder. The ICU team should talk with the patient's family or caregivers to determine the patient's mental status before

they were admitted to the hospital. This is an important step in differentiating delirium from the more chronic cognitive changes associated with dementia. It is important, however, for providers to be cognizant of the fact that delirium can be superimposed on dementia and that persons with dementia who develop delirium are at even greater risk for physical, functional, and cognitive morbidity. The importance of conducting a health history and physical examination in accurately determining the aetiology of delirium cannot be over-emphasized.

Delirium most often occurs as a direct physiological consequence of a new medical condition [2]. This is particularly true for older adults for whom a change in mental status is often the first 'clue' to deterioration in health status. A number of general medical conditions are associated with delirium (Table 227.1). It may be particularly helpful for ICU providers to use the mnemonic 'THINK' (**T**oxic situations and medications, **H**ypo/hyper states, **I**nfection and immobility, **N**on-pharmacological and neurological, and **K**+ (fluid and electrolyte disturbances)) when determining the likely cause of delirium [3] In all patients screening positive for delirium, a focused physical, neurological, and laboratory assessment, to determine if a new medical condition is present, is warranted.

Several illicit and prescription drugs are reported to cause delirium (Box 227.2) [2]. The most common in the ICU setting include benzodiazepines and opioids. Because critically-ill adults are exposed to numerous medications during their normal course of treatment, it is essential for providers to perform a careful medication review. Any medications identified as a potentially cause of delirium should be discontinued as soon as possible.

While it is beyond the scope of this chapter to fully discuss the assessment and management of drug withdrawal, it is important to note that delirium can also occur due to substance withdrawal. Withdrawal symptoms can develop after the cessation of heavy and prolonged alcohol use or in patients with long-term exposure to high-dose opiates or sedatives [2]. Withdrawal symptoms include

Box 227.2 Substances and medications associated with the development of delirium

Substance intoxication

- ***Commonly used in ICU setting***: sedatives, hypnotics, opioids, anxiolytics.
- ***Other***: alcohol, amphetamines and related substances, cannabis, cocaine, hallucinogens, inhalants, phencyclidine, and related substances.

Substance withdrawal

- ***Commonly used in the ICU setting***: sedatives, hypnotics, opioids, anxiolytics.
- ***Other***: alcohol.

Side effect of other medications

- ***Commonly used in the ICU setting***: anaesthetics, analgesics, anti-arrhythmics, anti-asthmatic agents, antibiotics, anticholinergics, anticonvulsants, antihistamines, antihypertensives, antimicrobials, β blockers, clonidine, corticosteroids, digoxin, diuretics, gastrointestinal medications, histamine H_2 receptor antagonists, immunosuppressive agents, other cardiovascular medications, psychotropic medications, particularly those with anticholinergic side effects.
- ***Other***: antidepressants, anti-parkinsonian drugs, antivirals, lithium, dopamine agonists, muscle relaxants, toxins including organophosphate (anticholinesterase), insecticides, carbon monoxide, volatile substances, herbal preparations.

autonomic hyperactivity, increased hand tremor, agitation, anxiety, nausea and vomiting, hallucinations or illusions, and rarely grand mal seizures [2]. Withdrawal symptoms typically develop when blood concentrations of the substance declines sharply after the substance has been discontinued. Symptoms in general can be relieved by either administering the substance from which the patient is withdrawing or the use of another CNS depressant [2]. Finally, in the absence of an obvious cause of delirium, or for patients with focal neurological findings, further testing (e.g. neuroimaging, lumbar puncture) may be warranted.

Utilize non-pharmacological measures

In older, critically-ill patients each day spent delirious in the ICU is associated with a 10% relative decrease in survival time [10], suggesting that reducing the duration of delirium should be an important goal of treatment. There is, unfortunately, a relative dearth of high quality studies examining the effect of non-pharmacological interventions on either the incidence or duration of delirium. A notable exception to this finding is the use of early mobility protocols. A strategy for whole-body rehabilitation, consisting of interruption of sedation and physical and occupational therapy in the

Table 227.2 Non-pharmacological interventions to prevent and manage ICU delirium—the PEACE acronym

Physiological	◆ Routinely monitor patient's vital signs, blood glucose, oxygen saturation, and laboratory profiles (monitor for deviations from baseline) ◆ Consider additional physiologic monitoring if applicable (i.e. telemetry to monitor QTc interval for patients receiving antipsychotic medications) ◆ Attempt to restore physiological and nutritional stability. Prevent and/or correct electrolyte disturbances and dehydration. Identify and treat infections. Consult support services as needed ◆ Consider using one-to-one observation in cases where tube/catheter dislodgement would threaten patient safety
Environmental	◆ Discontinue any unnecessary lines/tubes or equipment. If needed, consider 'camouflaging' them (e.g. abdominal binder for gastrojejunal tubes) ◆ Keep call bell in reach at all times. Use calendars/clocks to assist with orientation. Establish a consistent, structured routine ◆ Keep the environment as calm and quiet as possible with adequate light and limit noise level. Avoid frequent room changes ◆ Provide optimal level of environmental and cognitive stimulation ◆ Use music that has individual significance to help with relaxation
Activities of Daily Living	◆ Attempt to normalize sleep patterns. Use non-pharmacological sleep promotion strategies (e.g. noise reduction, use of low level lighting, avoidance of constant lighting, increase daytime activity). Avoid using diphenhydramine or benzodiazepines for sleep ◆ Provide glasses, hearing aids, or other assistive devices as needed ◆ Favour mobilization/avoid immobilization. Consider implementing early mobilization protocol and evaluation by physical and occupational therapy ◆ Assist with feeding/ADLs as needed. Initiate aspiration, safety, and fall precautions as needed
Communication/ **C**oordination	◆ *With patients:* a. Provide patient with a way of communicating their needs to staff and family (e.g. paper/pencil, communication boards, Passy Muir Valves for tracheostomies) b. Encourage patients to be involved in, and control, as much of their care as possible. Acknowledge patients feelings and fears, and provide reassurance as needed c. Use short, simple sentences; speak slowly and clearly; identify oneself by name and call patient by their preferred name. Repeat questions if needed, allow adequate time for response. Tell patients what you want done, not what not to do. Listen and observe behaviour ◆ *With family:* a. Inform significant other of patient's change in mental status and provide emotional support as needed b. Encourage scheduled visits and involvement of family and friends (for acute change in mental status it may be helpful to call in the family 24/7) ◆ *With staff:* a. Perform 'walking rounds' and discuss mental status exam with off-going care provider b. Notify charge nurse/supervisor of patients experiencing a change in mental status c. Collaborate with clinical nurse specialist and other nurses to formulate individualized plan of care for patient d. Encourage continuity of care providers or primary nurse
Education	◆ Educate staff on hazards of physical restraint use and bedrest ◆ Reinforce fact that delirium or an acute change in mental status in never '**normal**' ◆ Ensure continuity of care, and safe ICU and hospital discharge ◆ Ensure no informed consent is obtained from delirious patients ◆ Educate staff on hazards of polypharmacy

Data from Balas MC et al., 'Management of delirium in critically ill older adults', *Critical Care Nurse*, 2012, **32**(4), pp. 15–26.

earliest days of critical illness was found to be not only safe and well tolerated, but resulted in better functional outcomes at hospital discharge, more ventilator-free days, and a shorter duration of delirium [11].

A bundled approach to managing ICU acquired delirium and weakness through the use of spontaneous **A**wakening and **B**reathing trial **C**oordination, **D**elirium monitoring/management, and **E**arly mobility protocols (ABCDE bundle) has also recently been proposed in the ICU literature [12]. While based on the best available evidence, the effect this bundle has on patient outcomes has yet to be fully determined. One recent, single centre, before after trial found patients treated with the ABCDE bundle spent three more days breathing without mechanical ventilator assistance, had lower mortality rates, and had a near halving of the odds of delirium compared with patients before the bundle became standard of care [13]. It is encouraging, nevertheless, that interdisciplinary, multicomponent non-pharmacological intervention studies in patients hospitalized outside the ICU have proven beneficial [14]. Suggested non-pharmacological interventions that may be helpful in reducing ICU delirium are provided in Table 227.2.

When all else fails, consider pharmacological intervention

Maintaining critically-ill patients at a light level of sedation with non-benzodiazepine medications is associated with a number of favourable outcomes including a lower risk for delirium [15]. There are also data suggesting that critically-ill mechanically-ventilated patients sedated with dexmedetomidine may have a lower prevalence of delirium compared with those sedated with benzodiazepine infusions [16]. Despite their widespread use, however, there is little high quality evidence to support the administration of antipsychotic medications in the prevention and/or treatment of ICU delirium [15].

There have been few studies that have explored the role of antipsychotic medications in the prevention and treatment of delirium in the ICU. The first study of 105 mechanically-ventilated ICU patients found no difference in the number of days spent alive without delirium or coma in patients who were prophylactically treated with haloperidol, ziprasidone, or placebo [17]. In the second study of 36 ICU patients, researchers found that subjects treated with quetiapine compared to placebo experienced a quicker resolution of delirium [18]. In the third study, a similar decrease over time in delirium severity was noted between fixed-dose oral olanzapine and oral haloperidol in patients with delirium [19]. It is important to note that none of these studies identified serious safety concerns with the medications that were studied.

A more recent prospective, placebo-controlled blinded randomized study demonstrated that low dose intravenous haloperidol prophylaxis may reduce the prevalence of delirium in **low acuity** elderly post-operative patients who are admitted to the ICU [20]. In summary, there is little evidence that haloperidol reduces the duration of ICU delirium, there is some evidence suggesting that quetiapine may help reduce the duration of ICU delirium, and the use of antipsychotic medications in certain critically ill populations (e.g. older post-operative patients, adults undergoing cardiac surgery) may be beneficial.

Conclusion

There are several valid, reliable, and easily-administered delirium screening tools applicable for use in the critical care setting. Incorporating these tools into everyday practice will require sustained inter-professional education and a commitment to using the findings of screening to appropriately develop and/or modify patients' care. If delirium is identified, ICU providers should focus their efforts on identifying and promptly treating the underlying physiological or substance-induced causes. Non-pharmacological delirium prevention and treatment strategies, such as early mobilization, appear to be beneficial. While frequently used, the role antipsychotic medications play in the prevention and treatment of ICU delirium is yet to be determined.

PART 9.5

The unconscious patient

CHAPTER 228

Causes and diagnosis of unconsciousness

Robert D. Stevens and Joshua Kornbluth

Key points

- Changes in consciousness are seen in a range of physiological and pathological settings, including sleep, anaesthesia, brain lesions, metabolic disturbances, and complex partial or generalized seizures.
- In neurobiological terms, consciousness may be viewed as having an arousal dimension and an awareness dimension phenotypically expressed as the capacity to meaningfully integrate self or environmental stimuli.
- Loss of consciousness is associated with lesions that disrupt neuronal systems in the brainstem and diencephalon which mediate arousal, or thalamocortical, or corticocortical systems which mediate awareness.
- As there are many causes of unconsciousness, a timely and focused history and neurological examination are critical to defining the differential diagnosis.
- Care must be taken to differentiate states of unresponsiveness (e.g. locked-in syndrome) from unconsciousness.

Introduction

In the realm of medicine and biology, consciousness is generally understood as a state in which there are distinct, but interlinked arousal and awareness functions, which are necessary to process and respond to internal or external stimuli. Arousal is the overall level of responsiveness, and is analogous to vigilance or wakefulness. Awareness is the brain's ability to process self or environmental stimuli of different modalities. Isolated loss of a specific domain of awareness, such as hemispatial neglect following a non-dominant parietal lesion, will not impair awareness of other modalities and does not impact overall consciousness. Similarly, patients with receptive aphasia are impaired in their ability to interpret language and may mistakenly be viewed as having a global alteration in consciousness, although the level of awareness in other domains of consciousness may be intact [1]. The threshold for perceiving and responding to stimulus is also variable between individuals and within the same individual, influenced by both intrinsic (i.e. genetic factors, circadian regulation, and biological clocks) and extrinsic (i.e. stimulant or sedative pharmacologic compounds) variables.

The biology of consciousness

Loss of consciousness is a normal part of the sleep–wake cycle. Functional MRI studies in healthy controls have shown patterns of brain hypometabolism during sleep which are comparable with what may be seen in patients with disorders of consciousness. The key difference between sleep and pathological unconsciousness is that sleep is intrinsically reversible with stimulation. The patient with a disorder of consciousness may arouse with stimulation, but quickly returns to their baseline impaired consciousness when stimulation is withdrawn [1]. Pathological unconsciousness can be due to structural lesions or functional disturbances (Box 228.1).

Box 228.1 Differential diagnosis of coma

Primary cerebral disorders

Bilateral or diffuse hemispheric disorders

- Subarachnoid haemorrhage.
- Hypoxic-ischaemic encephalopathy.
- Cerebral venous thrombosis.
- Brain tumour.
- Central nervous system infections.
- Immunological disorders affecting the central nervous system.
- Generalized or complex partial seizures.
- Posterior reversible encephalopathy syndrome.
- Hydrocephalus.

Unilateral hemispheric disorders (with displacement of midline structures)

- Traumatic brain injury (contusions, subdural haematoma, epidural haematoma).
- Large hemispheric ischaemic stroke.
- Primary intracerebral haemorrhage.

Brain stem disorders.

- Central pontine myelinolysis.
- Compression from cerebellar lesions.

Systemic derangements causing coma

- Medication overdose/adverse effects (opioids, benzodiazepines, barbiturates, tricyclic antidepressants, neuroleptics, aspirin, selective serotonin reuptake inhibitors, paracetamol, anticonvulsants).
- Drugs of abuse (opioids, alcohol, methanol, ethylene glycol, amphetamines, cocaine).
- Exposures (carbon monoxide, heavy metals).

Toxic–metabolic

- Hypoxia, hypercapnia.
- Hypothermia.
- Hypoglycaemia, hyperglycaemic crises.
- Hyponatraemia, hypernatraemia.
- Hypercalcaemia.
- Hepatic failure.
- Renal failure.
- Wernicke's encephalopathy.
- Systemic inflammatory response syndrome, severe sepsis.

Endocrine

- Panhypopituitarism.
- Adrenal insufficiency.
- Hypothyroidism; hyperthyroidism.

Fig. 228.1 Neuronal systems responsible for arousal.
Key components of the ascending arousal system: The yellow pathway represents major inputs to the reticular nuclei of the thalamus originating from cholinergic (ACh) cell groups in the rostral pons, the pedunculopontine (PPT) and laterodorsal tegmental nuclei (LDT). These inputs facilitate thalamocortical transmission. The pathways demonstrated in red activate the cerebral cortex to make possible the processing of inputs from the thalamus. This arises from neurons in the monoaminergic cell groups, including the tuberomammillary nucleus (TMN) containing histamine (His), the dorsal and median raphe nuclei containing serotonin (5-HT), and the locus coeruleus (LC) containing noradrenaline (NA). This pathway also receives contributions from neurons in the lateral hypothalamus (LH) containing orexin (ORX) or melanin-concentrating hormone (MCH), and from basal forebrain (BF) neurons that contain gamma-aminobutyric acid (GABA) or ACh.

This may be a sustained or protracted process as in severe brain injury (e.g. trauma, stroke) or it may reverse within minutes as with syncope. Pathological unconsciousness may also be a result of a toxic or metabolic encephalopathy due to global cortical dysfunction as is the case with hepatic and septic encephalopathy

Arousal is dependent on the ascending reticular activating system (ARAS), an ensemble of neuronal systems originating the brainstem and projecting to the thalamus, hypothalamus, and basal forebrain. The ARAS is a necessary, but not a sufficient, determinant of conscious awareness, which also depends on the integrated function of brainstem, diencephalic and cortical networks (Fig. 228.1). The ARAS includes neuronal populations located in the tegmentum of the midbrain and the pons. These neurons project to the intralaminar nuclei of the thalamus and basal forebrain, which in turn project via glutamatergic and cholinergic efferents to disseminated cortical destinations. Nuclei in the upper brainstem modulate activity in the basal forebrain, thalamus, striatum, and cortex via norepinephrine, dopamine, and serotonin neurotransmission [2]. The hypothalamus also plays a major role in conscious–unconscious transitions via histaminergic outputs that are implicated in circadian regulation, and via orexin-producing neurons, which regulate arousal by modulating output from brainstem arousal centres [3,4]. Appreciation of a stimulus is not enough for consciousness; there needs to be sufficient motivation for stimuli to enter conscious awareness and be acted upon. Through lesional and functional brain imaging studies it appears that these goal-directed behaviours originate in the medial frontal and anterior cingulate cortices.

Aetiologies of unconsciousness

Aetiologies of pathological unconsciousness may be divided into structural causes and functional or metabolic ones (Box 228.1). The brainstem-diencephalic-cortical substrates of arousal and awareness have redundancy, and therefore discrete focal lesions rarely cause severe or durable derangements in consciousness [5]. Although small brainstem lesions may result in coma, they generally must involve bilateral or paramedian structures [1,6]. Alternatively, consciousness-impairing lesions disrupt communication between structures in the ARAS and their targets, as with bilateral thalamic infarcts in the 'top of the basilar' artery thrombosis. Supratentorial processes that impair consciousness tend to compress or distort diencephalic structures through herniation or excessive midline shift.

Unconsciousness may be the result of a functional derangement of systems necessary for maintaining consciousness. This is commonly associated with derangement of brain oxygen or of glucose delivery or utilization, for instance, as in hypoxia, ischaemia, hypoglycaemia, carbon monoxide, or cyanide toxicity [7]. There may be pathological changes in neuronal or astroglial function due to changes in cellular or extracellular volume, as is the case

with hyponatraemia, hepatic failure, or the dialysis disequilibrium syndrome. There may be changes in neuronal excitability as is the case with seizures, severe electrolyte disturbances, acidaemia and selected drug toxicities.

The degree of neurological impairment determined by a structural lesion or a metabolic derangement is directly linked to the time-course of the underlying disease process. A slowly growing neoplasm may produce minimal symptoms, whereas an acute haemorrhage causing the same degree of anatomical displacement may be neurologically devastating. Similarly, acute fulminant metabolic syndromes tend to produce rapid and severe alterations of consciousness, whereas chronic disorders may present with subtle changes in cognition without altering consciousness until late into the disease course [7,8].

Clinical disorders of consciousness

Classification of disorders of consciousness is made difficult both by the vast differential for these disorders and also by the use of inconsistent or imprecise nomenclature. The terms 'somnolence', lethargy', 'obtundation', 'stupor', and 'coma' are frequently used to characterize clinical phenotypes across the spectrum of impaired consciousness. **Somnolence** refers to a state of drowsiness or near-sleep; this is a normal state prior to sleep, but is pathological if protracted. Another common descriptor is **lethargy**, which denotes a state of extreme fatigue or drowsiness or abnormally prolonged sleep. Plum and Posner define **obtundation** as 'a mild to moderate reduction in alertness, accompanied by a lesser interest in the environment. Such patients have slower psychological responses to stimulation . . . and may be drowsy between bouts of sleep' [1]. **Stupor** is a 'condition of deep sleep or similar behavioural unresponsiveness from which the subject can be aroused only with vigorous and continuous stimulation' [1]. While often used, these terms lack face validity, and may not be meaningfully distinguishable. In clinical practice, it is more helpful to describe the patient's response to a provocative verbal or tactile stimulus [8].

Coma is a state in which both arousal and awareness are severely depressed. Coma is distinguished from transient causes of unconsciousness (syncope) by a duration of at least 1 hour [9]. Coma may resolve to wakefulness or may transition to the **vegetative state** (VS; also referred to as Unresponsive Wakefulness Syndrome) or the **minimally cognitive state** (MCS). As in coma, patients in VS show no evidence of environmental or self-awareness and may have spontaneous or stimulus-induced stereotyped reflexive movements, however they do have cyclic periods of eye opening without visual fixation or pursuit [5,8,10]. MCS is a term reserved for patients with a severe alteration in consciousness who have intermittent, but inconsistent behaviours indicative of self or environmental awareness [9]. VS is characterized by severely depressed function within corticothalamic/corticocortical systems, whereas in MCS there is some residual connectivity within these systems suggesting a greater potential for recovery [11].

Diagnostic approach to the unconscious patient

The first and most important step in assessing unconsciousness is a stepwise neurological examination. Examination of the acutely unconscious patient is necessarily concise and focuses on determining the underlying process, with a primary differentiation into structural versus functional or metabolic aetiologies [8]. On physical examination, particular attention must be paid to the threshold at which a response to stimulus is elicited, an assessment of brainstem function including observation of the breathing pattern, motor responses, and respiratory pattern.

Determining the threshold of responses to stimuli is most commonly achieved with a clinical tool such as the Glasgow Coma Scale (GCS) [12] or the Full Outline of UnResponsiveness (FOUR) score [13], both of which have been extensively validated in patients with coma from a variety of aetiologies (Table 228.1). GCS and FOUR facilitate communication between clinicians and are useful in grading disease severity, yet they also have significant limitations [14]. The assessment of cranial nerve function is critical in that it may have inferential value regarding neighbouring tegmental arousal systems; analysis of respiratory pattern may also help localize the brainstem dysfunction or damage. Extensor or 'decerebrate' posturing is characterized by a stereotypical adduction, extension, and pronation of the upper extremities and extension of the lower extremities, and is indicative of injury to the caudal diencephalon, midbrain, or pons. Flexor or 'decorticate' posturing is manifested by stereotypical flexion and adduction of arms and wrists with extension of lower extremities and is associated with hemispheric or thalamic damage that spares structures at or below the diencephalon [1].

The diagnostic evaluation of the unconscious patient is predicated in the first instance on the search for an aetiological diagnosis. Physiological perturbations such as hypo- or hypertension, bradycardia, respiratory pattern, and hypo- or hyperthermia, should be identified and corrected as they can be both a cause and a consequence of unconsciousness. Tests for hypoglycaemia or electrolyte abnormalities, liver function, renal function, and urine toxicology should be obtained as part of the initial assessment. Complete blood count and coagulation studies should be sent to identify a systemic infectious/inflammatory process or bleeding diathesis. Arterial blood gas should be analysed for hypoxia, hypercarbia, and acidosis. Thyroid function tests and tests of adrenal function should be sent in selected patients. Blood and urine cultures should be sent and a lumbar puncture considered for CSF analysis. Lumbar puncture can rapidly rule out CNS infection or subarachnoid haemorrhage. Brain imaging should be reviewed prior to lumbar puncture in order to assess for mass lesions, which might precipitate brain herniation.

Patients with an acute loss of consciousness whose aetiology is not immediately identified should be evaluated with computed tomography (CT). CT identifies intracranial haemorrhage, hydrocephalus, brain oedema, and compartmental shift, and may suggest stroke, abscess, or tumour [8]. Patients with persisting unexplained coma and/or absent or equivocal CT findings should be evaluated with magnetic resonance imaging (MRI). MRI is more sensitive than CT in identifying posterior fossa lesions, diffuse axonal injury, subtle changes associated with metabolic, septic, autoimmune, or infectious processes.

Patients with unexplained coma should also be evaluated with an electroencephalogram (EEG) to identify non-convulsive seizures or status epilepticus (NCSE). EEG monitoring can reveal NCSE in up to 19% of critically-ill patients being evaluated for a decreased level of consciousness [15]. EEG may also be helpful

Table 228.1 Comparison of the GCS and the FOUR score

Scale	Scoring	Advantages	Limitations
GCS	**Total score from 3 (poor) to 15 (good)** *Eye opening* 4 = Spontaneous 3 = To speech 2 = To pain 1 = None *Best verbal response* 5 = Orientated 4 = Confused conversation 3 = Inappropriate words 2 = Incomprehensible sounds 1 = None *Best motor response* 6 = Obeys commands 5 = Localizes to pain 4 = Withdrawal (normal flexion) 3 = Abnormal flexion (decorticate) 2 = Extension (decerebrate) 1 = None	Widely implemented Easy to learn Rapidly assessed	Prognostic value heavily weighted to motor sub-score No direct assessment of the brainstem Unable to identify a locked-in syndrome
FOUR	**Total score 0 (poor) to 16 (good)** *Eye response* 4 = Eyelids open or opened, tracking, or blinking to command 3 = Eyelids open, but not tracking 2 = Eyelids closed but open to loud voice 1 = Eyelids closed, but open to pain 0 = Eyelids remain closed with pain *Motor response* 4 = Thumbs-up, fist, or peace sign 3 = Localizing to pain 2 = Flexion response to pain 1 = Extension response to pain 0 = No response to pain or generalized myoclonus status *Brainstem reflexes* 4 = Pupil and corneal reflexes present 3 = One pupil wide and fixed 2 = Pupil or corneal reflexes absent 1 = Pupil and corneal reflexes absent 0 = Absent pupil, corneal, and cough reflex *Respiration* 4 = Not intubated, regular breathing pattern 3 = Not intubated, Cheyne–Stokes breathing pattern 2 = Not intubated, irregular breathing 1 = Breathes above ventilator rate 0 = Breathes at ventilator rate or apnoea	Adapted for testing responsiveness in intubated/aphasic/aphonic patients Evaluates aspects of brainstem function Able to identify patients with locked-in syndrome	Not widely implemented More complicated than the GCS, possibly more difficult to learn

in revealing characteristic patterns associated with metabolic or hepatic encephalopathy (e.g. triphasic waves) [7], herpes simplex encephalitis (temporal focus showing periodic lateralized epileptiform discharges or non-ictal sharp wave activity) [16].

Differential diagnosis of unconsciousness

The most important syndrome to be differentiated from coma is the locked-in syndrome (LIS). This results from de-efferentation with preservation of systems necessary for arousal and awareness. The classic lesion causing LIS is injury to the ventral pons just caudal to the third cranial nerve nuclei, resulting in total loss of corticospinal tract/motor function except vertical eye movements and blinking [1]. This may occur secondary to ischaemic stroke, haemorrhage or trauma. Severe neuromuscular disorders such as Guillain–Barré syndrome, botulism, and critical illness neuropathy can engender a state of de-efferentation akin to the LIS. Recently, a subset of patients has been identified who clinically appear to be in VS or MCS, but who retain elements of responsiveness when evaluated with functional MRI or EEG [17–19]; these subjects have evidence of higher-level cortical integration, which is not detectable by bedside neurologic examination—they are 'functionally locked-in' [20].

Coma must also be distinguished from **brain death**, which is the irreversible loss of all brain function, characterized clinically by the absence of consciousness, brainstem reflexes, respiratory drive and motor responses. This assessment is performed only after confounding variables are excluded. **Akinetic mutism** is a condition that may also mimic coma. This is a state of wakefulness in which patients do not move (akinesis) or speak (mutism) and do not appear to be able to respond to stimuli. This usually results from bilateral damage to the anterior cingulate gyrus, dorsal or central thalamus, basal forebrain, or midbrain [1,5,8]. **Catatonia** is psychiatric condition associated with schizophrenia, bipolar disorder, and depression. It manifests with open eyes and the apparent inability to move or purposeless activity not influenced by external stimuli. In the hyperactive subtype these patients appear agitated though this behaviour is not purpose-directed and is poorly responsive to intervention. This condition can be differentiated from coma by EEG and typically resolves with a benzodiazepine challenge.

CHAPTER 229

Management of unconsciousness in the ICU

Joshua Kornbluth and Robert D. Stevens

Key points

- Management of the unconscious patient centres on the search and treatment of the underlying cause, which may be structural or metabolic.
- Circulatory status, airway, and ventilation must be evaluated and stabilized in all cases both to prevent secondary brain injury, and to allow pursuit of diagnostic and therapeutic interventions targeted to the cause of unconsciousness.
- Physical examination may fail to identify ongoing neurological dysfunction and injury, hence selective evaluation and monitoring with non-invasive and invasive methods should be considered.
- In patients with severe TBI, current guidelines recommend ICP monitoring if GCS <9 and if there is an abnormal head CT.
- The prognosis depends on the aetiology, and should integrate available clinical and ancillary evaluations.

Introduction

The management of the unconscious patient centres on an efficient search for causative mechanisms, particularly those that can be halted or reversed by timely intervention. This task is made challenging by the non-specific nature of clinical signs and the large differential diagnosis for the causes of unconsciousness. Concurrent with the diagnostic evaluation, physiological imbalances likely to exacerbate brain dysfunction or damage must be rapidly identified and corrected. Lastly, prognostication and optimizing chances of recovery are equally important aspects of management.

Initial approach

Loss of consciousness results from either structural brain lesions or from toxic/metabolic disturbance. The initial management priority is to assess and stabilize cardiovascular, airway, and ventilatory status. Endotracheal intubation and mechanical ventilation is recommended unless the underlying aetiology of acute unconsciousness can be immediately identified and reversed. Systemic arterial hypertension, especially with associated bradycardia, should arouse concern for intracranial hypertension, yet it may also be the principal aetiological factor, as in intracerebral haemorrhage (ICH) or posterior reversible encephalopathy syndrome. For unconscious patients with traumatic brain injury (TBI) or those in whom trauma cannot be ruled out, the neck should be immobilized until stability of the cervical spine is confirmed clinically (i.e. after return of consciousness) or by imaging. For an overview of management of the acutely unconscious patient refer to Fig. 229.1 [1].

Physical examination

Physical examination must be directed and succinct. Assessment of coma centres on detailed evaluation of brainstem function and motor responses [2]. Different scoring systems exist to estimate the level of wakefulness. Best known are the Glasgow Coma Scale (GCS) based on an assessment of motor, verbal and eye responses, and the Full Outline of UnResponsiveness (FOUR), which incorporates cranial nerve reflexes and breathing patterns [3]. The remainder of the physical examination should evaluate for diagnostic signs: examination of the head and neck (e.g. meningismus), the extremities (e.g. Kernig's or Brudzinski's signs) the optic fundi (e.g. subhyaloid or vitreous haemorrhage in subarachnoid haemorrhage), and the skin (e.g. purpuric lesions in meningococcal meningitis).

Metabolic coma

Metabolic disturbances can cause dramatic alterations in consciousness (Table 229.1). Hence initial assessment should include measurement of core body temperature, serum glucose, and electrolyte concentrations, and a urine or serum toxicology screen. Additionally, the clinician should consider empiric thiamine and specific pharmacological antagonists, such as naloxone, where appropriate.

Seizure activity is identified in patients with rhythmic, repetitive, twitching or jerking movements of the head, face, eyes, or limbs, which resolves with administration of an intravenous benzodiazepine. A substantial proportion of unconscious critically-ill patients may have non-convulsive seizures or status epilepticus (StE NCSE), which may only be identified with an EEG [4].

Patients with suspected meningitis or encephalitis must be treated with appropriate empiric antimicrobial therapy. Loss of consciousness may also supervene in a subset of patients with a remote, non-neurological source of infection. Sepsis-associated

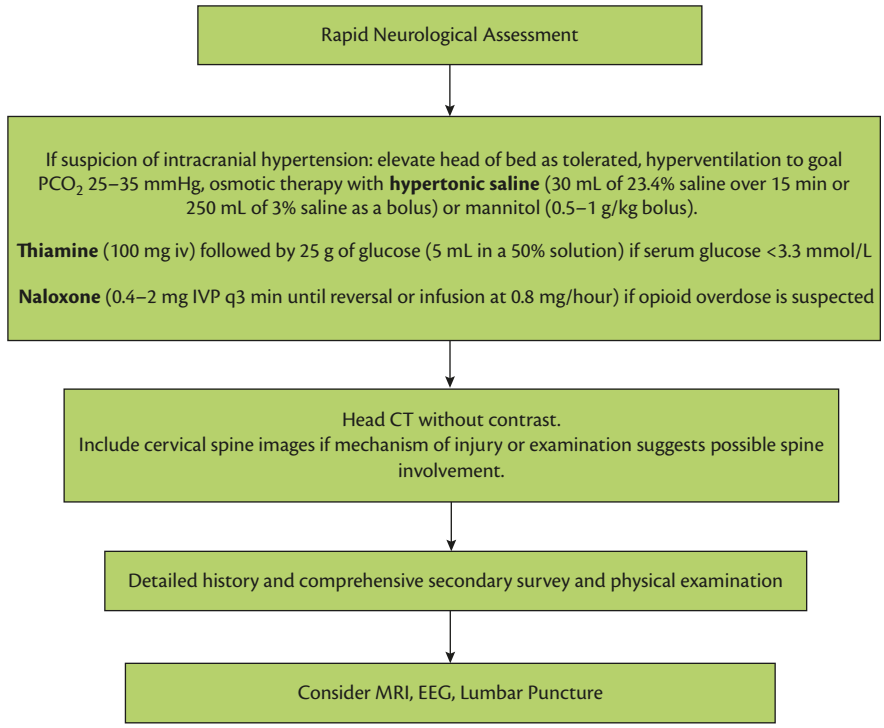

Fig. 229.1 Algorithm for management of the acutely unconscious patient.

IVP, intravenous push.

Table 229.1 Common causes of toxic-metabolic encephalopathy

Aetiology	Diagnostic studies	Management options or principles
Sepsis-associated encephalopathy	Infectious source identification, exclude meningoencephalitis	Antimicrobial therapy, source control
Hepatic encephalopathy	Liver function tests, serum ammonia, head computerized tomogram	If acute, treatment of cerebral oedema and intracranial hypertension. Consider N-acetyl cysteine Both acute and chronic, agents to decrease ammonia (i.e. lactulose, rifaximin)
Hyponatraemia	Serum and urine sodium concentration; serum and urine osmolalities	Rate of correction depends on chronicity of hyponatraemia; in general increase the serum sodium concentration by 4–6 mmol/L and by less than 9 mmol/L in any 24-hour period and less than 18 mmol/L in any 48-hour period
Hypernatraemia	Serum and urine sodium concentration; serum and urine osmolalities	Correct severe hypernatraemia by 1 to 2 mmol/L/hour to avoid cerebral oedema
Uraemic encephalopathy	Serum creatinine and urea	Renal replacement therapy
Hypoglycaemia	Serum glucose	Bolus iv 25–50mg glucose
Wernicke's encephalopathy	Classic triad of confusion, ataxia and ophthalmoplegia High index of suspicion, especially in nutritionally deficient populations (chronic alcoholics, advanced cancer, bariatric surgery)	Intravenous thiamine repletion
Hypoxic-ischaemic encephalopathy	Electoencaphalogram (EEG), somatosensory-evoked potentials (SSEPs), magnetic resonance imaging (MRI)	Therapeutic hypothermia
Toxidrome	Identification of toxic ingestion	Activated charcoal if recent oral intake and to disrupt hepatoenteric recirculation Antidotes/antagonists if available

is managed with source identification and control, antimicrobial therapy, and rigorous supportive measures.

Structural coma

When the cause of acute unconsciousness cannot be identified and reversed within the first minutes, the patient should undergo endotracheal intubation and a computed tomography (CT) of the head obtained immediately. Structural abnormalities associated with loss of consciousness include lesions in the arousal systems located in the rostral brainstem and diencephalon, unilateral hemispheric lesions with sufficient mass effect to affect the arousal systems, or lesions involving bilateral cerebral hemispheres [2]. In cases when a structural cause is not identified or well characterized with CT, brain MRI should be considered, in particular if acute cerebral ischaemia or infarction is a diagnostic consideration.

Loss of consciousness is a presenting sign in acute transtentorial herniation [2,5], and there is a correlation between the degree of lateral displacement of midline structures and the severity of alteration of consciousness [6]. The time-course during which midline structures are displaced will determine the likelihood and degree of alteration of consciousness (Fig. 229.2). Evidence of acute clinical herniation and/or increased intracranial pressure (ICP) (e.g. hypertension, bradycardia, apnoea) should be managed with hyperosmolar therapy, hyperventilation, and sedation to control brain oedema and cerebral blood volume, while surgical decompression options are explored [7]. For an overview of this approach refer to Fig. 229.3. If acute obstructive hydrocephalus is identified, emergent placement of an intraventricular catheter is indicated.

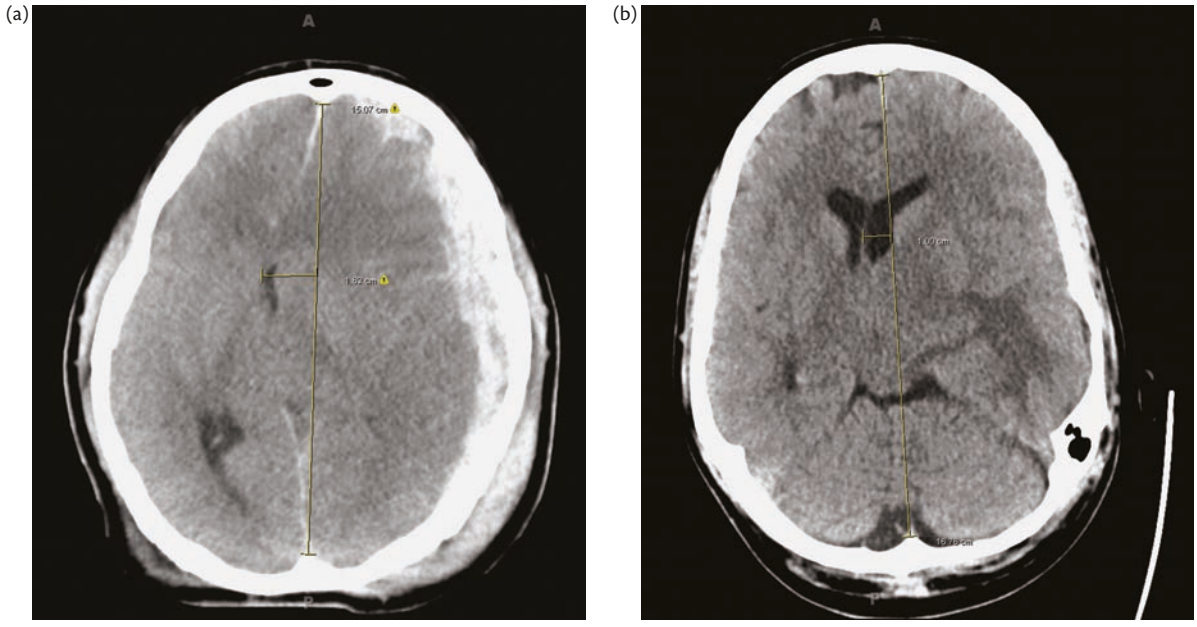

Fig. 229.2 (a) Non-contrast head CT of a 58-year-old patient with an acute left-sided subdural haematoma with resultant 1.8 cm of midline shift at the septum pellucidum—this patient had a GCS of 3. (b) Non-contrast head CT of a 67-year-old patient with a left-sided glioma with 1 cm of midline shift at the septum pellucidum—this patient had a GCS of 15.

Role of neuromonitoring

In patients with severe brain injury, perturbations in brain physiology and metabolism may not be apparent on physical examination, hence the need for neurophysiological monitoring. Continuous electroencephalography, somatosensory-evoked potentials (SSEP) and brainstem auditory-evoked responses are valuable electrodiagnostic modalities, which have established roles in the diagnosis and prognosis of unconscious patients. Other commonly used methods are ICP monitoring, cerebral microdialysis, and brain tissue oxygen monitoring.

Continuous EEG (cEEG) is indicated in unconscious patients to identify non-convulsive seizures or status epilepticus, and to monitor response to anti-epileptic drug therapy. Continuous EEG monitoring is also useful in pharmacologically-induced coma for treatment of refractory intracranial hypertension where burst-suppression is the goal. Selected patterns on EEG (e.g. burst suppression, lack of stimulus-evoked background reactivity) have significance in patients with anoxic-ischemic encephalopathy following cardiac arrest [8]. Non-convulsive seizures or (NCSE) may occur in up to 19% of patients after SAH, 21% of patients after ICHm, 11% after ischaemic stroke, 18% of patients after TBI, and as many as 35% of patients following cardiac arrest [9].

In patients with severe TBI, current guidelines recommend ICP monitoring if GCS <9 and if there is an abnormal head CT [10]. Increased ICP may cause permanent injury, both by direct effect of pressure on brain structures with subsequent herniation and by cerebral infarction via global or regional reductions in cerebral perfusion pressure (e.g. posterior cerebral artery occlusion resulting from transtentorial herniation). The role of routine ICP monitoring in other clinical settings is less well studied however a recent international multidisciplinary consensus conference recommended that ICP and CPP should be monitored in patients at risk for ICP elevation based on clinical and/or imaging features, and to guide medical and surgical interventions [11]. Cerebral oxygenation may be measured globally via sampling of jugular bulb oximetry whereas regional oxygenation may be assessed via an invasive probe that measures brain tissue oxygen tension (PbO_2). Evidence indicates that low values of PbO_2 are associated with adverse TBI outcome [12] and that decreased PbO_2 may occur independently of ICP changes [13]. Cerebral microdialysis allows near real-time monitoring of dynamic changes in brain neurochemistry, which can be influenced through physiological or metabolic intervention. Microdialysis-derived markers of cerebral metabolic distress, including elevated brain interstitial lactate-pyruvate ratio and low glucose, are independently associated with long-term neurological recovery after TBI [14].

Prognosis

In patients with acute loss of consciousness, prognosis is dependent on the underlying aetiology. Hypoglycaemic coma, for instance, will have an excellent prognosis if rapidly recognized and reversed. The most common aetiologies of coma are hypoxic/ischaemic injury following cardiac arrest and severe TBI, each of which carries a significant risk of death or long-term disability [2]. In both settings, prognosis relies on features of the neurological examination, anatomical and physiological changes identified with neuroimaging, abnormalities detected with electrodiagnostic methods, as well as physiological and biochemical imbalances at both the brain and systemic level.

In patients with severe TBI, prognostic scoring systems derived from multivariable models are able to discriminate between favourable and unfavourable 6-month outcomes, and have been validated both internally and externally [15,16]. Both IMPACT and CRASH scores include age, pupillary responses, motor responses, pattern of injury on head CT, and non-neurological perturbations, such as hypoxia, hypotension, and extracranial injuries [15,16]; notwithstanding, these systems do not have sufficient accuracy to determine prognosis for individual patients.

Following cardiac arrest, neurologic prognosis is determined on the basis of physical findings and selected electrophysiological markers [17]. Specific variables associated with adverse outcome include absent pupillary or corneal reflexes at 72 hours, absent or extensor motor responses at 72 hours, myoclonic status epilepticus, burst suppression on EEG, and bilaterally absent cortical signals on SSEP testing. Improved outcome observed in cardiac arrest patients treated with therapeutic hypothermia has prompted a re-evaluation of neurological prognostication, with recent studies demonstrating that selected clinical signs, such as the absence or abnormality of motor responses, have lost specificity as outcome predictors [9,18].

Recovery

Although early and intensive physical and occupational therapy have been linked to improved outcome in critically-ill patients [19], the rehabilitation of patients with persisting unconsciousness presents many inherent challenges. Studies conducted in unconscious patients following TBI indicate that pharmacological promotion of arousal may be associated with better short-term functional recovery, an effect that was recently demonstrated in a multicentre randomized controlled trial of amantadine [20]. Most of the data supporting the use of these drugs is in the subacute and chronic phase of recovery, potential benefits in the acute period need further study.

CHAPTER 230

Non-pharmacological neuroprotection in the ICU

Niklas Nielsen and David B. Seder

Key points

- After control of the primary process causing acute neurological injury, further control of secondary injury pathways can be achieved by manipulating brain temperature, and achieving biochemical and metabolic homeostasis.
- Surgical techniques are routinely used to remove blood or trapped cerebrospinal fluid, control mass effect, or repair unstable vascular abnormalities.
- Therapeutic temperature management to a defined target can be achieved and maintained using cold fluids, ice packs, body surface cooling pads, and surface and intravascular devices with servo (feedback) mechanisms.
- Successful temperature management requires attentive surveillance, and control of shivering and other potential complications such as bleeding, infection, cardiac arrhythmias, and electrolyte and metabolic disturbances.
- Extremes of oxygenation and ventilation are associated with worse long-term functional outcomes, and should be avoided.

Principles of neuroprotection

Following respiratory and haemodynamic stabilization, neuroprotection rests on two main principles. First, the rapid diagnosis and management of the primary brain injury: restore the spontaneous circulation in cardiac arrest, secure the bleeding aneurysm with surgery or coiling, and remove the acute thrombus in stroke. Secondly, the prevention of further secondary injury and cellular injurious processes facilitate a milieu of healing and repair by optimization of physiological and metabolic parameters. Table 230.1 describes general haemodynamic and metabolic causes of secondary injury that may exacerbate most or all types of neurological injury. This chapter outlines a clinical approach to managing neurological injury, focusing on non-pharmacological strategies.

Specific non-pharmacological therapies to decrease secondary neurological injury

Decompressive surgery

The routine use of decompressive hemi-craniectomy in stroke is supported by the pooled result of three small randomized clinical trials. In patients aged less than 60 suffering from large volume cerebral infarction due to carotid terminus or middle cerebral artery (MCA) occlusion, surgical decompression reduced mortality and improved overall neurological outcomes compared with best medical management alone [1]. The timing of hemi-craniectomy in stroke is likely to be crucial—performed too early, it may be done unnecessarily in a small number of patients, who would otherwise make a good recovery with medical therapy alone. Performed too late, the patient may suffer harm due to increased intracranial pressure (ICP), herniation, and its associated injuries. One trial suggested benefit primarily in patients whose surgery was less than 48 hours after stroke onset [2], which suggests that such patients require close monitoring, frequent brain imaging, and a predetermined plan in place in the event that oedema progresses to the point of needing surgery. With increasing brain swelling, small changes in intracranial volume result in large changes in ICP; understanding this relationship reinforces the need for constant observation and a predetermined management plan (Fig. 230.1). In European guidelines, decompressive craniectomy within 48 hours after symptom onset is recommended (Class 1, level A) in patients 60 years or younger with evolving malignant MCA infarction [3].

The appropriate use of surgical decompression is less clear in traumatic brain injury (TBI). One large trial randomizing patients with severe traumatic brain injury (TBI) and elevated ICP to early bifrontal decompressive craniectomy or best medical management showed no benefit with surgery [4]. Further trials are ongoing and pending those trial results, decompressive surgery remains a frequently used salvage therapy when the cranial vault can no longer contain its contents [5].

Targeted temperature management

In many clinical settings including, stroke, and following cardiac arrest and TBI, fever may be a marker of injury severity, a cause of secondary neurological injury, or both. Fever is associated with worse outcomes, which has led to the concept of therapeutic thermoregulation. Deliberate lowering the body and brain temperature to a level below the hypothalamic thermostat set point has been used for neuroprotection for decades. This intervention has traditionally been termed **induced** or **therapeutic** hypothermia, but recently **targeted temperature management** (TTM) was suggested to cover all dimensions where temperature is regulated with the goal of improving patients' outcomes [6].

Temperature management is used to protect organs during the ischaemia period before transplantation, during neurosurgery for

Table 230.1 General causes of secondary brain injury

Aetiology	Pathophysiology	Prevention/management
Hypotension	Inadequate cerebral perfusion pressure (CPP) Ischaemia and infarction	Maintenance of adequate blood pressure Optimize vascular tone Optimize intravascular volume
Hypoxia	Exacerbation of ischaemic injury	Interventions aimed at increasing O_2 delivery
Hyperoxia	Exacerbation of reperfusion injury, vasoconstriction	Normalize PaO_2
Hyperventilation	Arteriolar constriction decreases cerebral blood flow, increases volume of ischaemic tissue	Ventilate to normal pH and $PaCO_2$
Hypoglycaemia	Ischaemic injury	Target arterial or venous blood glucose levels >6 mmol/L
Hyperglycaemia	Increases oxidative damage	Target arterial or venous blood glucose levels <10 mmol/L
Increased intracranial pressure and brain oedema	Increases/potentiates ischaemia, may lead to brain herniation	Elevate head of bed Avoid jugular compression Manage discomfort and anxiety Optimize volume status Optimize plasma oncotic pressure Osmotherapy, cerebral perfusion pressure optimization, hypothermia, metabolic suppression, decompressive surgery
Fever	Increases inflammation, intracranial pressure, apoptosis, cellular metabolic activity, excitotoxicity	Infection control Antipyretics Targeted temperature management
Hyperperfusion	Loss of cerebral autoregulation	Antihypertensives

aneurysmal clipping, and has been a mainstay for protecting neurological function during cardiac surgery with induced circulatory standstill. In these examples, hypothermia is induced before the ischaemic event and is often maintained through reperfusion. When TTM is used in critical care the ischaemic event and even often reperfusion from the ischaemia have already taken place, and temperature management is used in an attempt to prevent further reperfusion injury and other secondary damage. Experimental animal studies indicate beneficial effect of hypothermia in both global and focal ischaemia models at various temperatures, ranging from very mild hypothermia of 35°C to deeper levels. The exact mechanism of the protective action of temperature modulation is not fully understood, but experiments have shown that hypothermia decreases the cerebral metabolic rate of oxygen and affects cell death pathways, such as excitotoxicity, apoptosis, inflammation, calcium homeostasis, gene expression and free radical production. Inducing hypothermia also decreases elevated ICP [7,8].

Clinically targeted temperature management is recommended in many guidelines for the treatment of patients resuscitated after cardiac arrest and in in hypoxic ischemic encephalopathy in neonates [9]. Other areas of potential use are spinal cord injury, traumatic brain injury, hepatic encephalopathy with cerebral oedema, and stroke, but these indications lack proof of efficacy.

Clinical trials indicate improved survival and neurological outcome when a target temperature of 32–34°C is employed for 12–24 hours in comatose adult patients with return of circulation after suffering

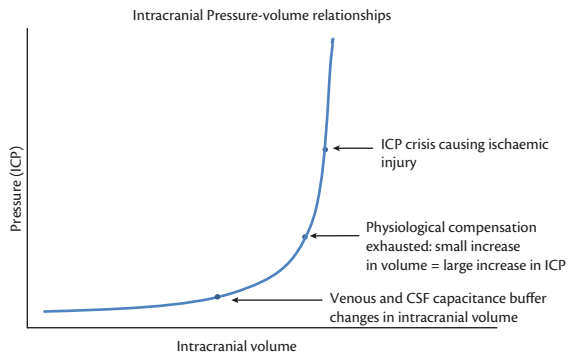

Fig. 230.1 Intracranial pressure–volume relationships. Initially displacement and reduction in the intracranial volumes of cerebrospinal fluid (CSF) and venous blood acts as a compensatory mechanism and ICP does not increase dramatically. Once this compensatory mechanism is exhausted the ICP increases exponentially.

out-of-hospital cardiac arrest from a shockable rhythm. During the last decade, this intervention has been widely implemented around the world. Clinical practice has also extended to cardiac arrests with other initial rhythms, and following in-hospital cardiac arrest. The population that might benefit most from targeted temperature management is not yet defined [6,10]. Moreover, the optimal depth, duration and timing of targeted temperature management are unknown. Since lower temperatures are associated with higher rates of infection, sepsis, coagulopathy, arrhythmias, and metabolic and electrolyte disturbances, and because the neuroprotective activity of hypothermia probably varies among indications, a tailored approach to the optimal use in an individual patient awaits further research. It is also unknown if targeting normothermia and preventing fever might be as effective as inducing hypothermia in a general population. Large trials in stroke, cardiac arrest and TBI are ongoing [11].

Targeted temperature management is divided in three phases: induction to the desired temperature, maintenance of the target temperature, and rewarming. Rapid infusion of cold crystalloid fluids and externally placed cooling pads can be used for induction of hypothermia. Intravascular or external servo-controlled temperature management systems are convenient means for inducing and maintaining hypothermia. At the end of the cooling period, the body temperature is gradually returned to normothermia at a controlled rate of up to 0.5°C/hour. Again, the optimal rate of rewarming is not known, but uncontrolled rewarming may result in rapid increase in temperature and rebound fever. Rewarming is a period in which ICP, seizures, and hypotension may cause secondary injury, and close monitoring is important. Continued fever control after the intervention period or even continued targeted temperature management to hypothermic levels could be considered if the underlying physiology is unresolved [7].

Ventriculostomy and cerebrospinal fluid (CSF) drainage

Patients with acute, obstructive hydrocephalus require urgent decompression by external ventricular drainage. When no functional intracranial mass lesion is present, and hydrocephalus is communicating in nature, lumbar drainage is a reasonable alternative. The choroid plexus produces 15–20 mL cerebrospinal fluid/hour in a normal adult. As a result, obstruction rapidly results in increased ICP and progressive obtundation. Standard therapy is placement of a ventricular catheter through a small frontal burrhole to drain cerebrospinal fluid (CSF). Ventricular drainage catheters have a high infection rate, and must be placed and handled using sterile and aseptic technique. Prophylactic antibiotics at the time of insertion or the routine use of antibiotic-coated or impregnated catheters may be reasonable practices to reduce infection risk, dependent on the local microbial environment [12].

Ventriculostomy is also used to monitor ICP, and CSF drainage to relieve pressure when the ICP is elevated. Although the exact level of intracranial pressure causing harm is unknown, most experts agree on treatment of ICP when it exceeds 20 mmHg and maintenance of cerebral perfusion pressure (CPP) >60 mmHg for adult patients [13,14].

Evacuation of blood

Animal models suggest blood is inherently inflammatory and probably harmful in the brain, ventricles, and subarachnoid space. In aneurysmal subarachnoid haemorrhage, the volume of subarachnoid blood is associated with the subsequent development of vasospasm [15], and lumbar drainage accelerates clearance of blood from the subarachnoid space and decreases delayed neurological deficits. Preliminary work in intraventricular haemorrhage shows benefit to an aggressive strategy of intraventricular clot removal, and a large randomized trial comparing intraventricular tissue plasminogen activator administration with placebo is currently underway.

Bedside care

To facilitate venous drainage from the skull jugular venous return should not be constricted—optimize head/neck position and avoid venous obstruction from tight endotracheal or tracheostomy ties, or from cervical spine collars. The effect of elevating the head of the bed to optimize ICP varies from patient to patient, and should be guided by volume status, and ICP and CPP monitoring.

Physiological homeostasis

Oxygenation

Hypoxia is a potent and well-established cause of secondary brain injury. The impact of hyperoxia is more controversial. Increased oxygenation levels are associated with the formation of reactive oxygen species and lipid peroxidation of neuronal cell membranes. When high fractions of oxygen are administered at normo- or hyperbaric conditions cerebral vessels constrict, with potential to worsen ischemia, and hyperoxia may provoke seizures related to increased cerebral excitation. There may also be adverse consequences for the respiratory system. Hyperoxia may, on the other hand, increase oxygen delivery, improve the cerebral metabolic rate of oxygen by improving mitochondrial function, and may be anti-inflammatory. The higher tension of oxygen may also help diffusion over swollen endothelium and decrease oedema formation associated with the primary injury. Animal experimental data are conflicting, and support both benefit and harm from hyperoxia. In clinical studies on stroke, hyperbaric oxygen does not seem to be beneficial, and several studies indicate worse outcomes with hyperoxia following resuscitation from cardiac arrest. Current data suggest there is no proven benefit of hyperoxia as an intervention in acute treatment of neurological injuries, and potential harm must be considered. Best current evidence suggests oxygen should be titrated to arterial normoxia as soon as initial resuscitation is accomplished [16].

Ventilation

Changes in blood carbon dioxide tension ($PaCO_2$) have profound effects on cerebral blood flow. Cerebral blood flow decreases due to arterial vasoconstriction when ventilation is increased and $PaCO_2$ falls. Vasoconstriction due to hypocapnia leads to decreased oxygen delivery in the already injured brain, with global or focal ischaemia, and may further increase neurological damage. Conversely, hypercapnia leads to cerebral vasodilation and may increase oedema and ICP. For patients with controlled ventilation and neurological injury, most evidence points in the direction of avoiding both hypo- and hypercapnia, and thus aim for normocapnia [17]. Therapeutic hyperventilation still has a role in the acute treatment of increased ICP with concomitant neurological deterioration, while awaiting more definitive treatments like haematoma evacuation, drainage,

or decompressive craniectomy [14]. For patients treated with hypothermia, it is even more important to pay close attention to ventilation and $PaCO_2$, since hypothermia will lower body CO_2 production and simultaneously increase gas solubility, sometimes leading to accidental hypocapnia and worsened ischaemia.

Blood gas analysis is also affected by body temperature. There are two approaches for blood gas presentation—gas tensions corrected for actual body temperature (pH-stat), and gas tensions not corrected for body temperature and thus analysed at 37°C (alpha-stat). Whether to use alpha- or pH-stat for blood gas analysis during hypothermia is open to debate, but it is important that the clinician is familiar with the differences of the two approaches [18].

Glycaemic control

Sustained hyperglycaemia is common in all forms of acute neurological injury and is associated with worse outcomes. In experimental models of stroke, TBI, and global ischaemia, hyperglycaemia increases neurological injury. There are few data to corroborate these causal relationships in humans, and it may be that hyperglycaemia results from the stress response seen with more severe injury.

Hypoglycaemic episodes lead to energy substrate deficiency in the injured brain, and are clearly associated with harm. The concept of 'tight glycaemic control' will lead to more hypoglycaemic episodes and may therefore be particularly problematic in patients with neurologically injuries. Most recommendations today, both for focal and global ischaemia, advocate a blood glucose concentration between 6 and 10 mmol/L after brain injury, and avoiding wide variations in blood glucose concentration [19,20].

Conclusion

Halting the primary injurious processes, preventing secondary brain injury, and restoring metabolic, haemodynamic, and biochemical homeostasis to allow healing are critical functions of the intensivist in treating neurological disease.

PART 9.6

Seizures

CHAPTER 231

Pathophysiology and causes of seizures

Thomas P. Bleck

Key points

- Several mechanisms linked to critical illness can lead to seizures.
- Seizures may be the primary reason for admission to the ICU, for example, for the treatment of status epilepticus, or occur secondary to another critical illness.
- Failure to remove glutamate and potassium from the extracellular space occurs in cerebral trauma, hypoxia, ischaemia, and hypoglycaemia.
- Loss of normal neuronal inhibition occurs during withdrawal from alcohol and other hypnosedative agents, or in the presence of GABA antagonists, such as penicillin or imipenem.
- Conditions such as cerebral trauma, haemorrhage, abscesses, and neoplasms produce physical distortions of the adjacent neurons, astrocytes, and the extracellular space. Although acute metabolic disturbances can produce seizures, an underlying structural lesion must always be considered and excluded.

Introduction

Seizures result from imbalances between excitation and inhibition, and between neuronal synchrony and dyssynchrony [1]. Current models of human seizures implicate the cerebral cortex in the genesis of seizures, although thalamic mechanisms (particularly the thalamic reticular formation) are involved in the synchronization of cortical neurons. These same systems are involved in the maintenance of consciousness and in sleep–wake cycling [2]. Often, the precipitants of a seizure at a particular time in the critical care setting are pharmacological, even in the patient with a predisposition to seizures. Others may reflect normal physiological rhythms; for example, sleep stage transitions are typically times of increased cortical and thalamocortical neuronal synchrony.

A clear distinction should be drawn between seizures, which are events occurring to the patient, and epilepsy, which is a chronic condition characterized by the tendency to have repeated seizures as a consequence of a central nervous system disorder. In the critical care unit, the majority of patients experiencing seizures do not have pre-existing epilepsy, and their chances of developing epilepsy in the future are usually more dependent on the cause of their seizures than on the number or intensity of seizures they experience. Because of other deleterious neuronal and systemic effects of seizures, however, their rapid diagnosis and suppression during a period of critical illness is almost always necessary [3].

The major excitatory neurotransmitters in the cerebral cortex are excitatory amino acids, particularly glutamate. These transmitters control a variety of ion channels and second messenger systems, some of which are linked to the production of nitric oxide. The ion channels gated during excitation allow the entry of sodium, which depolarizes the post-synaptic neuron, and calcium, which can trigger both intracellular metabolic processes and the transcription of a variety of gene products. During normal brain function, these processes are required for learning, memory, and other functions.

The line dividing normal neuronal physiology from the excessively rapid, hypersynchronous depolarizations, which characterize a seizure is quite narrow, and appears to depend upon several mechanisms that can be deranged by critical illnesses. Failure to remove glutamate and potassium from the extracellular space, functions performed predominantly by astrocytes, occurs in trauma, hypoxia, ischaemia, and hypoglycaemia. Loss of normal inhibition, which is provided in the cortex primarily by gamma-aminobutyric acid (GABA), and to a lesser extent, glycine, occurs during withdrawal from alcohol and other hypnosedative agents, or in the presence of GABA antagonists, such as penicillin or imipenem. The deleterious effect of the ICU environment on sleep–wake cycling alters thalamocortical rhythmicity, but its contribution to seizures is only beginning to be studied.

The reader will recognize that many of these mechanisms are common to other conditions, such as stroke and trauma, for which the patient may require critical care. In the future, one hopes that a more direct approach to correcting these mechanisms will improve the outcome of these patients. At present, the mainstay of therapy is the pharmacological effect to interfere with the processes that trigger or maintain seizures, particularly by employing GABA agonists (e.g. benzodiazepines), or agents that interfere with sustained high-frequency repetitive firing (e.g. phenytoin). While the currently available agents are relatively effective in this role, they all have significant adverse effects, and do not interfere with the process of epileptogenesis.

Many of the central problems regarding epileptogenesis remain to be solved, but the process involves several steps that are relevant to the intensivist. Focal cerebral cortical disorders, whether or not accompanied by seizures in their acute stages, may lay the foundation for later epilepsy. Conditions such as cerebral trauma, haemorrhages, abscesses, and neoplasms, all produce physical distortions

of the adjacent neurons, astrocytes, and the extracellular space. Deposition of iron in the cortex from the breakdown of haemoglobin appears particularly epileptogenic. The timely diagnosis and management of these conditions may prevent later epilepsy or lessen its severity.

Aetiology

In critical care, seizures may either be the patient's primary condition (because of status epilepticus), or develop as a complication of another illness. The physician must determine rapidly if a treatable aetiology is present. The patient suffering a single seizure, or a few discrete seizures, in the setting of a critical illness may not require antiseizure therapy, but this decision depends on the aetiology of the seizure and the confounding effects of other illnesses. The patient presenting in status epilepticus requires aggressive treatment, unless an underlying condition renders, such intervention pointless.

Discrete seizures

Seizures occurring during another critical illness usually represent a central nervous system manifestation of a systemic disorder. In our prospective study of neurological complications of critical medical illnesses, seizures were the second most common problem encountered and were almost as frequent as metabolic encephalopathy [4]. The most frequent causes were cerebrovascular disease, central nervous system infections, metabolic encephalopathies, neoplasms, hypoglycaemia, and osmolar disorders (including non-ketotic hyperglycaemia). At the Mayo Clinic, Wijdicks and Sharbrough retrospectively analysed seizures occurring in intensive care units (ICUs), finding that drug withdrawal was the commonest aetiology of seizures in their patients [5]. Box 231.1 summarizes common causes of seizures in ICU patients.

Iatrogenic precipitants of seizures should be rapidly detected and the cause removed, if possible, instead of treating the patient only with antiseizure agents. Seizures occurring because of the abrupt withdrawal of GABA agonists (e.g. hypnosedatives, such as barbiturates and benzodiazepines) are managed by using a drug of the same class, followed by a very slowly decreasing dose to prevent recurrence of withdrawal seizures. The actual agent selected may be different than that from which the patient is withdrawing; the choice depends on the other circumstances of the patient. Alcohol withdrawal seizures constitute a special type of hypnosedative withdrawal, because several neurochemical systems are involved in addition to GABA, and other withdrawal phenomena may be anticipated once seizures begin [6]. Although seizures due to alcohol withdrawal, and other hypnosedative agents, are usually thought to be primarily generalized, a substantial minority of alcohol withdrawal seizures have focal components [7]. These localized cortical disturbances probably reflect pre-existing areas of cortical hyperexcitability, as might follow remote head trauma, which are rendered more excitable by the loss of inhibition.

Acute metabolic disturbances commonly produce seizures in ICUs, but one must consider that seizures may be symptoms of structural disorders that are made manifest by metabolic disorders. Generalized convulsions are typical of metabolic disturbances, but two common exceptions are seizures due to non-ketotic hyperglycaemia or hypoglycaemia, which often have focal components [8].

Box 231.1 Common aetiologies of seizures in critically-ill patients

Anoxic encephalopathy (must be distinguished from myoclonic activity)

Central nervous system infections

- Brain abscess.
- Encephalitis.
- Meningitis.
- Subdural empyema.

Cerebrovascular disorders

- Central nervous system vasculitis.
- Cortical vein thrombosis.
- Intracerebral haemorrhage:
  - Ischaemic stroke.
  - Lupus cerebritis.
- Subarachnoid haemorrhage.
- Thrombotic thrombocytopenic purpura.

Drug intoxication

- Antibiotics with proconvulsant effects—high-dose penicillins in patients with renal failure:
  - Third and fourth generation cephalosporins.
  - Imipenem/cilastatin in patients with renal failure or damaged blood–brain barrier.
  - Function.
- Cocaine and other central stimulants.
- Dopamine antagonists.
- Meperidine metabolites (e.g. normeperidine).
- Theophylline: tramadol.
- Tricyclic antidepressants.

Drug withdrawal

- Alcohol withdrawal.
- Hypnosedative drug withdrawal (primarily benzodiazepines and barbiturates).
- Withdrawal of other anticonvulsants in patients with a history of seizures or a seizure: diathesis.

Head trauma

Metabolic encephalopathies

- Acute severe hyposmolality (e.g. water intoxication): hepatic failure (seizures are rare).
- Renal failure.
- Acute renal failure:
  - Drug or metabolite intoxication.
  - Hypertensive encephalopathy.

- Chronic renal failure:
  - Drug or metabolite intoxication.
  - Dialysis dementia.

Neoplasms

- Primary.
- Metastatic.

Acute hypo-osmolar states (that is, those developing over hours) frequently present with generalized convulsions, as well as evidence of increased intracranial pressure. Hypo-osmolar states developing over days are rarely associated with seizures; these patients more commonly present with weakness or confusion without seizures or loss of consciousness. Hypocalcaemia is frequently listed as a cause of seizures in children and adults, but it is rarely the sole cause of convulsions beyond the neonatal period and must not be used as an excuse to avoid investigation for other aetiologies, especially structural lesions (Bleck, 1991) [9]. The same is true of hypomagnesaemia.

Systemic infections may produce non-convulsive seizures that are difficult to detect in patients being sedated for mechanical ventilation [10,11].

Many drugs commonly used in intensive care are potentially epileptogenic, especially in patients with renal or hepatic dysfunction. One important example is the development of non-convulsive seizures in patients treated with cefepime [12].

Autoimmune and paraneoplastic disorders causing seizures often result in intensive care admissions for patients because of the need for airway control and mechanical ventilation [13].

Status epilepticus

When status epilepticus develops in a critically-ill patient, the aetiologies are the same as those of discrete seizures. Status epilepticus, especially in patients with systemic disorders affecting the central nervous system, may not manifest as convulsions and should be considered in any case of prolonged change in mental status [14]. For those patients admitted to ICUs primarily because of status epilepticus, the most frequent causes in recent series are alcohol or antiseizure drug withdrawal, anoxia, head trauma, central nervous system infection, acute metabolic disturbances, and tumours [15–17].

Non-convulsive status epilepticus is now recognized to be relatively common among critically-ill patients with impaired consciousness [18]. This is often overlooked in patients for whom another aetiology of altered awareness is present [19]. Non-convulsive status epilepticus may be present in up to 30% of patients being treated with therapeutic hypothermia after cardiac arrest; the value of various antiseizure treatments remains to be established, but the outcome of such treatment in some cases is dramatic [20].

CHAPTER 232

Assessment and management of seizures in the critically ill

Thomas P. Bleck

Key points

- Seizures may be difficult to detect in critically-ill patients who are sedated and/or paralysed with neuromuscular blocking agents. An urgent electroencephalogram should be obtained when seizures are suspected.
- Unless the cause is known, investigations may include an urgent computed tomography or magnetic resonance imaging (if this is logistically possible) and a lumbar puncture if central nervous system infection is suspected.
- Status epilepticus is continuous or recurrent seizure activity lasting five or more minutes without an intervening recovery period.
- Most seizures are self-limiting and stop after 1–2 minutes. Seizures that continue for more than 5 minutes should be treated.
- General supportive measures include attention to airway, breathing, and circulation (ABCs) and the exclusion of hypoglycaemia. Drug treatment is commonly with parenteral benzodiazepines; propofol and barbiturates are alternatives.

Introduction

Patients with seizures enter the intensive care environment either as a complication of another critical illness or for the management of status epilepticus. The diagnostic studies required vary with the presentation, and must often wait for the institution of emergent therapies, such as antibiotics in cases of suspected bacterial meningitis and antiseizure treatment for status epilepticus.

Discrete seizures

Recognition of a generalized seizure is straightforward in previously alert patients not receiving neuromuscular junction blocking agents, but such patients are less common in intensive care practice than in other areas. Partial (focal) seizures that do not secondarily generalize are also difficult to detect in these patients. The intensive care unit (ICU) staff must maintain a high index of suspicion for the development of seizures in such patients, and maintain a correspondingly low threshold to obtain neurological consultation and electroencephalographic studies. Box 232.1 presents some guidelines for the recognition of seizures in the ICU. One should strive to make a definitive diagnosis of the aetiology of altered alertness, even if that diagnosis is

Box 232.1 Recognizing seizures in critically-ill patients

- Make a positive diagnosis of the aetiology of altered awareness.
- In patients receiving neuromuscular junction blockade, evidence of sympathetic over-activity (e.g. pupillary dilation, hypertension, tachycardia) may reflect seizure activity, as well as pain or inadequate sedation. Only EEG monitoring can reliably distinguish between these possibilities.
- In patients with intact neuromuscular transmission, observe for a prolonged post-ictal state after a recognized seizure; facial myoclonus; unexplained fluctuations in the level of consciousness; and nystagmoid eye movements.
- In most situations, neuromuscular blocking agents can be discontinued transiently to assess the patient's neurological examination without harming the patient. If this cannot be done, one should consider intermittent (or continuous) EEG monitoring for patients receiving proconvulsant agents (e.g. imipenem/cilastatin) even in the absence of autonomic signs suggesting seizures.
- Hypnosedative agents may diminish the motor manifestations of seizures or status epilepticus without attenuating the electrical activity or preventing the consequent neuronal damage. Thus, one should either lower the dose of these drugs occasionally to assess the patient's neurologic status, or obtain intermittent (or continuous) EEG monitoring.
- Although elevations in serum prolactin and ACTH levels commonly accompany seizures, many common disorders and treatments in ICU patients may produce similar elevations (e.g. neuroleptic agents, which are also proconvulsant). Furthermore, this neuroendocrine response fatigues with frequent seizures. Thus, studies of these substances are often unreliable markers of seizure activity in ICU patients.
- Decerebrate (extensor) posturing and opisthotonic posturing are occasionally seen in ICU patients, and may be confused with seizure activity. If they cannot be distinguished on clinical grounds, an EEG should be obtained. Short-acting neuromuscular junction blockade may be necessary (e.g. vecuronium (0.1 mg/kg), with appropriate ventilatory and airway management). Succinylcholine should usually be avoided in this setting to avoid the possible precipitation of severe hyperkalaemia.

metabolic encephalopathy, to prevent missing the possibility of such remediable disorders as seizures or status epilepticus [1].

When a seizure is suspected, an electroencephalogram (EEG) should be obtained urgently. This is of special importance when a patient does not return to baseline mental status, which suggests progression to non-convulsive status epilepticus [2,3]. Most patients will need a brain imaging study in this setting, since a majority of critical care patients with new onset seizures have structural intracranial lesions [4]. Although magnetic resonance imaging is usually the study of choice in patients with new onset seizures, critically-ill patients may not be able to undergo this procedure for logistical reasons. Computed tomographic scanning remains a useful alternative. The need for other studies, such as lumbar puncture for cerebrospinal fluid analysis, depends on the likely diagnostic possibilities. If bacterial meningitis is suspected at any stage, appropriate antibiotic therapy should be instituted without waiting to obtain a lumbar puncture [5].

Classifying the seizure according to the International Classification of Epileptic Seizures [6] aids in the aetiological diagnosis, and often has therapeutic implications (see Boxes 232.1 and 232.2).

Status epilepticus

The usual definition of status epilepticus involves continuous or recurrent seizure activity without recovery; 5 minutes is now considered an operational definition of status [7]. The average duration of monitored single seizures is 62 seconds [8], and since most seizures end spontaneously within 4 minutes, one should consider treatment for status epilepticus after about 5 minutes.

Status epilepticus is easily diagnosed when the patient suffers prolonged convulsions or has numerous partial seizures without intervening recovering normal alertness. More challenge arises when status epilepticus occurs without obvious motor manifestations, especially if the patient has other reasons for unresponsiveness. In such circumstances, careful observation for small clonic movements (e.g. twitches of the corner of the eye) may suggest the diagnosis. Other neurologic symptoms such as aphasia may be signs of status epilepticus [9]. About 20% of status epilepticus is non-convulsive [10]. The EEG appearance of different forms and durations of status epilepticus is quite variable [11,12].

Management

Discrete seizures

The first concern in caring for any patient experiencing a seizure is to protect the patient from harm to the extent that this is possible. This is usually a straightforward task in the general hospital patient (e.g. preventing aspiration, removing sharp objects from the patient's vicinity), but assumes a new level of complexity in ICU patients who are critically dependent on devices whose connection to the patient is of limited or no flexibility (e.g. intra-aortic balloon pumps, high-frequency oscillatory ventilators). In such circumstances, immediate neuromuscular junction blockade may be necessary. If neuromuscular blockade is not immediately necessary the patient should be observed for seizure classification and possible intervention to maintain the airway and ensure adequate ventilation. When emergent therapy is indicated, the physician should proceed. In most cases, efforts should be made to make an aetiological diagnosis expeditiously, and institute treatment for the underlying cause if possible.

Box 232.2 Classification of epileptic seizures

Partial seizures (seizures beginning locally)

Simple partial seizures (consciousness not impaired)

- With motor symptoms.
- With somatosensory or special sensory symptoms.
- With autonomic symptoms.
- With psychic symptoms.

Complex partial seizures (with impairment of consciousness)

- Beginning as simple partial seizures and progressing to impairment of con-sciousness:
  - Without automatisms.
  - With automatisms.
- With impairment of consciousness at onset:
  - Without automatisms.
  - With automatisms.

Partial seizures (simple or complex), secondarily generalized

Generalized seizures (bilaterally symmetric, without localized onset)

Absence seizures

- True absence ('petit mal').
- Atypical absence.

Myoclonic seizures

Clonic seizures

Tonic seizures

Tonic-clonic seizures ('grand mal')

Atonic seizures

Unclassified seizures

Reproduced from 'Commission on classification and terminology of the International League Against Epilepsy (1981) Proposal for revised clinical and electroencephalographic classification of epileptic seizures', *Epilepsia*, **22**(4), pp. 489–501, copyright 1981, with permission from John Wiley and Sons Ltd.

Whether to administer antiseizure drugs after one seizure in a critically-ill patient is often a complex decision. The causes of the patient's seizure may be unknown or may be difficult to reverse. Another seizure may pose substantial risk to a patient with tenuous cardiopulmonary function, which may be sufficiently great that medications are justified after one seizure. In this circumstance, two treatment modalities are currently available. Our centre employs a long-acting benzodiazepine (e.g. lorazepam, or clonazepam), unless contraindicated by its effect on the patient's level of alertness. Acceptable alternative include levetiracetam, lacosamide, valproate, phenytoin, or fosphenytoin.

The choice of a maintenance antiseizure medication for those who remain at risk for further seizures is beyond the scope of this chapter. However, the physicians caring for the patient in the ICU

should realize that subsequent physicians may continue that initial agent for months or years, and should communicate the bases for their decision for later reconsideration.

Status epilepticus

Attention to basic life support issues (airway, breathing, and circulation) are central to the management of generalized convulsive status epilepticus. While the rapid termination of this condition is often the best way to deal with airway problems, emergent endotracheal intubation may be necessary for the patient unable to ventilate adequately, or if treatment to terminate status epilepticus causes respiratory depression. If laryngoscopic intubation is required in a patient with suspected intracranial hypertension, premedicate the patient with lignocaine, thiopentone, propofol, or etomidate to blunt the increase in ICP associated with laryngoscopy.

Therapy for status epilepticus was exhaustively reviewed in a recent guideline to which the interested reader is referred [13]. A study of the prehospital treatment of status epilepticus suggests that the rapidity of effective treatment is extremely important in the termination of the condition [14].

During the first 30–60 minutes of status epilepticus most patients are hypertensive; after this, blood pressure usually declines to normal or hypotensive values. Many drugs used to terminate status epilepticus can induce hypotension, so the clinician should always be ready to support the circulation with fluids and vasopressors.

Since hypoglycaemia may be associated with status epilepticus, either as an aetiology or as a consequence of prolonged seizure activity with autonomic failure, the blood glucose should be rapidly determined. Since the techniques employed for bedside determination lose accuracy outside the normal range, 'borderline' hypoglycaemic values should be treated (together with thiamine administration). Non-ketotic hyperglycaemia frequently presents with epilepsia partialis continua, which does not typically respond to antiseizure agents, but which usually remits with rehydration and control of the blood sugar.

Therapy for status epilepticus involves three principles:

- Terminating the condition.
- Preventing its recurrence.
- Managing its complications.

The US Department of Veterans Affairs study of status epilepticus compared four treatment regimens for generalized convulsive status epilepticus (lorazepam, diazepam followed by phenytoin, phenytoin alone, and phenobarbital alone). This study showed that lorazepam (0.1 mg/kg), terminated 63% of generalized convulsive status epilepticus episodes [15]. In another important result, about 20% of patients remained in electrical status epilepticus after their clinical seizure activity stopped. This reinforces the clinical suspicion of non-convulsive status epilepticus in patients who do not begin to wake within 15–20 minutes after the apparent termination of their seizures.

Recommended lorazepam doses vary from 0.05 to 0.2 mg/kg (up to 8 mg in adults), administered at a rate of 0.04 mg/kg/min. Increasing the dose above 8 mg does not appear to improve the response rate. If this drug fails, phenytoin is frequently chosen as a second-line agent. However, the aggregate response rate to all second-line drugs in the DVA study was about 9%, and to third-line drugs, 3% [16]. This suggests that additional conventional treatments have limited utility after the first choice fails.

At this juncture, the patient is refractory to standard therapy and one might use one of the 'definitive' treatments. These more aggressive treatments should be given in ICUs, since the patient requires ventilatory support and frequently needs haemodynamic support. EEG monitoring is also necessary, since these drugs typically abolish clinical evidence of seizure activity before achieving electroencephalographic control.

My practice is to use either midazolam or propofol at this juncture. Midazolam therapy starts with a loading dose of 0.2 mg/kg and an initial maintenance dose of 0.2 mg/kg/hour [17,18]. The maintenance dose is titrated to produce clinical and electroencephalographic suppression of seizures, rather than a burst-suppression EEG pattern. This agent is effective in over 70% of cases of refractory status pooled from three centres, but produces substantial tachyphylaxis. When the infusion rate reaches 2.0 mg/kg/hour, arbitrary change to another drug is recommended, usually propofol or pentobarbitone. This is often required in those situations in which the patient has a prolonged stimulus for epileptogenesis, such as encephalitis. Typical doses for propofol in status epilepticus range from 2 to 15 mg/kg/hour; we also use a loading dose of 2 mg/kg. Prolonged infusion of high dose propofol should be avoided because of the risk of inducing potentially fatal propofol infusion syndrome.

Recommendations for pentobarbitone loading doses vary from 5 to 12 mg/kg, with maintenance doses beginning at about 1 mg/kg/hour. An EEG goal of burst-suppression is traditional, but since there is no clear evidence to support this, I now choose seizure suppression instead [19]. A pentobarbitone dose adequate to produce burst-suppression or a completely flat EEG background is often necessary to suppress all seizures, and there are several examples of seizures arising from a background of this pattern. Thus, continuous EEG monitoring is required; intermittent sampling of the EEG to insure that this pattern is present is not adequate to be certain that no seizures are occurring [20]. The extent to which occasional seizures produce further brain damage in this setting is unknown.

Adverse effects of pentobarbitone include hypotension (from both venodilation and diminished myocardial contractility), immune suppression, poikilothermia, interference with the clearance of pulmonary secretions, and loss of gastrointestinal motility. Total parenteral nutrition may be required because of an ileus. Pulmonary embolism prophylaxis is necessary and gastric mucosal protection is advisable.

The optimal duration of these therapies is uncertain. To prevent recurrence of refractory status epilepticus, we typically institute a regimen of high-dose phenobarbital (aiming for a phenobarbital serum concentration of 50–100 μg/mL or higher) before withdrawing the agent being used for definitive control of status epilepticus. These choices are modified based on the patient's history. This withdrawal of therapy is attempted once or twice daily, and requires both EEG and clinical absence of seizures to be considered successful.

Many other agents have been reported to be useful in terminating status epilepticus, but none have been demonstrated to be superior to those discussed herein. Ancillary treatments, such as hypothermia and electroconvulsive therapy have been described, and are sometimes employed when drug therapy is not working or not tolerated. Surgical resection of a seizure focus, subpial transection, and the use of vagal nerve stimulators have also been employed.

Complications of status epilepticus include neuronal damage, rhabdomyolysis, hyperthermia, and cerebral oedema. The only

current approach to neuronal damage is to prevent it by rapid termination of status epilepticus, but excitatory amino acid antagonists are one of a number of promising neuroprotective treatments currently under study. Rhabdomyolysis from sustained muscular over-activity may be sufficient to produce renal damage. It may be preventable if treated early with volume expansion and alkalinization with sodium bicarbonate. Hyperthermia usually resolves after status epilepticus is controlled, but may contribute to neuronal damage prior to this point. External cooling is usually sufficient to control it once status epilepticus is terminated. Cerebral oedema due to status epilepticus is vasogenic in experimental models, and may be managed with steroids and mannitol in the rare case in which it produces symptoms. However, if marked oedema is present, the treating clinicians should consider the likelihood that both status epilepticus and the oedema reflect an underlying pathologic process.

PART 9.7

Intracranial hypertension

CHAPTER 233

Causes and management of intracranial hypertension

Nino Stocchetti and Andrew I. R. Maas

Key points

- Intracranial hypertension damages the brain.
- Intracranial pressure increases when a pathological process causes the total volume inside the cranial cavity to increase above a threshold limit.
- Acute hydrocephalus in subarachnoid haemorrhage worsens the neurological presentation. Cerebrospinal fluid should be drained before considering limiting active treatment.
- Decompression after malignant cerebral hemispheric infarction reduces ICP, but does not guarantee a better outcome.
- The most frequent cause of acute neurological worsening in a patient with a shunt system is dysfunction of the system itself.

Introduction

The pathophysiology of raised intracranial pressure (ICP), with particular reference to traumatic brain injury is covered in other chapters of this textbook. Values of ICP exceeding 15 mmHg are considered pathological in adults, and critical thresholds for treatment are generally set at 20 mmHg. Intracranial hypertension (HICP) is deleterious to the brain in two ways—by causing tissue distortion and herniation, and by causing low cerebral perfusion pressure (CPP). CPP is calculated as the difference between mean arterial blood pressure (MAP) and ICP: (CPP = MAP – ICP). A CPP lower than 60 mmHg is considered pathological in adults, because it may cause critical reductions of cerebral blood flow (CBF).

ICP is a function of intracranial volume. As a rule of thumb, the intracranial volume remains constant as expressed in the Monroe-Kellie doctrine:

$$V_{brain} + V_{blood} + V_{cerebrospinal\ fluid(CSF)} = \text{Constant} \qquad \text{[eqn 1]}$$

When the volume of one component in the intracranial cavity increases, and cannot be compensated for by a corresponding decrease in the volume of another component (for instance, by a displacement of CSF into the spinal space), ICP increases. Typically, the relationship between intracranial volume and pressure is not linear and shows three components. When additional volume enters the space, initially ICP remains relatively constant; when further volume is added, ICP starts rising. Finally, even a moderate addition of extra volume causes a sharp ICP increase.

The exponential volume–pressure relation has strong clinical implications, because ICP can decompensate rapidly, reaching dangerous, or even fatal levels after a time of apparently unremarkable fluctuations.

This chapter focuses on HICP in patients with four different pathologies:

- Subarachnoid haemorrhage (SAH).
- Spontaneous intraparenchymal haemorrhage.
- Malignant cerebral hemispheric infarction.
- Acute hydrocephalus.

Intracranial hypertension in SAH

Causes

Rupture of an intracranial aneurysm, the most frequent cause of subarachnoid haemorrhage, causes a massive increase in ICP. Bleeding occurs at high pressure (roughly equivalent to arterial pressure) and the patient (when fortunate enough to preserve consciousness and speech) complains of symptoms of acute intracranial hypertension, such as severe headache and vomiting.

In an experimental SAH model in rats, ICP rose to 55 mmHg in the first few minutes of bleeding. Despite a concomitant MAP increase, CPP fell to 19 mmHg, and local cortical blood flow declined to 22% of baseline [1]. Direct ICP measurement in humans during aneurysmal bleeding is, obviously, rare. In one patient who was undergoing ICP monitoring during aneurysm coiling, an episode of bleeding seen at angiography was accompanied by an immediate increase in ICP to 80 mmHg (personal observation).

Increased ICP is common during treatment in the ICU after SAH. In a series of 433 SAH admitted to ICU after surgical aneurysm repair, HICP was recorded in more than 50% of patients [2].

Several mechanisms may be responsible for an increase in ICP following SAH, but three are especially relevant—disturbances of the CSF circulation, global cerebral damage, and delayed ischaemic deficits. Disturbances of the CSF circulation, with impaired reabsorption and acute hydrocephalus, are common after SAH, more often in the acute phase, but in a minority of cases resulting in chronic hydrocephalus. Acute hydrocephalus may deeply affect the neurological presentation after SAH, placement of a ventricular catheter with external drainage of CSF is indicated before considering limitation of active treatment [3]. Despite concerns that early ventriculostomy might increase the risk of rebleeding, this risk

appears extremely low in expert hands, especially if over- drainage of CSF is avoided [4].

Although aneurysm rupture is a focal event, with blood extravasation and often haematoma formation around the site of bleeding, SAH causes diffuse damage to the brain, which is not limited to the location of the aneurysm or any accompanying haematoma. This damage, probably occurs at the time of aneurysm's rupture, impairs cerebral metabolism, and may induce cerebral oedema in the first days [5], with subsequent HICP.

Further ischaemia may develop after the first days/week. These delayed ischaemic deficits are often related to cerebral arterial vasospasm [6], but may also occur in the absence of overt vasospasm. Other mechanisms, including spreading depression, have been implicated [7]. When delayed ischaemia impairs the ionic pumps, intracellular water accumulates, and ICP may increase.

It is unclear if ICP is an independent predictor of worse outcome or more a marker of brain damage. Some studies report prognostic effects [8], but others in which ICP was entered in a multivariable model, do not [2].

Treatment

There are no studies proving that ICP monitoring or ICP-guided interventions improve outcome after SAH. However, HICP is a severe and treatable complication of SAH. Increased ICP is associated with severe disturbances of cerebral metabolism and oxygenation, further aggravating pre-existing cerebral damage. When microdialysis has been used in patients with HICP after SAH, signals of brain energy crisis have been detected [8]. For these reasons, ICP should be monitored in patients with high-grade SAH. An external ventricular drain is the recommended monitoring tool, offering both ICP measurement and CSF drainage. Drainage is the first reasonable treatment of increased ICP after SAH. It should be done cautiously, avoiding acute pressure gradients, particularly when the aneurysm is not yet secured. Special attention has to be paid to CPP, which is essential to prevent, or limit, further ischaemia. Mannitol was effective in lowering ICP and improving cerebral metabolism when used in 12 comatose SAH patients [9]. Agents capable of reducing ICP at the expense of MAP (such as sedatives or barbiturates) should only be used if arterial pressure and CPP are kept adequate.

Intracranial hypertension in spontaneous intraparenchymal haematoma

Causes

Intracerebral (I-C) haemorrhage is caused by the rupture of an intracranial vessel, usually in the basal ganglia. It is often a complication of systemic arterial hypertension or anticoagulant therapy. The amount of blood can vary, from asymptomatic microbleeds to large haematomas. Small bleeds can be relatively compensated by CSF displacement, while large haemorrhages (larger than 100 mL) may cause a severe increase in ICP at the moment of bleeding. The formation of an intracranial haematoma is a dynamic process, with expansion during the first day, due to further blood accumulation, and due to water accumulation in the parenchyma surrounding the haematoma [10]. Various mechanisms contribute to oedema formation, together with glutamate release, causing cytotoxic oedema, mediators such as oxygen-free radicals, complement factors and TNFα may increase permeability and lead to vasogenic oedema [11]. Tissue and vascular compression by the haematoma, further worsened by oedema, can cause hypoperfusion in areas not primarily affected by haemorrhage. However, the degree of cerebral blood flow (CBF) compromise around the haematoma is controversial, and ischaemia has not been confirmed in CBF studies. However, autoregulation is disrupted or lost, and after I-C haemorrhage the brain is especially vulnerable to reduction of arterial pressure and CPP. Several studies have demonstrated a close association between lesions demonstrated with magnetic resonance imaging (MRI) and low arterial pressure [12]. The crucial role of CPP in I-C haemorrhage has been confirmed using multimodal monitoring. CPP below 80 mmHg was associated with a greater risk of brain hypoxia and, to a lesser degree, with metabolic crisis [13]. Clinical seizures may occur in 9–13% of cases, and are detected more frequently with continuous EEG monitoring. Seizures may cause, or worsen, HICP [11].

Treatment

There are no studies proving that ICP monitoring or ICP-guided interventions, improve outcome following I-C haemorrhage. Management of increased ICP, however, seems a reasonable clinical target for reducing secondary brain damage and improving outcome [11]. Surgical removal of the haematoma aims to reduce the mass effect and ICP. Management of intraventricular haemorrhage can prevent hydrocephalus and improve ICP. Prevention and treatment of seizures may also help control ICP.

Osmotic agents have been used with contradictory results. In two randomised trials osmotic therapy did not improve CBF and outcome, while in a recent study a continuous infusion of hypertonic saline in 26 patients reduced the number of HICP episodes, compared with a control group, with potential outcome benefits, at the cost of hypernatraemia [14].

Intracranial hypertension in malignant hemispheric infarction

Causes

Massive hemispheric infarction follows acute obstruction of the middle cerebral artery (MCA), usually of embolic origin, with catastrophic effects. Complete ischaemia in the MCA territory is followed by oedema, which may involve a large portion of the hemisphere. When measured by MRI with diffusion-weighted imaging, volumes up to 300 mL have been recorded [15]. Following this, ICP increases and brain herniation is a frequent cause of death. The risk for such 'malignant' hemispheric infarction with secondary deterioration due to ICP is greatest in younger patients in who the lack of cerebral atrophy reduces intracranial compliance.

There is no effective medical treatment for this life-threatening event, and surgical decompression has been attempted in order to relieve ICP, preserve the unaffected brain, and improve outcome.

Despite the predominant role of ICP in this pathology, the benefits of ICP monitoring are unclear. Very few cases with accurate ICP measurement are reported in the literature. In 19 cases studied before surgical decompression with intraparenchymal probes, there was no correlation between the estimated volume of the infarct, on average 241 mL, and ICP. More concerning, pupillary abnormalities and severe brainstem compression were present in some patients despite normal ICP values [16].

Treatment

Osmotic agents have been used in order to control HICP after cerebral infarction. Two small series showed that mannitol does not alter midline shift, but can improve the neurological condition, acting preferentially on the non-infarcted, still perfused brain [17].

Surgical decompression may be a more effective treatment. Decompression lowers ICP, prevents herniation and decreases mortality after cerebral infarction. The big issue is that by reducing mortality it may increase the number of survivors with severe disability. In selected young patients, early decompression has been attempted with acceptable rates of disability [15]. Data from relatively small series in young patients have been pooled emphasizing the importance of three factors—age, early intervention, and infarct location. Older patients have consistently poorer outcome, regardless of treatment, so that recent trials have been restricted to patients in their fifties. Early intervention is crucial. Acceptable results, with reduced mortality and increased rate of favourable outcome compared with controls, can be achieved only when decompression is performed in the first 48 hours after stroke [18]. Finally, an infarct in the dominant, rather than in the non-dominant hemisphere may affect outcome differently. All these issues require further investigation [19].

Intracranial hypertension and hydrocephalus

Causes

Hydrocephalus is defined as an abnormal accumulation of CSF within the brain. The dynamics of CSF flow have been termed 'the third circulation' [20]. This term was coined from the realization that the CSF should not be regarded as simply a watery cushion for the brain, but rather as a dynamic and circulating medium with biological functions. These include functions as 'lymph' of the brain, and as transporter for mediators and neurotransmitters. The CSF is formed in the brain ventricles by secretion from the choroid plexus and by drainage of the extracellular fluid from the brain into the ventricular compartments. The production of CSF is, on average, 0.35 mL/min (approximately 500 mL/day); with a volume of approximately 150 mL, the CSF is almost completely refreshed 4–5 times per day. CSF flow is therefore relatively high and any disturbance in the triad of production, flow, and reabsorption can cause an abnormal accumulation of CSF within the brain, leading to HICP.

In general, three main causes of hydrocephalus may be differentiated:

- **Overproduction**: this concerns a relatively rare cause, resulting from a tumour of the choroid plexus, predominantly occurring in the paediatric population.
- **Obstruction of flow**: obstruction commonly occurs at narrow passages, such as at the level of the foramen of Monroe in the third ventricle, the aqueduct or in the fourth ventricle (infratentorial compartment).
- **Impaired reabsorption**: normally CSF is resorbed through the granulations of Pacchioni into the superior sagittal sinus. Any 'clogging' of these granulations, such as may occur following an infection or bleeding into the CSF space (e.g. following intraventricular or subarachnoid haemorrhage) can result in impaired reabsorption. Often, both a partial obstruction to flow and impaired reabsorption may contribute to the onset of symptoms.

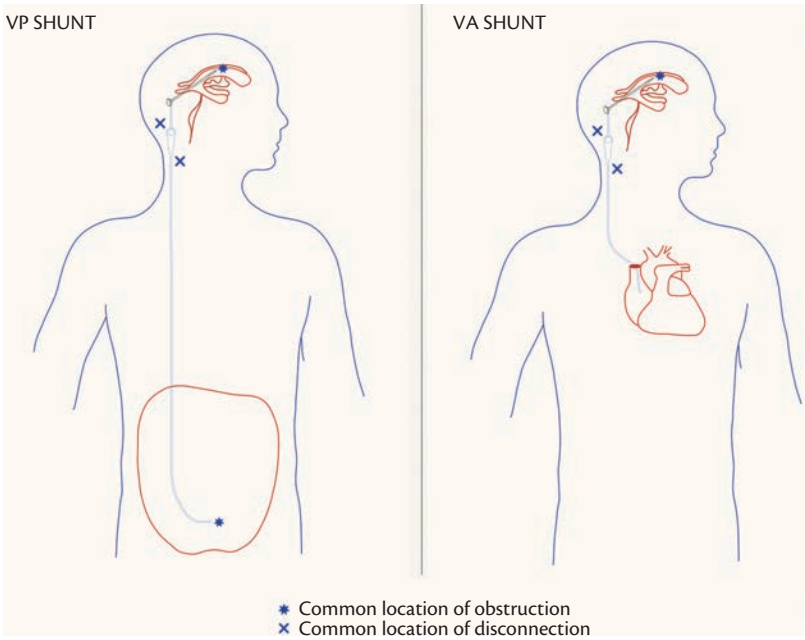

Fig. 233.1 A CSF shunt system consists of a ventricular catheter connected by a valve to the distal catheter draining CSF either to the abdominal cavity or to the right atrium of the heart. Disconnections commonly occur at the distal or proximal connections of the valve. Obstruction may occur at the level of the ventricular catheter (in-growth of choroid plexus into catheter) or in case of a ventriculoperitoneal shunt at the end of the distal peritoneal catheter. Frequently a low grade infection of the shunt system is the cause of the obstruction as the momentum covers the infection focus. A ventriculo-atrial shunt only functions adequately if the cardiac catheter is located within the right atrium (generally below the level of the 5th thoracic vertebra on chest X-ray).

Table 233.1 Diagnostic work-up of shunt dysfunction

Diagnostic test/examination	To detect
Radiographic examination of shunt system	
X-ray skull	Disconnection Check valve setting (in case of programmable valve)
X-ray abdomen* (for V-P shunt)	Intraperitoneal location
X-ray chest (for ventriculo-atrial shunt)	Position in right atrium
CT brain	Enlarged ventricles
Puncture of ventricular reservoir (if present) or valve with	
Pressure measurement	High ICP
Can CF be withdrawn?	Obstruction ventricular catheter
Send CSF to laboratory for: ◆ CSF culture. ◆ Cell count. ◆ Glucose/protein.	Infection

*Mark abdominal incision with metal object to locate entry into abdominal cavity.

Symptoms may develop gradually over time or acutely. Here, we focus on an acute onset of symptoms, which may occur with an obstruction of CSF flow, in the presence reduced intracranial compliance or because of an acute dysfunction of a CSF shunt. A CSF shunt is a valved internal drainage system, which diverts CSF either to the abdominal cavity (ventriculoperitoneal shunt) or via the jugular vein to the heart (ventriculo-atrial shunt). Dysfunction of the shunt system may be caused by a disconnection of one of the components of the drainage system or by obstruction of the ventricular or distal catheter. Disconnection commonly occurs proximal or distal to the valve, which is required to regulate flow and pressure whilst preventing backflow (Fig. 233.1). Presenting symptoms may include headache and vomiting followed by a decrease in the level of consciousness (Table 233.1). Emergency treatment is then life saving.

Treatment

Treatment of HICP due to hydrocephalus is relatively simple and consists of drainage of CSF. In the presence of an obstruction, CSF drainage should never be performed by lumbar puncture. Ventricular drainage is indicated. In acute situations a temporary solution is to insert a ventricular catheter to drain CSF externally. Drainage can be performed at a set pressure level (e.g. 15 mmHg) or be determined by the volume of CSF drained dependent on the indication for CSF drainage. When the indication is CSF leakage, the volume of CSF drained is important and drainage should be adjusted to a set volume. When the indication is intracranial hypertension drainage should be at a set pressure level. If the opening pressure is high, it is better to initially set the level at which CSF is drained high and then to slowly decrease it over the next 24 hours. The major risk of external CSF drainage is infection with infection rates of 2–10%. Strict sterile conditions should be maintained for every drain related procedure, but the routine use of extended antibiotic prophylaxis is not recommended. Periprocedural short duration prophylaxis may be considered an option. The infection rate increases with the duration of external CSF drainage. Routine catheter changes are however not recommended. The incidence of colonization of catheters may be decreased with the use of silver- or antibiotic-coated catheters, but the clinical benefit of these catheters in terms of reducing infections has not been definitively proven.

Temporary external drainage is indicated in emergency situations or in situations where the CSF obstruction may be resolved (e.g. surgery for a posterior fossa tumour). Definitive treatment of hydrocephalus can consist of either a third ventriculostomy (opening of the floor of the third ventricle into the basal cisterns) or an internal shunt procedure in which the CSF is most commonly diverted to the peritoneal cavity.

PART 9.8

Stroke

CHAPTER 234

Epidemiology of stroke

Candice Delcourt and Craig Anderson

Key points

- Approximately 20 million strokes occur in the world each year; stroke is the second most common cause of death resulting in 6 million deaths worldwide each year, 30% of survivors have permanent disability.
- Hypertension is the most important modifiable risk factor.
- Stroke has other major consequences in terms of residual physical disability, depression, dementia, epilepsy, and carer burden.
- Ischaemic strokes are more common than haemorrhagic strokes, and account for between 60 and 90% of strokes depending on the population.
- As with other forms of vascular disease, management of lifestyle-related risk factors offers the best approach to reducing the global burden of stroke.

Introduction

Worldwide, approximately 20 million strokes occur each year and over one-quarter of these are fatal. This makes stroke the second most common cause of death after ischaemic heart disease and responsible for about 6 million deaths (almost 10% of all deaths) annually [1]. Among survivors, at least 30% will have permanent disability, so stroke is also the fifth leading cause of premature life lost due to disability as defined by the metric 'disability-adjusted life years' (DALYs) [2]. Stroke also has consequences that extend beyond physical disability to that of depression (in about 30%), dementia (10%), and epilepsy (5%). Moreover, as stroke is often a manifestation of generalized vascular disease, around 20% of survivors experience either further stroke or serious vascular event within a few years of the index event [3]. There are also the considerable direct costs of care for patients with acute stroke, estimated to be about 2–4% of all the costs of healthcare, worldwide [4]. Finally, there are the indirect economic costs associated with lost productivity and the out-of-pocket expenses for families. The grief and suffering imposed by stroke are difficult to quantify, but are clearly enormous. With ongoing demographic changes, including the ageing and urbanization of populations, together with the persistence of highly prevalent risk factors related to adverse lifestyles, the global burden of disease related to stroke is predicted to increase substantially by 2030. Ischaemic stroke contributes the greatest share of the impact of stroke. It has a rate of approximately 1 in 1000 person-years, and accounts for between 60% of all strokes in Asia and 90% in Western 'white' populations.

Definition of stroke and transient ischaemic attack

Despite significant advances being made in diagnostic technology and the management of stroke in recent decades, the diagnosis remains largely clinical. For the last 40 years stroke has been defined by the World Health Organization (WHO) as 'rapidly developing clinical signs of focal (or global) disturbance of cerebral function with symptoms lasting 24 hours or longer (or leading to death), with no apparent cause other than vascular origin' [5]. Where the symptoms (and signs) resolve within 24 hours, the syndrome has traditionally been defined as transient ischaemic attack (TIA). However, this arbitrary time-based definition was established before the widespread availability of brain imaging (computerized tomography (CT) or magnetic resonance imaging (MRI)) and use of early treatment to recanalize an occluded cerebral artery. Patients with TIAs commonly have ischaemic lesions on brain imaging [6] and these carry the same prognosis for death, permanent disability, and recurrent stroke as that of a minor ('completed') ischaemic stroke [7,8]. For epidemiological purposes, the old definition of TIA is likely to remain, but for clinical management, the presence of an ischaemic lesion in association with an acute stroke syndrome should be considered an ischaemic stroke and patients managed accordingly.

Prediction of ischaemic stroke following TIA

A simple assessment called the ABCD^2 score, is calculated according to a 7-point scale that sums each patient's score on 5 risk factors: **A**ge ≥ 60 (1 point) versus < 60 years old (0 point), **B**lood pressure (BP) systolic ≥140 or diastolic ≥90 mmHg(1 point)), **C**linical features unilateral paresis (2 points), speech disturbance(1 point)), **D**uration of symptoms >60 minutes (2 points), 10–59 minutes (1 point) and <10 minutes (0 point), and **D**iabetes (1 point). This score can be used to identify patients at high risk of ischaemic stroke in the first days after TIA [9,10]: the higher the score, the higher the prediction. Rapid assessment of the internal carotid artery by CT or MRI angiography, or duplex ultrasonography, will allow the detection of an 'unstable' (i.e. irregular or ulcerated plaque) or high grade (>70%) stenosis that should be treated early to prevent the occurrence of a major stroke in an otherwise well patient.

Classification systems for ischaemic stroke

Ischaemic stroke can result from a heterogeneous range of disorders that are not necessarily related to atherosclerosis, have different manifestations of occurrence and patterns of outcome, and may require different management. Broadly speaking, ischaemic stroke,

which accounts for about 80% of stroke in 'white Caucasian' populations (other ethnic groups have a greater proportion of haemorrhagic strokes), can occur via the following principle mechanisms (with proportional frequencies) as applied in clinical research as the TOAST (Trial of ORD 10172 in Acute Stroke Treatment) criteria [11]:

- **Cardio-embolism (20–30%)**: secondary to atrial fibrillation (AF), valvular heart disease or from infectious endocarditis.
- **Large vessel atherosclerosis (20–30%)**: in situ atheromatous occlusion of intracerebral arteries (more common in Oriental Asian patients), or artery-to-artery embolism from carotid stenosis or plaques in the arch of the aorta.
- **Small vessel disease (10–20%)**: lacunar disease.
- **Arterial dissection (3–5%)**: mostly extra-cranial carotid or vertebral arteries
- **Rare forms (1–5%)**: includes secondary to recreational drug use (e.g. cocaine and amphetamines, which can also cause haemorrhagic strokes), haematological (e.g. polycythaemia), arteritis (e.g. temporal arteritis), metabolic (e.g. Fabry disease), cerebrovasoconstrictor syndrome, or many other disorders.
- **Unknown or undetermined cause ('cryptogenic') (5–10%).**

A popular classification of ischaemic stroke that uses only clinical symptoms and signs was derived from the Oxfordshire Community Stroke Project (OCSP) [12]. The OCSP syndromic classification system is based upon the extent of cerebral involvement and is a simple grading system of severity and prognosis covering total anterior circulation infarcts (TACI), partial anterior circulation infarcts (PACI), lacunar infarcts (LACI), and posterior circulation infarcts (POCI).

Haemorrhagic stroke

Parenchymal intracerebral (I-C) haemorrhage account for 10–40% of strokes around the world, but most of those affected live in developing countries where hypertension is common. I-C haemorrhage is the least treatable form of stroke, and carries a high risk of death and residual disability, 30-day mortality is 30–55%, with half of these deaths occurring within the first few days. I-C haemorrhage arises from the brain parenchyma, but can extend into the ventricular system and subarachnoid, subdural, or extradural spaces.

I-C haemorrhage is difficult to differentiate from ischaemic stroke at the bedside, but certain features raise suspicion of the diagnosis. Rapidly progressive neurological signs and symptoms, associated headache, vomiting and seizures, and a reduced level of consciousness that is disproportionate to any focal deficit (i.e. paresis), all suggest mass effect from an underlying haematoma. Neck stiffness indicates that blood has breached the subarachnoid space, generally via the ventricular system, which can produce chemical meningitis and/or hydrocephalus. The most reliable way to diagnosis I-C haemorrhage is a non-contrast computed tomographic (NCCT) brain scan.

Most I-C haemorrhage, approximately 80%, occur secondary to disease of small (<3 mm) penetrating arteries from chronically-elevated blood pressure (BP). I-C haemorrhage typically occurs in deeper locations of the brain, such as the putamen, thalamus, pons, and cerebellum. Another, increasingly recognized cause of I-C haemorrhage, is cerebral amyloid angiopathy, which is due to the deposition of amyloid β-peptide in small and middle size vessels. This is presumed to 'destabilizes' surrounding architecture to produce I-C haemorrhage.

Subarachnoid haemorrhage

The other form of haemorrhagic stroke is subarachnoid haemorrhage (SAH), most often due to spontaneous rupture of an intracranial aneurysm. It accounts for about 5% of strokes, but leads to a similar loss of productive life years as cerebral infarction. In Western countries, SAH has an annual incidence of 8–10 per 100,000, a 30-day case fatality of up to 45%, and leaves many survivors with varying degrees of physical disability and psychosocial problems.

Rates and risk factors

Stroke incidence varies between different countries and regions, and over time. Among recent (1990 onwards) population-based studies that have used standardized definitions and case ascertainment procedures, the age-standardized rates (per 100,000 person-years) of stroke have varied from 58 in France to 314 in Finland. Between 1970–1979 and 2000–2008, there has been a 42% decrease in age-adjusted rates in high-income countries, but a more than doubling of rates in low- and middle-income countries. Stroke mortality also varies between populations; age-standardized mortality is higher in Eastern Europe and low- and middle-income countries than elsewhere. In Asia, where the burden of stroke is particularly high, death from stroke is proportionally greater than that from myocardial infarction, a pattern that is the reverse of that seen in Western countries, and probably due to a greater proportion of strokes being due to I-C haemorrhage [13].

While age-standardized stroke incidence and mortality appears to have declined in high-income countries [14,15], the absolute number of people experiencing strokes, and mortality and dependency from stroke, will continue to increase [16], due to the ageing of populations and where the highest stroke rates occur. As a result, stroke is predicted to remain the second most common cause of death worldwide, accounting for an estimated 7.8 million deaths annually by 2030 [1,2].

Stroke is associated with a number of identified modifiable and non-modifiable risk factors; 90% of the population-attributable risk of stroke can be explained by 10 factors (hypertension, physical inactivity, abdominal obesity, ratio of apolipoprotein B to A1, smoking, diet, cardiac causes, diabetes mellitus, psychosocial stress or depression, and excessive alcohol intake) [17]. Elevated BP (defined as systolic >115 mmHg) is the most important modifiable risk factor, estimated to account for at least half of all strokes, with about half of this burden due to 'hypertension' defined as systolic BP >140 mmHg and/or diastolic BP >90 mmHg [18].

Elevated BP is a major determinant of initial (primary) and recurrent (secondary) ischaemic stroke. Observational studies demonstrate a strong and near continuous relationship between the risk of stroke and usual level of BP [19]. The association exists for both systolic and diastolic BP and continues among those with average or below average BP, with no threshold identified below which the risk of stroke does not decrease. The association becomes attenuated with increasing age although remains strongly positive for all age groups. A 10 mmHg lower usual systolic BP is associated with 40–50% lower risk of stroke among those under 60 years of age, but a 20–30% lower risk among those over 70 years. The association is consistent in men and women, non-Asian and Asian populations, and for both fatal and non-fatal strokes, but it appears steeper for I-C haemorrhage than for ischaemic stroke. Finally, disturbances of the normal diurnal

variation in BP, including absence of nocturnal drop ('non-dipping') and wide fluctuations, particularly excessive early morning acceleration in the peak ('morning surge'), are especially associated with strokes and other manifestations of cerebrovascular disease [9].

Other major risk factors include AF, extracranial carotid artery atherosclerosis, diabetes mellitus, cigarette smoking, and hyperlipidaemia.

In-hospital strokes

In-hospital strokes are not uncommon due to the increasing number of operations being performed on older patients, including those with known and asymptomatic co-morbid vascular disease. The major contributing procedures are in cardiothoracic surgery including coronary artery bypass grafting where risk of stroke may be as high as 5% overall, and 10% in those ≥75 years. For valvular cardiac surgery the risk may be as high as 10–15%. The management of anticoagulation in patients with AF is complex—it is not uncommon for peri-operative strokes to occur in patients who have had their anticoagulation stopped to reduce bleeding risk. The annual risk of stroke in the setting of AF varies from less than 1% in younger healthy adults with otherwise normal cardiac structure and function, to more than 10% according to the presence of one or more clinical characteristics such as congestive cardiac failure, hypertension, older age (≥75 years), diabetes mellitus, and a history of previous stroke or TIA. All 'high risk' patients should be considered for 'bridging therapy' with low molecular weight heparin prior to surgery and full anticoagulation recommenced as soon as possible (preferably within 48 hours) after surgery to lower the considerable risk of stroke. For most patients this carries an acceptable small increase in the risk of peri-operative bleeding, which can generally be managed. The risk of cardioembolic stroke in the context of peri-operative AF appears dependent on a variety of factors including the degree of cardiac enlargement, particularly of the atria (and propensity for clots to develop through stasis of blood in the atrial appendices), degree of transient hypercoagulability from the trauma of surgery, and the peri-operative development of a low cardiac output syndrome [20].

Conclusion

Stroke constitutes a major proportion of the global burden of disease, and causes premature death and disability across all ages. However, stroke is an eminently preventable and treatable disease. While the best opportunity for reducing the burden of stroke across the community is widespread implementation of broad-based prevention strategies, measures that increase awareness of the symptoms and timely use of diagnostic and treatment strategies can also provide benefits to patients, families, and society.

CHAPTER 235

Diagnosis and assessment of stroke

Candice Delcourt and Craig Anderson

Key points

- Approximately 20 million strokes occur in the world each year, making it the second most common cause of death resulting in 6 million stroke deaths worldwide each.
- Nearly half of stroke survivors have permanent disability.
- Stroke also has major consequences in terms of residual physical disability, depression, dementia, epilepsy, and carer burden.
- Diagnosis and assessment are essentially clinical and confirmed by CT or MRI scanning.
- Prognostication is difficult in the early phase of haemorrhagic stroke, and in ischaemic stroke is affected by the availability and timely use of treatments to recanalize the occluded vessel.

Diagnostic assessment and investigations

There are a wide range of simple structured diagnostic algorithms for the diagnosis of stroke intended to be used by paramedics and triage nurses. In Australia and many other countries, the most common tool in use is FAST:

- **Face**: unilateral facial weakness.
- **Arm**: arm weakness.
- **Speech**: speech disturbance.
- **Time**: known time of onset (and time to call the emergency number).

Diagnostic algorithms allow paramedical staff to rapidly recognize symptoms of stroke, assess eligibility for thrombolysis, and transport to a suitable hospital for treatment [1]. Effective delivery of acute stroke treatments involves efficient links in the chain, with will trained paramedical staff inserting a suitable intravenous access line, providing advanced notification to the emergency department, where there are responsive systems of triage, diagnostic assessment and management [2]. Such systems provide short door-to-imaging and door-to-needle times to allow rapid and probably safer use, and improved outcomes for thrombolytic therapy.

Following admission to the emergency department, all patients with a suspected stroke should have a non-contrast computed tomographic (NCCT) scan, or where available magnetic resonance imaging (MRI), of the brain, routine blood tests (blood count including platelet count, serum glucose, prothrombin time, and international normalized ratio (INR) electrolytes, urea, and creatinine), and an electrocardiogram. With rapid advances being made in brain imaging, the extra- and intracranial vessels (CT angiogram, MR angiogram) and the ischaemic penumbra (CT perfusion, MRI) can be readily visualized. However, these tests should not delay the use of thrombolysis in eligible patients with ischaemic stroke, but are useful in identifying those patients who are unlikely to respond to thrombolysis (massive infarct with dead tissue, large proximal vessel clot occlusion) or endovascular stent (clot) retrieval treatment. There is now good evidence that a second attempt at opening a brain vessel using intra-arterial thrombolysis or specific devices can restore brain function in a potentially salvageable area [3].

The ischaemic penumbra can be mapped using CT perfusion. The penumbra is the area where there is decreased cerebral blood flow (CBF) and increased mean contrast transit time without decreased cerebral blood volume.

In specialized centres, MRI diffusion-perfusion will be used. The diffusion abnormality identifies the core irreversibly injured tissue, while the perfusion abnormality identifies the tissue at risk of eventual infarction.

A period of up to 72 hours of electrocardiogram (ECG) monitoring is useful for the detection of intermittent or poorly-controlled atrial fibrillation (AF), which is an important cause of intracardiac thrombus formation and cardio-embolic stroke. If negative, ambulatory cardiac monitoring for several days, possibly longer with an implantable loop recorder, for patients with a cryptogenic ischemic stroke or transient ischaemic attack (TIA) is recommended. Transthoracic echocardiography is often performed, but rarely useful in altering patient management unless there is a high index of suspicion of an underlying cardiac abnormality (e.g. mural thrombus in a patient with recent myocardial infarction, established coronary artery disease, or poor left ventricular function). Transoesophageal echography is recommended to examine for underlying aortic atheroma, valvular disease (e.g. myxoma, endocarditis) or patent foramen ovale (PFO) in a young patient without a clear cause for cardio-embolic ischaemic stroke. The role of PFO is controversial. PFOs are very common in the general population and the risk of stroke is very small. When a stroke or transient ischaemic attack (TIA) occurs, it is most often small and in the context of a triggering event, such as prolonged air travel or exercise with a valsalva manoeuvre, that allows a small venous thrombus to cross through the PFO into the arterial circulation and block a cerebral vessel. However, more importantly, the risk of recurrent stroke in among those with known PFO is also very

small. Unless the shunt is particularly large (determined by the degree of shunt and enlargement of the left atria), treatment with aspirin is adequate for the prevention of thromboembolism. If the shunt is large, anticoagulation with warfarin is a sensible alternative. Closure of the PFO through use of an endovascular device is an alternative treatment; it requires a skilled proceduralist and carries small risks in particular of AF. Where angiography is less readily available, Transcranial Doppler ultrasound (TCD) can be undertaken to visualize intracranial artery stenosis, collaterals and the haemodynamic change related to a neck vessel stenosis.

Cerebral autoregulation and ischaemic cerebral injury

As the brain has high-energy requirements and is unable to store nutrients, it is totally dependent on having a secure blood supply. Cerebral autoregulation aims to ensure there is an adequate cerebral blood flow (CBF) (50 mL/100 g/min) within a tightly-regulated range despite changes in blood pressure (BP) and cardiac output in relation to posture and activity. When the lower limit of CBF is reached (<10 mL/min/100 g), cerebral ischaemia and neuronal death occur unless blood flow is rapidly restored. Following the occlusion of a cerebral artery that occurs in an acute ischaemic stroke (and TIA), there is immediate hypoxic injury and rapidly occurring death of neurons within a central core. However, there is a more delayed death in a region called the 'ischaemic penumbra', which is protected by virtue of being located in the watershed boundary of the lesion where some blood flow is maintained from collateral vessels. The size and reversibility of the ischaemic penumbra varies widely, although it is related to the extent of involvement of vascular territory in the brain. Outcome depends on rapid recanalization of the occluded vessel, either by natural means or through thrombolytic therapy or endovascular mechanical intervention. It also depends on the availability of a collateral blood supply. Unfortunately, the presence of collateral blood vessels and their response to injury is probably predetermined, and cannot be easily measured at the time of presentation of acute ischaemic stroke and is difficult to modify.

Prognostic predictors: ischaemic stroke

The chance of surviving an ischaemic stroke is a complex function of the brain lesion *per se* and of many other co-morbid and complicating factors. The size and location of the cerebral lesion have an impact on the immediate prognosis, while vascular and co-existing (cardiac) disease and complicating disorders, such as bronchopneumonia, urosepsis, and thromboembolism, all determine whether a patient will survive the first few weeks after onset. Cardiovascular disease also influences long-term survival. Although studies have emphasized the adverse effect that increasing age has on survival after stroke, this relationship is more complex and more related to the presence of other variables that are more common in older people. The presence of pre-morbid disability is particularly important, which underscores the importance of obtaining this information when making decisions about interventions and the prolonged use of supportive care.

The prognosis in terms of general recovery after ischaemic stroke can be assessed in terms of the following variables:

- **Severity of the initial neurological deficit**: including the degree of ataxia and paralysis will determine the speed and ultimate degree of recovery in physical function.
- **Speed of recovery of neurological deficit**: the rapid return of function in the first week is a good prognostic sign.
- **Attention, awareness and cognitive insight are important**: as rehabilitation involves re-learning and participation. Fatigue, poor memory, and lack of insight are major barriers to successful recovery.
- **A supportive spouse or personal carer**: can offset the degree of residual disability and determine whether a patient is able to return home or will require long-term residential care.

Recovery of physical function is most rapid in the first weeks after ischaemic stroke, and tends to plateau by 3–6 months.

Prognostic predictors: haemorrhagic stroke

As it is difficult to reliably predict clinical outcome in the early phase of intracerebral (I-C) haemorrhage, and evidence indicates that 'do-not-resuscitate' or 'withdrawal of care' orders are independent predictors of early mortality. A policy of 'active' care should be applied to patients with I-C haemorrhage upon admission to hospital unless there are extenuating circumstances. A period of acute care allows time for a patient's critical condition to stabilize, and to assess the effects of potential complicating factors, such as early seizure(s), dehydration, and sudden internal 'barotrauma' of the I-C haemorrhage on the brain. It also allows time for counselling and discussion with family members regarding ongoing management in the context of their various cultural, religious, and personal beliefs, including those known or assumed of the patient.

I-C haemorrhage is a dynamic illness, where expansion or 'growth' of the haematoma occurs in most patients. Substantial expansion is conventionally defined as a >33% relative or >12.5 mL absolute growth in the first 24 hours, which is what can be detected visually on a CT scan, occurs in at least one-third of patients within several hours of onset. Both the volume of haematoma on initial CT and the extent of growth are major determinants of outcome. Volumes greater than 30 mL invariably result in early death from neuronal trauma and mass effect, while patients with smaller haematomas may survive the initial event, but remain at risk of succumbing to the complications of residual disability or a recurrent event.

Conclusion

Stroke constitutes a major proportion of the global burden of disease, and causes premature death and disability across all ages. Diagnosis and assessment are essentially clinical and confirmed by CT or MRI. Prognostication is difficult in the early phase of I-C haemorrhage, and in ischaemic stroke is affected by the availability and timely use of treatments to recanalize the occluded vessel.

CHAPTER 236

Management of ischaemic stroke

Sully Xiomara Fuentes Patarroyo and Craig Anderson

Key points

- The diagnosis of acute ischaemic stroke is based on establishing a clear history of an abrupt onset of neurological symptoms and signs.
- Reperfusion therapy with thrombolysis using intravenous recombinant tissue plasminogen activator should be used routinely in all patients with acute ischaemic stroke within 4.5 hours of onset who have no bleeding risk.
- Endovascular stent (clot) retrieval therapy should be used in patients with documented proximal clot occlusion who are able to access appropriate specialist centres within several hours of onset.
- Patients should be actively monitored following thrombolysis.
- Secondary prevention includes blood pressure (BP) lowering, antiplatelet, or anticoagulation according to cardiothrombotic risk, cholesterol lowering, and selected use of carotid revascularization.

Introduction

Ischaemic stroke accounts for approximately 80% of all strokes worldwide. As the therapeutic time window to rescue the brain from ischaemic injury is extremely short (only a few hours at most) [1], effective management requires good systems of communication and a responsive expert team to ensure rapid diagnosis, and safe and effective delivery of acute treatment. Indeed, two of the most important therapeutic advances in stroke medicine are arguably the recognition that well-coordinated multidisciplinary care (not specifically hyperacute care) in the form of stroke care units [2], can significantly improve the chances of recovery from stroke, and that brain function can be preserved and satisfactory outcomes achieved through the use of reperfusion therapy, until recently limited to thrombolytic therapy but now open to mechanical stent (clot) retrieval treatment [3], to recanalize an occluded vessel and reperfuse the 'at risk' area of the brain, defined as the ischaemic penumbra [4]. Other aspects of management include the prevention of complications of the neurological disability [5], timely rehabilitation, realistic recovery goal setting, and prevention of recurrent stroke and other vascular events.

Diagnosis and acute treatment

Approach to the patient

The diagnosis of acute stroke is based on establishing a clear history of an abrupt onset of 'negative' (i.e. loss of function) neurological symptoms and signs. A brief yet accurate examination focused on detecting neurological deficit(s) is all that is required to identify both the presence and severity of an underlying stroke. The most popular structured scoring system, the National Institutes of Health stroke scale (NIHSS), enables a standardized and reproducible assessment of any neurological deficit, and it is highly predictive of short- and medium-term functional outcome. The NIHSS takes a person about 2 hours to become fully trained and accredited via an online method (see http://www.americanheart.org), and experienced users can streamline their assessment to under 2 minutes. The NIHSS is much more sensitive to neurological impairment than traditional measures, such as the Glasgow Coma Scale (GCS), which was developed for patients with traumatic brain injury.

Paresis ('weakness') or plegia ('complete loss of power') is the most common manifestation of stroke, but it is non-specific and can be attributed to a lesion anywhere along the corticospinal tract. Other features to indicate the lesion has a large size and more indicative of large vessel(s) occlusion in the brain include hemianopia, aphasia, and right gaze deviation and/or visual neglect. Although lacunar strokes are common in older people with hypertension (due to occlusion of small perforating vessels in the basal ganglia, thalamus, internal capsule, or brainstem), they are not be associated with any visual field, language or visuospatial deficit. Symptoms in the posterior circulation include vertigo, ataxia, or diplopia.

Rapid assessment and treatment

There is now compelling evidence from multiple randomized trials to support the routine use of thrombolysis with intravenous recombinant tissue plasminogen activator (rtPA) at a standard dose of 0.9 mg/kg (10% bolus, 90% infusion over 60 minutes, maximum dose 90 mg) in patients with acute ischaemic stroke within 4.5 hours of onset who are otherwise well and have no major contraindications to bleeding [1,4]. The earlier the administration of rtPA, the better the outcome, but the downside is risk of bleeding, the most serious being major symptomatic intracerebral haemorrhage (sICH), which occurs in about 5% of patients in experienced centres. This risk is generally deemed acceptable by most clinicians, patients and families. If a patient cannot give a reliable history, then the onset of the stroke must be taken from the time they were last seen well. This can be particularly difficult when the patient's symptoms are present on waking from sleep (so-called 'wake-up stroke'), in which case the onset time must be taken from when patient was last known to be well prior to going to sleep.

Modern brain imaging, such as computed tomographic (CT) perfusion or magnetic resonance imaging (MRI), can allow detailed assessment of the location and size of ischaemic tissue that

is both 'at risk' (i.e. the penumbra) and probably irreversible (i.e. infarction). However, such imaging is not always readily accessible and the extra time required for processing and measurement of the images delays use of rtPA and its potential benefit. CT or MRI angiography (CTA, MRA) is useful in identifying the location of the blocked cerebral vessel, especially when it is proximal, as indicated by the patient having a neurological deficit and a 'dense artery sign' on the non-contrast CT (NCCT). Due to the large clot burden, such patients are less likely to respond to rtPA and may benefit from mechanical clot retrieval [3,6]. Again, however, obtaining a CTA should not unduly delay treating the patient, due to the injection of contrast (and risk of nephrotoxicity if there is impaired renal function) and the need to obtain direct involvement of a radiologist in the procedure. Thus, a plain NCCT, which takes less than 5 minutes, is all that is required to establish the diagnosis of ischaemic stroke, and the absence of haemorrhage or any secondary structural lesion, to allow rapid treatment with rtPA.

Acute treatment options

Thrombolysis

The 'time is brain' motto is critical—assessment, diagnosis, and treatment needs to comply with an internationally accepted 'door to needle' performance time measure of less than 60 minutes. While there is a long list of potential contraindications to thrombolysis that can be seen in regulatory documents and guidelines, in practice the aim is to ensure that the risks of bleeding are not excessive, and there are no major comorbid medical conditions that may complicate the diagnostic work-up and outcome. Patients who are anticoagulated with warfarin should have their International Normalized Ratio (INR) returned to a near normal level (<1.8) before giving rtPA to avoid an excessive risk of bleeding. There is controversy as to the management of minor strokes (e.g. isolated aphasia or paresis; NIHSS <6). As they have been excluded from most clinical trials because of their good prognosis, greater potential for being a stroke mimic (i.e. migraine, post-seizure, functional, or metabolic disturbance), so rtPA may not provide a net benefit and pose an unnecessary risk. However, a case can be made for giving rtPA to such patients as at least 30% will progress due to an unstable lesion or cerebral blood flow, and the risk of sICH is low as the underlying deficit is small. There is less controversy over the avoidance of rtPA in patients with large strokes (i.e. NIHSS >24; drowsy and obtunded; deficit involving >1/3 of the middle cerebral artery territory) because they have a high risk of sICH and low likelihood of having any underlying reversible ischaemic tissue.

Mechanical clot retrieval

Interventional neuroradiology (INvR) by means intra-arterial thrombolysis (often with the catheter tip dislodging the clot) or more often use of mechanical clot retrieval (of which there are an increasingly wide range of devices/stents) are associated with higher rates of recanalization in comparison with intravenous rt-PA alone, particularly for large proximal clots (i.e. terminal internal carotid artery, proximal anterior or middle cerebral arteries). Recently, substantial evidence of efficacy has been obtained from several randomized trials indicating improved recanalization translates into improved clinical outcome limits the application of the treatment in practice [3]. Moreover, as INvR is a highly skilled, resource-intensive discipline, and the devices are expensive, effects are underway to assess the most appropriate organization of regional systems of care around INvR.

Hemicraniectomy

Malignant middle cerebral artery (MCA) infarction is the term used to describe rapid neurological deterioration from cerebral oedema with transtentorial herniation and brainstem compression [6]. It is most often seen within the first 24–48 hours of ischaemic stroke in younger people (<60 years) as older people are somewhat protected as brain atrophy allows room for expansion of cerebral oedema. It can be predicted from the initial CT by presence of early ischaemic changes of >50% of the MCA territory [7]. No medical therapy has proven to be effective for cerebral oedema, thrombolysis does not reduce the risk of developing malignant MCA infarction, and the prognosis is poor with a mortality rate up to 80%. Decompressive hemicraniectomy, involving resection of a large bone flap to relieve intracranial pressure, has been shown to be a life-saving procedure and improve neurological outcome. It should be considered in all younger patients with large MCA infarction and progressive neurological deterioration over 48 hours after onset. Such cases require early notification to a neurosurgeon to ensure appropriate timing (i.e. before the patient has fixed dilated pupils!) and reinforcement to involved clinicians and family members that the procedure results in most patients being left with degree of disability, but not necessarily requiring residential care.

Aspirin

The use of standard dose (100–300 mg) aspirin with 48 hours of the onset of ischaemic stroke has been shown to improve the chance of surviving free of disability at 6 months [8]. However, the treatment only has a modest effect, does not appear to be time-dependent, and may work more through the prevention of early recurrence of ischaemic stroke, rather than any improvement in the ischaemic deficit. It should be avoided for 24 hours in patients given rtPA (earlier use of antithrombotic agents increases the risk of sICH).

Neurological and physiological monitoring

Immediate period after reperfusion therapy

For at least 24–48 hours after admission to hospital, and particularly following thrombolysis or clot retrieval, patients should be cared for in a monitored facility, either in an intensive care unit or high dependency area of a stroke unit. The most appropriate location is dependent on the severity of the patient's status and availability of resources. Trained nursing (and medical) staff should undertake frequent monitoring and be able to take an appropriate action according to prespecified protocol(s). The most serious early complication of thrombolysis/clot retrieval is sICH, which should be suspected in anyone with sudden deterioration in neurological status, headache, nausea, vomiting, or elevation in blood pressure. An immediate NCCT will differentiate intracerebral (I-C) haemorrhage from cerebral oedema, the patient's coagulation and haematological parameters should be checked, and any residual effect of rtPA can be corrected by administration of 6–8 units of cryoprecipitate (containing clotting Factor VIII) and 6–8 units of platelets. Surgical evacuation of the I-C haemorrhage may be possible following treatment with platelets and cryoprecipitate, although the rapidity of

neurological deterioration is such that prognosis is grave, irrespective of any treatment. All invasive interventions must be balanced against the risk of bleeding:

- Invasive and in-dwelling catheters should be avoided at least an hour post-rtPA (if indicated, consider insertion prior to administration of rt-PA).
- Nasogastric tube, venipuncture, and arterial puncture for 24 hours post thrombolysis.
- Brushing teeth for 36 hours post-thrombolysis (mouth swabs should be used instead).

Blood pressure

Over two-thirds of patients are hypertensive at the time of an acute ischaemic stroke [9] and the higher the BP, the worse outcome [10]. However, in the absence of randomized evidence, there is uncertainty regarding the optimal management of high BP in this setting, particularly as aggressive BP reduction may reduce cerebral blood flow and aggravate ischaemia. Current guidelines, based on expert consensus opinion, recommend that antihypertensive medications be withheld unless the BP exceeds 220/120 mmHg except for those patients considered for rt-PA, where the BP should be lowered to ≤185/110 mmHg and kept at this level thereafter. Whether some drugs should be used preferentially is unknown.

Bed rest, and control of glucose and temperature

Patients should rest in bed for 24 hours after rt-PA, as a precaution against sICH. Cardiac rhythm should be monitored for up to 72 hours. Guidelines recommend monitoring temperature, oxygen saturation, respiratory rate, heart rate, and neurological status every 15 minutes for the first 2 hours, then every 30 minutes for 6 hours, then hourly for 16 hours (a total of 24 hours), and 6-hourly (i.e. four times daily) thereafter. Given the high prevalence of diabetes mellitus among patients with ischaemic stroke, all patients should have a screening blood glucose concentration on admission, and for those with known diabetes or high baseline levels, have glucose monitored 4-hourly for at least the first 24 hours. Although there is no randomized evidence, fever ≥38°C should be treated as should a blood glucose level of >10 mmol/L. As many patients present dehydrated, hydration should be maintained, and most effectively through the intravenous route as dysphagia is common.

Early complications of ischaemic stroke

Thromboembolism

Patients with acute stroke have an increased risk deep venous thrombosis and pulmonary embolism. This risk is higher in patients with severe neurological deficit, older age, and prolonged immobilization. Measures to reduce the risk include early mobilization, aspirin, and the use of external compression devices. The administration of subcutaneous low-dose unfractionated heparin or low-molecular weight heparin is recommended in patients with prolonged immobilizaton (>72 hours) to avoid an early excess risk of sICH; delayed for >24 hours after thrombolysis. External compression is useful in those patients that cannot tolerate an antithrombotic agent. The potential benefit of anticoagulation should be weighed against the small risk of haemorrhagic transformation of the cerebral infarction and of other bleeding complications.

Aspiration pneumonia

Aspiration pneumonia is a common and serious complication after acute stroke, conferring a three-fold increase in mortality [11]. Decrease level of consciousness, immobility, and dysphagia are risks factors with the latter being the most significant. Swallowing assessment by a speech therapist or a trained nurse is recommended for all patients, with the avoidance of food or fluids according to the degree of dysphagia. Care is required in the use of a nasogastric tube for feeding, as the regurgitation of the fluids/feeds can lead to aspiration. There is no evidence that prophylactic use of antibiotics is beneficial.

Seizures

Seizures occur in about 5% of the patients with an ischaemic stroke, but there is no data to support the use prophylactic anti-epilepsy drugs. If seizures occur, lamotrigine and gabapentine may be preferential because they do not interact with anticoagulants or antiplatelet agents [12].

Other complications

Other common complications of acute ischaemic stroke include:

- **Delirium**: causes agitation and distress, and the risk of falls and other injury.
- **Disturbance of sleep**: via multiple potential mechanisms, including sleep fragmentation due external stimuli.
- **Alteration:** in circadian rhythm, medications, either pre-morbid or stroke-related obstructive or central sleep apnoea.

Secondary prevention

Blood pressure lowering

Elevated BP is the single most important reversible risk factor for both first-ever and recurrent (secondary) stroke or TIA. Randomized evidence indicates that lowering BP can produce very large beneficial effects [13]; even a modest (e.g. 8/4 mmHg) average reduction can be associated with a 20–25% reduction in the risk of recurrent stroke and other serious vascular events, even in people with average or below-average levels of BP. The degree of BP lowering is far more important than the particular agent [14]. BP lowering can safely be commenced when the patient is medically stable (i.e. when mobilizing), and modified according to tolerability in the use multiple agents.

Antiplatelet therapy

Antiplatelet therapy (i.e. aspirin, clopidogril, combination low-dose aspirin and dipyridamole) is an essential strategy for the secondary prevention of ischaemic stroke, as well as for other cardiovascular events. While antiplatelet therapy confers a small absolute increase in the risk of I-C haemorrhage and major extracranial haemorrhage, the overall benefits outweigh the bleeding risks among high-risk patients.

Anticoagulation

Anticoagulation with warfarin or the new oral anticoagulants (NOACs) is highly effective at preventing strokes in patients with atrial fibrillation (AF), particularly in the elderly who are at highest

risk. Meta-analyses of trials show that adjusted-dose warfarin (target INR of 2.5) reduces the risk of stroke by about two-thirds, whereas aspirin only reduces the risk by about one-fifth [15], and the excess risks of I-C haemorrhage and major extracranial haemorrhage are small (about 1–2% and <0.3% per year, respectively). Since patients with AF and a history of ischaemic stroke/TIA have a risk of recurrent stroke of >12% per year, the absolute benefit is substantial. NOACs agents, such as the oral direct thrombin inhibitor dabigatran, offer comparable efficacy to warfarin with lower bleeding rates, and they avoid the need for the monitoring INR. However, the anticoagulant effect can only be reversed by dialysis and so the risk of bleeding complications has yet to be quantified.

Cholesterol lowering therapy

Randomized trials indicate that reducing total and low-density lipoprotein (LDL) cholesterol with HMG-CoA reductase inhibitors (statins) significantly reduces the risks of major vascular events, including stroke, across a wide range of lipid levels in patient populations at varying risk of vascular disease [16].

Carotid revascularization

Patients with high degrees (>70%) of carotid stenosis are at elevated risk of ipsilateral ischaemic stroke, most commonly in the first few days after a stroke or TIA. Randomized trials have established the benefits of carotid endarterectomy in such patients with acceptable perioperative risk (2–5%) [17]. The benefits of surgery decrease with time, emphasizing the need for rapid assessment and treatment of such patients. Percutaneous transluminal carotid artery stenting avoids the need for hospital admission and general anaesthesia, but several major randomized trials indicate that it is not superior to surgical endarterectomy [18].

Conclusion

Stroke is a common neurological emergency that requires rapid assessment and treatment, as the opportunities for recovery diminish rapidly with time. A NCCT of the brain can confirm underlying ischaemia and exclude haemorrhage or malignancy. New multimodal imaging (e.g. CT perfusion) offer considerable advantages in defining the location and extent of ischaemia, and assist decision making regarding use of treatments, such as mechanical clot retrieval, provided significant delays in the initiation of treatment can be avoided. Good outcomes are possible with an active approach to patient care, including the use of treatments that target cerebral reperfusion, early recognition, and avoidance of complications, and the initiation of rehabilitation and proven secondary prevention measures such as anti-platelet therapy, BP, and cholesterol lowering.

CHAPTER 237

Management of parenchymal haemorrhage

Candice Delcourt and Craig Anderson

Key points

- Spontaneous parenchymal intracerebral (I-C) haemorrhage affects several million people in the world each year and carries a high 30-day mortality.
- High blood pressure (BP) is both a causal and prognostic factor for ICH.
- Lowering systolic BP to a target of <140 mmHg within 6 hours after I-C haemorrhage results in better neurological recovery without increasing mortality or harm.
- The role of surgery remains controversial, with no clear evidence that it improves survival and functional recovery.
- Most patients with I-C haemorrhage should receive initial active treatment, with supportive care and rehabilitation among early survivors.

Introduction

Parenchymal intracerebral (I-C) haemorrhage affects several million people in the world annually [1], most of whom reside in developing countries where hypertension and other cardiovascular risk factors are highly prevalent. I-C haemorrhage is the least treatable form of stroke and carries a 30-day mortality of 30–55%, with half of these deaths occurring within the first few days [2]. I-C haemorrhage arises in brain parenchyma but can extend into the ventricular system and subarachnoid, subdural, or extradural spaces. Until recently, there has been no proven medical treatment, and the role of surgery remains controversial. Management is largely supportive and aimed at reducing further brain injury and preventing complications.

Clinical presentation

I-C haemorrhage is difficult to differentiate from ischaemic stroke at the bedside, but certain features raise suspicion of the diagnosis. Progressive neurological signs and symptoms, headache, vomiting, seizures, and a reduced level of consciousness disproportionate to focal deficits (i.e. paresis), all suggest mass effect from an underlying haematoma. Neck stiffness suggests chemical meningitis from blood in the subarachnoid space via the ventricular system. I-C haemorrhage is reliably diagnosed on an early computed tomographic (CT) brain scan.

Aetiological factors and pathophysiology of brain injury

I-C haemorrhage is a dynamic illness and haematoma 'growth' occurs in most patients. Substantial expansion is defined as >33% relative or >12.5 mL absolute growth in the first 24 hours. This can be detected visually on CT and occurs in at least one-third of patients within hours of onset. Both initial haematoma volume and growth are major determinants of outcome. Volumes greater than 30 mL invariably result in early death, while patients with smaller haematomas may survive the initial event but remain at risk of succumbing to the complications of residual disability or a recurrent event [3]. The impact of the haematoma also depends on the degree of perihaematoma oedema and secondary inflammation from thrombin and iron released during haematoma breakdown. If the haematoma stabilizes, and physical disruption is mild to moderate in size and remote from vital structures, the prognosis can be remarkably good.

High BP is both a causal factor for I-C haemorrhage and also a manifestation of large haematomas due to mass effect within the skull. The larger the haematoma, the greater the likelihood of expansion and rebleeding. Perihaematoma oedema develops immediately after I-C haemorrhage from pressure-induced extravasation of serum into brain tissue, rapidly increases over the first 48 hours, and peaks towards the end of the second week. The size of perihaematoma oedema and increases in intracranial pressure are directly related to haematoma size [4]. Although standard brain imaging gives the appearance of an 'ischaemic' halo around haematomas, advanced imaging indicates this is fluid, rather than ischaemia, despite a small reduction in blood flow from the mass effect [5].

Approximately 80% of I-C haemorrhage occur secondary to disease of small (<3 mm) penetrating arteries from chronically-elevated BP, and typically occur in deep brain areas, such as putamen, thalamus, pons, and cerebellum. Cerebral amyloid angiopathy is an increasingly recognized cause of I-C haemorrhage, and is due to deposition of amyloid β-peptide in small- and medium-size vessels. Hypertension is more common in deep I-C haemorrhage than in superficial cortical I-C haemorrhage. I-C haemorrhage in cerebral amyloid angiopathy is usually in association with elevated BP, antithrombotic agents, or trauma. Clinically silent microhaemorrhages (or microbleeds), with residual haemosiderin seen on magnetic resonance imaging (MRI), are typical of amyloid angiopathy. With an ageing population and greater use of warfarin for prevention of cardio-embolic stroke associated with atrial fibrillation, I-C

haemorrhage related to anti-coagulation is increasing and accounts for 10–20% of I-C haemorrhage cases in some centres. The natural history of warfarin-related I-C haemorrhage is for slower, but more protracted haematoma growth than in 'hypertension-related' I-C haemorrhage. Newer anticoagulants reduce I-C haemorrhage risk compared with warfarin, but are harder to reverse if I-C haemorrhage does occur.

Investigations

Non-contrast brain CT is the most appropriate initial investigation for I-C haemorrhage. It will confirm the presence of acute haemorrhage, but is less useful in establishing any underlying cause. CT or MRI angiography is the next step in diagnosing a vascular anomaly (present in 0.1–4.0% of the general population [6]) including arteriovenous malformations (AVM), angiomas, cavernomas, and intracranial aneurysms [7]. A secondary cause of an I-C haemorrhage should be suspected in the presence of subarachnoid haemorrhage, an irregular 'non-circular' shape to the haematoma, perihaematoma oedema disproportionate to haematoma volume, atypical deep or superficial location with associated mass, and in younger patients without a history of hypertension, drug use, or other predisposing factors. MRI gradient echo sequence (T2) is most sensitive for detection of microhaemorrhages. Recently, attention has focused on the 'spot sign'; extravasation of contrast producing a spot or blush within or at the edge of the haematoma. It signifies ongoing bleeding and predicts haematoma growth and poor outcome [8]. Conventional cerebral angiography is needed in cases where there is a high likelihood of a vascular anomaly and interventional treatment is being considered.

Management

General considerations

It is difficult to reliably predict clinical outcome in the early phase of ICH, and evidence indicates that 'do-not-resuscitate' or 'withdrawal of care' orders are independent predictors of early mortality [9]. Patients with I-C haemorrhage at should be treated actively unless there are extenuating circumstances. A period of acute care allows time for a patient's condition to stabilize and for assessment of the effects of complicating factors, such as seizures, dehydration, and brain 'barotrauma' from the I-C haemorrhage. It also allows time for counselling and discussion with family members about management in the context of the patients, and their cultural, religious, and personal beliefs. Patients should receive monitored care, either in an intensive care unit or high dependency section of an acute stroke unit. Inevitably, a sizable component of the management of I-C haemorrhage relates to managing severe neurological disability and providing palliative care.

Early intensive blood pressure control

Elevated BP is common after I-C haemorrhage and strongly associated with poor outcome. A series of pilot, and subsequent larger, clinical trials have demonstrated the feasibility, safety and efficacy of intensive BP lowering in I-C haemorrhage [1,10–12].

The largest clinical trial in I-C haemorrhage, the main phase Intensive Blood Pressure Lowering in Acute Cerebral Haemorrhage Trial (INTERACT2), resolved much of the uncertainty regarding management of elevated BP following I-C haemorrhage. Within 6 hours of I-C haemorrhage, 2839 patients were randomly assigned to intensive (target systolic BP of <140 mmHg within 1 hour) or guideline-recommended (target systolic BP <180 mmHg) BP lowering treatment. The primary outcome of death and major disability was reduced by intensive BP lowering, but fell just short of statistical significance (odds ratio 0.87; 95% confidence interval (CI), 0.75–1.01; $p = 0.06$). However, patients assigned to intensive BP lowering had significantly better functional recovery (modified Rankin scale: odds ratio for greater disability, 0.87; 95% CI 0.77 to 1.00; $p = 0.04$) and better physical and mental health-related quality of life (EQ-5D scale). The intensive treatment was shown to be safe, with no difference in mortality (12.0%) or serious adverse events between the groups.

While more data would strengthen these results, it seems reasonable, on the basis of INTERACT2, that early BP control (to 140 mmHg systolic BP target) in patients with I-C haemorrhage will improve their chance of functional recovery.

Surgery

Despite being part of clinical practice for several decades and having undergone evaluation in multiple randomized trials, the role of surgical decompression of I-C haemorrhage remains controversial, dominated by clinical judgment and variably applied. The totality of evidence indicates surgery is 'on average' beneficial [13]. The problem, however, is in applying this evidence to individuals. Does the chance of net benefit in reversing the neurological deficit overcome the potential for harm associated with cortical incision, general anaesthesia, potential rebleeding and infection? The pivotal Surgical Treatment of Intracerebral Haemorrhage (STICH) trial [14] showed no difference between early versus delayed surgery for supratentorial I-C haemorrhage, but meta-analysis of all trials indicates the greatest potential benefit of surgery is early (within 8 hours) and before patients enter coma [15]. However, the follow-up STICH II [16] trial, targeting conscious patients with isolated superficial cortical I-C haemorrhage also failed to demonstrate improved outcome, although there were non-significant trends in favour of early surgery in poor prognosis patients. Minimally-invasive surgical techniques with burrhole catheter-insertion and instillation of a thrombolytic for haematoma drainage are an attractive, but less widely available option [17].

Although there have been no randomized trials in posterior fossa I-C haemorrhage with brainstem compromise, surgical decompression is generally regarded as a standard treatment. Similarly, symptomatic obstructive hydrocephalus requires temporary or permanent drainage. There is no evidence that intracranial pressure monitoring improves outcome in patients with cerebral oedema.

Fluids

Isotonic fluid (0.9% saline) at 1 mL/kg/hour is standard intravenous replacement for patients with I-C haemorrhage. The use of hypertonic saline (2 or 3% sodium) at 1 mL/kg/hour is an alternative to normal saline in patients with perihaematoma oedema with mass effect.

Seizures

Seizures are common (5%) in acute I-C haemorrhage. Subtle or non-convulsive seizures may manifest as coma or a fluctuating conscious level disproportionate to haematoma size. There may be subtle twitches over the face, trunk or limbs. Seizures may be detected by intermittent or continuous electroencephalogram (EEG) monitoring, but this is complicated by sedation, movement

artefact and changes due to brain injury. Prophylactic antiepileptic drugs are not recommended. Seizures can be treated with IV phenytoin (loading dose of 20 mg/kg) or levetiracetam (500 mg qds) or a variety of oral anti-epileptic drugs.

Fever and hyperglycaemia

Fever (temperature >38°C) and extreme hyperglycaemia should be treated, but not aggressively, as multiple observational studies indicate that this is associated with poor outcome. Current recommendations are to target a blood glucose concentration of 6–10 mmol/L.

Deep venous thrombosis prophylaxis

In immobile patients early (≥1 day) use of low dose subcutaneous unfractionated or low molecular weight heparin or pneumatic calf compression [18] reduces the risk of venous thromboembolism with little risk of further I-C haemorrhage or other bleeding.

Cerebral oedema and raised intracranial pressure

Intracranial pressure can be reduced by nursing the patient in a head-up position (>30°). Patients should be sedated and mechanically-ventilated if agitated, at risk of aspiration, or if hypoxic. Although randomized evidence is lacking, monitoring of intracranial pressure and high level supportive care should be considered in patients with coma, significant mass effect from the haematoma, intraventricular blood or hydrocephalus [19]. Measures designed to lower intracranial pressure include: 20% mannitol (1.0–1.5 g/kg) by rapid infusion, although this is complicated by its gradual diffusion from the vascular compartment into the brain, causing rebound of intracranial pressure; boluses of 23.4% saline solution (0.5–2.0 mL/kg) and moderate hyperventilation. Hypotension can be managed with fluid resuscitation where appropriate and with vasopressors. Corticosteroids have not been shown to be beneficial, and may cause hyperglycaemia and dehydration. Barbiturates may be neuroprotective by blocking free-radical production and decreasing cerebral metabolic oxygen consumption, and hypothermia (to 32–34°C) may also be neuroprotective and reduce cerebral oedema.

Anticoagulant-associated I-C haemorrhage

While randomized evidence is lacking, standard practice is administer vitamin K to reverse the effects of anticoagulation (international normalized ratio (INR) <1.4) in the hope of arresting further bleeding in patients treated with warfarin or other vitamin K antagonists. As vitamin K takes several hours for an effect, a more rapid reversal of anticoagulation is obtained with unactivated prothrombin-complex concentrate (PCC), which consists of the vitamin K-dependent coagulation factors (II, VII, IX, and X). PCC can normalize the INR within 30 minutes of infusion, but it is costly (between US $1000 and $2000). A cheaper and equally effective option is fresh frozen plasma (FFP). However, FFP exposes the patient to transfusion risks including febrile, allergic, and anaphylactic reactions and volume overload, as well as delays associated with checking blood group compatibility, thawing, and the time for normalization of the INR. Currently, there are no antidotes to the new anticoagulants (dabigatran, rivaroxaban, and apixaban); activated charcoal might be given if the most recent dose was less than 2 hours prior. Rapid reversal of dabigatran requires dialysis over several hours. Blood products can be tried on an individual basis, otherwise the effects take 24–36 hours to clear.

Recombinant-activated factor VII (rFVIIa)

Despite strongly positive results in a proof-of-concept phase IIb trial, the pivotal Factor Seven for Acute Hemorrhagic Stroke Trial [20] of the use of recombinant Factor VIIa (80 μg/kg) administered within 4 hours of I-C haemorrhage onset, failed to demonstrate any improvement in outcome despite attenuating haematoma growth by approximately 4 mL at 24 hours. Moreover, those assigned to rFVIIa had an increased risk of venous and arterial thromboembolic complications, including ischaemic stroke and myocardial ischaemia. While there is interest in a more focused approach to using rFVIIa, such as in young patients with a low prevalence of underlying atherosclerosis and those at highest risk of ongoing bleeding (spot-sign positive), the routine use of rFVIIa is not supported.

Conclusion

I-C haemorrhage is a significant public health problem with an increasing burden of disease, particularly in developing countries. Apart from early control of elevated BP, there are no proven therapeutic options. Treatment is, therefore, based on good supportive care, active monitoring by trained staff in a suitable facility, and early detection and management of complications. This is largely on the basis of empirical guidelines in the absence of randomized controlled trials. Once patients are stable, early rehabilitation will reduce the risk of further complications, and promote recovery and return to everyday activities.

PART 9.9

Non-traumatic subarachnoid haemorrhage

CHAPTER 238

Epidemiology, diagnosis, and assessment on non-traumatic subarachnoid haemorrhage

Chethan P. Venkatasubba Rao and Jose Ignacio Suarez

Key points

- Non-traumatic subarachnoid haemorrhage (ntSAH) is a neurological emergency.
- The incidence of ntSAH varies greatly around the world.
- Peak incidence occurs around the age of 55 years and women are affected more commonly than men.
- Diagnosis is based on clinical presentation with severe headache and confirmed by cranial CT scan or examination of the cerebrospinal fluid.
- A ruptured cerebral aneurysm is the cause on 80% of cases and should be sought using either CT angiography or digital subtraction angiography.

Introduction

Non-traumatic subarachnoid haemorrhage (ntSAH) is a devastating neurological emergency in which there is extravasation of blood in to the cerebrospinal fluid (CSF) containing spaces of the central nervous system. Being a disease affecting a younger age group, ntSAH has the same impact on loss of productive years as acute ischemic stroke and haemorrhagic stroke [1]. The diagnosis and management continues to challenge neurologists, neurosurgeons, radiologists, interventionalists, and intensivists.

Epidemiology

ntSAH typically affects both males and females in their third to seventh decades of life, and the incidence increases with age with a peak in the sixth decade [2,3]. The incidence also is widely varied globally being as low as 2.0 per 100,000 population in Chinese population and as high as 24.7 in Finnish, and 25.2 in Japanese population (Table 238.1). The gender distribution of the disease also varies with males comprising less than a third of the cohort in the UK Oxfordshire community stroke project, and more than two-thirds in a study in Qatar. Its overall global incidence observing 45,821,896 patient years, when adjusted to age, sex, and diagnostic modality (CT scan) is approximated to be 9 per 100,000 populations. Women appear to be more affected than men by a factor of 1.24 (CI 1.09–1.42). This gender preference appears to be age dependent with men being more predominant in groups younger than 45 years and women in groups older than 45 years of age [2]. African Americans are twice as likely (2.1 (1.3–3.6)) to be affected by ntSAH as compared to Caucasians [4] and the increased risk in African Americans is present in all age groups but appears to be more evident for population younger than 65 years [5].

There is some evidence that the incidence of ntSAH is slightly decreasing. In their analysis evaluating epidemiological reports spanning over 45 years, de Rooij et al. [2] reported that the incidence of ntSAH is reducing annually by 0.6%. One of the main causes was thought to be the increasing use of imaging with head CT scan, which can possibly reduce the incidence of ntSAH, by 1% for every percentage point of patients scanned in the cohort. This was more evident for studies done prior to 1990 where the CT scans were used less consistently. For studies post-1990, the adjusted incidence was stable for individual centres [6]. Overall, the annual incidence of ntSAH appears to be reducing modestly in comparison to other types of strokes (0.6 versus 2% per annum respectively) [7]. This indicates the importance of genetic and other unknown factors that are probably different from the conventional cardio/cerebrovascular risk factors, which cause ntSAH.

Rates of ntSAH-associated mortality oscillate depending on whether the aetiology is aneurysmal or other causes. The mortality associated with aneurysmal ntSAH is approximated to be 40–50% with the majority occurring early in the course of the disease [8,9]. About 10–15% of deaths are estimated to occur prior to hospitalization [10], and about two-thirds occur in the first 48 hours with recurrent bleeding being the leading cause [11]. With advances in care there has been a gradual reduction in mortality. The mortality trends in the hospitalized patients in the United States between 1993 and 2003 show a 20% relative reduction (absolute 6% reduction from 30 to 24%). This improved mortality was more so in larger hospitals and in teaching centres [12]. A similar study assessing nationwide hospital deaths related to aneurysmal ntSAH between 1997 and 2006, estimated that the odds of better survival was 1.22 (1.13–1.32) in 2006 compared with 1997 (absolute rates 27 and 24%, respectively). Female sex (OR 1.02), increasing age (OR 1.02 per year of age) and multiple comorbidities (OR 1.44) were associated with increases in-hospital mortality [13]. In contrast, non-aneurysmal ntSAH (diffuse) carry a mortality of around 7.8% with a majority of patients returning to independent living [14].

Clinical Features

NtSAH should be always on the differential diagnosis in those patients presenting with headaches of nuchal and suboccipital origin, of sudden onset and high severity (often described as the worst headache ever,) and associated with photophobia, nausea, vomiting, or loss of consciousness [15]. Focal deficits may include third nerve paralysis with ipsilateral mydriasis seen in posterior communicating artery aneurysms, bilateral lower extremity weakness seen in anterior communicating artery aneurysms, hemispheric symptoms involving motor, sensory language, visuospatial dysfunction seen in the middle cerebral artery aneurysms, nystagmus, and ataxia seen in posterior circulation aneurysms. Sixth nerve involvement can be an indication of posterior circulation aneurysms or a false localizing sign of an elevated intracranial pressure (ICP). The presence of subhyaloid haemorrhages in retina, called Terson's syndrome, indicates the rapidity of raise in the ICP, and often a poor prognostic sign. About 1 in 10 patients with a severe headache and normal neurological examination have ntSAH while one in four patients have ntSAH if they have abnormal neurological signs on examination. About half of the patients present initially with a warning or sentinel bleed.

The diagnosis of ntSAH can be evasive with as much as a third to half of the patients initially misdiagnosed with a tension headache or a migraine headaches. Variable characteristics of headaches have been noticed in patients with ntSAH and this, in part, contributes to misdiagnosis. However, adherence to the international headache society's classification system will help physicians to diagnose ntSAH.

Many objective measures have been developed to assess the clinical severity of ntSAH, of which the World Federation of Neurological Surgeons (WFNS) and the Hunt and Hess scales are most widely used [15]. Both the scales incorporate level of consciousness, and presence or absence of focal deficits, and have been demonstrated to be predictive of clinical outcomes (Table 238.2). However, the WFNS scale has gained more popularity lately and has been the preferred scale in contemporary clinical trials.

Aetiology

Ruptured intracranial aneurysms account for 80% of ntSAH [15]. The risk of rupture increases with increasing aneurysm size, with the risk lowest in aneurysms less than 7 mm in diameter. Causative genetic factors isolated to date implicate candidate genes coding for connective tissue proteins [16]. One in 10 patients with adult polycystic kidney disease have intracranial aneurysms and a familial pattern of aneurysms increases the risk of rupture to 5–7-fold, while modifiable risk factors such as uncontrolled hypertension, smoking, and excessive alcohol consumption doubles the risk [17]. Other uncommon causes of non-aneurysmal ntSAH are noted in Box 238.1.

Assessment

The diagnosis of ntSAH is classically described as the presence of blood in the subarachnoid spaces on a cranial CT Scan, the presence of a bloody CSF (>2000 RBCs/mm^3) or the presence of xanthochromic CSF in the presence of an intracranial or

Table 238.2 Clinical and radiographic measures of subarachnoid hemorrhage and the associated mortality

Score	World Federation of Neurological Societies (W)	Hunt and Hess (H)	Fischer grade (F)	Mortality*
0	Unruptured aneurysm	Unruptured aneurysm	—	1.3% (W and H)
1	GCS 15, no motor deficits	Asymptomatic, mild headache, slight nuchal rigidity	No blood detected	4.9% (W): 1.4% (H): 0% (F)
2	GCS 14–13, no motor deficits	Moderate to severe headache, nuchal rigidity, no neurological deficit other than cranial nerve palsy	Diffuse blood with vertical layers <1 mm thickness	9.3% (W): 5.4% (H): 0% (F)
3	GCS 14–13, with motor deficits	Drowsiness/confusion, mild focal neurological deficit	Localized clots or vertical layers > 1mm thickness	20% (W): 18.8% (H): 57% (F)

intraparenchymal haemorrhages, intraventricular haemorrhage, hydrocephalus, and cerebral oedema. Fischer's score and modified Fischer's score, which require CT scans can be helpful in predicting the risk of vasospasm or delayed cerebral ischaemia, and clinical outcomes (Table 238.2). The sensitivity of CT is variable, 100% within 12 hours, 93% within 24 hours and less than 50% 7 days after symptom onset [15]. However, if the CT is negative, and the clinical suspicion is strong, a lumbar puncture should be performed. A decision algorithm for the diagnosis of ntSAH is depicted in Fig. 238.2. Once the diagnosis is established, the patient needs to be evaluated urgently for the presence of an intracranial aneurysm through a cranial CT angiogram or a conventional cerebral digital subtraction angiogram. Although conventional cerebral angiography has been advocated for identifying aneurysms, multidetector row CT angiograms have been shown to have comparable sensitivity and specificity [19]. A careful evaluation of the complete cerebrovascular tree is warranted as up to 15% of patients have multiple aneurysms (Fig. 238.1). The introduction of DynaCT angiogram offers added advantages to conventional angiograms in detecting smaller aneurysms which can be missed otherwise and provides additional structural details, which helps in selecting the operative or endovascular treatment.

Conclusion

ntSAH is a critical neurological emergency, with a wide varied distribution and evasive presentations. The most common cause of ntSAH is a ruptured intracranial aneurysm, and the treating physician should be aware of the pitfalls and the limitations of variable tests used to arrive at the diagnosis.

CHAPTER 239

Management of non-traumatic subarachnoid haemorrhage in the critically ill

Chethan P. Venkatasubba Rao and Jose Ignacio Suarez

Key points

- ntSAH is associated with high morbidity and mortality. 10% of patients die before obtaining medical attention and 25% die within the first 24 hours of the ictus.
- Immediate management goals are to prevent rebleeding, treat hydrocephalus, and secure the aneurysm.
- Delayed neurological deficits occur due to delayed cerebral ischaemia, seizures, fever, and electrolyte abnormalities.
- Complications following ntSAH can affect most organ systems and include myocardial dysfunction, pulmonary injury, sepsis, and fluid and electrolyte abnormalities.
- Due to the complexity of management, patients with ntSAH should be treated in a critical care environment by a collaborative team of neurosurgeons, neuroradiologists, neurologists, and intensivists.

Introduction

Non-traumatic subarachnoid haemorrhage (ntSAH) is a complex disease affecting multiple systems and the hospital course of affected patients can be variable. This chapter delineates the principles of management of patients in hyperacute (first 24–48 hours), acute (2–7 days), and immediate (7–21 days) phases of ntSAH. Specific complications unique to SAH patients are detailed [1,2].

Hyperacute phase of ntSAH

ntSAH is associated with high morbidity and mortality; 10% of patients die before obtaining medical attention and 25% die within the first 24 hours of the ictus [3]. The causes of early deaths are either rebleeding or hydrocephalus causing fatal increase in the intracranial pressure (ICP). The admission records of all patients with ntSAH should document the time of symptom onset, the World Federation of Neurosurgeons Scale (WFNS), and modified Fischer's scales. All patients with ntSAH should be treated with the fundamentals of critical care: circulation, airway and breathing (CAB) followed by the management of ICP and prevention of rebleeding. Table 239.1 presents a summary of the most common management issues in patients with ntSAH.

ICP and hydrocephalus

Hydrocephalus that develops in the acute phase of subarachnoid haemorrhage can cause significant morbidity or death by an increase in ICP. Immediate management should include placement of an external ventricular drain (EVD). Limited evidence indicates that this may cause an increase in re-bleeding, but the risks of not treating are far more severe [2]. The management of ICP should be based on the general principles outlined in the subsequent sections and in Table 239.1 to keep it less than 20 cmH_2O while maintaining a cerebral perfusion pressure (CPP) of 60–80 mmHg.

$$\text{CPP} = \text{mean arterial pressure}\left(\text{MAP}\right) - \text{ICP}. \qquad \text{[eqn 1]}$$

Seizures

Seizures, which occur in about 20% of the ntSAH patients, can also cause an increase in ICP. The risk is higher in patients over 65 years old, surgically repaired aneurysms and a thick subarachnoid clot or intraparenchymal haemorrhage. Routine use of anticonvulsants is not advocated due to adverse outcomes associated with their use. However, elderly individuals undergoing surgical treatment for an aneurysm repair with a thicker subarachnoid clot can be provided a short term (3–7 days) prophylaxis of anticonvulsants.

Prevention of aneurysm rebleeding

One of the predominant causes of early mortality is rebleeding [3]. Historically, this occurred in about 4% of patients within the first 24 hours and 1–2% per day over the next 14 days. Overall risk is 50% within the first 6 months and 3% yearly following that. The two most important modifiable risk factors for rebleeding are incomplete treatment of the aneurysms and delayed treatment. Current recommendation is that the aneurysm is treated as early as possible and within 24–48 hours of symptom onset as mentioned in the treatment of aneurysm section ('Treatment of Ruptured Cerebral Aneurysm') [1,2]. General measures to reduce rebleeding include controlling MAP to <110 mmHg, adequate pain control and sedation, limiting activity, and cautious drainage of cerebrospinal fluid.

Antifibrinolytics, such as Epsilon amino-caproic acid (EACA) and tranexamic acid (TXA) have been studied in preventing aneurismal rebleeding. However, due to the delay in the initiation of the antifibrinolytic and the increase in the duration of use

Table 239.1 Common neurological and non-neurological complications associated with aneurismal subarachnoid haemorrhage and their management

Complications	Management	Complications related to treatment
Hyperacute phase (24–48 hours from ictus)		
Hydrocephalus	External ventricular drain (EVD) placement	◆ Small chance of re-rupture of the aneurysm ◆ Parenchymal damage related to the placement of EVD
Elevated intracranial pressure (ICP)	◆ EVD placement ◆ Mannitol and hypertonic saline ◆ Control of seizures	◆ See EVD as above ◆ Mannitol and hypertonic saline: nephrotoxicity ◆ See seizures below
Seizures	Anti-epileptic drugs (AED) (use as prophylaxis for only 3 days)	◆ Somnolence ◆ Pharmacological toxicity of the AED
Aneurysm re-rupture	◆ Early treatment ◆ Surgical clipping	◆ Complications related to anaesthesia administration ◆ Parenchymal damage related to surgery ◆ Intra-operative rupture ◆ Bleeding in to subdural, epidural, subgaleal spaces ◆ Infections
	Endovascular coiling (please note that it is recommended that an EVD be placed before the angiogram is performed)	◆ Complications related to anaesthesia administration ◆ Access site haemorrhage ◆ Dissection of the vessels catheterized ◆ Intra-operative rupture of the aneurysm ◆ Residual aneurysm
	Antifibrinolytics (tranexamic acid, Epsilon amino caproic acid (EACA))	◆ Deep vein thrombosis ◆ Pulmonary embolism ◆ Myocardial infarction
	Hypertension management	Cerebral hypoperfusion if the ICP is high
Early phase (2–7 days)		
Delayed neurological deficits: delayed cerebral ischaemia (DCI)	Prophylaxis with nimodipine	◆ Hypotension ◆ Constipation ◆ Ileus, etc
Delayed neurological deficits: vasospasm (VSP)	Hypertension, normovolaemia (Triple H)	◆ Congestive cardiac failure ◆ Pulmonary oedema
Delayed neurological deficits: elevated ICP	See ICP above	
Delayed neurological deficits: seizures	See seizure management above	
Delayed neurological deficits: fevers	◆ Acetaminophen and ibuprofen ◆ Surface cooling devices ◆ Catheter-based cooling devices ◆ Evaluation of infective source and treatment with antibiotics	◆ Liver dysfunction (acetaminophen) and gastritis (ibuprofen) ◆ Skin breakdown ◆ Complications associated with catheter placement
Immediate phase (7–21 days)		
Cardiac complications: troponinaemia	Conservative management if not associated with ST segment changes	
Cardiac complications: ST–T segment changes	Conservative management if not associated with an elevating troponinaemia and other ECG changes suggestive of ischaemia	
Cardiac complications: neurogenic stunned myocardium (severe cases- Takotsubo cardiomyopathy)	Supportive care	

(*continued*)

Table 239.1 Continued

Complications	Management	Complications related to treatment
Cardiac complications: deep venous thrombosis	◆ Inferior vena cava filter ◆ Anticoagulation (left to the discretion of the treating physician and surgeon)	
Pulmonary complications: neurogenic pulmonary oedema	Diuretics	
Pulmonary complications: pneumonia	Appropriate antibiotics	
Pulmonary complications: pulmonary embolism	◆ Inferior vena cava filter ◆ Anticoagulation (left to the discretion of the treating physician and surgeon)	Anticoagulation related parenchymal or systemic bleeding
Metabolic complications: ◆ Hyponatraemia ◆ Cerebral salt wasting	◆ Hypertonic saline ◆ Vasopressin antagonist (VSPA)	◆ Hyperchloraemic acidosis ◆ Higher cost of care with VSPA
Metabolic complications: hyperglycaemia	Insulin for moderate control of hyperglycaemia	Hypoglycaemia
Gastrointestinal complications: stress ulcers	Prophylaxis with proton pump inhibitors, H2 blockers or sucralphate	

(post-securing of the aneurysm), the benefits from prevention of rebleeding seem to be offset by the increase in the risk of delayed cerebral ischaemia (DCI) and other thrombotic complications.

The current recommendations form the neurocritical care society strongly advocates the early securing of the aneurysm. However, the use of very short-term antifibrinolytics may be beneficial to the patients, but convincing data are not available as yet [2].

Treatment of ruptured cerebral aneurysm

The options for securing a ruptured aneurysm are endovascular treatment (coiling) or surgical repair. Many factors, such as the anatomy of the aneurysm, age of the patient, accompanying medical risks and the availability of expertise at the site of treatment determine the treatment modality. The international subarachnoid aneurysm trial ISAT-demonstrated that patients who had ruptured cerebral aneurysms treatable by either method were more likely to be alive and independent in 1 year if treated by endovascular coiling [4]. This study is criticized for selecting patients with better grade of aneurysms and enrolling only 24% of the screened patients and, hence, a newer trial enrolling patients with wide range of SAH severity, ISAT-2 is underway. Endovascular techniques employ a variety of coils and at times may include the deployment of stents to treat aneurysms with wider neck (Fig. 239.1). Stent-assisted treatment of aneurysms may require the use of dual antiplatelet agents (aspirin and clopidogrel), which carry the risk of haemorrhagic complications with ventricular drains and other surgical procedures.

Acute phase of SAH

The hospital course of ntSAH patients can include multi-organ dysfunction, which needs careful monitoring, prevention, and treatment. Complications that can arise are classified according to the organ systems in Table 239.1.

Differences between and importance of DCI and vasospasm

About 30% of all patients with SAH develop DCI within 2 weeks of a ntSAH. Typically, they present as a change in mentation or focal deficits akin to stroke. Vasospasm (VSP) is defined as a narrowing in the intracerebral arteries as a result of endothelial swelling, vasoconstriction, remodelling of the media, or subendothelial fibrosis. VSP is directly related to the clinical deterioration due to DCI, cerebral infarction, poor outcome, and mortality after ntSAH. Patients with ntSAH can have DCI in the absence of VSP and VSP without DCI. However, due to the close association between the DCI and VSP, the absence of a reliable examination in comatose patients and direct association of the VSP with cerebral infarctions, there is a tendency to interchange the usage of the terms. DCI, defined as a new onset focal neurological deficit or change in the level of consciousness with radiological evidence (CT or MRI) of cerebral infarction, is an independent predictor of death or severe disability.

Monitoring of DCI

Traditionally, DCI has been monitored by clinical examination, which becomes challenging in a comatose patient. Non-invasive monitors such as transcranial Doppler ultrasound (TCD), electroencephalogram (EEG), and near-infrared spectroscopy (NIRS) have been used to assess cerebral dysfunction and perfusion, respectively. TCD has become the widely-accepted screening tool for VSP and elevated velocities and Lindegaard ratio (ratio of the velocity of middle cerebral artery to that of the ipsilateral extracranial internal carotid artery) greater than 6 is a good predictor of VSP.

Invasive monitors such as brain-tissue oxygenation probes ($PtiO_2$), cerebral microdialysis (CMD), and thermodilution methods have been used to determine cerebral perfusion in real time. Although the initial results for these monitors are promising,

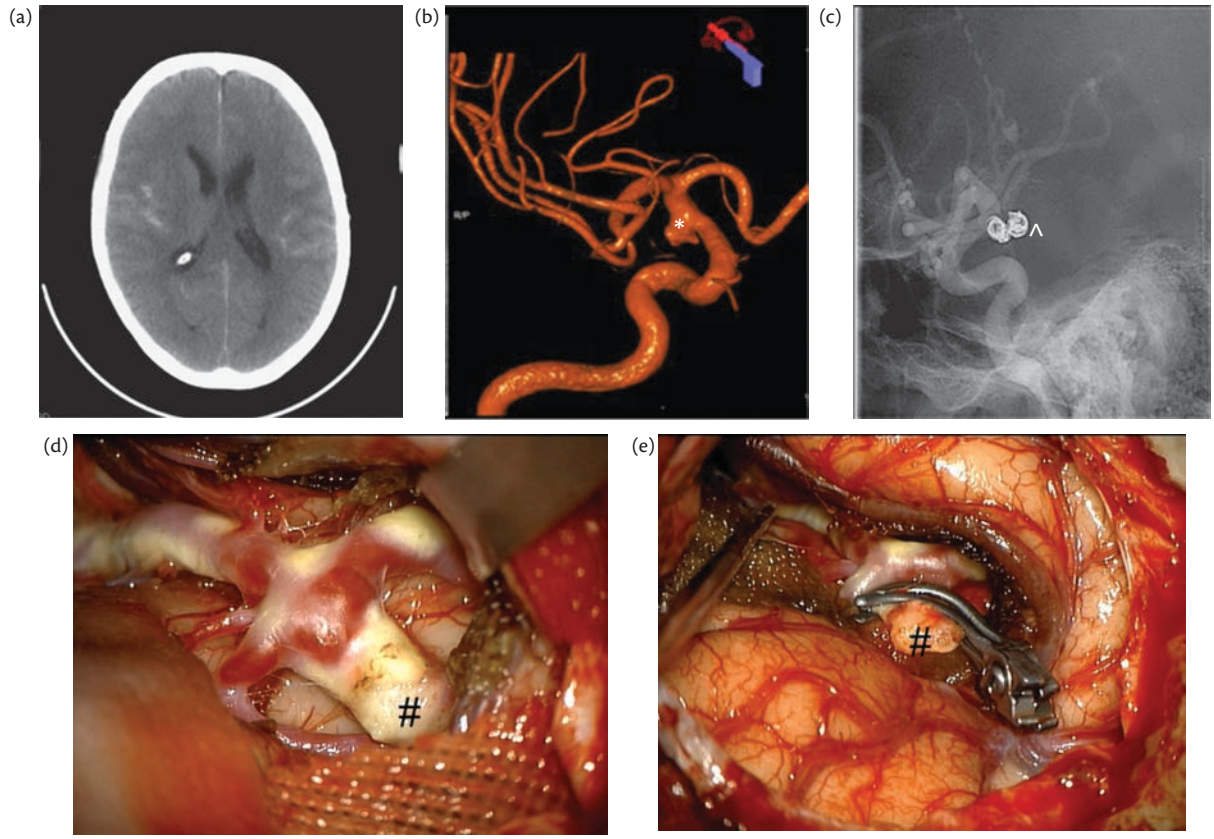

Fig. 239.1 Treatment of aneurysms. (a) Non-contrast CT scan of a 67-year-old female presenting with subarachnoid haemorrhage. (b) 3D reconstruction of a digital subtraction angiogram demonstrating the right middle cerebral artery (MCA) bifurcation aneurysm (*) in the same patient. (c) Digital subtraction angiogram demonstrating the endovascular coiling of the same aneurysm (^). (d) Right MCA bifurcation aneurysm (#) during surgical treatment in a different patient presenting with subarachnoid haemorrhage. (e) Right MCA aneurysm post-placement of an aneurysm clip during the surgery.

further investigations are needed to determine their role in daily clinical practice

How to treat DCI and VSP?

The treatment of VSP and resulting DCI has traditionally been through non-invasive and invasive measures. Neuroprotective agents such as nimodipine started prophylactically is the standard of care and augmenting blood pressure, volume, and cardiac output known as the triple-H therapy (hypertension, hypervolaemia, and haemodilution) are the available means of treating DCI.

Non-invasive measures

Neuroprotection

Nimodipine has been extensively studied as a neuroprotector in SAH and administration of 60 mg every 4 hours for the first 21 days is currently the standard of care. Important to note is that there is no effect of nimodipine on VSP, but DCI seems to improve, underscoring the importance of alternative pathways causing DCI. Other neuroprotective agents that have been investigated are the statins and magnesium. Current evidence does not support the routine use of statins but patients treated with a statin prior to the ntSAH should continue the treatment. Recently, MASH-2, a randomized control trial evaluating the routine use of 2 g of magnesium sulphate daily for 2 weeks in ntSAH patients failed to show any improvement in clinical outcomes and routine use of magnesium is not recommended [5].

Haemodynamic augmentation

VSP reduces the cross-sectional area arteries producing an increased resistance to flow, which reduces the flow rate by the fourth power of the radius. Accordingly, induced hypertension, hypervolaemia, and haemodilution have been traditionally used. Augmenting blood pressure can be challenging, as the response to increased pressure can be unpredictable in the absence of cerebral autoregulation. However, experimental and clinical data has shown that norepinephrine causes a more predictable increase in cerebral perfusion pressure (CPP) than dobutamine. Dopamine can increase CPP, while milrinone may not affect the CPP as much, but may cause a temporary improvement in the vessel wall diameter.

Augmentation of blood pressures in the presence of an unruptured aneurysm increases the chances of re-rupture, offers little to no risk if the aneurysm has been secured. To summarize, induced hypertension offers the most efficient increase in the CPP, but is not without side effects (such as pulmonary oedema and myocardial

dysfunction). In case of failure of these therapies, invasive measures can be used.

When to use triggers for invasive measures?

A multidisciplinary panel has recently defined intervention for VSP through a diagnostic and therapeutic cerebral angiogram in the same setting [6]. In low risk patients, the presence of a focal deficit that cannot be explained by other factors, an elevated TCD velocities and/or Lindegaard ratio should prompt a confirmatory evaluation. In poor grade ntSAH patients, the exam is difficult to obtain and invasive monitors such a $PtiO_2$, MCD monitors, can determine the need for intervention. Similarly, the cessation of the measures should be de-escalated in a gradual manner with carefully set goals assessed frequently.

What and how effective are the invasive measures?

Around 70% of all ntSAH patients have angiographic VSP between 5 and 14 days after symptom onset, of which 15–20% result in ischaemia or can be fatal. Prophylactic angioplasty of asymptomatic VSP within 48 hours of ictus has not been shown to improve clinical outcomes, but has demonstrated a reduction in the need for symptomatic treatment. Use of angioplasty in early symptomatic patients helps in improving the vascular diameter, as well as the neurological deficits. Agents that have been used as an intra-arterial adjunct to treat VSP with varying and conflicting results include verapamil, papavarine, and nicardipine. Associated complications, such as ischaemia caused by the cerebral arterial catheterization, as well as vessel rupture should be weighed against clinical benefit. Hence, interventional management of VSP should be attempted when medical therapy fails or is harmful.

Delayed neurological deficits

Delayed neurological deficits (DND) are defined as focal deficits that arise after SAH following initial stabilization that are not due to rebleeding. Some of the common causes of DND include DCI, hydrocephalus, cerebral oedema, fevers, seizures, and electrolyte abnormalities. All these underlying conditions need to be investigated and addressed immediately.

Cardiac complications

Increased serum troponin has been reported in up to 68 % of all the patients with ntSAH [7]. Left ventricular regional wall motion abnormalities (RWMA) are noted variably from as low as 9% to as high as 76% and global hypokinesis is seen in 10–15% of all the ntSAH patients [7]. Cardiac abnormalities after ntSAH (e.g. RWMA, elevated troponin I and B-type natriuretic peptide levels, Q waves, ST segment depression, and abnormal T waves) have shown to be associated with death, poor outcome, and DCI [7]. One of the hypotheses is an excessive sympathetic drive causing sub-endocardial myonecrosis, which could be regional or, when global, can result in Takotsubo's cardiomyopathy. Cardiac arrhythmias (atrial fibrillation/flutter, ventricular tachycardia, ventricular fibrillation) are seen in a third of all ntSAH patients; 5–8% can be fatal.

The management of these complications are focused on the primary pathology. When necessary, dobutamine can be used to augment cardiac output, which in turn can increase CBF. Beta blockers can be used to improve recovery from myocardial injury, and may improve clinical outcomes. No specific data are available regarding the treatment of cardiac arrhythmias.

Pulmonary complications

Pulmonary complications are relatively frequent after ntSAH and include pulmonary oedema, neurogenic pulmonary oedema (NPE), acute respiratory distress syndrome (ARDS), and pulmonary embolism (PE). In a case series of 650 patients with ntSAH, acute lung injury, was seen in 27% of patients. Pulmonary oedema has been reported to occur in 8–23% of patients. Due to the retrospective nature of the studies, it is difficult to determine the true incidence of neurogenic pulmonary oedema; however, there appears to be an association between NPE and the clinical grade of ntSAH, increased serum troponin and increased mortality. ARDS, on the other hand, is sparsely reported and ranges between 4 and 18% in several retrospective studies. Pulmonary oedema, pneumonia, aspiration, and sepsis are frequent causes of ARDS.

The management of pulmonary complications should be directed towards the inciting pathology. As there is a tendency to treat ntSAH patients with hypervolaemia, volume correction should be instituted upon recognition of pulmonary oedema. Goal-directed therapy for euvolaemia using pulmonary catheter-guided haemodynamic management has been shown to reduce the incidence of pulmonary oedema from 14 to 6%.Triple H therapy used to treat VSP in the setting of a left ventricular systolic and diastolic dysfunction (seen in 87% of ntSAH patients in a case series), can produce pulmonary oedema.

Metabolic derangements

Hyponatraemia

Hyponatraemia is the most common electrolyte abnormality, which occurs in 50% of ntSAH patients. It is also shown to be associated with cerebral infarctions and typically precedes VSP. Cerebral salt wasting (CSW) is associated with hypovolaemia and is probably the most common cause, while SIADH is associated with modest hypervolaemia. Despite these associations, hyponatraemia is not an independent marker for poor prognosis. To complicate matters, both conditions can co-exist in ntSAH.

Fludrocortisone and hydrocortisone have been used in randomized trials to treat hyponatraemia secondary to CSW. Vasopressin antagonists and hypertonic saline are also successfully used to treat hyponatraemia associated with euvolaemia/hypervolaemia and hypovolaemia respectively. Determination of volume status can be very challenging in these patients and the readers should refer to Wolf et al., and Gress et al. for further details [8,9].

Hyperglycaemia

Elevated glucose levels (>220 mg/dL; 12 mmol/L) are associated with increased infection rates in ntSAH patients. Intensive glycaemic control (80–120 mg/dL) has been associated with hypoglycaemic episodes, VSP, and poor outcomes. Currently, moderate glycaemic control is suggested for patients with ntSAH.

A comprehensive list of other complications is summarized in Table 239.1.

Conclusion

Multiple complications affecting many organ systems frequently complicate the hospital course of patients affected by ntSAH. Such patients are best cared for in a critical care environment by a specialist team, and intensivists should anticipate and institute appropriate measures for prevention and treatment as necessary. When

possible, the highest grade of evidence should be adhered and, when available, clinical trial enrolments should be encouraged.

PART 9.10

Meningitis and encephalitis

CHAPTER 240

Epidemiology, diagnosis, and assessment of meningitis and encephalitis

Simon Nadel and Johnny Canlas

Key points

- Acute brain infections are relatively rare.
- The presentation may have classical features, but a high index of suspicion is required to make a rapid diagnosis, and start appropriate therapy.
- Diagnostic tests are sensitive and specific, but therapy must often be empirical until diagnostic test results are available and treatment can be tailored accordingly.
- As a general principle, early effective treatment is essential to improve outcomes.
- Effective vaccines are becoming increasingly available for the most common CNS infections, but enhanced surveillance is vital to understand changing epidemiology in view of vaccination and antimicrobial pressure.

Introduction

Despite advances in antimicrobial and other adjunctive therapies, infections affecting the central nervous system (CNS) have a varied and unpredictable outcome often with a high morbidity and mortality. Although the spectrum between meningitis and encephalitis is wide, it is important to understand the pathophysiological processes, which take place that lead to meningitis and encephalitis. **Meningitis** is an inflammation of the pia and arachnoid meninges that surround the brain and spinal cord. Due to the occurrence of epidemics, worldwide acute bacterial meningitis is the most common form of serious intracranial infection. **Encephalitis** is an inflammation of the brain parenchyma. It is a relatively rare disease, which often presents as diffuse or focal neurological dysfunction.

Epidemiology

The worldwide incidence of acute bacterial meningitis (ABM) is difficult to ascertain because of wide variation in surveillance, together with underreporting from many developing nations. In the developed world, the incidence is 5 per 100,000 of the population per year. During pandemic meningococcal meningitis, in sub-Saharan Africa, attack rates may exceed 100–800 cases per 100,000 population per year, with the highest attack rates being as high as 1 in 100. Over 75% of all cases of bacterial meningitis occur in children under 5 years of age. Death or handicap may occur in up to 50% of patients depending on age, causative organism and clinical status at presentation [1].

For acute encephalitis, the annual incidence in Western and tropical countries is 7.4 and 6.3 cases per 100,000 population, respectively [2]. Encephalitis can occur following any infective process, the more common organisms include mycoplasma pneumonia, herpes simplex virus (HSV), the enteroviruses, adenoviruses, influenza viruses, and Japanese B virus. HSV encephalitis is the most common cause of sporadic, non-epidemic encephalitis in children and adults in Western countries, and it is usually caused by HSV-1. Disease may present with a variety of syndromes, which vary from the more benign to catastrophic CNS involvement and post-infectious encephalopathies.

In acute bacterial meningitis, the most likely causative organism is age-dependent. In industrialized nations, the incidence of neonatal meningitis is approximately 0.3 per 1000 live births. In developing countries, the incidence is as high as 6.1 per 1000 live births [1]. In neonates under 1 month of age, most of the causative organisms are acquired from the maternal genital tract during labour. Pathogens include **group B Streptococci** (GBStr), *Escherichia coli* and other coliforms, *Listeria monocytogenes*, and other colonic and genitourinary bacteria. Most cases in Europe are due to GBStr and *E. coli*, which together now account for at least two-thirds of all deaths from neonatal meningitis. In older children and adults, *Haemophilus influenzae* type b (Hib), *Streptococcus pneumoniae*, and *Neisseria meningitidis*, are responsible for over 90% of cases. Most children with ABM acquire the infection via haematogenous spread.

The epidemiology of ABM has changed dramatically in the last two decades with the introduction of new, highly effective vaccines. Prior to the introduction of the conjugate polysaccharide vaccine against Hib, Hib was the most common cause of ABM worldwide. The estimated global incidence of Hib meningitis for the year 2000 was 31 cases per 100,000 children younger than 5 years, with a case fatality rate of 43% in unimmunized populations. The incidence varies significantly between different regions, from 46 per 100,000 in Africa to 16 per 100,000 in Europe [1].

Currently, *Neisseria meningitidis* and *Streptococcus pneumoniae* are the most common causes of ABM in children. Invasive

meningococcal disease is endemic globally, and most cases are caused by five of the 13 meningococcal serogroups: A, B, C, Y, and W135. The majority of disease in Europe, South and Central America, and Australasia is caused by serogroup B and C organisms. The serogroup B polysaccharide capsule is not immunogenic in humans, and a number of protein-based vaccines against serogroup B disease are in development [3]. The peak incidence of meningococcal disease occurs in children aged 6 months to 2 years, with a second smaller peak at 15–19 years. The annual incidence of meningococcal disease across Europe is 2–89 per 100,000 in children under 1 year and 1–27 per 100,000 in 1-4 year olds [1].

In 2010, there were over 100,000 cases of pneumococcal meningitis in children worldwide, with a peak incidence in children under 2 years of age. Incidence was highest in Africa at 38 cases per 100,000, and lowest in Europe at six cases per 100,000 in children under 5 years of age. These data were gathered prior to widespread use of the 7-valent pneumococcal conjugate vaccine (PCV 7) [4].

In parts of the world where routine immunization has decreased the incidence of ABM caused by these common pathogens other organisms are gaining importance. In 2007, 13% of ABM across all ages in the UK was caused by *Mycobacterium tuberculosis* [5].

The exact incidence of tuberculous meningitis is difficult to ascertain because of difficulties with diagnosis and under-reporting, especially in the developing world. The WHO estimates that approximately one-third of the world population is infected with tuberculosis. The incidence is increasing in developed countries due to immigration and increasing prevalence of HIV infection. In the UK there was a 91.9% increase in the incidence of tuberculous meningitis from 1999 to 2006. In areas where tuberculosis is highly prevalent, meningitis occurs commonly in children aged under 4 years, while in low prevalence areas, most patients with tuberculous meningitis are adults.

Table 240.1 lists the causes of bacterial meningitis according to age and underlying conditions. (**Note**: *Mycobacterium tuberculosis* can cause meningitis at any age.)

The microbial epidemiology of meningitis is also changing in older children and adults in whom nosocomial meningitis accounts for an increasing proportion of infections. Many of these are associated with recent neurosurgical intervention or trauma. In such cases, *Pseudomonas aeruginosa*, enterococci, *Staphylococcus aureus*, and the coagulase-negative staphylococci are the most common causative organisms.

Table 240.1 Causes of acute bacterial meningitis according to age and underlying condition

Age	Organism
0–1 month (neonate)	*Streptococcus agalactiae* (Group B Streptococcus)
	Enteric bacilli (e.g. *Escherichia coli, Klebsiella pneumoniae, Proteus* spp.)
	Listeria monocytogenes
>1–3 months	*Streptococcus agalactiae* (Group B Streptococcus)
	Gram-negative Enteric bacilli (e.g. *Escherichia coli, Klebsiella pneumoniae, Proteus* spp.), *Listeria monocytogenes, Streptococcus pneumonia, Neisseria meningitides, Haemophilus influenzae* type b
>3 months–5 years	*Streptococcus pneumoniae, Neisseria meningitides, Haemophilus influenzae* type b
>5 years–50 years	Streptococcus pneumoniae
	Neisseria meningitidis
>50 years	Streptococcus pneumoniae
	Neisseria meningitidis
	Listeria monocytogenes
	Gram-negative bacilli
Immunocompromised (any age)	*Listeria monocytogenes, Streptococcus pneumoniae, Neisseria meningitides, Haemophilus influenzae* type b, Gram-negative enteric bacilli, *Salmonella* spp., *Pseudomonas aeruginosa*
Post-neurosurgery, post-skull trauma, and cerebrospinal fluid shunt	*Streptococcus pneumoniae, Neisseria meningitides, Haemophilus influenzae* type b, *Staphyloccus aureus*, Coagulase-negative staphylococcus, Gram-negative Enteric bacilli, *Streptococcus pyogenes*, Enterococci

Pathophysiology

Meningitis

Infection cannot occur until colonization of the host has taken place, usually in the upper respiratory tract. Infecting pathogens usually reach the cerebrospinal fluid (CSF) by haematogenous spread following colonization of the skin, the mucosal surface of the nasopharynx, respiratory, or gastrointestinal tract [6]. The organisms are then transported to the brain and translocate across the endothelial cells of the blood–brain barrier (BBB) in order to reach the CSF. Once in the CSF, bacterial products such as peptidoglycan, techoic acid, and endotoxin, stimulate the production of pro-inflammatory cytokines, such as tumour necrosis factor—alpha (TNF-α), interleukins 1 beta and 6, (IL-1β, IL-6), and other mediators (e.g. nitric oxide (NO), reactive oxygen species), leading to influx of leucocytes into the subarachnoid space. This inflammatory response is designed to inhibit bacterial proliferation, but acute inflammation in this confined space leads to pathological effects on brain function and structural brain damage due to oedema, thrombosis, and direct neurotoxicity.

Inflammatory mediators cause an increase in BBB permeability, leakage of plasma proteins into the CSF, further contributing to the development of cerebral oedema and subsequent neuronal damage. The damaged cerebral endothelial cells lead to vasospasm and thrombosis resulting in abnormal cerebral vascular autoregulation and a reduction in cerebral perfusion, and therefore further neuronal damage

Mucosal invasion and penetration occurs in those individuals where local mucosal immunity fails to contain bacterial proliferation, due to local factors such as colonization by virulent organisms and prior viral infection altering barrier function. The spleen plays a vital role in removing non-opsonized material from the circulation, particularly in non-immune individuals who do not have specific antibodies. Individuals who lack a functional spleen (i.e. sickle-cell disease, congenital asplenia, etc.) are at high risk of serious invasive infection, including meningitis, from encapsulated organisms. Other factors such as immunoglobulin, complement factors and inherent host immunity are important determinants of bacterial invasion.

Encephalitis

Viruses spread to the CNS via haematogenous or neuronal routes [7]. Haematogenous spread is more common and leads to an alteration in the BBB, as seen in arthropod-borne viral infections. In acute viral encephalitis, capillary and endothelial inflammation of cortical vessels is seen and this takes place within the gray matter or at the gray-white junction. Viruses also move into the CNS via intraneuronal routes, for example, the herpes viruses. Other data suggest the olfactory tract a route of access. On reaching the brain, the virus either lies dormant, or replication can take place intraneuronally, or can lead to cell-to-cell or extracellular spread. Encephalitis due to *Mycoplasma pneumoniae* may occur following direct bacterial invasion of the brain parenchyma, or due to auto-immune or thromboembolic phenomena [8].

Clinical features

Meningitis

Classically, patients with bacterial meningitis present with headache, fever, photophobia, vomiting, neck stiffness, and alteration of mental status. These signs and symptoms will be present at some stage in 85% of patients [9]. In infants and young children, the signs may be non-specific and fever may occasionally be absent. Where a child has fever with an altered level of consciousness, meningitis must be high in the differential diagnosis. Similarly, the elderly may be afebrile, but confused or obtunded, without the classical signs of meningitis. Other clinical findings may include cranial nerve palsy (particularly nerves III, IV, VI, and VII), focal neurological signs (10–20% of cases) and seizures (up to 30% of cases). Papilloedema is rare (about 1% of cases). With disease progression, signs of raised intracranial pressure (ICP), such as coma, hypertension, bradycardia, and altered respiratory status with focal brain involvement become more likely.

There appear to be two main patterns of clinical presentation of community-acquired meningitis. The first is a prolonged history of non-specific symptoms including lethargy, fever, and myalgias progressing over days and lasting up to a week. The second presentation is an acute fulminating course, with manifestations of both systemic sepsis and meningitis. This is frequently associated with severe cerebral oedema and raised ICP leading to brain herniation and brainstem compression. Depending on the aetiology, cutaneous manifestations may be seen. Approximately 50% of patients with meningococcal meningitis and the majority of patients with meningococcal septicaemia, will have a petechial or purpuric rash [9]. Seizures are common in bacterial meningitis, occurring in 20–30% of patients during the early stages of the illness. Generalized seizures are not associated with a worse outcome. However, focal seizures are likely to be associated with persistent neurological sequelae, as are focal neurological signs and cranial nerve palsies.

Encephalitis

The classic features of acute encephalitis are fever and headache, together with an altered level of consciousness. These may follow a prodrome of myalgia, lethargy, and other non-specific symptoms. Other findings may include neuropsychological disturbance, such as disorientation, confusion, hallucinations, and behavioural disturbances, focal neurological signs, and seizures. The clinical signs and symptoms represent disease progression and specific areas of brain involvement, which may be due to the action of the specific microbe (e.g. HSV has a predilection for the temporal lobes).

Diagnosis

Meningitis

Definitive diagnosis of bacterial meningitis requires isolation of the pathogen from cerebrospinal fluid (CSF). If, for clinical reasons, obtaining CSF is not possible, a clinical diagnosis of meningitis can be made by the finding of clinical signs of meningeal irritation (neck stiffness, positive Kernig's, or Brudzinski's sign), together with positive blood culture, latex agglutination test for bacterial polysaccharide in blood or urine, or positive polymerase chain reaction for

Box 240.1 Proposed criteria for diagnosing acute bacterial meningitis

Bacterial meningitis in children and infants >8 weeks old

Definite bacterial meningitis

- Compatible clinical syndrome:
  - *All ages*: fever (present in 94%).
  - *1–5 months*: irritability (present in 85%).
  - *6–11 months*: impaired consciousness (present in 79%).
  - *>12 months*: vomiting (present in 82%), neck rigidity (present in 78%).
- Plus one of:
  - Positive culture of CSF.
  - Positive CSF Gram stain.
  - Positive bacterial antigen/PCR.

Probable bacterial meningitis

- Compatible clinical syndrome.
- Plus positive blood culture/PCR.
- Plus one of the following CSF changes:
  - >100 leucocytes (neutrophils).
  - glucose CSF/serum ratio < 0.5.
  - protein >1 g/L.

Possible bacterial meningitis

- Compatible clinical syndrome.
- Plus one of the following CSF changes:
  - >100 leucocytes (neutrophils).
  - glucose CSF/serum ratio < 0.5.
  - protein >1 g/L.
- Plus negative cultures or antigen for bacteria, viral, fungal, or mycobacteria.

Neonatal meningitis <8 weeks old

- Compatible clinical syndrome.
- Plus abnormal CSF consistent with bacterial infection or one of:
  - Isolation of likely pathogenic organism from CSF.
  - Positive bacterial antigen/PCR.

bacterial DNA in blood or CSF. Definitions of CNS infection have been proposed and for the meningitis are divided into definitive, probable, or possible bacterial meningitis (Box 240.1) [9].

Purulent meningitis is associated with intracranial hypertension. Performing a lumbar puncture in the presence of intracranial hypertension may cause cerebral herniation. However, brainstem or tentorial herniation may occur even in the absence of lumbar puncture (approximately 5% of cases). Taking an accurate history, with appropriate recognition of the early systemic and neurological signs of meningitis and raised ICP allows an informed decision about whether a lumbar puncture can be performed safely. If signs of raised ICP are present, it is not safe to perform a lumbar puncture, even in the presence of normal brain imaging. Lumbar puncture is contraindicated in the following situations—a significant respiratory and/or haemodynamic compromise, presence of a bleeding diathesis, focal neurological signs, and a fluctuating or significantly reduced level of consciousness (GCS ≤ 8). If there will be a delay in performing lumbar puncture due to concerns about clinical status, it is important to start appropriate antimicrobial therapy as soon as possible. Table 240.2 shows the typical CSF findings in the differentiation between different types of meningitis.

There are several indications for obtaining radiological imaging of the brain in a child with suspected or confirmed meningitis. The main indication for cranial imaging is when the diagnosis is uncertain or to detect other possible intracranial pathology. It is important to bear in mind that normal imaging does not indicate normal intracranial pressure or that it is safe to do a lumbar puncture. If imaging shows evidence of raised ICP, lumbar puncture should not be performed. While CT is widely available and very useful for rapid assessment of hydrocephalus, mass lesions, haemorrhage, or cerebral oedema, MRI will detect more subtle findings. However, non-contrast CT and MRI can be normal in early meningitis [9].

The differential diagnosis for a child presenting with fever and signs of intracranial infection is large and, in addition, the complications of CNS infection include intracranial hypertension, and the presence of a space-occupying lesion. Where brain imaging was undertaken in children admitted with an acute febrile encephalopathy, in the absence of focal neurological signs, imaging played little part in the clinical management [10]. In children with meningitis who have undergone brain imaging using CT, where scans had abnormal findings, the abnormalities included subdural effusion, focal infarction, mild ventricular widening, contrast-enhancing basal meninges, cerebral oedema, and widening of the basal cisterns. Focal infarction and pus in the basal cisterns were associated with long-term neurological sequelae; transient dilatation of the subarachnoid space is a relatively common finding, not necessarily associated with long-term sequelae [11]. Performing imaging for prognostication appears to be of benefit.

Up to 50% of children with meningitis receive oral antibiotics before a definitive diagnosis is made. This treatment often leads to delay in presentation to hospital and may cause diagnostic confusion. CSF may be rapidly sterilized, although cellular and biochemical changes will persist. The only bacterium whose growth is likely to be significantly affected following oral antibiotic administration is meningococcus and this is thought to be due to the high sensitivity of the organism to low concentrations of antibiotics. It is essential that blood and CSF is sent for PCR and bacterial antigen detection, as these will not usually be affected by low CSF antibiotic concentrations following oral administration. Bacterial meningitis is likely in those with abnormal CSF parameters who have a significant raised white blood cell (WBC) count and/or C-reactive protein (CRP). A normal CRP and WBC count, however, do not rule out bacterial meningitis. If bacterial meningitis is suspected clinically and lumbar puncture has not been performed, children should be managed as such regardless of blood results [9].

Encephalitis

When searching for an infecting pathogen, it is important to establish certain epidemiological features including time of year, travel, and contacts. For example, in temperate climates, enteroviral infections are predominant during late summer and early winter [12]. As long as there are no contraindications, lumbar puncture is essential. Typical findings include pleocytosis (mononuclear cells predominate) with an increase in CSF protein. Some patients (3–5%) may have normal CSF and, under these circumstances, the diagnosis is made using assays to detect viral antigens or nucleic acids, as viral

Table 240.2 Cerebrospinal fluid findings in different types of meningitis

Condition	Leucocytes/mm^3	Glucose mmol/l	Protein g/l	Specific tests
Bacterial meningitis	100–500 (sometimes thousands) polymorphs	<60% of simultaneous blood glucose	>0.4	Gram stain, rapid antigen screen/PCR positive
Tuberculous meningitis	25–100 lymphocytes/monocytes predominate	<2.2 May be normal in early stages	Progressive increase to very high	Acid-fast organism on smear/PCR/culture
Viral meningitis	25–500 usually lymphocytes. Often polymorphs in first 24 hours	Usually normal	Mild increase <1	Viral culture, PCR
Fungal meningitis	0–500 lymphocytes	Mildly reduced/normal in early stages	Moderate increase	Fungal culture India ink, cryptococcal antigen
Partially treated bacterial meningitis	100–5000 polymorphonuclear cells/lymphocytes (50/50%)	Low/mildly reduced	Mild to moderate increase	Cultures negative, rapid antigen, and Gram stain positive/PCR
Parameningeal infection	Up to 100s variable mononuclear and polymorphonuclear cells	Normal/mildly reduced	Mild to moderate increase	CSF culture usually negative, cerebral imaging

PCR, polymerase chain reaction.

culture is of limited use. Cerebral imaging is a valuable tool and MRI changes may be present early on the disease. Characteristic changes may be present on an electroencephalogram (EEG) for example, the periodic high-voltage spike wave activity seen coming from the temporal lobes and slow-wave complexes at 2–3-second internals are seen in HSV infection [13].

Conclusion

Acute brain infections are relatively rare. The presentation may have classical features in some patients, but a high index of suspicion is required to make a rapid diagnosis and start appropriate therapy. Diagnostic tests are sensitive and specific, but therapy must often be empirical, at least initially, until more specific diagnostic test results are available and treatment can be tailored accordingly. As a general principle, early effective treatment is essential to improve outcomes. Recognition and appropriate interventions to treat complications are vital. Effective vaccines are becoming increasingly available for the most common CNS infections, but enhanced surveillance is vital to understand changing epidemiology in view of vaccination and antimicrobial pressure.

CHAPTER 241

Management of meningitis and encephalitis in the critically ill

Simon Nadel and Johnny Canlas

Key points

- Management of CNS infections requires specific antimicrobial agents, plus supportive treatment targeted at intracranial hypertension and other life-threatening complications.
- It is important that the need for management in an intensive care setting is considered early in the illness.
- Antibiotic resistance amongst the most common organisms causing bacterial meningitis is becoming more common and antibiotic therapy should be adjusted accordingly.
- Anti-inflammatory treatment, such as steroids should be started as soon as possible in patients with proven acute bacterial meningitis.
- In the future, effective vaccines should be available against all the common causes of bacterial meningitis and encephalitis, including *Neisseria meningitidis* serogroup b.

Introduction

The management of CNS infections requires specific antimicrobial agents to eradicate the infection and supportive treatment targeted at reducing raised intracranial pressure with neuroprotective strategies. Advances in the understanding of the pathophysiology of central nervous system infection have led clinicians to use anti-inflammatory agents in the treatment of bacterial meningitis. Some patients may require tracheal intubation and mechanical ventilatory support for the treatment of increased intracranial pressure, seizures, coma, shock, acidosis, and respiratory depression. This chapter will review the management of meningitis and encephalitis. It will necessarily concentrate on acute bacterial meningitis, as patients with this disease will tend to be more severely ill and are more likely to require intensive care management.

Management

Meningitis

Antimicrobial therapy

The initial management of suspected acute bacterial meningitis depends on early recognition, rapid diagnostic evaluation, and urgent introduction of antimicrobial and adjunctive therapy [1]. Antimicrobial therapy should not be delayed by imaging studies in the case of patients with focal neurological signs or papilloedema. Even if lumbar puncture is delayed, the CSF findings will still be important for diagnosis after the start of antimicrobial therapy, and a microbiological aetiology may be obtained by antigen detection or PCR. The longer the delay before starting appropriate antimicrobial therapy, the more likely that the disease will cause sequelae or be fatal. The current recommendation is to commence appropriate antimicrobial treatment for acute bacterial meningitis within 30 minutes of presentation. In cases of suspected meningococcal disease (i.e. presence of a purpuric or petechial rash), antibiotic therapy with parenteral benzylpenicillin is recommended before admission to hospital. In the absence of a rash, prehospital antibiotic treatment is not recommended unless there is a delay in transfer to hospital [2].

Empirical antibiotic therapy should be commenced based on the most likely causative organism for the individual patient, taking into account the patient's age, vaccination status, immune competence, and local patterns of antimicrobial resistance. In developed countries, most authorities recommend a third generation cephalosporin, such as ceftriaxone or cefotaxime, which have excellent CSF penetration and are active against most pathogens causing acute bacterial meningitis. Ceftriaxone should be avoided in infants who are jaundiced, hypo-albuminaemic, acidotic or born prematurely, as it may exacerbate hyperbilirubinaemia. In addition, it should not be administered at the same time as calcium-containing infusions as this may potentially precipitate cardiopulmonary adverse events [3]. *Listeria monocytogenes*, more common in infants <3 months and adults >50 years, is not sensitive to the cephalosporins. Therefore, the addition of a penicillin (e.g. amoxicillin or ampicillin) is recommended.

In the case of patients who are immunosuppressed, following surgery or where CSF leak is suspected, antimicrobial therapy should be broadened to include other Gram-negative organisms, the staphylococci, any possible opportunistic organisms, or *Mycobacterium tuberculosis*. In the post-neurosurgical patient, initial therapy must cover the Gram-negative organisms, including coliforms, *P. aeruginosa*, the skin flora, as well as community-acquired organisms. Broad antimicrobial coverage is essential in these patients. For example, vancomycin and ceftazidime, possibly in combination with an aminoglycoside. Table 241.1 summarizes the empiric choice of antibiotic for meningitis according to age and underlying condition [1].

There are now increasing reports of high-level cephalosporin resistance, conferring resistance of *S. pneumoniae* to the third generation cephalosporins. Factors reported to increase the likelihood

Table 241.1 Empiric choice of antibiotic for meningitis according to age and underlying condition

Age	Empiric choice of antibiotic (intravenous)
0–3 months[a,b,c]	**Broad spectrum cephalosporin and ampicillin:** ◆ Cefotaxime 100 mg/kg 8-hourly; or ◆ Ceftriaxone 80 mg/kg 12-hourly; plus ◆ Ampicillin or amoxicillin 100 mg/kg 8-hourly
>3 months–50 years[b,c]	**Broad spectrum cephalosporin:** ◆ Cefotaxime 100 mg/kg 8-hourly (adult 2 g 8-hourly); or ◆ Ceftriaxone 80 mg/kg 12-hourly (adult 2 g 12-hourly)
>50y[b,c]	**Broad spectrum cephalosporin and ampicillin:** ◆ Cefotaxime 100 mg/kg 8-hourly (adult 2 g 8-hourly) ◆ Ceftriaxone 80 mg/kg 12-hourly (adult 2 g 12-hourly) ◆ Ampicillin or amoxicillin 100 mg/kg 8-hourly (adult 2 g 4-hourly)
Immunocompromised host[c]	**Ceftazidime and ampicillin or amoxicillin:** ◆ Ceftazidime 50 mg/kg 8-hourly (adult 2 g 8-hourly) ◆ Ampicillin *or* amoxicillin 100 mg/kg 8-hourly (adult 2 g 4-hourly)
Post-neurosurgery, post-skull trauma, cerebrospinal fluid shunt	**Ceftazidime and vancomycin:** ◆ Ceftazidime 50 mg/kg 8-hourly (adult 2 g 8-hourly) ◆ Vancomycin 15 mg/kg 6-hourly (adult 2 g/24 hours)

[a]In neonates, in particular preterm neonates, drug dosages may have to be adjusted.

[b]Vancomycin 15 mg/kg 6-hourly (max. 2 g/24 hours, for resistant *Streptococcus pneumoniae*).

[c]If cephalosporin-resistant pneumococci are suspected add vancomycin as in b above.

Max., maximum.

Data from Agrawal S and Nadel S, 'Acute Bacterial Meningitis in Infants and Children. Epidemiology and Management', *Pediatric Drugs*, 2011, **13**(6), pp. 385–400.

Table 241.2 Recommended antibiotic therapy for specific pathogens

Organism	Antibiotic (intravenous)
Neisseria meningitidis	**Broad spectrum cephalosporin:** ◆ Cefotaxime 100 mg/kg 8-hourly (adult 2 g 8-hourly) ◆ Ceftriaxone 80 mg/kg 12-hourly (adult 2 g 12-hourly) ◆ Benzylpenicillin (depending on sensitivity: 300,000 units/kg/day; max. 24 million units/24 hours)
Streptococcus pneumoniae	**Broad spectrum cephalosporin and vancomycin:** ◆ Cefotaxime 100 mg/kg 8-hourly (adult 2 g 8-hourly) ◆ Ceftriaxone 80 mg/kg 12-hourly (adult 2 g 12-hourly) ◆ Vancomycin 15 mg/kg 6-hourly (max. 2 g/24 hours)
Haemophilus influenzae	**Broad spectrum cephalosporin:** ◆ Cefotaxime 100 mg/kg 8-hourly (adult 2 g 8-hourly) ◆ Ceftriaxone 80 mg/kg 12-hourly (adult 2 g 12-hourly)
Listeria monocytogenes	**Ampicillin and gentamicin (synergistic activity):** ◆ Ampicillin 100 mg/kg 8-hourly (adult 2 g 4-hourly) ◆ Gentamicin 7.0 mg/kg 24-hourly (check levels)
Streptococcus agalactiae	**Ampicillin and gentamicin (synergistic activity):** ◆ Ampicillin 100 mg/kg 8-hourly (adult 2 g 4-hourly) ◆ Gentamicin 5–7 mg/kg 24-hourly (depending on gestational age and level)

Max., maximum.

Data from Agrawal S and Nadel S, 'Acute Bacterial Meningitis in Infants and Children. Epidemiology and Management', *Pediatric Drugs*, 2011, **13**(6), pp. 385–400.

of infection with a resistant strain include patient's age (<10 or >50 years), immunosuppression, prolonged hospital stay, children in day care settings, infection by serotypes 14 and 23, and frequent or prophylactic use of antibiotics.

When *S. pneumoniae* meningitis is strongly suspected, vancomycin may be included in empirical therapy until the antimicrobial susceptibility of the isolate has been determined. Vancomycin penetrates the CSF adequately in the presence of meningeal inflammation and the combination of vancomycin and a third generation cephalosporin may be synergistic for meningitis caused by a high-level penicillin-resistant *S. pneumoniae* [1,2].

At present there are no data to suggest that quinolones or extended-spectrum macrolides are beneficial for the empiric therapy of bacterial meningitis. However, early studies with the carbapenem meropenem look promising as single agent therapy for a wide range of pathogens that cause bacterial meningitis. The recommended antibiotics and dosages for the treatment of ABM caused by specific organisms are outlined in Table 241.2.

The duration of antimicrobial therapy is dependent on the age and immune status of the patient, the aetiological agent, and the clinical course or development of complications. There is no universally accepted standard. As little as 7 days of therapy or shorter is appropriate for uncomplicated meningococcal meningitis. For meningitis due to *H. influenzae*, 10 days is the accepted duration, while for pneumococcal meningitis it is 14 days. Meningitis due to *L. monocytogenes* should be treated for 14 days, extending to 21 days in the immunocompromised host. Neonatal Gram-negative meningitis should be treated for at least 21 days following CSF sterilization. For meningitis due to *Streptococcus agalactiae*, at least 14 days treatment is recommended, depending on the clinical course.

The duration of therapy may need to be extended as a result of complications, such as the development of brain abscess or subdural empyema, prolonged fever, or the development of nosocomial superinfection. In such cases, the duration of therapy should

be individualized. Current recommendations in the UK are summarized in Table 241.3.

Anti-inflammatory treatment

Despite effective antimicrobial therapy, neurological morbidity and mortality remains a major consequence of acute bacterial meningitis (ABM). This is partly due to the damaging process within the brain that is mediated by activation of host inflammatory pathways, triggered by the release of endotoxin and other bacterial constituents. This is often accentuated by the use of powerful bactericidal antibiotics, and this has led to the hypothesis that injury to the brain may be reduced by the use of anti-inflammatory treatment.

The role of adjunctive corticosteroids in ABM has been widely studied in the last three decades. Initial trials showed a clear benefit from dexamethasone, with decrease in neurologic sequalae, particularly nerve deafness [4].

In 2007, a Cochrane analysis published a review of 20 randomized clinical trials on the safety and efficacy of corticosteroid use in ABM. According to this analysis, adjuvant corticosteroids were associated with lower case fatality rates, lower rates of severe hearing loss, and fewer long-term neurological sequelae. In children, the beneficial effects of corticosteroid use were less convincing, although there was a trend towards reduced hearing loss and short-term neurological sequelae in non-Hib meningitis, with the effect statistically significant in high-income countries compared with low-income countries. Subgroup analysis suggested that the case fatality rate was reduced by adjuvant steroids in patients with pneumococcal meningitis and that hearing loss was reduced in patients with Hib meningitis [5].

In the absence of any potentially significant harmful effects, dexamethasone is recommended for use in children with confirmed or suspected ABM above 3 months of age in the UK [2] and above 6 months of age in the US [6]. The recommended dosage is 0.6 mg/kg/day in four divided doses for 4 days, commencing prior to or simultaneously with the first dose of antibiotic, or within 4 hours of antibiotic administration.

In adults, the evidence for use of steroids in ABM is less convincing. However, in severe ABM, there are theoretical grounds for using steroids at the same recommended dosage as previously mentioned, without evidence of a worse outcome. The benefit of dexamethasone appears to be greatest if it is administered early in the course of the illness, preferably prior to antibiotic administration. There have been few side effects documented in patients receiving dexamethasone. In particular, there have been no reports of delayed CSF sterilization or treatment failure, although gastrointestinal bleeding has been observed in a small proportion of patients. However, the early reports of a beneficial effect of dexamethasone in bacterial meningitis should be interpreted with caution. There are no good data on the use of adjunctive steroid therapy in neonatal, post-neurosurgical or traumatic meningitis.

Supportive care

Antibiotic administration is only one component of the overall management of patients with meningitis. Neurological derangement often co-exists with circulatory insufficiency, impaired respiration, metabolic derangement, and convulsions. Measures to detect and correct any co-existing physiological derangement are probably important in improving the prognosis.

Neuroprotective strategies

All patients with bacterial meningitis are likely to have raised ICP as part of their disease process. Signs of raised ICP include altered level of consciousness, altered pupillary responses, hyper- or hypotension, reduction in resting pulse rate, altered respiratory pattern, and focal neurological signs. Papilloedema is a late sign. Patients with raised ICP due to bacterial meningitis and other intracranial infections should be assessed for airway, breathing, and circulation. The management is generally as for other causes of intracranial hypertension.

Table 241.3 Current UK guidelines for empirical and specific therapy in bacterial meningitis in children

Age group	Empirical therapy	Specific therapy
>3 months	**Ceftriaxone or cefotaxime:** ◆ +/– vancomycin ◆ 7 days for *N. meningitides* ◆ 10 days for *Hib* ◆ 14 days for *S. pneumonia*	Ceftriaxone
<3 months	Cefotaxime + amoxicillin/ampicillin	
GBS	≥14 days cefotaxime or penicillin or ampicillin + gentamicin	
Gram-negative organisms	21 days cefotaxime or ceftriaxone or meropenem +/– gentamicin	
Listeria monocytogenes	◆ 21 days amoxicillin/ampicillin + gentamicin for first 7 days ◆ +/– vancomycin	
Unconfirmed	◆ ≥14 days amoxicillin/ampicillin + cefotaxime ◆ Consider Aciclovir	

GBS, for Group B Streptococci.

Data from National Institute for Health and Clinical Excellence. Bacterial meningitis and meningococcal septicaemia: management of bacterial meningitis and meningococcal septicaemia in children and young people younger than 16 years in primary and secondary care. (Clinical guideline 102) 2010. www.nice.org.uk/CG102.

Fluid management

Fluid therapy should be guided by clinical assessment of hydration status. Over 50% of children with ABM have hyponatraemia at presentation, often attributed to increased secretion of antidiuretic hormone (ADH), and this may be a marker of severe disease contributing to cerebral swelling. By restricting intravenous fluid administration in the presence of SIADH, the risk of developing cerebral oedema is likely to be diminished.

In general, enteral fluids or feeds should be used where appropriate, and isotonic fluid when intravenous therapy is required. In developing world settings with high mortality and where children present late, full maintenance fluid therapy was associated with reduced spasticity, seizures, and chronic severe neurological sequelae [7].

Sedation and control of convulsions

Seizures occur within 48 hours of presentation in 20–30% of patients with bacterial meningitis. Seizures are especially dangerous in patients with raised ICP, as they result in increased metabolic demands, an increase in cerebral blood flow and may precipitate a further increase in ICP. Convulsions may be difficult to detect in patients who are treated with neuromuscular blocking agents for artificial ventilation. In such patients electrical monitoring should be used to detect seizure activity. The use of anticonvulsant treatment in non-ventilated patients may precipitate respiratory arrest and careful observation of respiration and ventilation could be undertaken during the treatment of seizures. Short- acting benzodiazepines can be used to control acute seizures, and standard anti-epileptic agents for longer term control.

Encephalitis

It may not always be possible to isolate the organism that causes encephalitis. In such circumstances, it is prudent to commence treatment with broad-spectrum antimicrobials and to cover the more likely causative agents. There are some specific therapies available for specific organisms as described in the following sections. Appropriate supportive intensive care may be required including the use of neuroprotective strategies. Newer antiviral agents are continually being identified and may be useful in the future treatment of specific encephalitides. Where organisms which cause encephalitis are endemic, such as Japanese B virus, vaccination programmes are very effective in reducing prevalence of disease.

Mycoplasma pneumoniae encephalitis

In patients with *Mycoplasma pneumoniae* encephalitis, a temporal clinical improvement has been reported in children treated with antibiotics. On the other hand some children recover without antimicrobials [8]. It is not clear whether encephalitis due to M. pneumoniae is an acute-infectious process or a post-infectious/auto-immune process. However, it is probably prudent to treat suspected or confirmed *M. pneumoniae* encephalitis with antimicrobials with activity against mycoplasma. Macrolides are considered the antibiotic of choice despite their poor penetrance of the blood brain barrier. Azithromycin has been found to achieve a high concentration in brain tissue [9].

Herpes simplex encephalitis

Aciclovir is the treatment of choice in *Herpes simplex* encephalitis. The current standard of care for adults and children over the age of 12 months is intravenous aciclovir at a dose of 500 mg/m^2 every 8 hours for 21 days. In infants <12 months, the recommended dose is 20 mg/kg every 8 hours for 21 days. Shorter duration of treatment increases the risk of relapse. Neonatal HSV infection may require a longer duration of therapy. With this regimen, mortality from neonatal HSV encephalitis has fallen to 5%. 40% of survivors develop normally. Outcome is dependent upon age of patient, level of consciousness at presentation, duration of encephalitis, and viral load. If presenting Glasgow Coma Score (GCS) <7, outcome is universally poor. Where treatment was instituted less than four days following the onset of symptoms, the survival at eighteen months increased from 72% to 92% [10].

Other viral encephalitides (enterovirus, rabies virus, arthropod-borne virus)

The enteroviruses include polioviruses, Coxsackie viruses, and echoviruses. They are known to cause both encephalitis and aseptic meningitis, and the management for these cases is supportive. Rabies virus encephalitis is virtually always fatal. It can be prevented by appropriate immunization even when exposure has occurred [11]. The management is generally supportive. Encephalitis due to arthropod-borne viruses is very common worldwide. There are no specific therapies for these apart from supportive care of organ failure.

Enterovirus 71 encephalitis

Enterovirus 71 (EV71) causes major outbreaks of hand, foot, and mouth disease (HFMD), most frequently affecting children. Although present throughout the world, the largest outbreaks of disease have been seen in the Asia–Pacific region and neurological manifestations range from aseptic meningitis to acute flaccid paralysis and brainstem encephalitis.

Brainstem encephalitis, especially affecting the medulla and associated with cardiopulmonary dysfunction has become the most notable feature in EV71 epidemics in Asia. Children typically present with a brief febrile illness and mild neurological signs, which may progress to myoclonic jerks, after which they develop signs of tachycardia, poor perfusion, and tachypnoea that rapidly develop into acute, intractable cardiac dysfunction, and fulminant pulmonary oedema or haemorrhage.

Post-mortem examination and MRI studies of children with EV71 brainstem encephalitis showed extensive inflammation of gray matter of the spinal cord and the whole medulla oblongata.

Treatment of complications

Complications of CNS infections vary according to the aetiological agent, duration of symptoms prior to initiation of appropriate therapy, and the age and immune status of the patient. Early complications are seizures, haemodynamic instability, SIADH, or other dysregulation of the hypothalamic-pituitary axis (such as diabetes insipidus), an acute increase in ICP, profound shock, and DIC. Neonates with any form of bacterial meningitis are likely to develop shock and DIC. Children may suffer severe and permanent neurological sequelae, or mild subtle behavioural disturbance. The most common complication of bacterial meningitis is sensorineural hearing loss.

Focal neurological signs including hemiplegia and quadriplegia may develop in the early stages of meningitis, but are more common in the later stages. Vasculitis and thrombosis may explain these clinical findings. Awareness of other conditions that require acute

Table 241.4 Risk of sequalae from bacterial meningitis in adults and children globally

	Risk after:		
	S. pneumonia (%)	*Hib (%)*	*N. meningitidis (%)*
Hearing	7.5	3.2	2.6
Motor deficit	5.8	2.2	1.0
Behavioural problems	4.6	2.1	0.6
Cognitive difficulties	4.2	1.1	1.6
Epilepsy	2.5	1.5	0.5
Visual disturbances	1.1	0.5	1.5
At least one sequelae	34.7	14.5	9.5
Multiple impairments	5.7	2.6	1.3

neurosurgical intervention is necessary. These include the development of subdural empyema, brain abscess, and acute hydrocephalus. Subdural effusions are more common after *Haemophilus influenzae* meningitis, but can occur with any organism. They usually resolve spontaneously, but the presence of significant and persistent neurological symptoms including seizures, paresis, raised ICP, and development of empyema are indications for drainage. Cerebral abscess must also be considered in any child who deteriorates neurologically, usually following the acute phase of bacterial meningitis, and is often accompanied by persistent fever. Table 241.4 is a summary of risk sequelae from bacterial meningitis worldwide [12].

Conclusion

The successful introduction of vaccines against encapsulated organisms that cause bacterial meningitis has significantly reduced the incidence in developed countries, but there is still a substantial burden of disease in developing countries. Molecular diagnostics are being increasingly used in the diagnosis of non-bacterial encephalitides. Clinical trials on vaccines against *Neisseria meningitidis* serogroup B and newer antimicrobial agents against resistant pneumococcal strains and other viral pathogens are underway. However, there remains limited information on optimum duration of antimicrobial therapy, indications for corticosteroid treatment and optimum fluid therapy. Clinical trials to evaluate best therapies, optimal duration of treatment, adjunctive therapies, neuroprotective agents and new vaccines are urgently needed.

PART 9.11

Non-traumatic spinal injury

CHAPTER 242

Pathophysiology, causes, and management of non-traumatic spinal injury

Oliver Flower and Matthew Mac Partlin

Key points

- Non-traumatic spinal cord injury is at least as common as traumatic spinal cord injury and its incidence increases with age.
- Non-traumatic spinal cord injury has a wide spectrum of aetiologies with varying pathophysiology.
- A high index of suspicion must be present to avoid delayed diagnosis and treatment.
- Management of non-traumatic spinal cord injury focuses on diagnosing and treating the precipitating cause, supportive management, and preventing complications.
- The outcomes of non-traumatic spinal cord injury are similar to those of traumatic spinal cord injury.

Introduction

Non-traumatic spinal cord injury (NTSCI) is the myelopathy caused by a host of conditions other than trauma. While NTSCI shares many clinical and pathological features with traumatic spinal cord injury (TSCI), it has a separate epidemiology and pathophysiology, and its own distinct management elements, largely related to the precipitating causes. Like TSCI, NTSCI has enduring consequences for the individual, their families, and society.

Epidemiology

The incidence of NTSCI equals that of TSCI (10–83/million population/year) [1,2], and in some regions exceeds TSCI [3]. Unlike TSCI, the incidence increases with age, predominantly affecting those between 30 and 60, unlike the male preponderance seen in TSCI [3,4].

Causes

A diverse range of aetiologies may cause NTSCI. The most common causes described in case series in developed countries are degenerative disc disease, canal stenosis, tumours, vascular diseases and inflammatory conditions [5,6]. The International Spinal Cord Society (ISCoS) have compiled a validated and comprehensive classification system, which refers to aetiology by cause, time frame of onset, and whether there was an iatrogenic component to the injury [7]. The aetiologies are summarized in Table 242.1. Other time-critical diagnoses should be considered with the presentation of acute non-traumatic paraplegia or tetraplegia, such as intracranial vascular or space-occupying lesions, peripheral neuropathies including Guillain–Barré syndrome, disorders of the neuromuscular junction, myopathies, toxidromes, and metabolic disorders, such as hypoglycaemia.

Pathophysiology

Anatomy

The adult spinal cord is approximately 46 cm long and ends around the L1 vertebral level. It is therefore shorter than the length of the vertebral column and spinal cord segmental levels (innervation of myotomes and dermatomes) do not correspond to vertebral levels; for example, the L4 spinal cord segment is at approximately the T11 vertebral level.

The vascular supply to the spinal cord is via the vertebral arteries, which form the single anterior and two posterior spinal arteries. These, in turn, are supplied by segmental radicular arteries that are small branches of the cervical, thoracic and lumbar vessels. The largest of the radicular arteries is the artery of Adamkiewicz, often given off from the T10 level, but varying in position from T7 to L4 [8].

Pathology

Spinal cord injury is usually considered in terms of primary and secondary mechanisms [9]. Traumatic spinal cord injury usually consists of a primary compression or contusion or penetration injury followed by secondary injury (often aggravated by hypoxia and hypoperfusion). The primary injury mechanisms in NTSCI include:

- **Compression/contusion**: e.g. disc prolapse, tumour, extradural abscess.
- **Inflammation**: e.g. infection, transverse myelitis, multiple sclerosis (MSc), radiation.
- **Ischaemia**: e.g. aortic dissection, thromboembolic events.
- **Intracellular defects**: e.g. metabolic defects, genetic disorders, congenital disorders.

Table 242.1 Classification of the aetiology of NTSCI (condensed)

Acquired abnormalities	Vertebral column degenerative disorders	◆ Disc prolapse ◆ Ligamentum flavum hypertrophy ◆ Ossification of the posterior longitudinal ligament ◆ Spinal osteophytosis ◆ Spondylolisthesis ◆ Spondylosis ◆ Spinal stenosis
	Metabolic disorders	◆ Deficiency (B12, folate, copper, Vit D) ◆ Osteoporosis ◆ Paget's disease ◆ Osteomalacia
	Vascular disorders	◆ Haemorrhage (epidural or elsewhere) ◆ Vascular malformations ◆ Ischaemia (atherosclerosis, aortic dissection, Takayasu's arteritis, atheromatous emboli, thromboemboli, fibrocartilaginous emboli, decompression sickness, venous infarction, hypotensive-hypoperfusion, fat embolism, idiopathic)
	Inflammatory and autoimmune diseases	◆ Demyelination ◆ Collagen vascular disease (SLE, Sjogren's, rheumatoid, ankylosing spondylitis, vasculitis) ◆ Sarcoidosis ◆ Paraneoplastic ◆ Arachnoiditis
	Radiation related	Radiation myelitis
	Toxic	◆ Organophosphates ◆ Others
	Neoplastic	◆ Benign (Primary vertebral, extradural, intradural and intrameduallary) ◆ Malignant (Neural, primary vertebral, leptomeningeal, secondary, haematological)
	Infection	Viral, bacterial, spirochaetal, fungal, parasitic
	Miscellaneous	◆ Motor neurone disease ◆ Syringomyelia
Congenital	Spinal Dysraphism	e.g. Spina bifida occulta
	Arnold–Chiari malformation	Types 1–4
	Skeletal malformations	e.g. Atlanto-axial dislocation
	Other congenital	Congenital syringomyelia
Genetic Disorders	Hereditary spastic paraparesis	
	Spinocerebellar ataxias	
	Adrenomyeloneuropathies	
	Other leukodystrophies	
	Spinal muscular atrophies	

Adapted by permission from Macmillan Publishers Ltd and International Spinal Cord Society: *Spinal Cord*, New PW and Marshall R, 'International Spinal Cord Injury Data Sets for non-traumatic spinal cord injury', **52**, pp. 123–32, copyright 2013.

For acquired aetiologies, such as acute disc prolapse, epidural abscess and acute infection, the primary injury involves axonal death, gray matter haemorrhage with necrosis, microglial activation, and release of inflammatory cytokines. The pathology of secondary injury evolves with time. In the initial hours to days, the pathological features are predominantly inflammation, vasogenic, and cytotoxic oedema, haemorrhage, demyelination, neuronal death, and axonal swelling. This may be a protracted process when the aetiology is ongoing (e.g. tumour) or recurrent (e.g. MSc). This is followed in the subsequent weeks by resolution and initial repair, and then over months to years there is gliosis, further demyelination, and potentially syrinx formation related to altered CSF flow.

Through preserved axons, adaptive functional plasticity may occur. For genetic and congenital disorders secondary injury phases may not occur.

Management

NTSCI should be considered in any patient presenting with symmetrical weakness or hypoaesthesia at a defined spinal level that continues caudally. Presentation may be highly variable depending on aetiology, the neurological level of injury, and completeness of injury. Specific syndromes also have different presentations (see Table 242.2).

As acquired NTSCI is often an unexpected event, a high index of suspicion may be required for timely diagnosis. An approach of synchronous resuscitation and evaluation should be taken. Resuscitation should be considered in the same manner as TSCI. A careful history and examination considering other differential diagnoses, followed by urgent appropriate investigations is essential.

History

A focused history should be taken, mindful of the potential aetiologies of acquired NTSCI and differential diagnoses. There may be a clear precipitant, such as thoracic abdominal aneurysm surgery, a lumbar puncture in a coagulopathic patient, an air embolism post-diving or previous radiotherapy, making NTSCI a likely diagnosis. Red flag symptoms may point to specific aetiologies, for example, weight loss, night back pain, or a history of cancer may suggest a neoplastic cause. Fever, intravenous drug abuse, recent infections elsewhere, and immunocompromised states make an infective aetiology more likely. Prolonged use of steroids, increasing age, osteoporosis, and mild trauma suggest a degenerative disorder of the vertebral column. A more insidious onset in individuals with pernicious anaemia or nutritional deficiencies may suggest subacute combined degeneration of the cord (SCDC) from Vitamin B12 deficiency. Relapsing and remitting symptoms involving different areas of the CNS is suggestive of MSc.

Examination

This is covered in greater detail in the other chapters involving SCI. A detailed neurological examination is essential, utilizing the globally accepted guidelines of the American Spinal Injury Association [10] documenting the neurological level of injury and the grade of injury, which requires determination of sacral sparing delineating whether the injury is complete or incomplete. Examination may yield clues as to the precipitant, such as a pulsating enlarged aorta with an aneurysmal dissection, features of sepsis for an infectious cause or the other features of a toxidrome such as those seen in organophosphate poisoning

Investigations

Imaging is required to define a lesion's location, extent, relations and features, and the sequence of imaging will depend on the presentation. Magnetic resonance imaging (MRI) is usually required to adequately demonstrate NTSCI. MRI is more sensitive and specific than computed tomography (CT), can differentiate myelopathy from radiculopathy and better visualizes intervertebral discs and ligaments. If MRI is contraindicated (e.g. older cochlear implants or pacemakers), a CT myelogram (with contrast) may provide additional information to a plain CT. Imaging must be performed urgently in NTSCI as aetiologies, such as epidural abscesses or haematoma may require urgent surgical intervention to prevent further or permanent cord injury. A CT angiogram or digital subtraction angiography may be required to diagnose vascular causes of NTSCI and may offer the potential for concurrent intervention with the latter.

Laboratory studies may help with diagnosis. A leucocytosis, elevated CRP, and positive blood cultures suggest an infective aetiology. Coagulation abnormalities, including thrombocytopenia, support a haemorrhagic cause. A low vitamin B12 level supports a diagnosis of subacute combined degeneration. Elevated serum angiotensin-converting enzyme (ACE), hypercalcaemia, and an elevated alkaline phosphatase are consistent with sarcoidosis. Tumour markers or, in the case of lymphoma, flow cytometry may help diagnose a specific malignancy. Cerebrospinal fluid (CSF) analysis may be helpful, but should not delay urgent imaging. For example, oligoclonal bands help in diagnosing MSc, CSF ACE suggests sarcoid, tumour cells may be found, the typical features of bacterial or viral infections demonstrated, and important differential diagnoses such as Guillain–Barré syndrome excluded. For other specific conditions, further investigations may be indicated, such as evoked potential to diagnose MSc or a positron emission tomography in certain malignancies.

Table 242.2 Cord syndromes

Syndrome	Explanation
Central cord	Weakness and sensory loss greater in the arms than the legs. Typically follows a hyperextension injury with pre-existing canal stenosis. Ischaemia or haematoma in the centre of the cord affect the cervical segments more due to the pattern of lamination of the corticospinal and spinothalamic tracts.
Anterior cord	Loss of motor function, and pain and temperature sensation below the neurological level of injury (NLOI), with preservation of fine touch and proprioception. Less common, typically following interruption of the blood supply to the anterior spinal cord.
Brown–Séquard	Ipsilateral loss of motor, proprioception and fine touch, with contralateral loss of pain and temperature sensation below the NLOI. Usually follows a penetrating SCI damaging only one-half of the spinal cord.
Conus medullaris	Sudden onset, symmetrical paraplegia with mixed upper and lower motor neuron findings, caused by injury at T12/L1.
Cauda equina	Often asymmetrical, gradual onset, lower motor neuron lower limb weakness with saddle area hypoaesthesia or paraesthesia, with bladder and bowel areflexia. Caused by injuries below L1 damaging the sacral nerve roots.

Treatment

The supportive care described in other chapters for TSCI also applies to NTSCI, and these patients should also be managed in specialised spinal injury units [11]. However, the specific cause responsible for the NTSCI must be addressed.

Vertebral column degenerative disorders causing demonstrable cord injury usually require surgical decompression and stabilization. Metabolic causes require correction of the underlying pathology, for example, vitamin B12 deficiency requires immediate and ongoing treatment with parenteral or oral cobalamin. Haemorrhage causing NTSCI from a compressing haematoma requires immediate correction of any coagulopathy and commonly surgical decompression to prevent further cord damage. Ischaemic NTSCI is commonly managed conservatively; however, there may be a role for intravenous thrombolysis, or intra-arterial clot lysis or retrieval in specialist centres, although the effectiveness of such treatments is currently unknown. The use of lumbar CSF drains to improve intra-operative spinal cord perfusion pressure during thoracic aortic surgery has been shown to reduce NTSCI [8,12]. Spinal arteriovenous malformations may be managed with endovascular embolization, either alone or in combination with surgery. Inflammatory conditions, such as transverse myelitis, MSc, or sarcoidosis potentially respond to corticosteroid treatment and other immunomodulatory agents. Early-delayed radiation-induced myelopathy is usually reversible and rarely treated, whereas when it is late-delayed, it is likely to be permanent. There is no evidence to support specific treatment for this, although steroids are often used [13]. The management of the wide variety of spinal tumours differs depending on the type and location of the tumour. Treatment options include chemotherapy, radiotherapy, pre-operative embolization, and surgery. Epidural infections usually require surgical or radiological drainage, as well as appropriate antimicrobial therapy. Congenital causes of NTSCI require surgical intervention once they become symptomatic, for example Arnold–Chiari malformation is commonly managed with occipital and cervical vertebral decompression, spinal dysraphism requires early surgery to prevent urinary incontinence, and symptomatic atlanto-axial dislocation requires cervical decompression and fusion. For genetic causes NTSCI, treatment is supportive and should include genetic counselling and provision of screening for relatives.

PART 9.12

Neuromuscular syndromes

CHAPTER 243

Epidemiology, diagnosis, and assessment of neuromuscular syndromes

David Orlikowski and Tarek Sharshar

Key points

- Admission to intensive care unit (ICU) with severe limb weakness or respiratory failure or the occurrence of a motor deficit and failure to wean from mechanical ventilation, while in the ICU are the common presentations of a neuromuscular disease.
- An accurate neurological examination and complementary investigations are necessary for both diagnosis and for evaluating the severity of the disease.
- Assessment of respiratory muscle function by measurement and monitoring of vital capacity, and of maximal inspiratory and expiratory pressures guide the need for mechanical ventilation and subsequently its' weaning.
- Hypercapnia often indicates an impending respiratory arrest, but normocapnia can be seen in a patient with a severe reduction in VC. Hypoxaemia can be due to hypercapnia, pulmonary injury (atelectasis or pneumonia), or pulmonary embolism.
- Cardiac evaluation is important as cardiomyopathies are frequent in myopathies.

Circumstances

There are essentially two circumstances in which an Intensive Care Unit (ICU) physician has to manage a patient with a neuromuscular disease. First, a patient is admitted for a severe limb weakness and/or a respiratory failure, which reveals a neuromuscular disease (acute or chronic) or complicates an already diagnosed neuromuscular disorder. The ICU-physician then needs to establish the diagnosis in the former situation and to identify the cause of exacerbation, in the latter one. The second circumstance is when a patient develops a neuromuscular disease after his admission in ICU, usually revealed by limb weakness or through difficulty in weaning from mechanical ventilation. In this latter scenario it is necessary to determine whether the patient has a critical illness neuropathy, myopathy, or neuromyopathy, or another neuromuscular disease that has not been diagnosed at time of admission in ICU. For instance, a patient admitted with pneumonia and in whom an amyotrophic lateral sclerosis (AmLS) complicated by swallowing dysfunction will be a secondary diagnosed.

In all these situations, an accurate neurological examination is necessary for both the diagnostic approach and the choice of complementary investigations, and to evaluate the severity of the disease. Investigations are sometimes urgently required to confirm or exclude time-sensitive lesions, such as spinal cord compression requiring urgent neurosurgical decompression, or an ethical decision not to proceed to invasive mechanical ventilation, or a tracheostomy in a patient with end-stage neuromuscular disease such as AmLS. As almost all neuromuscular diseases occur without alteration of consciousness, patients can be interviewed and give a history, even when invasively mechanically-ventilated. Neurological examination should be completed by a general examination as some neuromuscular disease can affect other organs.

This chapter considers the diagnostic approach of a peripheral nervous system disorder and presents the features of the main neuromuscular diseases requiring admission to ICU. It briefly describes the clinical and neurophysiological features of critical illness neuromyopathy, which are comprehensively presented in Chapter 247, 'Diagnosis, Assessment, and Management of Hyperthermic Crises'.

Clinical assessment

Clinical history

A detailed clinical history should elicit features of the onset of the disease (acute, subacute, or chronic), its course (fluctuating, relapsing, or progressive), the patient's age at onset (childhood or adult), the occurrence of an identifiable triggering event (infection, drugs, other), the presence of pain (myalgia, cramp, paraesthesia, dysaesthesia, etc.) and the symptoms (weakness, dyspnoea). Additionally, a family history may reveal the existence of a neuromuscular disorder in a relative suggesting a genetic aetiology.

Neuromuscular diseases include neuronopathies, neuropathies, myasthenic syndromes, and myopathies, whose main clinical features are described in Table 243.1. Neuropathies encompass mononeuropathy (injury of a nerve trunk, root or plexus), mononeuritis multiplex (multifocal, sequential, and asymmetric injury

Table 243.1 Semiology of main peripheral nervous system syndromes

	Motor neuron disease	Neuropathy	Myasthenic syndrome	Myopathy
Symmetry	Bilateral ± symmetrical	**Variable:** MM: asymmetrical PN: symmetrical PRN: symmetrical	Bilateral and symmetrical	Bilateral and symmetrical
Proximal versus distal	Proximal or distal	MM: distal PN: distal PRN: proximal	Proximal ++	Proximal ++
Topography	Limbs, bulbar, respiratory	MM: ≥1 nerve PN: limbs ± respiratory PRN: limbs, trunk, bulbar, facial, respiratory	**Variable:** Limbs, facial, bulbar, trunk or respiratory Ptosis (often unilateral) and diplopia	**Variable:** Limbs, facial, bulbar, trunk, respiratory
Tone	Flaccidity	Flaccidity	Flaccidity	Flaccidity
Tendon reflexes	Lost or pyramidal signs (AmLS)	Lost or decreased	Preserved	Preserved
Myotatic irritability	Preserved	Preserved	Preserved	Absent
Atrophy	Pronounced	Pronounced	No	Variable
Other motor signs	Fasiculation	—	Fatigability Fluctuation	Myalgia Myotonia
Other neurological signs	Cramps	± sensory loss ± dysautonomia	No sensory loss (except Lamber– Eaton)	No sensory loss

MM, mononeuropathy multiplex; PN, polyneuropathy; PRN, polyradiculoneuropathy.

of nerve trunk), polyneuropathy (distal, bilateral, and symmetric) and polyradiculoneuropathy (proximal, bilateral, and symmetric). Clinically, neuropathy can be pure motor, pure sensory, or sensory motor and associated with dysautonomia. Electrophysiologically neuropathies may be axonal or demyelinating.

Neurological examination must at least assess the motor system (muscle strength and tone, tendon reflexes, Babinski sign, presence of atrophy, fasciculations, and myotonia), the sensory system (pain and temperature, touch and vibration/position sense, presence of sensory level) and the cranial nerves (with a focus on 3rd, 6th, 7th, 9th, and 10th nerves). This chapter focuses on signs that guide the diagnosis or are highly suggestive of a particular disease (Table 243.1). The presence of a sensory level suggests a spinal cord injury. Hypereflexia and hypertonia are not observed in peripheral nervous system disorders, except in AmLS, which combines upper and lower motor neuron degeneration. By definition, neuronopathy, myasthenic syndrome (except Lamber–Eaton disease) and myopathy are not associated with sensory deficit. Alterations in pain and temperature perception are reported in axonal neuropathy and proprioceptive signs in demyelinating ones. Localized muscle atrophy (shoulder, hand, or antero-external part of the leg) is observed in neuronopathic or neuropathic process, while diffuse atrophy is present in most myopathies. Hypertrophy is a feature of particular myopathies. In neuronopathy, fasciculation are frequent and must be sought on limbs and tongue. Delayed relaxation of muscle after contraction indicates a myotonic dystrophy or a paramyotonia when the lack of relaxation increases with effort (often related to channelopathies). Pupillary light reflex and myosis during convergent gaze are preserved in patients with myasthenia gravis, and are abolished in botulism or sometimes in Guillain–Barré syndrome (GuBS). Bilateral lack of facial expression, weakness of orbicularis oculi, and ptosis are frequent in myopathies. In myasthenia gravis, ptosis may be unilateral or bilateral, but asymmetric and fluctuating. In chronic disease, distribution of muscular impairment and weakness is also important to characterize, i.e. symmetric or not, distal or proximal, presence of hyperlaxity, presence and localization of contracture, presence of orthopaedic deformation (limb or paraspinal).

Usually, in neuromuscular disease requiring admission in ICU, the motor deficit is bilateral and symmetric and involves the four limbs and the axis (neck and trunk). Muscle strength can be assessed with the help of Medical Research Council sumscore (Box 243.1). For each motor disease, specific muscle or functional scores have been validated. Evaluation of sensation may be difficult in ICU patients due to inattention, and as a result sensory deficits must be assessed with caution and electrophysiological testing can be used to assess or confirm a sensory neuropathy.

Assessment of respiratory muscle function is a key step for deciding the need for mechanical ventilation and its weaning. Acute respiratory insufficiency may not be clinically obvious in patients with neuromuscular disease and treating clinicians should consider patient's subjective symptoms, such as dyspnea and orthopnoea (i.e. that is a sign of diaphragm weakness), and also assess cough and the presence of rapid shallow breathing, use of accessory

Box 243.1 Medical research council sumscore

Functions assessed

- **Upper extremity**: wrist flexion, forearm flexion, shoulder abduction.
- **Lower extremity**: ankle dorsiflexion, knee extension, hip flexion.

Score for each assessment

- **0**: no visible contraction.
- **1**: visible muscle contraction, but no limb movement.
- **2**: active movement, but not against gravity.
- **3**: active movement against gravity.
- 4: active movement against gravity and resistance.
- 5: active movement against full resistance.

Maximum score: 60 (four limbs, maximum of 15 points per limb—normal).

Minimum score: 0 (quadriplegia).

Box 243.2 Criteria for invasive mechanical ventilation in Guillain–Barré syndrome and myasthenia gravis

Major criteria

- Signs of respiratory distress.
- VC < 15 mL/kg, PI_{max} or PE_{max} < 25 cmH_2O.
- $PaCO_2$ > 6,4 kPa.
- PaO_2 < 7.5 kPa (FiO_2 = 0.21).

Minor criteria

- Expectoration inefficient.
- Severe bulbar dysfunction.
- Atelectasis.

Adapted from AH Ropper and SM Kehne, 'Guillain-Barré syndrome: Management of respiratory failure', *Neurology*, **35**, 11, pp. 1662–5, Copyright 1985, with permission from the American Academy of Neurology.

muscles and thoraco-abdominal paradox. Bedside measurement of vital capacity (VC), maximal inspiratory and expiratory pressures (MIP and MEP) with a portable spirometer can provide an objective assessment of respiratory muscle strength. Bulbar dysfunction has to be sought as it might contribute to respiratory failure, notably by inducing aspiration. Chest X-ray and arterial blood gas analysis complete the respiratory evaluation. Hypercapnia indicates an impending respiratory arrest but normocapnia should not be reassuring. Indeed, a patient with severe reduction in VC can still be normocapnic. Need for intubation is decided upon objective criteria that include clinical signs, functional tests (VC, MIP, or MEP), blood gases, and chest X-ray (Box 243.2).

Complementary investigations

If any doubt on a spinal cord injury, a magnetic resonance imaging (MRI) should be performed. Electrophysiological testing is very helpful for confirming the diagnosis of neuropathy, neuromuscular junction disorder and myopathy, and for distinguishing axonal from demyelinating neuropathy or a pre- from a post-synaptic myathenic syndrome. Briefly, measurement of motor and sensory conduction velocities is necessary for the diagnosis of neuropathy, search for decrement (or increment) by repetitive stimulation for the diagnosis of neuromuscular junction disorder and needle electromyography (at rest and during voluntary muscle contraction) for the diagnosis of myopathy. Demyelinating neuropathy is characterized by slow conduction velocity, and conduction block and axonal neuropathy by decreased action potential amplitude, increased distal latency, and denervation (muscle spontaneous activity on needle EMG). Decrement is found in post-synaptic disorder and increment in presynaptic ones. As it is a time-demanding test, electroneuromyography has to be guided by neurological symptoms and done by an experienced neurophysiologist, especially because of the electrical artefacts induced by ICU environment. Phrenic nerve and diaphragm electrophysiological testing can be helpful for the diagnosis of neuromuscular respiratory failure. Biological test include at least standard screening exams and measurement of creatinine phosphokinase. Thus, hypo- or hyperkalaemia can be seen in periodic paralyses, hyperlactataemia in mitochondrial diseases, increased plasma CPK level in myopathies. Increased sedimentation rate will suggest an inflammatory process. Secondarily, biochemical, hormonal, immunological, toxicological, and genetic investigations may be indicated depending on clinical, electrophysiological, and biological features. Muscle or muscle-nerve biopsy may be required.

Main diagnoses

Guillain–Barré syndrome

GuBS is an acute inflammatory polyneuropathy with an incidence of 1·2–1·9 per 100,000 per year in Europe [1]. In two-thirds of cases, GuBS it is preceded by an infection within the previous 6 weeks, notably flu-like illness or gastroenteritis. Although the responsible organism is often not identified, a range of bacteria (*Campylobacter jejuni, Mycoplasma pneumonia*) and viruses (cytomegalovirus, influenza) have been incriminated. Acute inflammatory demyelinating polyradiculoneuropathy (AIDP) is the most frequent subtype in comparison with pure motor and sensory axonal entities (AMAN and AMSAN) that are associated with gastroenteritis and *C. jejuni* infection [1]. GuBS is discussed in detail in Chapter 246, 'Diagnosis, Assessment, and Management of Guillain–Barré Syndrome'.

Myasthenic syndromes

Myasthenia gravis is an auto-immune disease with auto-antibodies directed against acetylcholine receptors (80% of cases) or against the muscle specific tyrosine kinase (in about 10% of cases) and is often associated with hyperplasia (especially in patients less than 40 years

old) and thymoma (in about 10%). It is the most frequent disorder of the neuromuscular junction, with an incidence of 1 in 20,000 [2]. Myasthenia gravis and myasthenic syndromes are discussed in detail in Chapter 244, 'Diagnosis, Assessment, and Management of Myasthenia Gravis and Paramyasthenic Syndromes'.

Myopathies and spinal muscular atrophy

Patients with chronic neuromuscular disease represent less than 10% of those receiving mechanical ventilation in the intensive care unit (ICU) and have a low probability of death in the ICU [3]. Myopathies are mainly of genetic origins and are rarely acquired (inflammatory, toxic, or endocrine myopathies). Myopathies can be classified by age of onset (congenital, childhood, or late onset), the topography of weakness or muscular wasting (distal myopathy, limb girdle myopathy, facioscapulohumeral myopathy), the characteristics of muscular impairment (myotonia), pathophysiological mechanism (metabolic myopathies) or genetic mechanism (mitochondrial myopathies). Spinal muscular atrophy (SMA) a genetic disease due to *SMN* gene deletion provoking progressive and early degeneration of motor neurons must be also considered for this problematic (Table 243.2) [4].

Improvement of quality of care and development of specialized centres for neuromuscular disease has significantly increased survival and quality of life of patients with neuromuscular disease. This is particularly true for progressive diseases like patients with Duchenne muscular dystrophy (DMD) for whom introduction of respiratory care and home ventilation changed natural course of the disease [5]. Patients with previously diagnosed neuromuscular disease may be admitted to ICU due to an acute episode, rather than evolution of the myopathy. Alternatively, an undiagnosed myopathy may present as acute respiratory insufficiency, is which case the problem is to recognize the neuromuscular origin of respiratory failure. Sometimes acute and transitory episodes of respiratory failure may reveal hypokalaemic periodic paralysis.

Many myopathies are progressive with good correlation between limb and respiratory weakness. The beginning is usually during childhood and disease progression is relatively homogeneous. Respiratory involvement is usually constant for several myopathies like DMD, other muscular dystrophies (Emery–Dreyfuss muscular dystrophy), some limb girdle myopathies (LGMD2C and D, LGMD2I), and some congenital muscular dystrophies (Ullrich CgMD). In congenital myopathies hypotonia, weakness, and respiratory failure occur during neonatal period with usually little progression later in life. Some myopathies may start at adult age like myofibrillar myopathies (desmin-related myopathy).

In other cases LGM2B (Dysferlin), facioscapulohumeral myopathy, respiratory impairment is sometimes observed or is exceptional like in LGM2A (Calpain), or may be dissociated of limb weakness and be present at the first plan. This is the case in subgroups of CgMD (CgMD with rigid spine syndrome mainly due to *SEPN1* gene mutation or collagenopathies like Ullrich's disease). This is also possible for late onset forms of Pompe disease or in rare cases of hereditary myopathy with early respiratory failure related to *Titin* gene mutations [6], where an acute respiratory insufficiency episode may reveal the myopathy.

For SMA, respiratory impairment is common and increases with the severity of disease. Both inspiratory and expiratory muscles may be involved, but with a prominent weakness affecting accessory muscles like intercostal or abdominal muscles explaining that management of cough and respiratory impairment are major targets in this disease even in absence of need of mechanical ventilation [4].

Myotonic dystrophy type 1 (DM1, Steinert's myotonia) merits specific mention. DM1 is the most frequent of adult muscular dystrophies. Respiratory failure is a frequent complication that progresses with the severity of the motor deficit and the duration of the disease; it and is the primary cause of morbidity and mortality [7]. In contrast to other myopathies like DMD or other neuromuscular disease like AmLS, no published data support the use of nocturnal ventilation with regard to survival and quality of life. The causes of respiratory impairment are multiple and complex. If in the severe and advanced forms the muscle deficit can explain the alveolar hypoventilation, in less evolved forms mechanical factors, such as myotonia reduce the compliance of the respiratory system. The consequence is a change of the ventilatory pattern characterized by a decreased of tidal volume and high respiratory rate in spite of a normal or increased respiratory drive [8]. The nervous command of cortical or peripheral origin can be also altered, and irregularities of the respiratory rate are observed during awakening

Table 243.2 Chronic neuromuscular disease expressing respiratory impairment

Constant respiratory weakness	Frequent	Inconstant	Respiratory failure revealing neuromuscular disease
Duchenne muscular dystrophy	Myotonic dystrophy type 1	Limb girdle myopathy 2B (Dysferlin)	Pompe disease
Limb girdle myopathy 2C and D (α and γ sarcoglycanopathy)	Spinal muscular atrophy (accessory ++)	Limb girdle myopathy 2A (calpain)	Myotonic dystrophy type 1
Limb girdle myopathy 2I (α dystroglycanopathy)		Facioscapulohumeral myopathy	Hereditary myopathy with early respiratory failure (Titin)
Ullrich congenital muscular dystrophy		Becker muscular dystrophy	Periodic hypokalaemia (acute episode)
Desmin-related myopathy			
Pompe disease			
Emery–Dreyfuss muscular dystrophy			
SEPN1 congenital muscular dystrophy			

indicating a disorder of the voluntary command of ventilation [9]. Proprioceptive and reflex anomalies modulating the ventilatory response are also possible. These various anomalies increase with effort or during stress (in particular in the post-operative period) and can explain episodes of respiratory failure even in absence of previous hypercapnia. Sleep apnoeas or hypopnoeas, are common and represent an aggravating factor of diurnal anomalies [10].

Patients with chronic myopathies may have orthopaedic deformation, limited mouth opening or macroglossia that makes tracheal intubation difficult, especially in an emergency. Subsequently tracheostomy may be needed for successful weaning from mechanical ventilation and to enable discharge from the ICU. However, a tracheostomy may limit the choice and possibilities of long-term discharge from the hospital [11]. In myopathies with a known course, such as Duchenne muscular dystrophy the option of tracheotomy can be discussed with the patient and their family in advance of it being needed, this may not be possible in myopathies with less stereotypical evolution.

The most frequent cause of acute respiratory failure in patients with myopathies is upper airways infection (UAI), which as accounts for more than 90% of the hospitalizations in this population. Other possible causes are cardiogenic pulmonary oedema, pulmonary embolism, and pneumothorax). The infection, which is usually of viral origin, is responsible for a decrease of respiratory muscles strength and respiratory capacity, but also of maximal inspiratory and expiratory pressures [12]. It is associated with the development or with the worsening of alveolar hypoventilation, when CV or the maximal inspiratory pressure (PI_{max}) became lower than 30% of theoretical values. A major problem is coughing difficulties, which may be exacerbated by associated bulbar weakness [13].

The efficiency of the cough can be objectified by the measure of the cough peak-flow [14]. The 'flow rate cough' is correlated with various respiratory parameters: Vital capacity (VC), total lung capacity (TLC), maximal insufflation capacity (IC_{max}), expiratory reserve volume (ERV), PI_{max} and maximal expiratory pressure (PE_{max}) and peak flow. The main determiners of the cough are essentially the MIC (44%), the ERV (13%) and the PEmax (2%) [14]. A cough flow rate lower than 270 L/min [15] is associated with a more important morbidity and a flow rate lower than 160 L/min is usually considered as the threshold for weaning of invasive ventilation.

Maintaining coughing ability is thus fundamental in these patients, and various techniques are available, [16] including air stacking with glossopharyngeal breathing (frog), volumetric ventilation, hyperinsufflation by using a resuscitation device or intermittent positive pressure breathing (IPPB). These techniques are superior to manual assisted coughing provided by a physiotherapist, although the combination of manual assisted coughing and mechanical insufflation produces a more effective cough than either used alone, [14] as does mechanical insufflation/exsufflation. The major concern during respiratory decompensation of neuromuscular disease and myopathies is to avoid tracheal intubation.

As in acute pathologies, the clinical evidence of acute on chronic respiratory failure will initially be discreet and the classic signs of respiratory distress occur late and indicate imminent decompensation. Orthopnoea and paradoxical abdominal respiration are also warning signs, as is hypoxaemia. When appropriate for the individual patients these signs indicate the need for mechanical ventilation.

Non-invasive ventilation (NIV) is recommended as first line treatment to avoid endotracheal intubation, if possible [17]. Intubation can be hazardous because of the association of little of respiratory reserve, orthopaedic, and/or orofacial deformations, and the potential risk from anaesthetic agents or muscle relaxants [18]. There are no recommendations regarding the choice of mask for NIV; a full face mask can be dangerous in a patient for who it is not correctly fitted or with impaired swallowing. Use of a nasal mask seems preferable but may limit the efficiency of ventilation due to buccal leaks. On the contrary, a nasal mask will limit the risk of inhalation by allowing the oropharyngeal aspiration and easier cough assistance [19,20].

CHAPTER 244

Diagnosis, assessment, and management of myasthenia gravis and paramyasthenic syndromes

Ugan Reddy and Nicholas Hirsch

Key points

- Acquired myasthenia gravis is an autoimmune disease in which antibodies directed towards the neuromuscular junction cause reduction in the number of post-synaptic acetylcholine receptors.
- The reduced receptor density causes fatigable muscle weakness.
- Treatment aims to enhance neuromuscular transmissions with anticholinesterase drugs, while suppressing autoantibody production with immunosuppressant agents.
- Thymectomy improves most patients with antibody- positive myasthenia gravis.
- Myasthenic crisis is defined as severe muscle weakness occurring in the myasthenic patient who requires tracheal intubation and mechanical ventilation. Treatment includes plasma exchange and intravenous immunoglobulin.

Introduction

The neuromuscular junction (NMJ) provides the link between myelinated motor nerves and skeletal muscle, and is an integral component of a biological amplification system, which converts minute nerve action potentials into muscle contraction. Diseases that affect the NMJ interfere with normal nerve transmission and cause weakness of voluntary muscles [1]. The two most commonly encountered are acquired myasthenia gravis and the Lambert–Eaton myasthenic syndrome (LEMS).

Myasthenia gravis

Acquired myasthenia gravis (MG) is an autoimmune disease in which IgG antibodies are directed towards the post-synaptic acetylcholine receptors (AChR) at the NMJ. It has a prevalence of 200 per million of the population and has a bimodal distribution, tending to affect young women and older men. MG can be divided into several subtypes based on differences in clinical presentation, age at onset, antibody profile and the presence or absence of thymic pathology. The most practical clinical classification divides patients into early-onset MG, late-onset MG, associated thymoma, ocular MG and MuSK MG [2]. Details of the clinical features, antibody distribution and thymic pathology are detailed in Table 244.1.

Clinical features

The clinical hallmark of MG is a fatigable weakness of affected muscle groups that fluctuates daily over months. It is often worse in the evenings and following activity, and improves following periods of rest.

Ocular weakness resulting in ptosis and diplopia is the commonest presenting feature and affects 90% of patients with MG. In 15% of patients the disease is confined to the eyes (ocular MG), but in the remainder it progresses to generalized disease, usually within 2 years.

Bulbar weakness is common and causes dysphagia, dysarthria (especially associated with emotion) and difficulty with chewing. Severe bulbar weakness, often associated with atrophy of bulbar muscles, is a prominent feature of anti-MuSK MG. Respiratory muscle weakness often accompanies bulbar involvement, but is rarely seen in isolation.

The limb weakness seen in MG affects the arms more than the legs and proximal muscles more than distal ones.

The severity of weakness in MG has been classified by the Myasthenia Gravis Foundation of America (MGFA) (Box 244.1).

Pathogenesis

85–90% of patients with acquired MG have detectable levels of anti-AChR antibodies (seropositive MG) that are responsible for the destruction of postsynaptic AChRs. These auto-antibodies cause a reduction in AChR density through three mechanisms, the most important of which is a complement-mediated lysis of the post-synaptic membrane resulting in a distortion of the normally convoluted morphology. In addition, the antibodies cross-link adjacent AChR resulting in an increased rate of degradation of the receptors. Finally, there may be some direct blocking of

Table 244.1 Subtypes of myasthenia gravis

Subtype	Clinical features	Auto-antibodies	Thymic pathology
Early onset MG (<40 years)	Female > male Associated autoimmune diseases, especially thyroid disease	AChR	Thymic hyperplasia
Late onset MG (>40 years)	Male > female Typically more severe disease present with ocular, generalized weakness or oropharyngeal weakness Frequent crises	AChR, to striated muscle proteins (ryanodine, titin)	Normal thymic histology
Thymoma	10% of MG patients. Present in middle age, associated with other autoimmune disorders. Clinical improvement following thymectomy more unusual	none	T-lymphocyte containing epithelial cell tumour
Musk MG	70% of seronegative MG patients. Ocular involvement, frequently evolves to severe bulbar and facial weakness Limbs unaffected	MuSK	Normal
Ocular MG	15% cases disease confined to eyes, but may become generalized later	50% positive for AChR	Maybe associated with thymic hyperplasia

Box 244.1 The MGFA classification of myasthenia gravis

- Class I—ocular myasthenia (may also have weakness of eye closure).
- Class II—mild weakness of non-ocular muscles.
- Class III—moderate weakness of non-ocular muscles.
- Class IV—severe weakness of non-ocular muscles.
- Class V—myasthenic crisis requiring tracheal intubation +/– mechanical ventilation.

Reproduced from Barohn RJ, 'Standards of measurement in myasthenia gravis', *Annals of the New York Academy of Sciences*, **998**, pp. 432–9, copyright 2003, with permission from John Wiley and Sons Ltd and the New York Academy of Sciences.

docking of ACh molecules by the auto-antibody. The net effect of this antibody-mediated reduction in the AChR density is a loss of the safety margin seen with normal neuromuscular transmission (Ruff, Lennon 2008). This leads to a reduction in post-synaptic action potential generation, which in turn leads to weakness of muscle contraction.

10–15% of patients with MG have no detectable AChR antibodies (seronegative MG). About 60% of these patients have been found to have an antibody to another post-synaptic NMJ protein called muscle specific protein kinase (MUSK). This protein is necessary to allow clustering of AChR around the NMJ and its loss causes a reduction in the number of functional AChRs [4].

Patients with MG without AChR or MUSK antibodies have recently been found to have low affinity IgG antibodies that bind specifically to AChRs and it may be that past assay techniques have been too insensitive to detect them.

Although the precise mechanism is unclear, the thymus gland appears to be involved in the generation of AChR antibodies, especially in early-onset MG [5]. Furthermore, removal of the often hyperplastic thymus appears to promote complete or partial remission in a high proportion of these patients. Thymoma is also seen in MG and although its removal is not associated with such a high degree of remission, it is necessary as the tumour may be locally invasive.

Diagnosis

Diagnosis of MG requires a high degree of clinical suspicion coupled with pharmacological and electrophysiological testing and detection of anti-AChR antibodies.

The Tensilon® test consists of administering the short-acting anticholinesterase edrophonium intravenously and assessing clinical improvement in muscle strength. Unfortunately, the test has a limited sensitivity and specificity in diagnosing MG. An alternative relatively non-invasive bedside test consists of placing an icepack over the eyes and looking for an improvement in ptosis.

The mainstay of electrophysiological testing for MG is repetitive nerve stimulation which, at rates of 2–5 Hz, shows a progressive decrement (or fade) in successive compound muscle action potentials. In experienced hands, the test is abnormal in 80% of patients with generalized MG and 50% in those with ocular MG [6]. Single fibre electromyography can raise the sensitivity in the former to 95%.

Finally, detection of anti-AChR or anti-MUSK antibodies confirms the diagnosis. Following confirmation, a chest CT/MRI should be performed to detect any thymic mass.

Treatment of MG

Treatment of MG is directed at enhancing neuromuscular transmission with long-acting anticholinesterases (e.g. pyridostigmine) and long-term immunosuppression with corticosteroids (e.g. prednisone) and steroid-sparing agents (e.g. azathioprine). Patients with exacerbations of their MG may also require short-term immunomodulation with either plasma exchange or intravenous immunoglobulin (Box 244.2).

Thymectomy is usually reserved for patients with anti-AChR antibody positive generalized myasthenia and those with a thymoma. Although no randomized controlled trials exist, meta-analysis suggests thymectomy promotes clinical improvement in the former group of patients [7].

Box 244.2 Treatment options in MG

Long-term treatments

Anticholinesterases: pyridostigmine, neostigmine

Rarely effective as single therapy

Immunosuppressive agents

- Prednisolone:
  - First choice of immunosuppressant therapy.
  - May cause worsening of MG if started on high dose.
  - Aim for lowest possible alternate day dose when stable
- Azathioprine: steroid sparing drug.
- Mycophenolate: steroid sparing drug.
- Ciclosporin: steroid sparing drug.

Thymectomy

- Indicated for anti-AChR antibody positive MG.
- Remission may take up to 2 years to realize.

Acute treatments

- IVIg.
- Plasma exchange:
  - 1–2 g/kg over 5 days.
  - Daily/alternate day exchanges for 5–10 days.

Other forms of myasthenia gravis

Neonatal MG is due to the transplacental flow of maternal anti-AChR antibodies and affects 15% of babies born to mothers with MG. It is usually transient, but may be prolonged if there are associated antibodies which affect fetal AChR.

Congenital MG is a collection of hereditary diseases resulting in defects in the structure and function of the presynaptic, synaptic, or post-synaptic regions of the NMJ. They result in variable degrees of muscular weakness.

Drug-induced MG is indistinguishable from acquired MG and is most commonly caused by D-penicillamine or interferon alfa. Remission usually occurs within 6 months of stopping the drug.

Intensive care management of MG

Patients with MG require intensive care management when they present in myasthenic crisis or for post-operative care following thymectomy.

Myasthenic crisis

Myasthenic crisis is defined as any muscle weakness due to MG severe enough to necessitate tracheal intubation and mechanical ventilation. The definition is also extended to surgical myasthenic patients who require >24 hours of post-operative tracheal intubation due to muscle weakness.

The incidence of myasthenic crisis in early-onset MG is 15–20% and usually occurs within 1 year of diagnosis. Treatment results in a relatively rapid response and recurrence rates are low. In contrast, myasthenic crisis occurs in up to 50% of patients with late-onset myasthenia, is often difficult to treat and has a high relapse rate [8]. Common triggers for both forms include infection and initiation of corticosteroid therapy.

In the past, much emphasis has been placed on differentiating myasthenic weakness and muscle weakness due to overdose of anticholinesterase therapy (cholinergic crisis). In practice, the latter is extremely rare, but is suggested by meiosis, lachyrimation, and bradycardia.

Myasthenic crisis may be the first presenting feature of MG and the diagnosis may not be immediately apparent. Differential diagnoses include Guillain–Barré syndrome, botulism, and polymyositis.

Management

The mainstay of management of myasthenic crisis is early recognition of impending respiratory or bulbar failure, and rapid tracheal intubation and mechanical ventilation. This should be based on clinical signs, rather than waiting for deterioration in arterial blood gases. These include increasing agitation, tachypnoea, use of accessory muscles, paradoxical abdominal movement on inspiration, and an inability to swallow secretions. A bedside measurement of forced vital capacity of <20 mL/kg supports the decision to intubate, but patient technique is often poor when performing the test in these conditions.

Although non-invasive ventilation has been used in myasthenic crisis to avoid tracheal intubation, it is rarely useful because bulbar failure almost invariably co-exists with respiratory failure and intubation is necessary to protect the airway from aspiration.

Following intubation and mechanical ventilation, anticholinesterase therapy is usually stopped as are any other medications, which can worsen neuromuscular function (Box 244.3).

Although randomized controlled trials comparing plasma exchange and IVIg in management of myasthenic crisis have found them to be of equal efficacy most authorities favour plasma exchange because of its more rapid action [9]. Evidence suggests that daily PE is as effective as alternate day exchange. Because its action results in only temporary improvement, PE is supplemented with long-acting immunosuppressive agents (most commonly prenisolone 1 mg/kg/day). PE is contraindicated in patients with severe sepsis, cardiac failure, hypotension and pregnancy, and IVIg is therefore used in these situations.

Extubation should only be considered when any co-existing infection has been thoroughly treated, forced vital capacity is >30 mL/kg and bulbar function has been assessed as adequate. Even

Box 244.3 Drugs to be avoided or used with caution in myasthenic conditions

- Neuromuscular blocking drugs.
- Antibacterial drugs—aminoglycosides, polymixins, ciprofloxacin.
- Chloroquine.
- β-adrenergic receptor antagonists.
- Magnesium.
- Calcium channel antagonists.

when these conditions are met, up to 30% of myasthenic patients need re-intubation, most commonly in older patients, those with atelectasis and patients who have required prolonged periods in the intensive care unit [10]. Bi-level positive pressure ventilation may be helpful in avoiding re-intubation [11].

If managed in a specialized unit, the mortality of myasthenic crisis is 5%. Most deaths are due to cardiac events or sepsis.

Thymectomy

Most myasthenic patients undergoing thymectomy can be safely extubated at the end of the procedure. A small percentage requires more prolonged mechanical ventilation; pre-operative predictive factors for this include severe generalized MG, poor bulbar function, previous myasthenic crisis and a reduced FVC. All patients need careful nursing in an intensive care unit with the close co-operation of anaesthetists, intensivists, and neurologists. Adequate analgesia is essential and thoracic epidural analgesia has been used successfully. Anticholinesterase therapy is restarted in the post-operative period, but reduced requirements are often seen in the first 48 hours.

Lambert–Eaton myasthenic syndrome

The Lambert–Eaton myasthenic syndrome (LEMS) is a rare autoimmune disease in which IgG antibodies are directed towards the presynaptic voltage-gated calcium channels (VGCC) at the NMJ [12]. This results in decreased mobilization and release of acetylcholine vesicles following nerve action potentials that, in turn, causes weakness of muscle contraction. Patients present to the intensive care with respiratory failure or with prolonged paralysis following the administration of neuromuscular blocking agents during anaesthesia, to which they are extremely sensitive.

50–60% of patients with LEMS have associated malignant disease, most commonly a small cell carcinoma of the lung.

The diagnosis of LEMS is based on clinical signs, electromyography, and detection of VGCC antibodies. The characteristic clinical triad consists of proximal muscle weakness (often starting in the legs and rapidly spreading to the arms), reduced tendon reflexes and automonic symptoms. Ocular and bulbar weakness is common and respiratory failure can occur. Autonomic features include dry mouth, erectile dysfunction, and orthostatic hypotension.

Characteristic electromyography findings include an incremental response in the compound muscle action potential on high rates of tetanic stimulation or following exercise [13].

VGCC antibodies can be detected in 90% of patients with LEMS [14]; seronegative patients are thought to have other types of circulating antibodies to proteins at the NMJ.

Treatment

The mainstay of treatment of LEMS is 3,4-diaminopyridine, which by blocking voltage-gated potassium channels presynaptically, prolongs the nerve action potential and lengthens the opening time of the VGCC. In addition, most patients require long-term immunosuppression. Acute exacerbations may require plasma exchange.

CHAPTER 245

Diagnosis, assessment, and management of tetanus, rabies, and botulism

Jeffrey Lipman and Robert J. Boots

Key points

- Tetanus and botulism are caused by neurotoxins, whereas rabies is a viral zoonosis.
- *Clostridium tetani* exotoxins cause generalized muscle rigidity, autonomic instability, and sometimes convulsions. Without expensive intensive care treatment the disease is often fatal.
- As tetanus does not produce immunity, active immunization with antitetanus toxin must follow.
- Botulism is a toxin-related illness generally due to food poisoning, which leads to an ascending paralysis with neural destruction. Recovery is prolonged and often incomplete.
- Rabies and associated Lyssavirus encephalitis in the previously unimmunized is a fatal illness.

Tetanus

Clostridium tetani exotoxins cause tetanus, a syndrome characterized by generalized muscle rigidity, autonomic instability, and sometimes convulsions. Without expensive intensive care treatment the disease is often fatal.

Epidemiology and pathogenesis

With widespread immunization programs, tetanus has become a disease of the elderly, debilitated, and neonates of unimmunized mothers.

C. tetani is an obligate anaerobic, spore-bearing, Gram-positive bacillus. Spores are ubiquitous, existing in soil, and in animal and human faeces. Only after gaining access to devitalized tissue, do spores proliferate in the vegetative form, producing the toxins, tetanospasmin, and tetanolysin.

The usual mode of entry is through a puncture wound or laceration, dental infection, abortion, and childbirth. Spores can lie dormant in human bowel and tetanus may follow surgery, burns, gangrene, or chronic ulcers. In 20% of cases there is no history or evidence of a wound [1]. *C. tetani* infection remains localized, but the exotoxin, tetanospasmin, is distributed widely via the blood stream, taken up into motor nerve endings, and transported into the nervous system. The symptoms of tetanus appear only after tetanospasmin has diffused from the cell body through the extracellular space, and gained access to the presynaptic terminals of adjacent neurons [1]. Tetanospasmin is preferentially bound by inhibitory interneurons, i.e. glycinergic terminals in the spinal cord, and *y*-aminobutyric acid (GABA) terminals in the brain [2]. Its principal effect is to block these inhibitory pathways. It affects motor neurone end-plates in skeletal muscle (rigidity, spasms), the spinal cord (dysfunction of polysynaptic reflexes), and the brain (seizures, inhibition of cortical activity, and autonomic dysfunction).

Prevention by active immunoprophylaxis

Natural immunity to tetanus does not occur, nor does the disease result in subsequent immunity [1,3]. Tetanus toxoid (TT) is a cheap and effective vaccine. In adults, a full immunization course consists of three doses. A second should be given 6–12 weeks after the first and the third 6–12 months after that. A single dose will offer no immediate protection in the unimmunized. Neonates of immunized mothers have immunity from maternal antibodies. Children over 3 months should be actively immunized, needing four TT doses in total. Two or more TT doses given to child-bearing women over 14 years will protect any child born within the next 5 years. Pregnant women who are not immunized should be given two spaced-out doses of TT 2 weeks to 2 months before delivery. Booster doses of TT should be given routinely every 10 years.

Clinical presentation

The incubation period (time from injury to symptom onset) varies from 2 to 60 days [1,3]. The period of onset (from first symptom to first spasm) similarly varies. Nearly all cases (90%) present within 15 days of infection [4]. The shorter the incubation period and period of onset, the more severe the disease.

Presenting symptoms are pain and stiffness, which gives way to rigidity and spasms. Most (75%) non-neonatal generalized tetanus present with difficulty in mouth opening, i.e. lock-jaw or trismus [4]. Spasms can be life-threatening when they involve the larynx and/or diaphragm.

Neonatal tetanus presents most often on day 7 of life [3], with a short (usually 1-day) history of the infant failing to feed.

Autonomic dysfunction occurs in severe cases of tetanus[1,3,5], and begins a few days after the muscle spasms. There is increased

basal sympathetic tone, with episodes of marked sympathetic surges, involving both α-and β-receptors, usually of short duration, and occurring with or without provocation.

The role of the parasympathetic nervous system is more debatable. Episodes of bradycardia, low peripheral vascular resistance, low central venous pressure and profound hypotension are occasionally seen [3]. These events have been attributed to total withdrawal of sympathetic tone, since they are unresponsive to atropine [6]. Patients afflicted with the autonomic dysfunction of tetanus are at risk of sudden death.

Local tetanus and **cephalic tetanus** are uncommon forms of tetanus. With the former, the signs and symptoms are confined to a limb or muscle; the latter results from head and neck injuries, eye infections and otitis media.

Diagnosis

Tetanus is a clinical diagnosis, often straightforward, with no specific laboratory tests. In only one-third of cases can *C. tetani* be cultured from the wound. Differential diagnoses include dystonic reaction to tricyclic antidepressants, strychnine poisoning, local temporomandibular disease, local oral disease, convulsions, tetany (for example, secondary to hypocalcaemia), intracranial infections or haemorrhage, or psychiatric disorders.

Management

Here, there are four objectives [3]:

- To neutralize circulating toxin (passive immunization).
- Prevent it from entering peripheral nerves and eradicating the source of the toxin (wound care, extensive surgery, and antibiotics).
- Minimize the effect of toxin already bound in the nervous system.
- Provide general supportive care.

Passive immunization

Human antitetanus immunoglobulin (HIG) has now largely replaced horse antitetanus serum (ATSe) as it is less antigenic. HIG will, at best, neutralize only circulating toxin, not affecting toxin already fixed in the CNS. It does not ameliorate symptoms already present. The minimum dose for prophylaxis is 250 IU or 500 IU if the wound is grossly contaminated or more than 24 hours old [5]. Some suggest that unimmunized patients or those with unknown immunization status should be given HIG on presentation with contaminated wounds.

Intrathecal administration of HIG or ATSe is still controversial. Two meta-analyses reported differing results [7,8]. If HIG is not available, equine ATSe can be used after testing and desensitization [1].

Eradication of the organism

Wound care

Often the wound can look 'normal' as the spores are non-immunogenic. Nevertheless, once HIG has been given, the infected site should be thoroughly cleaned and all necrotic tissue extensively debrided.

Antibiotics

Metronidazole 500 mg given intravenously (iv) 8-hourly for 10 days is the drug of choice. Alternatively benzylpencillin G 1–3 MU iv 6-hourly for 10 days, noting the drug is a GABA antagonist in the CNS [9].

Suppression of effects of tetanospasmin

Controlling muscle spasms

Initially, the patient is most at risk from laryngeal and respiratory muscle spasms, and the airway should be secured urgently if such spasms occur. If respiratory muscles are affected full mechanical ventilation with neuromuscular blockade may be required. Deep sedation alone may prevent such spasms and improve autonomic dysfunction.

Management of autonomic dysfunction

Autonomic dysfunction manifests in increased basal sympathetic activity and episodic catecholamine surges [3]. Hypertension, tachycardia, and sweating do not always occur concurrently. Traditionally, a combination of various α and β-adrenergic blockers has been used to treat sympathetic overactivity. Unopposed β-adrenergic blockade cannot be advised as it may worsen hypertension.

Rather than blocking effects of catecholamines, it may be more logical to decrease catecholamine output with sedatives. Benzodiazepines and morphine have been used successfully. Morphine and diazepam act centrally to minimize the effects of tetanospasmin. Morphine probably acts by replacing deficient endogenous opioids [1]. Benzodiazepines increase the affinity and efficacy of GABA [1]. Very large doses of these agents are well-tolerated.

Magnesium has been used as an adjunct to sedation [3,10]. Calcium supplementation may be needed. Anecdotally, clonidine, a central α2 stimulant, has been used successfully to produce sedation with control of autonomic dysfunction. Intrathecal baclofen has produced similar beneficial results in a series of cases, but may cause significant respiratory depression [11].

Supportive treatment

Basic intensive care support is important, with special attention paid to prevention of contractures.

Complications

Muscle spasms usually disappear by 3 weeks, but residual stiffness may persist [1,3,5]. Although most survivors recover completely by 6 weeks, cardiovascular complications, including cardiac failure, arrhythmias, pulmonary oedema, and hypertensive crises can be fatal.

Outcome

Recovery from tetanus can be complete. However, in 25 non-neonatal patients followed for up to 11 years [12], 15 were reported to have one or more abnormal neurological features, such as intellectual or emotional changes, fits and myoclonic jerks, sleep disturbance, and decreased libido.

Mortality figures depend on the availability of intensive care. In neonates, the mortality from African countries with no ICU facilities can be up to 80%, but decreases to under 10% with intensive care. However, as tetanus is easily and completely preventable, any loss of life may be considered unacceptable.

Rabies

Epidemiology and pathogenesis

Rabies is an RNA viral zoonosis (Lyssavirus) that occurs on all continents except Antarctica. It causes a neurological illness with

a high mortality rate. Common modes of transmission are the bite of a rapid animal, or saliva contamination of wounds or mucosa. Rare modes are from viral laboratory aerosols, and corneal or solid organ transplants [13]. Worldwide, dogs represent 90% of the animal reservoir [14], although bats are the commonest reservoir in North America.

The virus remains latent at the inoculation site. It enters nerves via the neuromuscular end plate with retrograde axonal transport to the CNS and subsequent anterograde transport along the peripheral nerves. It may be found in hair follicles in diagnostic skin biopsies.

Clinical presentation and differential diagnosis

Incubation is usually 1–3 months, but can vary from years to under a week [15]. A 7-day viral prodrome is associated with paraesthesia, pruritus, pain, hyperaesthesia, and anaesthesia at the site of virus entry.

There are two common clinical presentations, the furious form occurs in 80% and the paralytic form in 20%.

The furious form (80%) develops in patients with intact cell-mediated immunity to rabies virus. It is characterized by agitation with hyperactivity and typically autonomic dysfunction manifest as priapism, pilo-erection, cardiac arrhythmias, hyperpyrexia, mydriasis, increased salivation, sweating, and lacrimation. Hydrophobia and aerophobia represent painful muscle spasms of the oropharynx and larynx following drinking or air blowing onto the face. The clinical illness lasts a few days, and ends in death from coma or cardiac arrhythmia.

The paralytic form is characterized by the insidious onset of symmetrical or asymmetrical ascending paralysis from the infected limb, leading to quadriplegia, bulbar paralysis, and respiratory failure, with bladder and bowel dysfunction developing over longer periods.

The differential diagnosis includes other viral encephalitides, Guillain–Barrè syndrome, poliomyelitis, cerebral malaria, diphtheria, botulism, drug intoxication (e.g. the serotonin syndrome), and drug withdrawal syndromes.

Diagnostic work-up

Examination of CSF during the first week typically shows a predominant mononuclear pleocytosis of only 100 cells/μL with mild protein elevation and a normal glucose. Human infection may show viral RNA using PCR in saliva, tears, or in nuchal skin biopsies. Serum antibodies maybe found in vaccinated individuals, but CSF antibodies represent clinical infection.

Prevention

Vaccination programs of potential domestic wildlife animal vectors, stray animal controls, leashing of pets, and pet owner education, generally control animal rabies.

Pre-exposure prophylaxis

Modern tissue culture vaccines reduce neurological side effects with weekly intramuscular doses for three weeks providing 98% seroconversion [15]. Cell culture vaccines are safe in pregnancy.

Post-exposure prophylaxis

The most important component of therapy is wound cleaning and care, leaving the wound unsutured [16].

For previously non-immune patients, up to 20 IU/kg of human rabies immune globulin is injected into the wound as tolerated, the remainder given intramuscularly distant to the wound. Equine rabies immune globulin (40 IU/kg) is has a higher incidence of hypersensitivity reactions. Active immunization should be commenced with four intramuscular injections on days 0, 3, 7, and 14. Previously vaccinated individuals only require two injections on day 0 and day 1. There have been no recorded failures of the combined pre- and post-exposure vaccination with subsequent post-exposure treatment.

Therapy

There is no effective therapy once symptoms develop, with rare reports of survival in the previously immunized.

Botulism

Epidemiology and pathogenesis

Botulism, caused by the exotoxin of *Clostridium* botulin and related species, is most typically associated with food poisoning, but can result from contaminated wounds or directly inhalation.

C. botulinum, an anaerobic Gram-positive, spore-forming bacillus. It is found in soils and aquatic beds worldwide. Human neurological disease is caused by serotypes A, B, E, and more rarely F. Serotype G has been associated with sudden death, but not neurological disease. Related *Clostridium* species associated with disease are *C. argentinese, C. baratii*, and *C. butyricum*. The highly toxic exotoxin is destroyed by heat (greater than 121°C or 250°F for 30 minutes) and most water purification systems [17]. Spore germination does not occur in intact adult gastrointestinal tracts, but may cause disease in infants and adults with a diseased or surgically-altered gut. Food-borne botulism typically results from ingestion of preformed toxin in contaminated food. Germination in food occurs generally in preservation processes under anaerobic and moist conditions with low acidity and salinity.

Botulinum toxin is actively absorbed across the gastrointestinal tract and being too large to cross the blood–brain barrier manifests illness in the peripheral nervous system. Toxicity results from inhibiting acetylcholine mediated neurotransmission at the neuromuscular junction, sympathetic, and parasympathetic ganglia and parasympathetic post-ganglionic sites. Recovery is prolonged requiring regrowth of the axon and severely affected patients may require many weeks of intensive care treatment [18].

Clinical presentation and differential diagnosis

Infant botulism results from early intestinal colonization [19]. Botulism from food ingestion results from anaerobic growth from food spoilage and contamination. Type E toxin is associated with fish products from the arctic regions. Preserved vegetables are the most common source in Europe, China (bean curd), and the USA. Meats are a common source in Central Europe. Wound botulism results from bacterial contamination.

The incubation period depends on the amount of preformed toxin. Mild nausea, vomiting, and diarrhoea can occur. In severe disease, the initially manifestation is a descending pure motor flaccid paralysis with bulbar palsies. Pupillary dilation, diplopia, and ptosis are followed by facial, and bulbar paralysis, and then paralysis of the larger muscle of the arms. Intercostal, diaphragm, and leg involvement occur late. Weakness may not be symmetrical and

deep tendon reflexes may remain intact. There is typically no fever or leukocytosis.

Wound botulism may take a week or longer for the onset of symptom and maybe associated with fever due to concomitant wound infection by other organisms.

Diagnostic possibilities should include myasthenia gravis, Guillian–Barré syndrome (Miller Fisher variant), tick paralysis, and polio.

Diagnostic work-up

Diagnosis is usually clinical. Anaerobic transport of serum, gastric contents or stool may isolate *Clostridium* organisms and can be screened for toxin [19].

Therapy

Although not reversing symptoms, administration of equine antitoxin arrests disease progression [20]. Progression to respiratory failure occurs in only 10% of patients receiving antitoxin within 24 hours of symptom onset, but in 46% when antitoxin is not given.

Heptavalent

Botulinum antitoxin (H-BAT) covers all serotypes and is administered in 20 mL over 60 minutes. Baby botulinum immune globulin (BabyBIG-IV) is human antitoxin derived from plasmapheresis and used in the management of infant botulism.

Prevention

Clostridium botulinum is killed by heating food above 121°C and storage at less than 4°C [19]. The addition of acidifying agents, such as citric acid is recommended for canning of vegetables to prevent spore formation.

CHAPTER 246

Diagnosis, assessment, and management of Guillain–Barré syndrome

David Brealey and Nicholas Hirsch

Key points

- Guillain–Barré syndrome is an acute polyneuropathy consisting of several variants of differing pathology, presentation and outcome.
- 10–30% of patients with Guillain–Barré syndrome require mechanical ventilation for respiratory and/or bulbar failure.
- IVIg or plasma exchange significantly accelerates recovery and reduces disability. Corticosteroids are not indicated.
- Autonomic disturbance is common and potentially life threatening.
- Overall mortality is approximately 5%, with 20% remaining severely disabled.

Introduction

Guillain–Barré Syndrome (GuBS) is an acute inflammatory polyneuropathy first described by George Guillain, Jean-Alexandre Barré, and Andre Strohl in 1916. They described an acute transient motor weakness with loss of tendon reflexes in two soldiers. This was associated with an increased albumin in the cerebrospinal fluid (CSF) without a cellular reaction. Since the eradication of poliomyelitis, GuBS is the commonest cause of acute flaccid paralysis in the Western world. Up to one-third of patients with GuBS require mechanical ventilation and, therefore, the condition is of importance to all those involved in intensive care.

Variants of GuBS

GuBS represents a spectrum of acute neuropathies with a number of variants. The most common form in Europe and the United States (95% of cases) is **acute inflammatory demyelinating polyradiculoneuropathy** (AIDP). In the remainder, the nerve axon, rather than the myelin sheath is affected the axons targeted may be purely motor (**acute motor axonal neuropathy** (AMAN), more common in China), purely sensory (**acute sensory neuropathy**) or both (**acute motor and sensory axonal neuropathy** [AMSAN]). Neurophysiological testing allows distinction between these variants. In its pure form the **Fisher syndrome** variant consists of the triad of acute ophthalmoplegia, ataxia, and areflexia; if the triad is accompanied by degrees of limb and respiratory muscle weakness it is known as the **Fisher overlap syndrome**.

Epidemiology

The incidence of GuBS increases with age and in Europe and the USA is reported as 1.2–1.9 per 100,000. Men are affected 1.5 times more frequently than women.

In about two-thirds of cases, the onset of weakness is associated with an infective episode such as an influenza-type illness or gastroenteritis within the preceding 6 weeks. Possible infective triggers for the condition include *Camplylobacter jejuni*, cytomegalovirus, Epstein–Barr virus, *Mycoplasma pneumoniae*, and the human immunodeficiency virus (HIV). Seasonal fluctuations of GuBS are seen in China with an increased incidence following *Camplyobacter* outbreaks.

An increased incidence of GuBS in the Southern US in 1976 following a swine influenza vaccination programme, raised concerns that immunization may trigger the condition. However surveillance programmes have estimated that vaccination against influenza may result in only one additional case per million vaccinated. GuBS can often be linked temporally to the administration of other vaccines, but the actual incidence appears to be no higher than that of the general population. Case reports and small series have also linked GuBS with a diverse range of aetiologies, such as systemic lupus erythematosus, trauma, surgery, transplantation, and lightning strikes.

Pathophysiology

GuBS is considered an immune-mediated condition and half the patients with the condition have detectable antibodies in their sera. Most commonly, these antibodies are directed towards gangliosides, present in high concentrations in neurons and involved in neural development, calcium homeostasis, and synaptic transmission. Although no consistent antibodies are found in AIDP, specific antiganglioside antibodies have been commonly detected in patients with axonal forms of GuBS (Table 246.1).

The most attractive hypothesis to explain the presence of ganglioside antibodies in GuBS is that infecting agents (e.g. *Campylobacter jejuni*) raise antibodies, which then cross-react with peripheral nerve gangliosides. This molecular mimicry theory is supported

Table 246.1 Anti-ganglioside antibodies associated with GuBS and its variants

Variant	Associated antibodies
AIDP	Unknown
AMSAN and AMAN	GM1, GM1b, GD1a
Acute sensory neuropathy	GD1b
Fisher syndrome	GQ1b, GD3, GT1a

by the finding that lipo-oligosaccharides present on *Campylobacter jejuni* contain ganglioside-like structures.

Clinical features of GuBS

The diagnosis of GuBS is usually straightforward although the variable rapidity of onset of weakness provides a wide differential diagnosis (Box 246.1).

Patients classically present with a symmetrical ascending motor paralysis that develops acutely and progressively evolves over hours to weeks. Weakness usually involves both distal and proximal muscle groups. 90% of patients have reached the nadir of their weakness within 3 weeks and recovery tends to occur 2–4 weeks after progression has ceased. If the weakness continues to progress after four weeks, the alternative diagnosis of chronic inflammatory demyelinating polyneuropathy (CIDP) should be considered. Differentiation between GuBS and CIDP is essential as the treatment of these conditions fundamentally differs. Occasionally, GuBS has an explosive onset causing total motor and autonomic paralysis, which can mimic brainstem death.

Although approximately 25% of patients with GuBS remain mobile, the remainder are more severely affected, with 10–30% of patients requiring mechanical ventilation for severe respiratory muscle weakness.

Deep tendon reflexes almost invariably disappear during the first week of the condition. Although sensory changes may be profound in the rare acute sensory variant, in AIDP mild distal parasthesia and numbness are usual. Approximately 50% of patients with GuBS have pain at presentation usually affecting the back and legs and 90% will experience pain during the course of their illness. The cranial nerves are involved in up to 75% of patients causing facial and bulbar weakness and ophthalmoplegia.

Autonomic nerve involvement occurs and is more commonly seen in those with severe weakness and those requiring mechanical ventilation; common manifestations include tachy- and bradyarrhythmias, labile blood pressure, abnormal sweating, ileus and urinary retention.

Box 246.1 Differential diagnosis of GuBS

Brainstem pathology: stroke
- Encephalitis.
- Brainstem death.

Spinal cord pathology
- Acute poliomyelitis.
- Transverse myelitis.
- Space-occupying lesion.
- Paralytic rabies.

Peripheral neuropathy: critical illness neuropathy
- Vasculitic neuropathy.
- Acute intermittent porphyria.
- Heavy metal poisoning.
- Tick bite paralysis.
- Marine toxins.

Neuromuscular junction disorders
- Myasthenia gravis.
- Lambert–Eaton myasthenic syndrome.
- Botulism.
- Organophosphate poisoning.

Muscle disorders: critical illness myopathy
- Hypokalaemia.
- Periodic paralyses.
- Inflammatory myopathies.

Diagnosis of GuBS

The diagnosis of GuBS relies on history, clinical features, examination of the cerebrospinal fluid (CSF) and neurophysiological studies. Essential and supporting criteria for the diagnosis were defined in 2003 [1].

Examination of CSF

The immune-mediated destruction of neuronal myelin and/or axons results in an inflammatory infiltration of nerve roots and disruption of the blood–CSF barrier with leakage of albumin into the CSF. Although CSF protein concentration may be normal in 15% of patients in the first week [2], most patients with GuBS will have a raised CSF protein 1 week after the onset of the weakness. In contrast, 90% of patients will have a cell count of < 3 per mm^3. A cell count of > 50 per mm^3 should raise doubts about the diagnosis or the co-existence of HIV infection.

Neurophysiological examination

Nerve conduction studies (NCS) and electromyography (EMG) are central to confirming the diagnosis, identifying the sub-type and helping with prognosis.

NCS may be normal early in the condition, but as the disease progresses certain electrophysiological changes occur. In AIDP absent or pronged F waves (conduction block) recorded from motor nerves occur in up to 80% of patients [3]. Abnormal sensory nerve action potentials (low amplitude or absent) are often found, particularly in the upper limbs, but with relative sparing of the lower limbs. Axonal disease is associated with small motor action potentials and, in AMAN, normal sensory potentials.

Management of GuBS

The admission of a GuBS patient is often protracted and complex. The key to successful management is a cohesive multi-disciplinary team approach with close cooperation between neurologists, intensivists, specialized nursing staff, physiotherapists, speech and language therapists, and specialists in neurorehabilitation.

The management of GuBS can be divided into immunotherapy (plasma exchange and IVIg) [4] aimed at shortening the acute phase of the disease and supportive treatment including intensive care management.

Plasma exchange

Plasma exchange (PE) significantly accelerates recovery and reduces disability at 4 weeks compared to supportive care alone.

Although arbitrarily set, most authorities perform five single plasma volume exchanges (200–250 mL/kg) over 7–14 days. PE requires central venous access, specialist equipment, and staff expertise, and is therefore often confined to specialist centres. Adverse events (haemodynamic compromise, sepsis, and technical difficulties) occur in approximately 75% of patients and in 14% of patients these result in the procedure being abandoned [5,6]. Co-existing infection is a relative contraindication to PE as removal of circulating antibodies may result in worsening of sepsis.

Intravenous immunoglobulin (IVIg)

The action of IVIg is poorly understood, but is thought to interfere with the immune system in a number of ways including neutralization of activated complement factors, interference with Fc receptor signalling and inactivation of pro-inflammatory cytokines.

Five trials, have demonstrated IVIg to be as efficacious as PE in the treatment of GuBS [4]. The usual dosing regimen of IVIg is 0.4 g/kg/day for 5 days. There is no benefit in combining PE and IVIg. Many authorities now consider IVIg the treatment of choice for GuBS as it has equal efficacy to PE, is easy to administer and has fewer side effects.

Corticosteroids

Despite widespread use of corticosteroids in other autoimmune diseases no overall benefit has been demonstrated in GuBS. A systematic review [7] concludes that oral corticosteroids are probably harmful, while intravenous steroids in conjunction with IVIg have, at best, a small short term benefit. Corticosteroids are currently not indicated in the management of GuBS (unlike CIDP).

Little evidence exists to guide treatment of the patients who do not respond or relapse after initial treatment. Small case series suggest patients who have not responded to treatment with IVIg may improve with repeated courses or subsequent PE [8,9].

Intensive care management of GuBS

Intensive care management of the patient with GuBS consists of providing appropriate ventilatory support, treatment of autonomic instability and pain, while maintaining meticulous supportive care.

Respiratory support

Up to 30% of patients with GuBS need tracheal intubation and ventilation. Respiratory and bulbar failure are the most common cause of intensive care admission. Respiratory muscle weakness and immobility lead to atelectasis, and the inability to clear secretions, while bulbar failure results in aspiration.

Changes in clinical signs or gas exchange are highly variable and may only markedly alter just prior to respiratory collapse. A gradual decline in vital capacity (VC) is often seen in the days leading up to intubation. A VC of 60% predicted [10] or a 30–50% fall from admission [11,12] are predictive of subsequent ventilation. A VC of <1L is associated with imminent requirement for ventilation [11].

Autonomic dysfunction and paralytic ileus can make the induction of anaesthesia and intubation hazardous. Administration of suxamethonium may induce a fatal hyperkalaemia from the denervated muscle; rocuronium is a suitable alternative.

As median duration of ventilation ranges from 15 to 43 days, early tracheostomy is often indicated.

Weaning from ventilation cannot begin until muscle strength has started to return and is unlikely to be successful if VC is <15–20 mL/kg.

Autonomic manifestations

Autonomic dysfunction affects up to 27% of patients. It tends to occur early and is maximal at the peak point of paralysis. It manifests as cardiovascular disturbance, gastrointestinal disturbances, urinary retention, and abnormal sweating abnormalities [13].

Approximately 20% of patients admitted to ICU suffer from cardiac arrhythmias, which may be life threatening [14]. These may be supraventricular tachycardias or bradycardias, which may require temporary pacing or progress to asystole. Bradycardia may be precipitated by other complications or interventions, such as endotracheal suctioning.

Although large swings in blood pressure with episodic hypertension and hypotension can occur, blood pressure can remain persistently elevated or depressed. ECG changes including, ST depression, T wave inversion and prolonged QT intervals may occur.

Urinary symptoms tend to improve as the disease regresses, but occasionally persist requiring surgical intervention.

Autonomic dysfunction can result in constipation, diarrhoea, paralytic ileus, and gastric paresis. Management is supportive and may include rectal tubes, gastric drainage via nasogastric tubes and parenteral nutrition.

Venous thromboembolism

The incidence of clinical DVT in patients with GuBS ranges from 4%-9%, 2-7% have evidence of pulmonary emboli. All immobile patients should receive venous thromboembolism prophylaxis.

Management of pain

Pain in GuBS is almost invariable, often precedes the onset of weakness and usually affects the back and legs. It is both nociceptive and neuropathic and may be severe [14]. Allodynia and dysaesthesia may persist many years after the resolution of the acute disease. Patients often require a combination of simple and opioid analgesics, and adjuvant analgesics, such as gabapentin or carbamazepine.

Other complications and management

Major morbidity affects up to two thirds of GuBS patients treated in intensive care [14]. Lower respiratory tract infections complicate between 27 and 54%, urinary tract infections 20–46%, and line sepsis 3%.

Prolonged immobilization results in wasting, contractures, hypercalcaemia, and pressure sores, particularly in those with more sensory involvement. An individual neurorehabilitation programme needs to start from the outset [15]. Alterations in mental state are common in patients with severe GuBS and are not due to critical illness alone. Anxiety or depression affects up to 82% of patients.

Outcome of GuBS

The overall mortality of GuBS ranges from 2.4 to 8%, increasing to 7 to 20% in patients treated with mechanical ventilation. Lower mortality rates are seen in neuro-medical ICUs experienced in managing the condition [16]. Causes of death include respiratory failure, aspiration, and ventilator associated pneumonia, sepsis, thromboembolic events, and unexpected cardiac arrest.

Recovery is often prolonged with 20% of patients being unable to walk at 6 months and a similar percentage remaining severely disabled. Recovery of muscle strength can continue for up to 2 years and a neurorehabilitation programme is recommended. Many patients are left with long term sensory deficits, pain and fatigability. Poor prognostic factors include advancing age, severity of disease, and axonal involvement.

CHAPTER 247

Diagnosis, assessment, and management of hyperthermic crises

Kevin Thornton and Michael Gropper

Key points

- MH is a life-threatening hypermetabolic disorder associated with exposure to halogenated volatile anaesthetics and succinylcholine that should be treated by discontinuing the anaesthetic agent, active cooling, and the administration of dantrolene.
- NMS is a syndrome classically associated with exposure to antipsychotic medications, but may also be caused by withdrawal of medications such as L-dopa.
- Serotonin syndrome probably represents one end of a spectrum of symptoms associated with increased central nervous system (CNS) serotonergic activity. It is associated with the use of selective serotonin reuptake inhibitors, monoamine oxidase inhibitors (MAOIs), and tricyclic antidepressants; clonus is the most significant clinical finding.
- In patients who may have been exposed to an MAOI, extreme care should be exercised to avoid prescribing any medications that may increase CNS serotonin levels including pethidine (meperidine) and indirect sympathomimetic agents.
- As all three of these disorders may progress to life-threatening hyperthermia, supportive therapy should include active cooling, intravenous hydration, and monitoring for laboratory abnormalities, including those associated with rhabdomyolysis, hepatic dysfunction, coagulation abnormalities, and electrolyte disturbances.

Introduction

Hyperthermic crises in the intensive care unit (ICU) are often challenging for the clinician due to their relative rarity, their complex underlying mechanisms and predisposing factors, and their high morbidity and mortality if not recognized and treated appropriately. Malignant hyperthermia, neuroleptic malignant syndrome, and serotonin syndrome are the prototypical disorders associated with hyperthermia in the ICU. While they share many similarities, they are distinct clinical entities with different aetiologies, pathophysiological mechanisms, clinical characteristics, and treatments.

Malignant hyperthermia

Malignant hyperthermia (MH) is a rare, life-threatening disorder characterized by a combination of muscle rigidity, severe hyperthermia, and mixed respiratory and metabolic acidosis associated with exposure to halogenated volatile anaesthetics (e.g. sevoflurane, desflurane, isoflurane) or depolarizing muscle relaxants (succinylcholine). It may occur intra-operatively or up to 24 hours following exposure to triggering agents. Without the correct treatment, mortality can be as high as 70%, although prompt recognition and management can reduce mortality to less than 5% [1,2].

Epidemiology and pathophysiology

Estimates of the prevalence of MH vary widely from 1 in 10,000 anaesthetics to 1 in 250,000. A recent cohort study in New York State demonstrated the risk to be approximately 1 in 100,000 in surgical patients with a substantially greater risk among male patients [3]. The clinical syndrome results in uncontrolled release of calcium from the sarcoplasmic reticulum in skeletal muscle and is thought to be mediated by an abnormal ryanodine receptor calcium channel. Numerous genetic mutations to this receptor (inherited in an autosomal dominant fashion) have been shown to produce MH and it has been postulated that the common mechanism may be disruption of the inhibitory function that magnesium ions normally exert on calcium flux. All volatile anaesthetics currently in clinical use are able to trigger MH. Succinylcholine administered alone may trigger MH, albeit this may be quite rare. However, when succinylcholine is administered in combination with volatile anaesthetics a more fulminant form of MH often develops [2].

Clinical features and diagnosis

MH presents as a syndrome characterized by a variety of manifestations that result from hypermetabolism. The features can be divided into muscular manifestations (masseter spasm, generalized muscle rigidity, evidence of rhabdomyolysis, hyperkalaemia), respiratory manifestations (increased CO_2 production, respiratory acidosis, tachypnoea) and metabolic acidosis. In a review of 196 cases of MH in North America, the most common presentation pattern seen was a combination of muscular symptoms and

respiratory acidosis. Metabolic acidosis was present or the sole presentation in a minority of cases which may indicate that this is a later feature of the disease process. Complications include cardiovascular collapse, ventricular arrhythmias, disseminated intravascular coagulation, bleeding, renal failure, hepatic dysfunction, and death. Importantly, more than half of the patients in this analysis had previously undergone uncomplicated general anaesthesia and prior uneventful anaesthesia does not preclude the diagnosis of MH [4].

The diagnosis of MH must be made clinically as confirmatory testing requires either a muscle biopsy for the 'caffeine-halothane contracture test', which serves as the gold standard, or genetic testing to confirm the presence of a mutation in the ryanodine receptor [5]. In a patient who has recently been exposed to either volatile anaesthetics or succinylcholine, signs of rapidly increasing temperature, increased carbon dioxide production (respiratory acidosis, increasing minute ventilation or tachypnoea) and muscular rigidity (which is not always present) should prompt the concern for MH. Rapid recognition is critical as the syndrome evolves rapidly and patients deteriorate quickly without proper treatment [5].

Management

Discontinuation of all volatile anaesthetics and the administration of dantrolene, a ryanodine receptor antagonist, are the foundations of therapy. Dantrolene is notoriously difficult to dissolve in solution and treatment may require the aid of multiple providers. The initial recommended dose is 2.0–2.5 mg/kg, which may be repeated every 5 minutes up to a total dose of 10 mg/kg until a decrease in CO_2 production is seen. Continuous end-tidal CO_2 monitoring is recommended as a means of monitoring the response to treatment in real time. As dantrolene itself is a mild muscle relaxant and may cause respiratory weakness, non-intubated patients may require endotracheal intubation [1]. In the United States, the Malignant Hyperthermia Association of the United States (MHAUS) operates a 24-hour telephone hotline for providers seeking expert clinical assistance and has material online that can be of assistance when treating a patient having an acute crisis (www.mhaus.org).

In addition to discontinuation of the offending agent(s) and administration of dantrolene, treatment focuses on supportive care and monitoring for organ dysfunction. Active cooling is recommended as is the administration of bicarbonate to treat the metabolic acidosis and to alkalinize the urine. Administration of 100% oxygen and an increase in the minute ventilation being delivered are essential to meet the demands of the increased metabolic rate and to compensate for the resultant respiratory acidosis. As rhabdomyolysis may occur in severe cases, monitoring of urine output and laboratory evaluation for elevated creatine kinase, urine myoglobin, and other electrolyte abnormalities as well as for hepatic dysfunction and DIC is also recommended [6].

Recrudescence up to 24 hours following the initial episode occurs in up to 50% of cases so continued vigilance for signs of hyperthermia and increased CO_2 production is warranted and additional doses of dantrolene are often required [7]. Following recovery, patients should be counselled as to the risks and implications of MH for both themselves and their family members. Additionally, they should be referred for confirmatory testing by either muscle biopsy or genetic testing especially if the diagnosis is in question [8].

Neuroleptic malignant syndrome

Neuroleptic malignant syndrome (NMS) is a clinical syndrome seen most commonly in patients who are taking traditional antipsychotic medications, but may also be seen less commonly in those being treated with atypical antipsychotics, promethazine, or metoclopramide. NMS is characterized by altered mental status, muscular rigidity, fever, and autonomic dysfunction, which can lead to rhabdomyolyis, acute renal failure, metabolic acidosis, and other life-threatening systemic manifestations [6].

Epidemiology and pathophysiology

NMS is seen most commonly in patients taking potent antipsychotic medications such as haloperidol. However, it remains quite rare with estimates of the incidence of occurrence in this patient population of 0.2–12% and it may be decreasing in frequency with the increasing use of atypical antipsychotic agents [9]. NMS is associated with use of medications that decrease dopaminergic activity along nigrostriatal and hypothalamic pathways in the central nervous system (and the withdrawal of medications that increase it). This reduction of dopaminergic activity has been postulated to be causative in the disorder. In addition to patients taking antipsychotic medications, it has been described in patients receiving other dopamine-receptor blocking agents, including promethazine, metoclopramide, and following withdrawal of drugs such as L-dopa. It can occur at any point during treatment with these agents, not just during the initiation of therapy. How the peripheral effects (muscle rigidity and rhabdomyolysis) of this syndrome develop is not well understood [10].

Clinical features and diagnosis

The hallmarks of NMS are altered mental status followed by the development of rigidity, hyperthermia, and autonomic dysfunction including diaphoresis, incontinence, and haemodynamic instability. However, in critically-ill patients, NMS often remains a diagnosis of exclusion. Tachycardia and labile blood pressure are common, and overt shock may develop. Mortality estimates range from 11.9 to 18.8%. Laboratory manifestations include the development of leukocytosis, elevated creatine phosphokinase (CK), rhabdomyolysis, elevated lactate dehydrogenase (LDH), and alanine and aspartate transaminases (AST and ALT). Renal failure may develop due to rhabdomyolysis. While the DSM-IV diagnostic criteria require the presence of treatment with an antipsychotic medication, it is clear that this is not always the case. New criteria have been proposed whereby the patient must have hyperthermia, rigidity, and elevated CK in addition to four out of five of the following: tachycardia, abnormal blood pressure, altered consciousness, leukocytosis, and diaphoresis [6].

Management

Discontinuation of the offending agent is the most important intervention that should be made. Otherwise, care is largely supportive and should be aimed at reducing fever via active cooling, hemodynamic support, hydration, and the relief of muscular rigidity. Treatment may need to continue for up to 10 days or as long as 2–3 weeks in patients who have received depot forms of antipsychotic medications. Patients with NMS are at increased

risk for venous thromboembolism and pharmacologic prophylaxis is recommended [10]. Benzodiazepines have been described as potential agents to aid in the treatment of rigidity, but may worsen mental status. Dantrolene and bromocriptine have both been described as potential agents that may be used to treat NMS, but it is unclear if they offer benefit compared with supportive therapy alone. Bromocriptine, a dopamine agonist, may worsen hypotension, if present, and its use should be considered carefully. Electroconvulsive therapy (ECT) has also been evaluated in refractory or severe cases of NMS and found to have some benefit. Finally, there is significant risk for recurrence of NMS if the offending agents are reintroduced and affected patients should be counselled regarding this [6].

Serotonin syndrome

The serotonin syndrome (SS) represents a spectrum of clinical findings seen in patients who are taking medications, or combinations thereof, which increase serotonergic activity in the CNS. The clinical syndrome varies from mild to life-threatening. Classically, it is described as a triad of tremor or neuromuscular abnormalities (clonus and hyperreflexia being most common), altered mental status, and autonomic dysfunction. Hyperthermia is often a late finding in more severe cases. It is most commonly associated with the use of selective serotonin reuptake inhibitors (SSRIs), tricyclic antidepressants (TCAs), and monoamine oxidase inhibitors (MAOIs), but a variety of medications have been implicated including opiate analgesics, dextromethorphan, antibiotics including linezolid, and illicit drugs, such as 3,4-methylenedioxy-N-methylamphetamine (MDMA or 'ecstasy') [11].

Epidemiology and pathophysiology

It is estimated that approximately 14% of patients suffering from SSRI overdose will have SS and the incidence increases with ingestion of multiple serotonergic medications [12]. Additionally, the accidental combination of certain medications, such as MAOIs and pethidine (meperidine), may cause a very severe form of SS. With the increasing use of serotonergic agents, it is suspected that the incidence may be increasing but good epidemiologic data are lacking [12].

Serotonin (5-HT) functions as a neurotransmitter in the CNS and there are several subtypes of 5-HT receptors. It appears that the 5-HT_{2A} receptor may contribute substantially to the development of serotonin syndrome. Since serotonin receptors in the CNS play a key role in the regulation of wakefulness, thermoregulation, motor tone, gastrointestinal motility, and vascular tone it is likely via these receptors that the clinical manifestations of the syndrome are mediated [11].

Clinical features and diagnosis

While classically described as a triad of altered mental status, neuromuscular abnormalities including tremor, and autonomic dysfunction, serotonin syndrome exists as a spectrum of clinical manifestations that range from mild to life-threatening. Mental status changes range from mild agitation to delirium and coma. Tremor, hyperreflexia, and myclonus are the hallmarks of the neuromuscular findings and clonus and hyperreflexia may be worse in the lower extremities [11]. In fact, the presence of clonus may be the most sensitive physical exam finding [13]. Hyperreflexia and clonus may progress to muscular rigidity with increased tone sufficient to produce rhabdomyolysis, metabolic acidosis, renal failure, and DIC. Autonomic manifestations range from mild tachycardia and diaphoresis, gastrointestinal hypermotility, and mydriasis, to severe hypertension, and shock [11].

The Hunter Serotonin Toxicity Criteria (Box 247.1) have been shown to have superior sensitivity and specificity to older diagnostic models when evaluating a patient for serotonin syndrome. The authors stress the importance of clonus (spontaneous, inducible, or ocular) as a physical finding that is strongly associated with SS [13].

Management

Treatment of SS primarily involves the discontinuation of the inciting agent, supportive therapies aimed at relieving agitation and autonomic instability, and treatment of hyperthermia. In mild cases, sedation with benzodiazepines is usually sufficient. In moderate to severe cases, $5HT_{2A}$ antagonists such as cyproheptadine may have a role. In cases where hyperthermia is severe, deep sedation, tracheal intubation, and neuromuscular paralysis with a non-depolarizing muscle relaxant are recommended in addition to active cooling [14].

Benzodiazepines are the mainstay of therapy in mild to moderate cases as they will improve both the agitation and muscular rigidity. Additionally, they have been shown in animal models to improve survival. When treating hypotension that results from autonomic instability, it is important to recognize that indirect-acting sympathomimetics such as dopamine may have exaggerated and dangerous effects in patients who have been exposed to MAOIs and direct-acting agents are preferred [11].

The use of $5HT_2$ antagonists such as cyproheptadine have been described, but their clinical efficacy has not been clearly established in human studies. Typically recommended for only moderate and severe cases, cyproheptidine is only available as an oral agent and the recommended initial dose is 12 mg followed by 2 mg every 2 hours if symptoms persist. Some data suggests that for optimal

Table 247.1 Comparison of MH, NMS, and SS

	Malignant Hyperthermia (MH)	Neuroleptic Malignant Syndrome (NMS)	Serotonin Syndrome (SS)
Associated medications	◆ Volatile halogenated anaesthetics ◆ Succinylcholine	◆ Antipsychotics ◆ Metoclopramide ◆ Promethazine	◆ SSRIs, MAOIs, TCAs ◆ Opiates ◆ Dextromethorphan ◆ Linezolid
Common clinical findings	◆ Hypercarbia and respiratory acidosis ◆ Tachycardia ◆ Rigidity	◆ Muscular rigidity ◆ Fever ◆ Altered mental status ◆ Autonomic dysfunction	◆ Clonus (spontaneous or induced) ◆ Hyperreflexia ◆ Altered mental status ◆ Autonomic dysfunction
Onset and duration	◆ Onset within minutes up to 24 hours following exposure ◆ Recrudescence may occur up to 24 hours later	◆ Can occur at any time during treatment with offending medications ◆ Often associated with dosage increase or medication change ◆ Prolonged course if depot antipsychotic used (2–3 weeks).	◆ Unpredictable onset ◆ Exists as a clinical spectrum ◆ Resolution dependent on half-life of causative agent—usually in 24 hours

receptor blockade, a dose as high as 30 mg may be needed [14]. Chlorpromazine use has also been described in the past, but is no longer recommended for routine use. Both olanzapine and risperidone also have $5HT_2$ blocking effects but their use in the treatment of SS has not been well studied [14].

In severe cases, rhabdomyolysis, renal failure and DIC may develop and patients should be closely monitored for the development of these complications. In most instances, the syndrome resolves within 24 hours, although patients who were exposed to medications with extended half-lives may require prolonged therapy.

Conclusion

Malignant hyperthermia, neuroleptic malignant syndrome, and serotonin syndrome are all life-threatening clinical disease processes associated with hyperthermia. While they have many similar features, they are distinct entities, which clinicians must be able to distinguish as the outcome will be largely dependent on timely recognition and initiation of appropriate therapy (Table 247.1). Vigilance is necessary to evaluate for the signs of systemic involvement that can lead to serious complications including rhabdomyolysis, renal failure, and death.

CHAPTER 248

Diagnosis, assessment, and management of ICU-acquired weakness

Nicholas Hart and Tarek Sharshar

Key points

- ICU-acquired weakness (ICU-AW) is common in critically-ill patients.
- ICU-AW can be categorized as critical illness polyneuropathy (CIP), critical illness myopathy (CIM) and critical illness neuromyopathy (CINM) by detailed electrophysiological investigation, but this is only required when there is diagnostic uncertainty.
- ICU-AW can be diagnosed using the Medical Research Council sumscore with a value less than 48 out of 60.
- Risk factors for ICU-AW include illness severity on ICU admission, duration of mechanical ventilation, prolonged immobility, and duration of sedation.
- Intervention exercise therapy and rehabilitation strategies are required to minimize the effects of developing of skeletal muscle wasting and weakness.

Introduction

In the eighteenth century, William Osler first reported the physical manifestation of prolonged sepsis, describing the progressive 'loss of flesh' with pronounced 'weakness'. Over a century later, there is a widespread acknowledgement of the major psychological and physiological consequences of critical illness. Enhanced survival rates, as a result of advances in modern intensive care medicine, have resulted in greater attention being focused on diagnosing, characterizing and treating these adverse consequences. In particular, neuromuscular deficits in survivors of critical illness contribute to long term impairment in physical function, which persists for many years following the index admission [1]. Intensive care unit-acquired weakness (ICU-AW) is the clinical term applied to weakness developed secondary to critical illness, but this seemingly simplistic label significantly underestimates the complex pathophysiological changes occurring in nerves and muscle during critical illness. In addition to the term ICU-AW, which simply reports muscle strength, other terms have been described such as critical illness polyneuropathy (CIP), critical illness myopathy (CIM) and critical illness neuromyopathy (CINM), all of which require detailed electrophysiological investigation to confirm the diagnosis. Although this level of detail has limited clinical utility in terms of long term clinical outcome [2], CIP has been shown to be associated with more severe long-term disability. Despite these inconsistencies in terminology, an important consequence of this growing interest in critical illness induced weakness is the emphasis on early identification of those at greatest risk of developing weakness. The current therapeutic goal is to develop targeted interventions and strategies that ameliorate, or even prevent, muscle wasting and weakness.

Definitions of muscle weakness associated with critical illness

Muscle wasting and weakness are characteristic in survivors of critical illness [3,4] and ICU-AW is a collective term for the neuromuscular deficit observed. It is defined as clinical weakness in the absence of any neurological or metabolic cause, other than the systemic inflammatory response stemming from the original critical illness [2]. Weakness is bilateral, affecting proximal muscle groups to a greater extent than distal groups, with sparing of the facial muscles. Less commonly sensation can be altered, in particular, temperature and pain perception, indicating the presence of an axonopathy. In general, however, patients typically present with profound generalized weakness resulting in impaired mobilization and difficulty weaning from mechanical ventilation [2,5]. Two comprehensive reviews of the diagnosis and classification of ICU-AW propose clear schematic approaches to differentiating between clinical presentations [2,5]. Fig. 248.1 outlines the classification of ICU-AW.

Where ICU-AW is present, use of electrophysiological and other techniques, such as electromyography, nerve conduction studies and muscle histology, will add more diagnostic accuracy, e.g. to diagnose CIP, CIM, or CINM [2,5,6], but this is often only required when there is diagnostic uncertainty. Tables 248.1 and 248.2 highlight the definitions and diagnostic criteria of the differing terms that describe critical illness induced neuromuscular deficit [2].

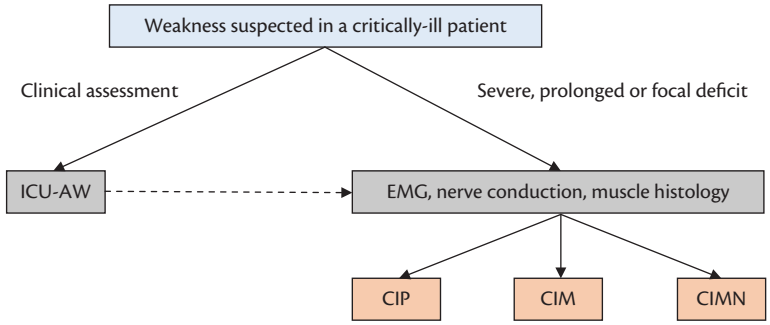

Figure 248.1 ICU-AW classification.
ICU-AW, intensive care unit-acquired weakness; EMG, electromyography; CIP, critical illness polyneuropathy; CIM, critical illness myopathy; CINM, critical illness neuromyopathy.

Table 248.1 Different terminology used to describe neuromuscular deficit in critically-ill patients

Term	Definition
Intensive care unit-acquired weakness (ICU-AW)	Weakness solely attributable to critical illness
Critical illness polyneuropathy (CIP)	Sensorimotor axonal polyneuropathy with reduced compound muscle and sensory nerve action potential amplitudes, but normal nerve conduction velocity
Critical illness myopathy (CIM)	Acute primary myopathy with reduced amplitude of sensory nerve action potentials, low-amplitude motor unit potentials +/−fibrillation and reduced excitability on direct muscle stimulation
Critical illness neuromyopathy (CINM)	Syndrome involving overlap between both CIP and CIM

Table 248.2 Diagnostic criteria for presentations of neuromuscular deficit in critically-ill patients

ICU-AW	CIP	CIM	CINM
◆ Generalized weakness post-critical illness ◆ Diffuse and symmetric in nature, of proximal and distal muscles with sparing of cranial nerves ◆ MRC sumscore <48/60 (Box 243.1) ◆ Protracted weaning from mechanical ventilation ◆ All other causes of weakness excluded	◆ Criteria for ICU-AW met ◆ CMAP amplitudes decreased to <80% of lower normal limit in ≥2 nerves ◆ SNAP amplitudes decreased to <80% of lower normal limit in ≥2 nerves ◆ Normal nerve conduction velocities without conduction block ◆ Absence of a decremental response on repetitive nerve stimulation	◆ Criteria for ICU-AW met ◆ SNAP amplitudes >80% of lower normal limit in ≥2 nerves ◆ Needle EMG in ≥2 muscle groups showing short-duration, low-amplitude motor unit potentials with early or normal full recruitment ◆ Direct muscle stimulation demonstrates reduced excitability in ≥2 muscle groups ◆ Muscle histology consistent with myopathy (such as fibre atrophy, necrosis)	◆ Criteria for ICU-AW met ◆ Criteria met for CIP ◆ Criteria met for CIM

ICU-AW, intensive care unit-acquired weakness; CIP, critical illness polyneuropathy; CIM, critical illness myopathy; CINM, critical illness neuromyopathy; MRC, Medical Research Council; CMAP, compound motor action potential; SNAP, sensory nerve action potential; EMG, electromyogram.

Risk factors for development of weakness during critical illness

The absence of a robust experimental animal model to investigate risk factors in isolation has led to the current established risk factors being reported from regression analysis following observation cohort studies and clinical trials [5]. The risk factors described include illness severity on ICU admission, duration of mechanical ventilation, prolonged immobility, duration of sedation, and hyperglycaemia [5,7,8]. Contrary to earlier belief, a recent review of the evidence, including randomized controlled data, has demonstrated limited harmful effect from the use of neuromuscular blocking agents in modern critical care practice [9]. In addition, a deleterious effect of treatment with corticosteroids is also now controversial.

Clinical assessment of ICU-AW

Electrophysiological testing

Although confirming CIP, CIM and CINM has diagnostic utility, these neuromyopathic conditions often have limited correlation with the severity, distribution or the clinical consequences of ICU-AW [10]. Furthermore, such testing requires a high level of operator skill, as well as expert clinical interpretation rendering the general availability of these tests limited. This is also true for the objective tests that measure the strength of isolated muscle groups, such as adductor pollicis muscle, which can be performed using either electrical, and more recently, magnetic stimulation of the nerve [11]. Furthermore, these complex tests are not always practical in the ICU environment where factors such as oedema, signal artefact from other electrical devices, and the presence of monitoring lines make technical application difficult [5]. Finally, and more important to the clinician, is the lack of any current effective treatment for CIP, CIM, or CINM. Outcome studies have therefore focused on changing aspects of critical care management, such as early exercise therapy and subsequent rehabilitation, which can modify the severity of ICU-AW rather than focussing on the electrophysiological diagnosis [5].

Manual muscle testing

As ICU-AW is primarily a 'bedside diagnosis' [5], it requires a clinically appropriate tool for screening. The most commonly used tool is the Medical Research Council MRC sumscore (MRC-SS) [12], a form of manual muscle testing (MMT). The MRC-SS assesses the strength of six upper and lower limb muscle groups using the ordinal MRC scale from 0 (no strength) to 5 (normal strength). The test is relatively quick, simple and easy to perform requiring no additional equipment and therefore can be used to sequential chart the MRC-SS during the ICU admission and following discharge from the ICU. It has been used in retrospective and prospective studies with a MRC-SS less than 48/60 indicative of ICU-AW e.g. a score of less than 4 in each muscle assessed [3,4]. Handgrip dynamometry, another form of MMT, has also been used to measure muscle strength in critically-ill patients. A direct relationship has been demonstrated between handgrip dynamometry and MRC-SS, with ICU-AW diagnosed at a cut-off level of 11 kg-force for males and 7 kg-force for females [3].

Challenges using manual muscle testing in critically-ill patients

Volitional tests in critically-ill patients

The use of MMT to diagnose ICU-AW in critically-ill patients has clinical limitations. Patients must be sufficiently awake, alert, and cognitively intact to follow the instructions necessary for testing each muscle. Screening tools can facilitate assessment of this, gauging patient response to simple commands such as 'Open your eyes', 'Follow my finger' or 'Nod your head' [3,4]. Clinicians must be confident that patients perform their maximum volitional effort, given that the ICU environment is not always conducive to such testing. Extraneous factors, such as pain and analgesia, level of sedation, arterial monitoring and venous access lines, patient motivation, and compliance with the assessment can influence the outcome of this test and adversely impact the validity and reliability of the results. In addition, the MRC scale for grading muscle strength has a flawed construct with differential sensitivity evident across the range of scores. For example, scores at level 3 or below incorporate gravity as an objective reference quantity, whereas for levels 4 and 5, quantity of additional resistance required is not specified. The validity and reliability of scores greater than level 3 are dependent on the context of the interaction between clinician and patient, and the experience of the clinician in delivering and interpreting the assessment. These inconsistencies have resulted in conflicting data reporting the reliability of the MRC-SS for diagnosing ICU-AW. In stable patients recovering from critical illness, high levels of inter-rater reliability have been demonstrated [13]. However, agreement between clinicians remains poor when testing critically-ill patients whilst in the ICU, assessed at the time of awakening [14]. Assessment at this time point is also difficult as up to a third of patients are unable to perform manual muscle testing [14]. Finally, the clinical predictive value of the MRC-SS at awakening is poor, in particular, there was no relationship between an MRC-SS <48/60 at awakening, considered the diagnostic cut-off for ICU-AW, and ICU or hospital mortality. Although there was a significant association evident for ICU and hospital length of stay, further test characteristic analysis revealed a poor positive predictive value, but a high negative predictive value for an ICU length of stay of more than 2 weeks. Clinically, this suggests that a diagnosis of ICU-AW based on an MRC-SS <48/60 had poor predictive value, whereas an MRC-SS greater than 48 predicted a more favourable outcome [14].

ICU-AW and physical functional ability

Only moderate correlations have been shown between MRC-SS and two common measures of physical function (Barthel score and the elderly mobility scale), which is not unexpected given these represent different domains, i.e. muscle weakness versus physical function [14]. Indeed, the MRC-SS is a composite score of peripheral muscle strength, based on single muscle group manoeuvres. It fails to capture the spectrum of complex motor tasks and interaction between skeletal muscle strength and endurance, balance, co-ordination, and higher-level cognition required for complex physical function activities.

Clinical outcome associated with ICU-AW

Using an MRC-SS cuff off of less than 48/60, the reported prevalence of ICU-AW at the time of awakening ranges from around 24% to 65% [5,6,12] with a significant proportion of such patients demonstrating ICU-AW 7 days after awakening. In terms of short-term outcome, ICU-AW is an independent predictor of prolonged mechanical ventilation [15], with an associated increase in ICU and hospital length of stay [3]. In addition, a direct relationship has been shown between MRC-SS and vital capacity, maximal inspiratory and expiratory pressures, with an MRC-SS less than 41 demonstrated as an independent risk factor for weaning failure [16]. We must emphasize that post-extubation respiratory failure in patients can occur after 48 hours, indicating that patients with ICU-AW should not be discharged from ICU prematurely. Furthermore, ICU-AW is associated with increased ICU and hospital mortality [4]. In the long-term, ICU-AW impacts significantly

on health-related quality of life [17] with impairments in physical function persisting for up to 5 years following index critical illness [1]. Despite these observations, a recent study has shown that an MRC-SS <48/60, indicative of ICU-AW, has no clinical predictive value in terms of ICU and hospital mortality and, indeed, it has a low positive predictive value for determining clinical outcome such as ICU and hospital length of stay [14].

Prevention and treatment

Physical and occupational therapy delivered to patients within the ICU has been shown to improve functional outcome in critical illness survivors when compared with standard treatment [18]. However, a subsequent study rehabilitation trial, which was novel in that it advocated the continuum of rehabilitation from admission to the ICU to the home setting, showed no clinical benefit [19]. Although these results were disappointing, this was not unexpected as it highlighted the difference in therapy provision to critically-ill patients between different healthcare systems, and, in particular, the frequency, duration and intensity of physical rehabilitation therapy treatment delivered. Future management of such patients will require a thorough understanding of the trajectory of acute skeletal muscle wasting. Data from the MUSCLE-UK study [20] showed that muscle wasting occurs early and rapidly during the first week of critical illness and it was greater in those patients with multi-organ failure compared with single organ failure. Importantly, muscle protein synthesis was at the same level as starved controls on admission to the ICU, but with recovery to the synthetic level of fed controls by the end of the first week. Muscle protein breakdown was shown to be elevated on admission and remained elevated after one week. These pathophysiological observations occurred despite enteral feeding and higher protein delivery was associated with greater muscle wasting. These data highlight that future work to prevent muscle wasting and weakness should consider a combination of nutrition, exercise therapy and pharmacological anabolic and anti-catabolic agents.

Conclusion

ICU-AW and weakness is a major clinical consequence of critical illness. It has an impact on clinical outcome with significant short-term and long-term effects on the patients, carers and healthcare organizations. More robust clinical tools are required to diagnose both wasting and weakness to risk stratify those patients most likely to benefit from interventions, such as exercise therapy.

SECTION 10

The metabolic and endocrine systems

PART 10.1

Physiology

CHAPTER 249

Normal physiology of the endocrine system

Simon Baudouin and Steve Ball

Key points

- The endocrine system describes an array of chemical signals (hormones).
- Working in concert with the nervous system, the endocrine system forms a complex neurohumoral network communicating changes in the environment to facilitate adaptive responses.
- The endocrine system has inherent rhythmicity. This has important implications for the integration and coordination of metabolism, and how we measure endocrine signals in clinical settings.
- At a cellular level, hormone action is mediated through a series of discrete, but interacting signal transduction pathways.
- Specificity, sensitivity, amplification, and integration of endocrine signalling reflect the combined properties of hormones, hormone receptors, and down-stream intracellular signal transduction cascades.

Introduction

Hormones as biological messengers

Human physiology encompasses complex processes through which we adapt to changes in the external and internal environment. These adaptations are characterized by coordinated responses across a range of systems. While each component of a given response may appear distinct, taken together they form an integrated package. This requires a complex coordination function, able to both sense and produce an effect, respond over an appropriate time span, and articulate with other mechanisms that may be working in parallel. The endocrine system is a key communication component of this function, one based on circulating chemical signals. In concert with the central and peripheral nervous systems, the endocrine system forms a sophisticated neurohumoral network linking cell-, organ-, and system-based processes to produce coherent adaptive responses (Table 249.1)

Hormone chemistry and hormone production

The endocrine system is composed of a series of discrete glands, each producing one or more chemical messengers (hormones) that act on target sites following release into the general circulation. Some hormones have additional effects close to the site of production (paracrine), or at the very site of production (autocrine), independent of distribution through the circulation.

Hormones range from small and relatively simple molecules to large, multi-subunit complexes (see Table 249.2 for classification). Hormone chemistry is important, as physical characteristics contribute to mechanism and range of action. Larger, water-soluble hormones (such as peptides) do not readily access the interior of target cells. In contrast, lipid-soluble hormones, such as steroid and thyroid hormones are more likely to circulate bound to plasma proteins and can readily cross the cell membrane.

Endocrine physiology

The endocrine system adapts physiology to environmental context. All endocrine glands have a method to sense the internal and external environment. This may be neural, humeral (through another hormone), or a combination of both.

The hypothlamo-pituitary endocrine axes

The hypothalamus is a discrete collection of nuclei lying in close relationship to the floor of the third ventricle, integrated through afferent and efferent projections with key higher and lower centres, including those regulating autonomic function. Functionally, the hypothalamus is a neurohumoral junction where the two communication systems meet information is integrated and a coordinated output generated through both neural and humoral (endocrine) pathways.

The pituitary gland lies inferior to the hypothalamus, linked though the pituitary stalk. While anterior and posterior components of the gland are anatomically related, they are developmentally and functionally discrete [1].

Hypothalamic neurosecretory efferents project to terminals lining the venous hypophyseal-portal system that drains to the anterior pituitary via the pituitary stalk. Small peptides and amines released into the portal venous system constitute the principle mechanism of positive and negative regulation of anterior pituitary hormone secretion. The posterior pituitary hormones (oxytocin and vasopressin) are synthesized in the cell bodies of magnocellular neurones in the paraventricular (PVN) and supra-optic nuclei (SON) of the hypothalamus. These magnocellular neurones project directly to the posterior pituitary, through the hypophyseal-portal tract and pituitary stalk, where they terminate in the vascular bed draining the posterior pituitary gland.

Within the anterior pituitary, specific hormones are produced by discrete populations of cells and released into the systemic circulation through the venous system draining the gland. Arginine-vasopressin (AVP) and oxytocin are produced by discrete

Table 249.1 Hormones have a wide range of physiological actions. Some have a single point of action, some act at multiple points in the same physiological process, while others act at multiple points in a range of different, un-related pathways

Hormone	Physiological action
ACTH	Regulation of adrenocortical steroid hormone production
TSH	Regulation of thyroid hormone production
LH	Regulation of gonadal hormone function
FSH	Regulation of gonadal function
Prolactin	Stimulation and maintenance of lactation
Growth hormone	Promotion of linear growth, regulation of intermediary metabolism
Vasopressin	Increases renal water reabsorption, stimulation of glycogenolysis and gluconeogenesis
Oxytocin	Milk let down, reproductive tract contraction
Thyroxine (T4), triiodothyronine (T3)	Cell growth and differentiation, intermediary metabolism
Cortisol	Vascular integrity, intermediary metabolism
Aldosterone	Increased renal sodium reabsorption and potassium excretion
Epinephrine and norepinephrine	Vascular smooth muscle tone, intermediary metabolism
Oestrogen and testosterone	Reproductive function, bone metabolism, intermediary metabolism
Insulin	Blood glucose control, intermediary metabolism
Glucagon	Blood glucose control, intermediary metabolism
Somatostatin	Paracrine regulation of islet cell function, gut motility, growth hormone production

magnocellular neurones and released independently in response to chemical and neural inputs to the PVN and PVN.

Anterior pituitary hormones fall into one of two categories:

- Hormones that act directly on target tissues to enable physiological change.
- Hormones that act on other endocrine glands and produce indirect effects through the action of hormones produced by these secondary target glands.

Production and release of specific anterior pituitary hormones reflects the balance of positive and negative stimuli acting on the respective populations of cells producing the hormone. Systemic hormone feedback is also exerted at the level of the hypothalamus. (Fig. 249.1, Table 249.3)

In keeping with a predominant role in the regulation of renal water excretion, AVP is released in response to increasing osmotic pressure or reduced vascular volume, with relevant afferent sensory input affecting both AVP production and release by PVN/SON neurones. Oxytocin production/release is triggered through reproductive tract and breast sensory afferents.

Biological clocks and rhythms

In common with many biological processes, many endocrine systems have intrinsic pulsatility or rhythm. The frequency and amplitude of

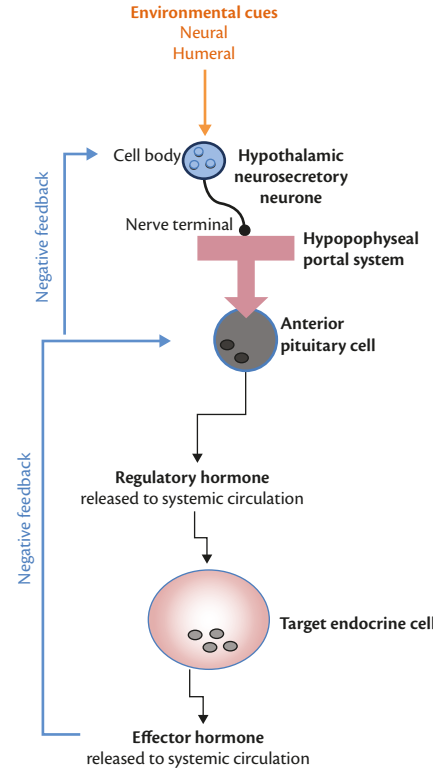

Fig. 249.1 The hypothalamo-pituitary-endocrine axis and feedback control systems.

these rhythms are key characteristics of specific endocrine systems and have critical functional roles. Cellular responses to endocrine signals are rarely simple, binary responses reflecting the presence or absence of a hormone. The magnitude of response can be influenced by the magnitude or amplitude of the signal (quantitative modulation). Moreover, responses may be modified by the frequency of the hormone rhythm (frequency modulation). In some systems, frequency modulation can be profound. Anterior pituitary gonadotrophs produce luteinising hormone (LH) and follicle stimulating hormone (FSH) in response to pulsatile gonadotropin-releasing hormone (GnRH) signals *in vivo* and *in vitro*. In contrast, gonadotroph LH and FSH production is reduced when the GnRH signal is constant, reflecting functional desensitization [2].

Classification of endocrine rhythms

- *Ultradian rhythms*: these cycle over several days. In mammals, this periodicity can parallel seasonal environmental changes, such as light period or temperature.
- *Circadian rhythms*: periodicity that runs within or close to a 24-hour cycle is described as circadian. Circulating levels of several hormones cycle over this range in phase with the day–night photoperiod.
- *Infra-radian rhythms*: cyclical oscillations that demonstrate pulsatility over minutes are described as infra-radian. Many hypothalamic hormones regulating anterior pituitary hormone production demonstrate infra-radian rhythmicity.

The origins and integration of endocrine rhythms

The dominant central 'pacemaker' controlling neurohumeral rhythms is the suprachiasmatic nucleus (SCN) of the hypothalamus. SCN neurons are sensitive to day–night photoperiodicity,

Table 249.2 Hormone classification. Hormones can be classified by chemistry, site of origin, or mechanism of action

Hormone	Source	Chemistry	Receptor	Subtype	Second messenger cascade
Adrenocorticotrophic hormone	Pituitary	Peptide	Plasma membrane	G-protein coupled	Cyclic nucleotide-mediated intracellular phosphorylation cascade
Thyroid-stimulating hormone	Pituitary	Glycopeptide			
Luteinizing hormone and follicle stimulating hormone	Pituitary	Glycopeptide			
Glucagon	Pancreas	Peptide			
Epinephrine and norepinephrine	Adrenal medulla	Amine			
Growth hormone	Pituitary	Peptide		Tyrosine kinase	Receptor- mediated intracellular phosphorylation cascade
Prolactin	Pituitary	Peptide			
Insulin	Pancreas	Peptide			
Cortisol	Adrenal cortex	Steroid	Cell nucleus	Glucocorticoid receptor (GR)	Regulation gene expression with transcriptional co-activators and repressors
Aldosterone	Adrenal cortex	Steroid		Mineralocorticoid receptor (McR)	
Oestrogen	Ovary	Steroid		Oestrogen receptor (ER) α and β	
Progesterone	Ovary	Steroid		Progesterone receptor (PR)	
Testosterone	Testes	Steroid		Androgen receptor (AR)	
Thyroxine (T4) & triiodothyronine (T3)	Thyroid	Iiodothyronine		Thyroid hormone receptor (TR) α and β	

receiving direct input from retinal-SCN afferents. In turn, the SCN has efferent connections with autonomic centres in addition to other hypothalamic nuclei regulating anterior pituitary hormone production. The hard-wiring of the SCN enables integration of photo-period and metabolic signals, facilitating a coordinated neurohumeral output response adapted to these two key 'zeitgebers' (time-givers) determining the central clock-set [3].

Important recent data have demonstrated the presence of key clock-machinery in many peripheral tissues. The concept of a central, neural pacemaker driving physiological rhythms through neurohumoral mechanisms must be modified to take into account the potential for peripheral clocks to generate their own, intrinsic rhythms: influenced by the local metabolic environment in addition to SCN-generated control [4].

Endocrine rhythms and hormone measurement

There are additional, important impacts of endocrine rhythms. While we have sophisticated methods for laboratory-based hormone measurement, measuring a dynamic system can be problematic. In some situations, we need to consider standardized timing. In others, a simple 'snapshot' may not be a reliable assessment of the function or functional capacity of the system—a dynamic evaluation may have greater reliability and validity. There are clear implications for valid reference ranges and data interpretation.

Signal transduction: the principles of hormone action

Generic signal transduction

Good communication-effector systems run on generic principles—fidelity, specificity, reliability. The right message gets to the right place and the right thing happens every time. These are the key principles of hormone action. Signalling molecules released into the circulation (hormones) need a mechanism through which they communicate with individual target cells to bring about change. This requires signalling, receiving, and signal transduction [5]. Signal

Table 249.3 Anterior pituitary hormones and their regulation. Anterior pituitary hormone production is controlled through a combination of specific hypothalamic factors and the feedback of hormones produced in response by target glands, controlled by the anterior pituitary

Anterior pituitary hormone	Hypothalamic regulation		Target tissue	Negative feedback
	Positive	Negative		
Adrenocorticotrophic hormone	Corticotrophin-releasing factor, arginine-vasopressin		Adrenal cortex	Cortisol
Thyroid-stimulating hormone	Thyrotropin-releasing hormone		Thyroid gland	Thyroxine, triiodothyronine
Luteinizing hormone	Gonadotropin-releasing hormone		Gonad	Testosterone, oestrogen
Follicle-stimulating hormone	Gonadotropin-releasing hormone		Gonad	Testosterone, oestrogen
Prolactin	Thyrotropin-releasing hormone	Dopamine	Breast Liver	
Growth hormone	Growth hormone-releasing factor	Somatostatin	Liver, skeletal muscle, adipocytes, bone	Insulin-like growth factor-1

reception and transduction are brought about by hormone binding to a receptor on or within a target cell. This hormone–receptor interaction underpins the fidelity, sensitivity, and specificity of the communication system. Hormone–receptor interaction is coupled to a further, multistep signal transduction cascade with amplification and integration leading to the target cell response (Fig. 249.2).

Hormone receptors

Peptide and other hydrophilic hormones bind to receptors on the cell surface, triggering an intracellular signal-transduction cascade. This cascade can impact rapidly on a range of intracellular metabolic processes; longer-term effects can be produced via effects on the expression of target genes. In contrast, the receptors for steroid and thyroid hormones are hormone-sensitive nuclear transcription factors. In response to hormone–receptor binding, they interact with DNA directly and influence gene expression through recruiting co-activators and co-repressors of the transcriptional machinery.

Affinity, specificity, sensitivity

Affinity and specificity are dictated by the degree of 'fit' of the given hormone for the ligand-binding domain of the cognate receptor in both absolute fit (affinity) and relative (specificity) terms. Sensitivity reflects the bio-physical impact of hormone–receptor interaction on downstream processes. The number of receptors activated and the impact of hormone binding on receptor conformation initiates and drives subsequent steps in the signal transduction cascade. Key to fidelity in hormone action is the specificity of hormone–receptor interaction. While ligands of similar chemical composition may cross-interact with a number of related receptors in vitro, cross-interaction is rarely a problem in vivo, except in circumstances of aberrant receptor expression or supraphysiological hormone levels.

Pre- and post-receptor modification of hormone action

Control of hormone production, fidelity, and sensitivity of hormone-receptor interaction provide a substantial degree of control over hormone action. Many hormones (e.g. steroid and thyroid hormones, growth hormone, and insulin-like growth factor-1) circulate bound to plasma proteins. The hormone is only able to interact with its cognate receptor or enter the target cell in the 'free' state. Concentration of 'free' hormone depends on a number of factors. including total hormone concentration, concentration of the binding protein, and affinity of the binding protein for the given hormone. Concentration of binding protein is open to physiological regulation and can change significantly in a range of pathophysiological situations [6]. In addition, hormone-binding protein kinetics can be affected by a range of substances that may compete for non-specific ligand binding sites on plasma binding proteins (e.g. free fatty acids).

Additional prereceptor modification of hormone action occurs in some systems through local generation or inactivation of active hormone. While the major hormone produced by the thyroid gland is thyroxine (T4), the active thyroid hormone is triiodoyhyronine (T3), generated from T4 by deiodination of the outer thyronine ring. Local deiodinase activity can modulate thyroid hormone action through increasing or reducing local T3 concentrations [7]. The mineralocorticoid receptor (McR) mediating the actions of aldosterone also binds cortisol with high affinity. Circulating cortisol levels are much higher than corresponding levels of aldosterone. Mineralocorticoid target tissues express high levels of the enzyme 11-β-hydroxysteroid dehydrogenase type 2 (11 βHSD2), which metabolizes cortisol to the inactive cortisone, thus protecting the McR from inappropriate activation by glucocorticoids. The reciprocal process, generation of cortisol from cortisone through the action of 11 βHSD1, can also modify local glucocorticoid action. The activities of both 11 βHSD enzymes are under physiological regulation. Breakdown in the regulation of 11 βHSD activity has significant pathophysiological consequences [8].

There are additional receptor and post-receptor mechanisms for modifying hormone action—alteration of receptor number or modification of downstream transduction cascades can produce either sensitization or desensitization to hormone signalling.

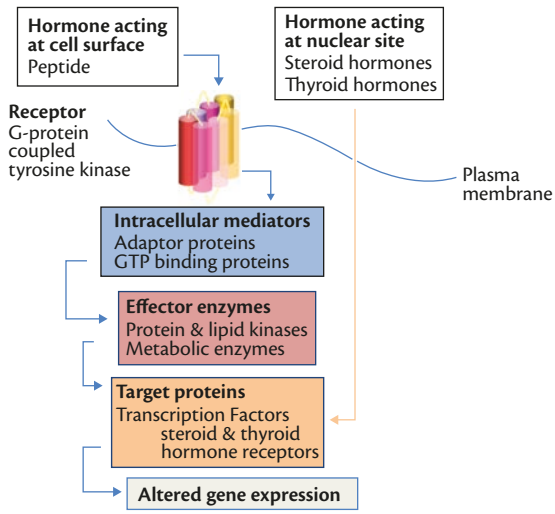

Fig. 249.2 Mechanisms of hormone action and signal transduction. While mechanisms of hormone action are diverse, they encompass generic principles of signal sensing, signal transduction, and activation of effector pathways.

Amplification, cross talk, and integration of signal transduction

Cell physiology is complex and involves multiple, integrated processes. Systems regulating these processes require similar characteristics to be fit for purpose. A number of hormones may impact on common or related cell processes. Integration of these multiple inputs is managed through convergence on key points in cell physiology pathways. The phenomenon of a hormone having differential effects on a number of cell processes (divergence and selective amplification of signal transduction) also involves signal flux through key regulatory points, each of which may be influenced by a number of parallel systems [9].

Taken together, the mechanisms of hormone action cover a bewildering range and complexity that match those of the very cellular processes they regulate.

Biochemical characteristics of endocrine pathology

Failure of a component in any complex system may be primary (reflecting a problem with the individual component) or secondary (reflecting a problem with an upstream component that is responsible for regulating/controlling the component in question). Similarly, underproduction of a given hormone may

reflect a problem with the gland making the hormone in question (primary failure). Alternatively, it may reflect a problem with the hypothalamo-pituitary axis that drives the gland in question (secondary failure). In secondary failure, the relevant hypothalamo-pituitary hormone will be low or normal, while in primary failure it will be high.

Hormone resistance states can produce unusual patterns of clinical features and biochemical test results that appear incongruous. Clinical features generally suggest normal or underactivity of the hormone in question, in contrast with biochemical test data that are dominated by high levels of the hormone. Acquired insulin resistance secondary to obesity is common, characterized by normal or high fasting glucose levels, and elevated insulin levels. Other hormone resistance states are more unusual. They can be congenital or acquired. Congenital hormone resistance can be isolated or involve multiple endocrine systems. Congenital isolated hormone resistance suggests loss of receptor function through gene deletion or loss of function mutation. A more wide-ranging problem suggests loss of function in downstream signal transduction, given transduction cascades of several hormones may share common components.

Constitutive activity within an endocrine pathway in the absence of hormone can also produce incongruous data. The molecular pathology may also reflect a problem at receptor or post-receptor level [10].

PART 10.2

Electrolyte disturbance

CHAPTER 250

Disorders of sodium in the critically ill

Howard L. Corwin and John K. McIlwaine

Key points

- Hypernatraemia and hyponatraemia are common clinical conditions.
- Maintenance of normal sodium concentration is a balance between water intake and water excretion. Water excess results in hyponatraemia and water deficit results in hypernatremia.
- Central nervous system symptoms predominate in patients with serum sodium abnormalities.
- The severity of symptoms reflects the degree of sodium abnormality and the time over which the abnormality has developed.
- The rapidity with which serum sodium abnormalities should be corrected depends upon the presence of symptoms and the length of time over which the abnormality has developed. Too rapid correction of patients with more chronic sodium abnormalities can lead to neurological deterioration.

Introduction

Sodium disorders, i.e. hyponatraemia and hypernatraemia, are among the most common clinical problems observed in the critically ill. Up to one-third of patients have some degree of dysnatraemia on admission to ICU [1,2]. Hyponatraemia is more common than hypernatraemia—18% of patients present with some degree of hyponatraemia, while 7% of patients present with hypernatraemia [1]. These disorders also develop commonly during an intensive care unit (ICU) admission, with approximately 30% of surgical patients in one study developing an ICU-acquired dysnatraemia [3]. While these disorders are often asymptomatic, there may be symptoms ranging from minor to life threatening. Independent of the severity of symptoms, dysnatraemias, including very mild abnormalities, are associated with worse clinical outcomes [1–3]. Even fluctuations of sodium within the normal range have been associated with an increase in mortality [3]. Mortality in hypernatraemia can be as high as 70% [4–6]. Although this high mortality rate no doubt reflects the severity of underlying disease in these patients, there is still important morbidity related to hypernatraemia [4]. Neurological sequelae from hypernatraemia are common, particularly in the paediatric population [6]. Mortality in acute hyponatraemia is reportedly as high as 50%, and 10–20% in chronic hyponatraemia [7–10]. Whether prevention or treatment of these disorders will improve clinical outcomes remains to be proved, although the treatment of dysnatraemia is an important challenge in the ICU.

The approach to treating sodium disorders in the ICU patient involves balancing the risk of treatment versus the risk of the disorder, as too vigorous treatment can result in complications. In treating dysnatraemia it is important to keep in mind that sodium disorders generally reflect abnormalities of water balance that may at times also involve changes in sodium balance. Plasma sodium concentration is the main factor in plasma osmolality. Hyponatraemia generally reflects hypo-osmolality, while hypernatraemia reflects hyperosmolarity.

Hypernatraemia

The maintenance of a normal serum sodium concentration (135–145 mmol/L) is dependent on the balance between water intake and water excretion. Hypernatraemia usually results from a net free water deficit that leads to an increase in serum tonicity or osmolality. Hypernatraemia may be associated with either volume depletion, euvolaemia, or hypervolaemia, depending on the balance of salt and water loss and intake. At the same time, sodium content may be low, normal, or high, in each of these circumstances. Hypernatraemia can occur when water loss exceeds sodium loss resulting in hypovolaemia and hypernatraemia. Hypernatraemia can also occur with positive sodium balance such as with hypertonic saline infusion or with replacing water loss with normal saline. Relative sodium and volume status has important implications for the treatment of hypernatraemia patients.

The brain is particularly susceptible to the effects of hypernatraemia. In the presence of hypernatraemia, achieving osmotic equilibrium results in intracellular dehydration as fluid moves out of cells in response to the acute increase in extracellular tonicity resulting from the hypernatraemia. The net result is a loss of brain volume, which in turn can place mechanical stress on cerebral vessels, possibly resulting in bleeding [6]. This is particularly the case with acute hypernatraemia. In contrast, with chronic hypernatraemia, cellular adaptation occurs due to the accumulation of so-called idiogenic osmoles in brain cells, minimizing cellular dehydration. The presence of these idiogenic osmoles presents a risk for the development of cerebral oedema during the treatment of hypernatraemia.

Central nervous system (CNS) symptoms are most common with hypernatraemia. However, hypernatraemia symptoms are often non-specific and thus difficult to distinguish from those of underlying illnesses, particularly in critically ill patients. Symptoms

in early stages can include encephalopathy, delirium, weakness, and lethargy that may progress to seizures, coma, and death in the later stages. CNS symptoms result from the water movement out of the brain cells and resulting cellular dehydration, rather than the hypernatraemia per se. Neurological deterioration can be seen during rapid correction of hypernatraemia as a result of decreasing extracellular tonicity and the resultant movement of water back into cells causing the development of cerebral oedema. This is particularly seen in more chronic states in which idiogenic osmoles are present in brain cells. Depending on the aetiology of the hypernatraemia, signs of either volume depletion or volume overload may be present with the hypernatraemia on presentation.

Treatment

The treatment for hypernatraemia is water repletion. Assuming total body water is 60%, the water deficit may be estimated as follows:

$$\text{Water deficit} = [0.6 \times \text{Total body Weight}] \times [(\text{Plasma sodium concentration}/140) - 1] \quad \text{[eqn1]}$$

While the percentage of water relative to total body weight is 60% for males, it is closer to 50% in women, so 0.5 should be used; however, it is independent of gender in the elderly. The optimal correction rate for hypernatraemia has not been definitively determined. Treatment (water deficit replacement) should be at a rate that balances the risk of hypernatraemia, particularly if symptomatic, with the risk of too rapid correction, particularly in cases of chronic hypernatraemia. It has been suggested that rate of correction of sodium should be no more than 0.5 mEq/L per hour or 12 mEq/L per day [11]. However, the speed of correction should be determined by the acuteness of onset and severity of symptoms. Neurological status needs to be closely monitored during replacement for evidence of the development of cerebral oedema. Ongoing fluid and electrolyte losses also need to be replaced during treatment.

In patients with volume depletion who have haemodynamic instability associated with the hypernatraemia, volume replacement with isotonic saline is indicated. Once the patient is haemodynamically stable, water replacement can be initiated. Hypotonic saline (e.g. 0.45% saline) may be preferable to water as the replacement fluid for these patients. If hypernatraemia is associated with hypervolaemia treatment should be directed towards removing the excess sodium. Reducing sodium intake while inducing sodium loss with diuretics and replacing urine loss with free water can be use in this situation. Dialysis may be necessary if renal failure is present.

Hyponatraemia

Hyponatraemia is a water, rather than a sodium problem. Although total sodium balance may be abnormal, when hyponatraemia is present there is almost always water excess relative to sodium. Hyponatraemia is generally associated with hypo-osmolality. Hyponatraemia with elevated plasma osmolality can be seen in clinical situations in which solutes are added to the extracellular space, e.g. elevated glucose, drawing water out of cells, resulting in hyponatraemia. Hyponatraemia with normal osmolality used to be seen with severe hyperlipidaemia or hyperproteinaemia, which interfered with the correct measurement of sodium concentration. In many of the clinical conditions associated with hyponatraemia there is impaired water excretion by the kidney impairing the ability of the kidney to correct the sodium concentration. Patients who are hyponatraemic may be volume depleted (water deficit and sodium deficit), euvolaemic (water excess with normal sodium balance), or hypervolaemic (water excess and sodium excess). Similar to hypernatraemia, volume status has implications for the treatment of hyponatraemia.

In the presence of hyponatraemia, the extracellular compartment is hypotonic relative to the intracellular compartment. This hypotonicity results in water movement from the extracellular into the intracellular space resulting in cell swelling. In the CNS, cell swelling manifests as cerebral oedema and results in the symptoms associated with hyponatraemia. The degree of cerebral cell swelling correlates with the symptom severity. The CNS can adapt to hyponatraemia in two ways. First, cerebral oedema causes an increase in interstitial hydrostatic pressure and results in the movement of fluid from the interstitial space into the cerebrospinal fluid (CSF), leading to some amelioration of cerebral oedema, assuming normal CSF production and reabsorption. Secondly, solutes are lost from cells, resulting in a decrease in intracellular osmolarity and cellular water efflux back into the extracellular space. The initial solutes lost are sodium and potassium, followed over several days by organic solutes. Because of this cerebral adaptation, the severity of neurological symptoms is related to the acuity and magnitude of the hyponatraemia. If hyponatraemia develops gradually, brain cells can compensate by decreasing intracellular osmolality, limiting the degree of cerebral oedema and resultant neurological dysfunction. On the other hand, during the correction of chronic hyponatraemia, the regeneration of these intracellular osmolytes can lag behind the correction of the sodium; as a consequence, cerebral dehydration can occur with too rapid correction.

In acute hyponatraemia, nausea, vomiting, lethargy, and confusion can occur and in turn may progress to coma, seizures, eventual cerebral herniation and death [10,12]. The elderly and the young are more likely to be symptomatic from hyponatraemia [8]. Menstruating women also tend to be more symptomatic and are at greater risk for neurological complications from acute hyponatraemia [10]. Early in the development of hyponatraemia, the symptoms are difficult to distinguish from those related to the underlying disease process.

Treatment

Treatment of hyponatraemia is primarily dependent on symptoms, although the acuteness of the hyponatraemia is also a consideration. More severe symptoms tend to occur with acute hyponatraemia. Since brain adaption to hyponatraemia occurs rapidly, after 24–48 hours hyponatraemia is considered chronic. Acute (<48 hours) or chronic (>48 hours) hyponatraemia with severe symptoms (e.g. seizures) requires immediate therapy. Treatment must balance the risk of the hyponatraemia versus the risk of rapid correction—with severe symptoms the risk favours treatment. However, the optimal approach for the treatment has been controversial [13–15]. The controversy results from reports of the occurrence of a central demyelination syndrome, osmotic demyelination, associated with the correction of hyponatraemia in some patients [12,16–18]. This syndrome appears to be more common with chronic hyponatraemia (>48 hours), overcorrection of hyponatraemia, or large rapid corrections; more than 10–12 mmol/L per 24 hours or 18 mmol/L in 48 hours [12,17–19].

The approach to the treatment of acute symptomatic hyponatraemia is infusion of hypertonic (3%) saline. Therapy is targeted toward resolution of symptoms, which usually can be achieved with a 4 to 6 mmol/L increase in serum sodium concentration [19]. Bolus infusions of 3% saline, e.g. 100 mL are recommended [19]. If symptoms persist, an additional one or two boluses can be given. Current recommendations suggests that the goal of treatment should be an increase in sodium of no more than 6–8 mmol/L in 24 hours, 12–14 mmol/L in 48 hours, and 14–16 mmol/L in 72 hours in order to avoid iatrogenic injury due to overcorrection while treating the acute symptoms. In treating patients with chronic (>48 hours, or of unknown duration) symptomatic hyponatraemia, the higher risk of neurological complications related to therapy mandates a cautious approach. As with acute hyponatraemia, neurological symptoms predominate in the clinical presentation of these patients. Initial treatment with 3% sodium chloride should be directed toward the resolution of symptoms as noted previously.

The hypertonic saline necessary to correct the serum sodium concentration to a safe level (e.g. 120 mEq/L) can be estimated by calculating the sodium deficit:

$$\begin{aligned}\text{Sodium deficit} = {} & 0.5 \times \text{lean body weight} \\ & \times (\text{desired serum sodium concentration} \\ & - \text{observed serum sodium concentration})\end{aligned} \quad \text{[eqn 2]}$$

The amount of hypertonic saline required to replace the deficit is then infused at a rate that permits correction within the parameters noted in eqn 2. Frequent checking of electrolytes is necessary to ensure that correction is not too rapid. Diuresis is often the cause for overcorrection and can be reversed by administration of desmopressin [19].

Most patients with hyponatraemia are asymptomatic, or have subtle neurological symptoms. Aggressive correction of serum sodium in these patients is not indicated. Treatment in asymptomatic patients is based on the underlying cause of the hyponatraemia and the patient's volume status: euvolaemic, hypovolaemic, or hypervolaemic (oedema).

Patients with chronic hyponatremic are often euvolaemic. In this group, the syndrome of inappropriate antidiuretic hormone (SIADH) is the most common diagnosis. The inappropriate (non-osmotic) presence of antidiuretic hormone impairs free water excretion by the kidney; impaired water excretion coupled with water intake results in hyponatraemia. Water restriction is the mainstay of therapy for these patients. The amount of water restriction must be sufficient to achieve negative water balance (i.e. the difference between the total intake and excretion of water), or hyponatraemia correction will not occur. Therefore, all water losses (insensible losses, urinary losses, and gastrointestinal losses) must be considered when deciding on the degree of water restriction. If urine osmolarity is high, it may be necessary to decrease it to achieve a negative water balance. This can be achieved by adding a loop diuretic; however, salt intake must be increased to correct for losses resulting from the increased natriuresis with diuresis. Less commonly, demeclocycline (300–600 mg bd), which interferes with the action of antidiuretic hormone, is used to decrease urine osmolarity. In patients with more pronounced hyponatraemia, the combination of normal saline (or high salt intake) and a loop diuretic can be used to correct hyponatraemia. In asymptomatic patients the use of hypertonic saline is rarely, if ever, indicated.

Hyponatraemia associated with volume depletion is a result of the loss of both sodium and water, combined with the simultaneous intake of water or hypotonic fluids. The release of antidiuretic hormone stimulated by hypovolaemia inhibits the kidney's ability to excrete water. The net result is positive water balance relative to sodium and hyponatraemia. The treatment of hyponatraemia in this setting is infusion of normal saline to correct the volume depletion. As volume status is corrected, antidiuretic hormone excretion is turned off, and the kidney excretes the excess water, correcting the serum sodium concentration. The cause of the initial sodium and water loss should also be identified and treated.

Hyponatraemia associated with hypervolaemia is very common and is generally associated low 'effective' volume states, such as, but not limited to, heart failure, cirrhosis, and nephrotic syndrome. The hallmark of these conditions is the presence of oedema. The mechanism for the development of hyponatraemia in these settings is diminished effective circulating volume leading to sodium and water retention. The water retention is a result of non-osmotic antidiuretic hormone release impairing the kidney's ability to excrete water. In this respect, the mechanism is similar to that responsible for hyponatraemia associated with volume depletion. Therapy is directed toward correcting the primary disease process responsible for the decrease in effective circulating volume. Specific treatment of the hyponatraemia consists of sodium and water restriction. The use of loop diuretics may facilitate free water excretion and correction of the hyponatraemia; notably, thiazide diuretics may exacerbate hyponatraemia and should be avoided.

Conclusion

There are now vasopressin receptor antagonists available—either selective V_2 or non-selective V_{1A} and V_2, tolvaptan and conivaptan, respectively [20]. Both have indications for euvolaemic hyponatraemia and tolvaptan has an additional indication for hypervolaemic hyponatraemia. At this point vasopressin receptor antagonists are not recommended for the routine treatment of hyponatraemia [20].

CHAPTER 251

Disorders of potassium in the critically ill

Matthew C. Frise and Jonathan B. Salmon

Key points

- Most true hyperkalaemia results from renal insufficiency since the kidney is responsible for the vast majority of potassium excretion.
- Acidosis favours potassium shift from within cells to the extracellular fluid in exchange for hydrogen ions.
- Glucose-insulin infusions and sodium bicarbonate promote entry of potassium into cells and loop or thiazide diuretics increase potassium excretion.
- Calcium salts are appropriate for patients with severe hyperkalaemia or dysrhythmias.
- Hypokalaemia may be present in patients with low, normal, or high total body potassium.

Physiology of potassium balance

Potassium is the major intracellular cation with only 2% found extracellularly. Plasma levels are maintained in health between 3.5 and 5.0 mmol/L, and are determined by the balance between absorption and excretion, and by internal shifts between extracellular and intracellular compartments. There is no regulation of gastrointestinal absorption; of the normal daily intake of 50–150 mmol, 85–90% is absorbed with the remainder excreted in faeces. Excess potassium is renally excreted—if renal function is compromised plasma potassium rises sharply.

Renal excretion is normally 3–300 mmol/day, but adaptation allows excretory capacity to reach 500 mmol/day in chronically high potassium intake. Renal responses to excessive intake are relatively rapid [1] with approximately half an acute load appearing in the urine within 12 hours. Conversely, renal responses to dietary depletion are slow, with excretion falling gradually over 7–14 days such that total body deficits of 200 mmol or more may develop.

Plasma potassium reflects total body potassium only in stable states at normal pH. In acutely-ill patients, particularly those with acid–base disturbances, plasma and total body potassium may vary in opposite directions, with plasma potassium rising in acidosis and falling in alkalosis. These changes are more marked with metabolic than with respiratory disturbances.

Hyperkalaemia

Aetiology and pathophysiology of hyperkalaemia

Causes of hyperkalaemia are given in Box 251.1. Since the kidney is responsible for 90% of potassium excretion, most true hyperkalaemia results from renal insufficiency. Hypertrophy of renal tubules usually maintains the ability to balance potassium until the glomerular filtration rate falls below 10 mL/min, provided that dietary intake is normal. An increased potassium intake or tissue release may lead to hyperkalaemia at much higher glomerular filtration rates, as may drugs that modify renal handling of potassium. Hyperosmolar infusions may also provoke hyperkalaemia [2].

The major physiological effects of changes in potassium levels are seen in excitable tissues. Electrocardiogram (ECG) changes of hyperkalaemia include peaked T waves, widening of the QRS complex, loss of the P wave, a sine wave configuration [3] and ventricular fibrillation. Unfortunately, this well ordered sequence is not always observed and cardiac arrest may occur due to hyperkalaemia with an unremarkable ECG.

Hyperkalaemia is convincingly associated with early and late mortality in critical illness [4]. Signs and symptoms are usually absent and appropriate treatment depends upon clinical suspicion and monitoring of potassium levels. This is particularly important in conditions where potassium may be released in large quantities in association with incipient renal dysfunction, for example rhabdomyolysis [5], tumour lysis syndrome and reperfusion of ischaemic tissue. Rapid metabolic changes in such circumstances may produce lethal hyperkalaemia in a short period of time. Suxamethonium, when used for rapid sequence intubation, predictably produces a rapid rise in serum potassium of around 0.5–1.0 mmol/L, but levels may rise much more steeply in susceptible patients, provoking life-threatening dysrhythmias [6]. This effect is particularly important in those with a prolonged ICU stay, certain neurological conditions and burns.

True hyperkalaemia must be distinguished from pseudohyperkalaemia, which may follow *in vitro* haemolysis or lysis of white blood cells (usually only at levels above 200×10^9/L) or platelets (usually only when the platelet count is above 750×10^9/L). Aggressive, inappropriate treatment of pseudohyperkalaemia risks iatrogenic hypokalaemia.

Treatment of hyperkalaemia

Irrespective of the cause, the primary goals of therapy are myocardial protection and return of plasma potassium to a safe level. Secondary goals are the correction of co-existing metabolic disturbances and treatment of the underlying cause. Measures to correct plasma potassium are commonly initiated above 5.5 mmol/L. Treatment includes discontinuation of drugs that promote potassium retention, while limiting potassium intake in feeds and

Box 251.1 Causes of hyperkalaemia

Pseudohyperkalaemia

- Faulty venesection technique.
- *In vitro* haemolysis.
- Extreme leucocytosis.
- Thrombocytosis.
- Leaky cell syndrome.

Transcellular shift

- Acidosis.
- Diabetic ketoacidosis.
- Hyperosmolality.
- Hyperglycaemia.
- Drugs
  - Beta-blockers.
  - Suxamethonium.
  - Digoxin.
- Rhabdomyolysis.
- Tumour lysis syndrome.
- Haemolysis.
- Malignant hyperthermia.
- Exercise.
- Hyperkalaemic periodic paralysis.

Renal

- Severe renal failure.
- Excess potassium load with renal dysfunction.
- Adrenocortical insufficiency.
- Aldosterone deficiency.
- Hyporeninaemic hypoaldosteronism.
- Drugs
  - Non-steroidal anti-inflammatory drugs.
  - Angiotensin-converting enzyme inhibitors.
  - Cyclosporin.
  - Potassium-sparing diuretics.
  - Heparin.
- Enzymatic defects.
- Tubular disorders.
- Ureterojejunostomy.

infusions. At levels above 6.5 mmol/L, aggressive measures should be adopted and calcium salts given if there are cardiac dysrhythmias or broadening of the QRS complex. Temporary control is achieved most effectively by promoting potassium shifts into cells; these methods require at least **15 minutes to begin to take effect** [7].

Calcium

Calcium salts, which antagonize the membrane depolarizing effects of hyperkalaemia, should be reserved for patients with severe hyperkalaemia or life-threatening dysrhythmias. The usual dose is 10 mL of 10% calcium gluconate given rapidly intravenously, repeated where necessary up to 30 mL. The duration of effect is less than an hour. Calcium chloride is more irritant if peripheral access is used. Care must be taken to avoid the simultaneous infusion of sodium bicarbonate because of the risk of precipitation. If concomitant digoxin toxicity is suspected calcium is not contraindicated, but should be given cautiously and the theoretical risk of provoking malignant dysrhythmias remembered [8].

Glucose–insulin infusions

Insulin promotes potassium entry into cells by mechanisms separate from glucose entry; glucose is given to prevent hypoglycaemia. Commonly used prescriptions include 15 units of soluble insulin in 50 mL 50% glucose given over 20–30 min, and 15–20 units of insulin in 500 ml of 10 or 20% glucose over 30 to 60 min. All methods reduce plasma potassium by approximately 1 mmol/L over a period of 30–60 min and will usually maintain potassium at the lower level for several hours. This is usually inadequate in hypercatabolic patients and those with established renal failure. In such cases it may, however, act as a temporizing measure.

Supraphysiological levels of insulin are required for a therapeutic effect [9], and although oral glucose stimulates insulin secretion in normal individuals to a sufficient degree to cause a fall in plasma potassium, a paradoxical hyperkalaemic response to a glucose load is recognized [10,11]. Administration of an insulin bolus alone where hyperkalaemia is accompanied by significant hyperglycaemia is perhaps more reasonable, but iatrogenic hypoglycaemia is a risk with this strategy [12].

Beta-2-agonists

Nebulized beta-2-agonists are as effective as glucose-insulin and valuable where immediate intravenous access is a problem, but appear most effective when combined with glucose-insulin [13]. Clinicians may worry about arrhythmogenic effects in severely-ill patients, particularly those with co-existent cardiac disease that frequently accompanies CKD, but there is no good evidence for harm [14]. The usual adult dose of salbutamol is 10–20 mg by nebulizer over 10 minutes or 0.5 mg intravenously over 10–15 minutes.

Sodium bicarbonate

Sodium bicarbonate theoretically promotes entry of potassium into cells by reducing hydrogen–potassium exchange, but there is uncertainty about its clinical utility [13]. It may be valuable in extreme cases. Concerns exist about volume overload and exacerbating hyperkalaemia by an effect on plasma osmolality. Preparations range in strength from 1.26–8.4%, the latter must be given centrally except in arrest situations.

Diuretics

Promotion of a diuresis with loop diuretics or thiazides increases potassium excretion. Since this effect is augmented by increasing sodium delivery to the distal tubule, combining volume loading with diuretics in patients with prerenal failure may augment kaliuresis.

Haemofiltration and haemodialysis

Acute renal replacement therapy (RRT) is usually unnecessary in patients with intact renal function. Those with predictably transient

hyperkalaemia can usually be managed with a combination of the therapies discussed previously. In established acute or acute-on-chronic renal failure, or if these methods fail, hyperkalaemia usually reflects a generalized metabolic disturbance and is an indication to start RRT. In extremis, peritoneal dialysis has been used successfully in the management of hyperkalaemic cardiac arrest pending institution of more conventional treatments [15].

Cation-exchange resins

These can be administered orally or by retention enema. Although these resins may have a place in the management of isolated renal failure, duration of onset is slow and initial effect small. Moreover, gut function in critically-ill patients is often compromised and there is a significant risk of causing intestinal necrosis with some preparations that may be fatal [16]. For these reasons, acute RRT is usually a better choice if an acute reduction in total body potassium is required. Sodium zirconium cyclosilicate is a new non-absorbed oral cation exchanger that is effective in treating hyperkalaemia associated with chronic renal failure. It has been suggested as a potential therapy for acute severe hyperkalaemia [17], though data on its safety and efficacy in the setting of critical illness are awaited.

Special cases

Rhabdomyolysis and cell lysis syndromes

Plasma potassium levels may rise very rapidly in these situations. Provided swift action is taken it is usually possible to prevent lethal hyperkalaemia. The key is to correct hypovolaemia and stimulate a diuresis. Alkalinization with intravenous sodium bicarbonate is controversial and, aside from data from uncontrolled case series, there is no good evidence for a benefit over volume repletion with crystalloid [5]; similarly, mannitol probably offers no benefit and may be harmful. Urine outputs of up to 12 L/day have been advocated, but 4–6 L/day is usually adequate. Following resolution of the acute phase of these syndromes, total body potassium will be low and will require replenishment.

Diabetic ketoacidosis

In diabetic ketoacidosis hyperkalaemia may develop as a consequence of metabolic acidosis, insulin deficiency, and reduced renal excretion, but a significant whole-body potassium deficit is the rule. It is unusual for extreme methods of potassium control to be needed, and potassium levels will usually return to normal with correction of the volume and insulin deficits. Indeed, significant hypokalaemia may be an issue if potassium containing fluids are not used relatively early in the course of volume resuscitation. Very occasionally, it is necessary to give calcium salts for myocardial protection. A period of RRT may be required in patients with coexistent oliguric renal failure.

Potassium channel syndrome

A life-threatening syndrome associated with excessive drug-induced K_{ATP} channel activation has been reported, characterized by refractory hypotension and hyperkalaemia in the setting of drugs such as nicorandil, cyclosporin, and isoflurane. Therapy with glibenclamide appeared to be effective [18]. Further work in this area is required before firm conclusions can be drawn.

Hypokalaemia

Causes of hypokalaemia

Hypokalaemia and potassium depletion are common in critically-ill patients. Box 251.2 gives an overview of causes.

Box 251.2 Causes of hypokalaemia

Potassium depletion

- Non-renal (urine K^+ <20 mmol/day).
  - Inadequate intake.
  - Excessive sweating.
  - Gastrointestinal losses.
    - Diarrhoea.
    - Vomiting.
    - Laxative abuse.
- Renal losses (urine K^+ >20 mmol/day).
  - Renal tubular acidosis.
  - Diabetic ketoacidosis.
  - Chloride depletion.
  - Mineralo- and glucocorticoid excess.
  - Magnesium depletion.
  - Antibiotic therapy.
  - Amphotericin.
  - Leukaemia.
  - Bartter's or Gitelman's syndrome.
  - Osmotic diuresis.
  - Polyuria.

Transcellular shift

- Alkalosis.
- Insulin excess.
- Beta-2 adrenergic stimulation.
- Poisoning.
- Theophyllines.
- Chloroquine.
- Barium.
- Toluene.
- Hypothermia.
- Hypokalaemic periodic paralysis.

Diuretics

Diuretics (except for triamterene, amiloride, and spironolactone) promote kaliuresis by increasing delivery of sodium to the distal tubule. Carbonic anhydrase inhibitors increase potassium loss by increasing the tubular concentration of bicarbonate, which acts as a non-reabsorbable anion.

Vomiting

The low concentration of potassium in upper gastrointestinal secretions prevents even severe vomiting from causing profound potassium depletion in its own right. It is instead the accompanying hypochloraemic alkalosis, which leads to a shift of potassium into

cells and increased potassium loss from the kidney that causes the hypokalaemia seen in this setting.

Diarrhoea

Stool contains 50–100 mmol/L of potassium. Diarrhoea is usually associated with significant losses of bicarbonate and, hence, a metabolic acidosis. This may be further exacerbated by the effects of hypovolaemia. The consequent shift of potassium from cells may mask the true extent of potassium depletion. In certain conditions, such as villous adenoma of the rectum and non-insulin-secreting islet cell tumours, diarrhoea may contain high chloride concentrations. In such cases, potassium loss occurs without an accompanying acid-base disturbance, and hence, hypokalaemia tends to be more profound for a given whole-body potassium deficit. Laxative abuse similarly produces a profound hypokalaemia without alterations in acid-base status. Patients with ureterosigmoidostomies, where urine is allowed to stagnate in the colon, may develop a profound hypokalaemic hyperchloraemic acidosis. Potassium losses are increased in conditions of rapid intestinal transit, small bowel fistulas, intestinal drains, malabsorption, and small bowel bypass.

Mineralocorticoids and hyperaldosteronism

Secondary hyperaldosteronism due to Bartter's syndrome, renin-secreting tumours and malignant hypertension may produce severe potassium depletion. Bartter's syndrome may be mimicked by bulimia nervosa, laxative or diuretic abuse, and primary renal tubular disorders, such as cystinosis. In Bartter's syndrome, there is failure to retain chloride on a high-chloride diet, whereas in bulimia and following diuretic abuse chloride is retained avidly.

Effects of hypokalaemia

Cardiac muscle

The ECG changes of hypokalaemia consist of ST depression, flattening of the T wave and prominent U waves. Subsequently, there may be widening of the QRS complex and atrioventricular block. More significant are arrhythmias, ranging from single or multiple ectopics to atrial or ventricular tachycardia and fibrillation. Membrane hyperpolarization and an increased refractory period lead to prolongation of the action potential, and an increased tendency to re-entrant tachycardias. ECG changes are rare at serum potassium levels above 3 mmol/L and arrhythmias uncommon in healthy subjects at these levels. In critical illness even small reductions in plasma potassium may be associated with dysrhythmias, and it is common practice to maintain plasma potassium levels towards the upper end of the normal range. The range of serum potassium observed to be associated with the lowest risk of mortality in patients with acute myocardial infarction has received attention [19] as has the excess mortality seen in those who are hyperkalaemic on admission to critical care environments [7], but evidence to guide a minimum safe level as a target is lacking.

Effects on other muscles

Profound potassium depletion may lead to impaired skeletal muscle function with weakness and hyporeflexia, compromising weaning from mechanical ventilation. Accompanying hypophosphataemia, common because potassium depletion leads to renal tubular phosphate wasting, may exacerbate the situation. Impaired gut motility may lead to paralytic ileus, whilst vascular smooth muscle contractility may be reduced, leading to reduced pressor responses to catecholamines and angiotensin.

Renal effects

Hypokalaemia may produce a state resembling diabetes insipidus as a result of reduced medullary solute concentrations. There is an association between potassium depletion and metabolic alkalosis, particularly in the hypovolaemic patient, at least partly due to shifts of hydrogen ions into cells, but probably also reflecting increased renal sodium and bicarbonate retention.

Metabolic effects

These include reduced protein synthesis, a negative nitrogen balance, glucose intolerance, metabolic alkalosis, and reduced carbohydrate synthesis.

Treatment of hypokalaemia

Underlying causes should be corrected where possible. Potassium should be replaced in conjunction with correction of other metabolic and electrolyte abnormalities. If there are symptoms or ECG changes, or plasma potassium is below 2 mmol/L, this should be replaced rapidly (up to 40 mmol/hour). At higher potassium levels and in asymptomatic patients, intravenous correction rates of 10–20 mmol/hour are usually adequate. Replacement is typically with potassium chloride, although potassium phosphate can be used if there is concomitant phosphate deficiency. Potassium citrate has a role in the setting of renal tubular acidosis where a chloride load is undesirable. In extremis (malignant arrhythmias in the presence of severe hypokalaemia), potassium can be given by rapid infusion of 50–100 mL of 40 mmol/L KCl over 2–5 minutes. In patients with co-existent metabolic acidosis and hypokalaemia, potassium should be replaced before correction of the acidosis in order to prevent further severe falls in serum potassium.

After the extracellular deficit has been corrected, there will usually be a whole-body intracellular deficit to correct. There is no single satisfactory way of judging adequacy of potassium repletion, but an increase in urinary potassium, tendency for plasma potassium to stay elevated after potassium infusion and correction of a metabolic alkalosis may all give useful clues. Continuing replacement of magnesium should accompany potassium replacement. Hypomagnesaemia is found in up to 40% of patients with hypokalaemia [20] and magnesium is needed for potassium to enter cells and prevent continuing renal potassium wasting. Hypokalaemia in hyperaldosteronism may be minimized by reducing sodium intake. Spironolactone may also be useful for reducing renal potassium wasting.

CHAPTER 252

Disorders of magnesium in the critically ill

Figen Esen

Key points

- Magnesium is the main intracellular earth metal cation and plays an essential role in fundamental cellular reactions.
- Hypomagnesaemia is frequent post-operatively and in the intensive care unit (ICU), and this often unrecognized condition is responsible for increased morbidity and mortality.
- The assessment of actual magnesium status in critical illness is problematic. There is no agreed laboratory method beyond serum total magnesium level.
- Hypomagnesaemia should be detected and corrected systematically.
- Magnesium is an effective medical therapy in many different medical conditions in the ICU.

Introduction

Magnesium is a critical ion that is essential for life. It is the fourth most common cation in the body, and the second most common intracellular cation after potassium. It is involved in many enzymatic reactions for energy metabolism and is essential for protein synthesis, fat, and carbohydrate metabolism, and for cellular functions including membrane stability, ion permeability, and action potential generation. Although magnesium has been the 'forgotten ion' for many years, its importance in critical care practice has been highlighted by the high incidence of hypomagnesaemia in patients admitted to an intensive care unit (ICU). Magnesium deficiency has been reported in 20–65% of patients in an intensive care unit [1]. Reduction in serum total magnesium on admission to ICU has been shown to be associated with increased morbidity and mortality [2]. Hypomagnesaemia has also been implicated in the development of organ dysfunction and systemic inflammatory response syndrome in ICU patients [3]. However, there is little guidance for clinicians treating critically-ill patients on the best way of magnesium supplementation in critically-ill patients [4].

Magnesium physiology and metabolism

Magnesium serves as an important cofactor for numerous enzymes and in many biochemical reactions. It is essential for the function of important enzymes that use nucleotides as cofactors. It is also required for cellular energy metabolism and has an important role in membrane stabilization, nerve conduction, ion transport, and calcium channel activity. With these physiological functions, magnesium is involved in muscle contraction, neuronal activity, control of vasomotor tone, cardiac excitability, and neurotransmitter release.

Magnesium modulates ion transport by pumps, carriers, and channels. It intervenes in the action of calcium and sodium-potassium ATPase activation. Serving as a cofactor in this enzyme system, it influences sodium and potassium flux across cell membranes. Magnesium blocks outward movement of potassium through potassium channels in cardiac cells [5]. Decreases in magnesium cause outward movement of potassium, inducing depolarization and causing cardiac arrhythmias. Moreover, disorders of magnesium, by altering sodium/potassium gradients and transmembrane potentials, may result in neuromuscular excitability or irritability.

Magnesium acts as a calcium antagonist either on intracellular sites or in membrane channels. Its interaction with calcium channels exerts a competitive antagonist action against calcium inflow. By inhibiting calcium activation on sarcoplasmic channels, it also limits the outflow of calcium from the sarcoplasmic reticulum, which is the main site of intracellular calcium storage [6]. With this mechanism magnesium regulates the intracellular calcium levels and thereby influences smooth muscle tone. By failure of regulation of smooth muscle tone, magnesium deficiency may cause hypertension, neuromuscular hyperexcitability, bronchial airway constriction, coronary spasms, and seizures [4].

Magnesium is primarily an intracellular cation. The body normally contains 21–28 g magnesium, of which more than half is stored in bone, and the rest in muscle and soft tissue. Extracellular magnesium accounts for only 1% and serum magnesium comprises only approximately 0.3% of total body magnesium. Two-thirds of serum magnesium is found in the ionized form and the rest is protein bound and complexed [7]. In contrast to calcium, the maintenance of magnesium homeostasis is highly dependent on dietary intake. Compensatory mechanisms to maintain magnesium homeostasis are not fully understood. Early studies have proposed a specific hormonal control of magnesium homeostasis; however, knowledge of endocrine factors that control circulating or urinary magnesium is incomplete. Neither vitamin D nor parathyroid hormone (PTH) have been shown to affect magnesium status directly [8]. A number of factors cause shifts in the usual intracellular: extracellular ratio of magnesium. Both acidosis and ischaemia promote release of magnesium from intracellular binding sites and lead to an efflux of magnesium from the cell. A number of commonly encountered

situations in critical care, such as re-feeding syndromes, insulin use, intravenous (iv) solutions containing glucose and amino acid infusions may lead to an acute shift of magnesium into the cells [9].

Magnesium units are expressed in mg, mmol, or mEq; 1 g of magnesium sulphate is equivalent to 4 mmol, 8 mEq, or 98 mg of elemental magnesium. The daily average requirement is 200 mg for females and 250 mg for males [10]. A healthy person will ingest 200–350 mg of magnesium daily, and half of the ingested magnesium is absorbed in the jejunum and ileum by both active and passive mechanisms. Unlike other cations, magnesium is absorbed equally well in the ileum and the jejunum by passive absorption. This absorption is inversely proportional to the amount ingested. The kidney serves as the principal organ involved in magnesium regulation. The kidney filters about 2.5 g of magnesium per day and excretes about 5% of this total. The remainder is reabsorbed by the renal tubules with 60–70% of the reabsorption of magnesium taking place within the ascending loop of Henlé. Many factors, both hormonal and non-hormonal, e.g. parathyroid hormone, calcitonin, glucagon, vasopressin, magnesium restriction, acid-base changes, and potassium depletion influence reabsorption of magnesium. The major regulator is the plasma magnesium itself [11].

Magnesium deficiency and hypomagnesaemia in the critically ill

Magnesium deficiency is common in the general population and it is multifactorial. Epidemiological studies demonstrated a relationship between cardiovascular disease, cardiac deaths, and magnesium depletion induced by a diet and drinking water low in magnesium. Intake of magnesium seems to be declining in the western population due to the increased use of processed foods [9].

Magnesium deficiency has been demonstrated in 7–11% of hospitalized patients and in up to 40% of patients with other electrolyte abnormalities.

Hypomagnesaemia (serum magnesium concentration <1.5 mg/dL) is frequently observed in critically-ill patients and has been associated with increased mortality. The prevalence of hypomagnesaemia among ICU patients ranges from 11 to 65%. When present, hypomagnesaemia is usually undetected [4].

Critically-ill patients who are hypomagnesaemic fall into three categories—those with decreased intake, those with altered intracellular-extracellular distribution, and those with increased losses.

Increased losses may occur from either the kidney or gastrointestinal tract. Surgery, trauma, infection or sepsis, burns, blood transfusion, and malnutrition are major causes of hypomagnesaemia in the ICU. Certain medications (e.g. digoxin, diuretics, aminoglycosides, amphotericin B, cisplatin, cyclosporin) have also been associated with hypomagnesaemia. Total parenteral nutrition (TPN) is often associated with hypomagnesaemia. High glucose and amino acid infusions drive magnesium into the cell and lipid solutions chelate free magnesium in serum. Diarrhoea, nasogastric suctioning, removes significant amount of magnesium from the body. Various malabsorption syndromes, short bowel syndromes, and pancreatitis can lead to hypomagnesaemia in the ICU setting [9].

Renal magnesium wasting (urinary magnesium >12 mg or 0.5 mmol/day) is associated with diabetes, alcoholism, hyperthyroidism, hypercalcaemia, and hypophosphataemia. Acute renal injury may promote wasting of magnesium. Drugs like diuretics, especially loop diuretics, many chemotherapy agents, amphotericin B, and aminoglycosides induce severe hypomagnesaemia together with hypokalaemia. Metabolic acidosis, elevated levels of circulating cathecolamines cause intracellular shift of magnesium. Large volume of hypotonic fluids also promote hypomagnesaemia.

Clinical sequel of hypomagnesaemia

Hypomagnesaemia is usually asymptomatic. The clinical consequences of isolated hypomagnesaemia are difficult since patients with hypomagnesaemia may also have hypokalaemia, hypocalcaemia, and hyponatraemia. Symptoms due to hypomagnesaemia have been reported at modest degrees of depletion, but in general serious effects are rare until total serum levels drop below 1.0–1.2 mg/dL [6].

Neuromuscular irritability is a common sign of magnesium depletion. Patients can develop Trouseau's and Chvostek's signs despite a normal ionized serum calcium concentration. Severe depletion can cause nystagmus, tetany, and seizures, and sometimes muscle weakness and fatigue. Hypokalaemia is commonly associated with hypomagnesaemia. Other than common causes like diuretics, alcoholism, and diarrhoea that result in both hypokalaemia and hypomagnesaemia, hypomagnesaemia itself causes renal potassium wasting that is refractory to potassium supplementation until magnesium is replete. Low intracellular magnesium slows ATP production, which causes a negative effect on sodium-potassium ATPase and results in the loss of intracellular potassium. Hypocalcaemia is common in hypomagnesaemia. Hypomagnesaemia supresses the release of PTH. Additionally, hypomagnesaemic patients have end-organ resistance to PTH and low vitamin D levels. Like hypomagnesaemic hypokalaemia, this hypocalcaemia is refractory to calcium supplementation until the magnesium deficit is corrected [11].

Hypomagnesaemia has been associated with a variety of arrhythmias, both atrial and ventricular. The arhythmogenic effect of magnesium depletion was shown to be independent of changes in serum potassium. Ventricular arrhythmias caused by hypomagnesaemia do not respond to conventional therapy and require replacement therapy. So this has led to the recommendation for empiric magnesium infusions for torsades de pointes. ECG findings with hypomagnesaemia include flattened T waves, U-waves, prolonged QT interval and widened QRS complexes. ECG findings are similar to hypokalaemia and they may be secondary to changes in potassium [12].

Measuring magnesium

Magnesium exists in four forms in the body. In addition to intracellular magnesium, extracellular magnesium exists in three forms—30% protein bound, 15% chelated to anions, and 55% ionized or active form. Like calcium, low albumin levels are associated with decreased total magnesium levels due to a decrease in the protein bound fraction. Assessment of magnesium status is a complex area. The most common test is serum magnesium concentration. Standard measurement of serum total magnesium includes ionized, protein bound and complexed forms, which account for 0.3% of total body magnesium content. It is obvious that measuring total serum magnesium does not give much information about the body stores of magnesium or the biologically active ionized form. An alternative to total serum magnesium is

the assessment of the ionized serum magnesium concentration as an active form. Recent technological advances in ion selective electrodes for magnesium have provided a rapid determination of ionized magnesium on an analyser [13]. Discordance between total serum and ionized magnesium has been reported in some, but not in all studies. Reports have conflicting results in terms of deciding whether measurement of serum ionized magnesium has a greater impact than total serum magnesium in patients for whom magnesium status is required. In situations of suspected hypomagnesaemia, ionized magnesium is preferred over the routinely measured serum total magnesium. However, problems with the ion selectivity and interference from calcium ions have been suggested to reduce the relevance of the ionized magnesium assay [14]. As ionized magnesium determinations have not yet proved to be superior to the routinely used available measurement of total serum magnesium, further assessments are needed in critically-ill population.

Erythrocyte, mononuclear cell and muscle magnesium levels have been used to assess magnesium status more accurately; however, no advantage over measurement of serum levels could be demonstrated. In normal subjects there is no correlation among magnesium levels in mononuclear cells compared with serum and erythrocytes [15]. There are also recently introduced techniques for measuring intracellular free magnesium using magnetic resonance imaging and magnesium sensitive dyes, or isotopic analysis of magnesium [6]. However, these are largely used as research tools and have little clinical application. A parenteral loading test with subsequent evaluation of percentage retained has been used for many years as a reliable assessment of total body magnesium status in those patients at risk of hypomagnesaemia. Retention of more than 50% of the administered dose indicates magnesium deficiency. However, the 'loading' test may not be practical and reliable in critically-ill patients as necessary steady state conditions are infrequent.

Replacement strategies

Measuring serum magnesium is still the standard, although we know that it might not reflect the total body stores. Low levels indicate deficiency, but normal levels does not rule out hypomagnesaemia. Symptoms and signs are absent most of the time in the ICU so the clinical assessment of patients at risk for magnesium deficiency remains vital for making a timely diagnosis. The goals of therapy should be to avoid symptoms, if present, and return the serum magnesium concentration to 1.5–2.4 mg/dL. The iv route of administration is preferred in critically-ill patients.

Treatment recommendations for hypomagnesaemia in the intensive care are not very clear because of a lack of data regarding the complex magnesium homeostasis and assessment issues. It is not clear if correction is associated with definable clinical changes, although several generalizations are appropriate for treatment in which the kidney function should be assessed prior to therapy. Renal elimination of magnesium is rapid, with up to 50% of an iv dose of magnesium excreted in the urine, so additional supplementation may be required in patients with normal creatinine levels [7].

For patients with mild to moderate hypomagnesaemia, 4–16 mmol (1–4 g magnesium sulphate or up to 0.5 mmol/kg) of magnesium should be given. Severe hypomagnesaemia should be treated with 16–32 mmol of magnesium (up to 0.75 mmol/kg) up to 6 g of magnesium sulphate can be infused over 8–12 hours, with higher doses infused over 24 hours. Maximum administration rate for magnesium is 1 g/hour (4 mmol/hour) with a total dose not exceeding 12 g over 12 hours. Serum magnesium levels should be monitored at least once daily during magnesium repletion, in addition to routine monitoring.

Supplemental magnesium in critical illness

Magnesium has been used as a therapeutic agent for several hundred years. There are large number of theoretical benefits of magnesium therapy, although obstetrics and cardiology provide the most compelling evidence. Parenteral magnesium therapy has been used in the treatment of pre-eclampsia since the beginning of last century. Magnesium is used in peri-operative analgesia, post-operative shivering, and tetanus. It has been and is still being studied in myocardial infarction, cardiac dysrhythmias, and asthma in the emergency department. Many of the studies in these clinical conditions have shown beneficial effects of magnesium administration and the guidelines for iv use have been presented with specific focus on the low risk of adverse effects [12]. Other current interest in magnesium therapy are cerebral protection, adjunctive analgesia and its effect on the inflammatory response. Possible roles of magnesium on the immune system have been widely studied in experimental models. Experimental magnesium deficiency produces a clinical inflammatory syndrome characterized by leukocyte and macrophage activation, release of inflammatory cytokines, acute phase proteins, and production of free radicals. Although the underlying mechanism for inflammatory response in magnesium deficiency are not clearly elucidated, it has been suggested that magnesium deficiency may induce a pro-inflammatory response by modulation of intracellular calcium concentrations, release of neurotransmitters or the activation of nuclear factor kappa B (NF- κB) implicated in the regulation of immune and inflammatory response. Experimental trials demonstrated magnesium deficient animals are more sensitive to septic shock [15]. In humans an inverse association between markers of systemic inflammation and endothelial dysfunction has been reported [16]. Magnesium supplementation in patients with heart failure significantly reduced CRP levels (a marker of systemic inflammation, and a well-known predictor of both diabetes and cardiovascular disease). There is a lack of human data on the association between magnesium levels and sepsis. In the prevalence study, the incidence of hypomagnesaemia was particularly common in patients with sepsis and septic shock. Sepsis was reported as one of the independent risk factors for developing hypomagnesaemia, which is also associated with poor outcome in sepsis. More experimental and clinical data are needed to determine whether magnesium supplementation in sepsis and septic shock can alter outcomes.

CHAPTER 253

Disorders of calcium in the critically ill

Matthew R. Rosengart

Key points

- Critical illness related hypocalcaemia occurs in up to 88% of intensive care unit (ICU) patients.
- Despite hypocalcaemia, intracellular calcium concentration is elevated in severely injured and severely septic ICU patients.
- Calcium is toxic and the primary objective of cellular regulatory mechanisms is to compartmentalize calcium and maintain a low (100 nM) cytosolic calcium concentration.
- A systematic review concluded there are no data to support the routine parenteral administration of calcium in the management of asymptomatic critical illness related hypocalcaemia.
- Acute, symptomatic hypocalcaemia necessitates parenteral supplementation as 10% calcium gluconate or 10% calcium chloride to prevent tetany, seizures, and cardiac arrhythmias.

Introduction

Evolutionary pressures have yielded several regulatory mechanisms to maintain total body quantity and distribution of each electrolyte within the intracellular and extracellular compartments at concentrations compatible with life. The preservation of such electrochemical gradients is fundamental for homeostatic cell function and ultimately organ physiology. Thus, life and patient survival are dependent upon these balances despite the continual changes imposed by both internal physiological processes and external stressors.

During periods of critical illness these process are commonly overwhelmed, and disorders of electrolyte homeostasis are highly prevalent among ICU patients. Merely normalizing measured concentrations to within 'normal' laboratory ranges without addressing the underlying pathophysiology does little to improve outcome. Understanding the biochemistry, physiology, and pathophysiology of calcium regulation, in combination with a systematic approach to diagnosis and therapy are complementary components that, at the bedside, are essential for patient recovery.

Normal homeostasis

Calcium is vitally important for normal cellular signalling and function. However, its toxicity necessitates that intracellular calcium concentration [Ca^{2+}] be tightly regulated and compartmentalized. Recognize that high intracellular [Ca^{2+}] is incompatible with life, and all cells require an effective homeostatic system to maintain intracellular calcium at 100 nM, about 20,000 times lower than the extracellular milieu. Similarly, organ physiology, most notably cardiac conduction and neuromuscular function is dependent upon rapid Ca^{2+} transients; yet, physiologically active [Ca^{2+}] is kept within a narrow range: 1.0–1.25 mmol/L. Although originally addressing an evolutionary pressure for cell survival, these electrochemical Ca^{2+} gradients, the components maintaining them (endoplasmic reticulum, mitochondria, and sarco-/endoplasmic reticulum calcium ATPase), have been integrated into one of the most versatile and ubiquitous signalling machineries of the cell.

Normal homeostasis of total body and plasma Ca^{2+}, and phosphate (PO_4^{3-}) is maintained by parathyroid hormone (PTH) and vitamin D, which regulate gastrointestinal absorption, bone formation and resorption, and urinary excretion. Most PO_4^{3-} and 98% of total body Ca^{2+} are compartmentalized in the skeletal system. The physiologically active form of plasma Ca^{2+} is distributed into three phases—ionized (50%), protein bound (40%), and complexed (10%) with organic anions, such as HCO_3^- or PO_4^{3-} [1]. A true disorder of Ca^{2+} concentration and regulation necessitates confirming an alteration in the ionized form: $[Ca^{2+}]_i$ [2].

In responding to low $[Ca^{2+}]_i$, PTH is released and effects the metabolism of large Ca^{2+} stores within bone and the renal metabolism of vitamin D and handling of Ca^{2+} and PO_4^{3-} [2]. Osteoclastic bone resorption releases Ca^{2+} and PO_4^{3-}. The renal conversion of calcitriol (i.e. vitamin D_3) increases bone resorption of Ca^{2+} and PO_4^{3-}, intestinal absorption of Ca^{2+} and PO_4^{3-}, and the renal reabsorption of Ca^{2+} and excretion of PO_4^{3-}. This last step minimizes the formation of Ca_2PO_4, and enables PTH and vitamin D to alter Ca^{2+} and PO_4^{3-} concentrations independently [3]. Calcitriol may also be induced directly by hypophosphataemia. Calcitonin is produced by the thyroid C-cells and acts to decrease bone resorption and to decrease urinary calcium excretion [4].

Pathophysiology

During critical illness, derangements in calcium homeostasis occur with considerable frequency. Indeed, hypocalcaemia occurs in up to 88% of critically ill intensive care unit (ICU) patients suffering from trauma, sepsis, and burns [5]. Prior studies suggest that the development of hypocalcaemia is an independent risk factor for increased mortality. The aforementioned observations, in combination with the known importance of calcium for homeostatic organ function, led to the current practice guidelines of treating

low serum $[Ca^{2+}]_i$ with the parenteral administration of calcium [5,6]. However, a causal relationship between hypocalcaemia and multiple organ dysfunction syndrome (MODS) or mortality has not been elucidated. Furthermore, evidence has emerged to challenge this common practice. A recent systematic review concluded that no study has been conducted to identify a benefit in treating critical illness related hypocalcaemia [7].

Although **systemic** hypocalcaemia is prevalent during critical illness, **intracellular** calcium concentration $[Ca^{2+}]_i$ is elevated in the liver [8], the myocardium, and vasculature [9,10], and immune cells [11] in experimental models of sepsis or septic patients, in models of ischaemia/reperfusion and in severely-injured trauma patients. Impaired intracellular calcium handling is often cited as the mediator of aberrant inflammation underlying toxic cell death and subsequent organ injury and dysfunction [12]. It has been hypothesized that persistent elevation of $[Ca^{2+}]_i$ sustains the septic inflammatory response after the infection has been eliminated and leads to organ dysfunction (MOD). In accordance with this hypothesis, several animal models of sepsis and trauma document increased mortality and organ dysfunction with calcium replacement [13–15], and others report improvement with calcium antagonism [16,17].

Myocardial dysfunction consequent to sepsis, trauma, or ischaemia has been correlated with elevated $[Ca^{2+}]_i$ [18]. Clinical trials of calcium supplementation during cardiopulmonary bypass or sepsis note worsened myocardial function with supplementation [19], whereas reducing calcium overload improved contractility [10,17] Similar dysfunction or cellular injury consequent to elevated cytosolic $[Ca^{2+}]_i$ is observed in skeletal muscle, red blood cells, and the liver, and reductions in cellular dysfunction and injury in models of sepsis have been achieved by maintaining low extracellular $[Ca^{2+}]_i$ or administering calcium antagonists [4,8]. Despite such evidence and, in part, because of the integral role of calcium in nearly every vital and cellular function, supplementation to normalize serum $[Ca^{2+}]_i$ in critically-ill patients is recommended [6,20].

Calcium and inflammation

A prominent feature of sepsis and major trauma is a systemic inflammatory response with an elevation of pro-inflammatory cytokines such as platelet-activating factor (PAF), tumour necrosis factor-α (TNFα), IL-1, IL-8, IL-6, and HMGB1. Clinical and experimental evidence suggest perturbations in intracellular calcium homeostasis potentiate the inflammatory response. Initial leukocyte recruitment is mediated by integrin and intercellular adhesion molecules whose cell surface concentrations and affinity are increased with elevated $[Ca^{2+}]_i$. Increased cytosolic $[Ca^{2+}]_i$ activates pro-inflammatory signalling cascades, such as the mitogen-activated protein kinases (MAPK), which mediate signal transduction for both septic and traumatic insults. During endotoxaemia, the irrepressible influx of calcium into Kupffer cells results in cell activation and subsequent synthesis of several inflammatory mediators, such as PAF, nitric oxide (NO), and eicosanoids. Elevating basal neutrophil and monocyte $[Ca^{2+}]_i$ induces cytokine production and markedly enhances lipopolysaccharide (LPS)-induced TNFα, IL- 8, reactive oxygen species (ROS), and procoagulant activity; inhibiting this elevation abrogates the response [15,16]. Furthermore, a sustained increase in macrophage or platelet intracellular $[Ca^{2+}]_i$ is sufficient for inducing arachidonic acid release, which may fuel the production of pro-inflammatory mediators. We have observed that calcium supplementation in an in vivo murine model of sepsis markedly increased TNFα, IL-6, IL-10 and HMGB1 production, observations that were reproduced in vitro in macrophages. This was associated with a marked increase in vascular leak, renal and hepatic dysfunction, and increased mortality. The 'receptor' interpreting these alterations in calcium transients has not been identified, although work in our laboratory implicates the family of calcium/calmodulin-dependent protein kinases (CaMK) as potential mediators.

Diagnosis and treatment

Hypocalcaemia: $i[Ca^{2+}]_p$ < 1.1 mmol/l

Hypocalcaemia is most commonly the result of chronic renal failure due to diminished calcitriol formation and hyperphosphataemia (Table 253.1). More contemporary and better risk-adjusted studies suggest that although hypocalcaemia may be associated with ICU mortality, it is not in the causal pathway. Other causes of hypocalcaemia include sepsis, alkalosis, rhabdomyolysis, acute pancreatitis, and vitamin D deficiency (Table 253.1) [1].

Symptoms stem from neuromuscular excitability, and include muscle spasms, carpopedal spasm (Trousseau's sing), facial grimacing (Chvostek's sing) laryngeal spasm, and convulsions. Hypotension and heart failure have been reported in hypocalcaemia. Prolongation of the QT interval may progress to malignant arrhythmias.

A careful history and physical examination will usually determine the cause. If the diagnosis remains elusive, simple laboratory measurements of serum albumin, blood urea nitrogen (BUN),

Table 253.1 Aetiology of calcium disorders

Hypocalcaemia	Hypercalcaemia
PTH absent	Parathyroid
Hypoparathyroidism	Primary hyperparathyroidism
Hypomagnesaemia	Familial hypocalciuric hypercalcaemia
PTH ineffective	Ectopic PTH/malignancy
Deficient active vitamin D	*Metastasis*: breast
	Humoral: lung, renal
Inactive vitamin D	Hypervitaminosis D
Anticonvulsant therapy	Granulomatous disease (TB)
Pseudohypoparathyroidism	Vitamin D intoxication
PTH overwhelmed	High bone turnover
Hyperphosphataemia	Hyperthyroidism
Acute pancreatitis	Immobilization
	Paget's disease
Drugs	Drugs
Protamine	Thiazide diuretic
Heparin	Milk–alkali syndrome
Plicamycin	
Glucagon	
Chronic renal failure	Chronic renal failure
Vitamin D deficiency	Secondary hyperparathyroidism
Hyperphosphataemia	Milk–alkali syndrome

Table 253.2 Treatment of calcium disorders

Hypocalcemia	Hypercalcemia
Parenteral therapy Calcium chloride Calcium gluconate	Hydration normal saline *Onset*: hours *Duration*: during infusion
Oral therapy Calcium: 1–2 g/day	Bisphosphonates *Onset*: 1–2 days *Duration*: 5–7 days
Calcitriol: 0.25–2.0 μg/day	Calcitonin *Onset*: hours *Duration*: 10–14 days
Thiazide diuretic	Plicamycin *Onset*: after 5 days *Duration*: 7–10 days
	Dialysis *Onset*: hours *Duration*: 1–2 days

$[Ca^{2+}]_i$, PO_4^{3-}, pH, and $PaCO_2$ should be obtained. Measurement of intact PTH is necessary if hypoparathyroidism or pseudohypoparathyroidism is suspected.

Acute, symptomatic hypocalcaemia necessitates parenteral supplementation as 10% calcium gluconate or 10% calcium chloride to prevent tetany, seizures, and cardiac arrhythmias (Table 253.2) [1]. Intravenous calcium in a concentration of 5–7.5 mmol may be given immediately and followed by 0.375 mmol/kg elemental Ca^{2+} over 4–6 hours. Long-term therapy depends upon the cause and includes oral Ca^{2+} supplementation, vitamin D administration (ergocalciferol: 50,000 to 100,000 unit/day; calcitriol: 0.5–2 μg/day), and thiazide diuretics.

Hypercalcaemia: $i[Ca^{2+}]_p$ >1.35 mmol/l

Hypercalcaemia may result from an alteration in the equilibrium between the bone mineral and extracellular fluid, from increased gastrointestinal absorption of Ca^{2+} or from a combination of these factors (Table 253.1) [1]. In the general population it is uncommon, and primarily due to hyperparathyroidism or malignancy (Table 253.1). Malignancy is a more prevalent cause among hospitalized patients, producing hypercalcaemia through either destruction of bone or the secretion of ectopic PTH, called humoral hypercalcaemia of malignancy. Granulomatous diseases (e.g. sarcoidosis, tuberculosis) elevate vitamin D activity.

The signs and symptoms of hypercalcaemia are protean. As Ca^{2+} serves a fundamental role in neuromuscular function, neuromuscular signs and symptoms predominate—fatigue, depression, mental confusion, and proximal muscle weakness. Moderate hypercalcaemia has a positive inotropic effect on the heart, causing hypertension; severe hypercalcaemia is associated with short QT intervals and arrhythmias. Several renal manifestations have been described including nephrolithiasis, nephrocalcinosis, nephrogenic diabetes insipidus (DI), and acid-base disorders. Constipation occurs with mild hypercalcaemia due to an inhibitory action on smooth muscle; this progresses to nausea, anorexia, and vomiting due to delayed gastric emptying. Metastatic calcification into soft tissues, blood vessels, and joints can occur, particularly in primary hyperparathyroidism and a high $Ca^{2+} \times PO_4^{3-}$ product (>70).

The diagnosis of hypercalcaemia is confirmed by measuring an elevated $[Ca^{2+}]_i$. Determining the aetiology is relatively straightforward, recognizing that the most common causes are hyperparathyroidism and malignancy. Additional laboratory measurements of serum PO_4^{3-}, arterial pH and PCO_2, intact PTH, and calcidiol/calcitriol are guided by the history and physical examination, and will narrow the differential [1].

Treatment depends upon the acuity and magnitude of hypercalcaemia (Table 253.2). Mild hypercalcaemia may require no therapy other than diagnosing and correcting the primary disorder. In the outpatient setting, this is most commonly due to primary hyperparathyroidism, for which surgery is typically curative. Hypercalcaemic crisis or symptomatic hypercalcaemia, because of the attendant risks of alterations in cardiac conduction and neuromuscular function, necessitates urgent institution of therapy. The standard interventions include saline, loop diuretics, inorganic phosphate, calcitonin and bisphosphonates (Table 253.2) [1]. Rarely haemodialysis is needed. Serial monitoring of $[Ca^{2+}]_i$ is necessary to ensure an appropriate response to therapy.

CHAPTER 254

Disorders of phosphate in the critically ill

Daniël A. Geerse and Marcus J. Schultz

Key points

- Critically-ill patients have a high prevalence of hypophosphataemia due to the presence of multiple causal factors—the prevalence of hyperphosphataemia in critically-ill patients is uncertain.
- Hypophosphataemia may lead to a multitude of symptoms, including cardiac and respiratory failure, and is associated with higher mortality.
- The relevance of hyperphosphataemia in critically-ill patients is less clear and symptoms are mainly associated with subsequent hypocalcaemia.
- Correction of hypophosphataemia has not been shown to improve outcome.
- Although multiple studies confirm the efficacy and safety of intravenous phosphate administration, it is unknown which treatment strategy is superior.

Introduction

Hypophosphataemia is a frequently encountered electrolyte disorder in critically-ill patients. Reliable data about the prevalence of hyperphosphataemia in critically-ill patients are lacking. It is uncertain when and how to correct hypophosphataemia, and whether correction affects outcome in critically-ill patients. While evidence-based guidelines for monitoring serum phosphate levels, and treatment of hypophosphataemia and hyperphosphataemia are lacking, this chapter provides a practical approach to diagnosis and treatment of hypophosphataemia and hyperphosphataemia in critically-ill patients.

Phosphate metabolism

Phosphorus is an essential element for all living cells, with many different functions including energy storage and modulation of oxygen release by haemoglobin, activation of enzymes and intracellular signalling, acid–base buffering of the blood, and genetic translation [1]. Phosphorus is also an essential element of the cell membrane and bone structures.

Of the total phosphorus content of the human body (approximately 700 g) 85% is stored in bones, 14–15% in other tissues, and <1% circulates in the extracellular fluid. The phosphate balance is a complex interplay between uptake and excretion (Fig. 254.1). Dietary intake of phosphorus is approximately 20 mg/kg/day, of which more than half is absorbed. Under normal conditions, most of filtered phosphorus is reabsorbed in the kidneys. Reabsorption of phosphate increases significantly with low phosphate states.

Laboratory assessment

Laboratory assessments of serum phosphate measure mainly $H_2PO_4^-$ and HPO_4^{2-}, and report this as total serum phosphorus levels, with normal values of approximately 0.80–1.45 mmol/L (2.5–4.5 mg/dL). Hypophosphataemia is typically defined as mild, moderate or severe, when serum phosphate levels are 0.65–0.80 mmol/L (2.0–2.5 mg/dL), 0.32–0.65 mmol/L (1.0–2.0 mg/dL) or < 0.32 mmol/L (< 1.0 mg/dL). Hyperphosphataemia is considered significant when phosphate levels are higher than 1.6 mmol/L (5.0 mg/dL).

Pathophysiology

Hypophosphataemia

Hypophosphataemia can result from decreased intestinal absorption, increased renal excretion or internal redistribution of inorganic phosphate (Fig. 254.1). In most patients with severe hypophosphataemia, there is both depletion of total body phosphorus stores and redistribution of phosphate to the intracellular space [1,2]. Decreased intestinal absorption of phosphate is rarely a cause for hypophosphataemia, since a low phosphate diet enhances intestinal uptake of phosphate and increases renal reabsorption. Renal excretion of phosphate is increased by metabolic acidosis. Diuretics, glucocorticoids, aminoglycosides, antiretroviral drugs, and anti-cancer drugs increase renal phosphate excretion. Redistribution across the cell membrane is the most common cause of hypophosphataemia in critically-ill patients [3]. Redistribution can be caused by multiple clinical conditions, including respiratory alkalosis (the increase of intracellular pH causes phosphate to enter the cell by stimulating glycolysis), administration of glucose, and insulin (stimulates phosphate transport into the cells along with glucose), and high serum levels of catecholamines, whether endogenous or exogenous (stimulation of cellular metabolism increases phosphate uptake). Cellular uptake of phosphate is also increased under certain specific conditions, such as the hungry bone syndrome, and diseases with rapid cell proliferation, such as acute leukaemia. Hypophosphataemia is frequently seen in alcohol addicts, in whom there is often a combination of poor dietary

	HYPOPHOSPHATAEMIA	HYPERPHOSPHATAEMIA
	Decreased intestinal absorption	Increased intake
	Malnutrition Phosphate binding agents Vitamin D deficiency/resistance Secretory diarrhoea Steatorrhoea Vomiting Nasogastric suctioning	Vitamin D intoxication Phosphate suppletion Phosphate containing enemas
	Internal redistribution	Release from cells
	Respiratory alkalosis Recovery from malnutrition Recovery from diabetic ketoacidosis Glucose/insulin therapy Catecholamines Rapid cell uptake/proliferation (e.g. hungry bone syndrome, acute leukaemia)	Rhabdomyolysis Tumour lysis Haemolysis
	Increased renal excretion	Decreased renal excretion
	Metabolic acidosis Diuretics Volume expansion Corticosteroids Tubular disorders Hereditary syndromes Malignancy-induced hypophosphataemia Hyperparathyroidism Parathyroid hormone-related protein	Chronic renal failure Acute renal failure Parathyroid hormone deficiency Parathyroid hormone resistance

Fig. 254.1 Phosphate metabolism, and causes of hypophosphataemia and hyperphosphataemia.

intake, vitamin D deficiency and increased urinary loss due to secondary hyperparathyroidism and a direct toxic effect of alcohol on the renal tubules [1].

Serum phosphate levels are inversely correlated to levels of the inflammatory cytokines interleukin–6 and tumour necrosis factor–alpha [4]. The exact mechanism is unclear. Renal phosphate excretion is very low in patients receiving interleukin therapy for cancer, suggesting that high interleukin levels must cause internal redistribution of phosphate. Hypophosphataemia may be caused by increased phosphate utilization by immune cells.

Hypophosphataemia can also be found in patients with severe infections, such as sepsis. Patients with Gram-negative bacteraemia may be particularly prone to developing hypophosphataemia. Hypophosphataemia correlates with severity of illness and has even been suggested as a prognostic parameter in septic patients. Infection with *Legionella* species is particularly associated with hypophosphataemia.

Hypophosphataemia often develops after surgery. Multiple causal factors may be present, such as respiratory alkalosis, administration of insulin, and the use of diuretics. This is particularly true for major surgery, such as cardiac and abdominal aortic [5]. The role of cardiopulmonary bypass is unclear. After major hepatic surgery hypophosphataemia is extremely frequent. Reported mechanisms involve both shifts of phosphate into hepatocytes, as well as renal phosphate wasting [6]. Hypophosphataemia is frequently encountered in trauma patients in whom an altered renal phosphate handling results in inadequately increased urinary phosphate excretion. Hypophosphataemia is even more frequent in burn wound victims, in whom phosphate is lost through the skin. In patients with head trauma, induction of polyuresis may be an aggravating factor.

Patients with malnutrition may develop hypophosphataemia as part of the so–called refeeding syndrome when receiving enteral or parenteral feeding. With refeeding depletion of total body phosphorus stores and redistribution of phosphate to the intracellular compartment can result in severe hypophosphataemia.

Hypothermia induces polyuria and as such may cause hypophosphataemia. The use of (continuous) renal replacement therapy may also lead to hypophosphataemia, unless phosphate enriched replacement solutions or dialysates are used. Patients who require high flux dialysis for intoxications are especially at risk.

Finally, patients with diabetic ketoacidosis commonly present with hypophosphataemia due to increased urinary phosphate excretion. Phosphate levels generally decrease further during treatment due to intracellular shifting along with glucose and potassium.

Hyperphosphataemia

Hyperphosphataemia in critically-ill patients can be caused by increased intake of phosphate, decreased phosphate excretion, and redistribution of phosphate from the intracellular space (Fig. 254.1). Increased intake of phosphate can be caused by vitamin D intoxication, intravenous or oral supplementation, and sporadically by the use of phosphate-containing enemas. Decreased excretion of phosphate most commonly occurs in acute or chronic renal failure. Patients with renal failure usually have a low phosphate diet and are treated with phosphate-binding agents. Redistribution of

phosphate occurs when phosphate is released from damaged cells, as in rhabdomyolysis, tumour lysis, or haemolysis.

Epidemiology

The reported incidence of moderate and severe hypophosphataemia in the general hospital population ranges between 2.2–3.1% and 0.2–0.4%, respectively. Hypophosphataemia occurs much more frequent in critically-ill patients, with reported incidences of hypophosphataemia in medical and surgical intensive care unit patients from 30 to 80%. The incidence of severe hypophosphataemia in this population ranges from 3 to 6% [2,4].

Hypophosphataemia has a higher incidence in certain patient groups such as patients with diabetic ketoacidosis, sepsis, and after major surgery, such as cardiac and hepatic surgery. Trauma patients have a higher incidence of hypophosphataemia, especially patients with burn wounds and head trauma.

There are no studies reporting the incidence of hyperphosphataemia in critically-ill patients.

Symptoms

Hypophosphataemia

Since serum phosphate levels do not accurately reflect total body phosphorus stores, the degree of hypophosphataemia may not always correlate to the presence of symptoms. Although the majority of patients with hypophosphataemia do not develop symptoms, severe complications of hypophosphataemia may occur [7]. A common mechanism in hypophosphataemia-caused symptoms is impaired energy metabolism, leading to cellular dysfunction in multiple organ systems.

Hypophosphataemia may cause respiratory muscle dysfunction, potentially resulting in (acute) respiratory failure and weaning problems [8]. The mechanism is considered to be decreased availability of phosphate-containing energy sources. In addition, depletion of 2,3-diphosphoglycerate shifts the oxygen dissociation curve to the left, decreasing oxygen delivery to peripheral tissue [9]. This might be especially relevant in patients with chronic pulmonary disease, as these patients tend to have higher 2,3- diphosphoglycerate levels to compensate for hypoxaemia.

Hypophosphataemia may also lead to myocardial dysfunction. Phosphate depletion causes impaired energy metabolism in the myocardium, leading to decreased contractility, e.g. in patients after cardiac surgery [10]. Hypophosphataemia also correlated with development of supraventricular and ventricular arrhythmias and premature beats [11].

Finally, hypophosphataemia may cause haematological dysfunction, including haemolysis and leukocyte dysfunction, insulin resistance, and a number of neuromuscular complications, including polyneuropathy, skeletal muscle weakness, seizures, central pontine myelinolysis, and rhabdomyolysis.

There is a clear association between hypophosphataemia and increased mortality [2]. Severe hypophosphataemia has been reported to predict up to 8-fold increased mortality rate in septic patients [12]. It remains unclear whether hypophosphataemia actually contributes to mortality, or is merely a marker for severity of illness. In a recent study hypophosphatemia was not an independent predictor of ICU or in-hospital mortality in critically ill patients[13]. Whether correction of hypophosphataemia reduces mortality is uncertain. Notably, hypophosphataemia has not been associated with increased mortality after cardiac surgery [5,10] and in diabetic ketoacidosis [14].

Hyperphosphataemia

Hyperphosphataemia-associated symptoms are mainly associated with hypocalcaemia caused by the precipitation of phosphate with calcium. Hypocalcaemia, in turn, can cause neuromuscular symptoms, such as paraesthesia, tetany, and convulsions, as well as cardiovascular symptoms, such as hypotension, decreased myocardial function, and arrhythmia. There is few data demonstrating the effects of acute hyperphosphataemia in the absence of hypocalcaemia, although hyperphosphataemia is associated with increased tissue and vascular calcification in patients with chronic renal failure. Also, the combination of acute hyperphosphataemia and volume depletion may lead to acute phosphate nephropathy, in which tubular deposition of calcium and phosphate leads to acute renal failure. While hyperphosphataemia is clearly associated with increased mortality in patients with chronic kidney disease [15], there is no data on the association between hyperphosphataemia and mortality in the critically ill.

Practical approach

Hypophosphataemia

With the high prevalence of hypophosphataemia in critically-ill patients, as well as their susceptibility to life-threatening symptoms, frequent laboratory monitoring seems warranted, especially in the previously mentioned high-risk groups. It is generally recommended that hypophosphataemia should be corrected in patients with severe hypophosphataemia and in any hypophosphataemic patient with associated symptoms [3,8]. However, it should be noted that there is no randomized controlled evidence for whether correction of hypophosphataemia in apparently asymptomatic patients leads to improved outcome [2]. Taking this into account, the indication for and recommended frequency of laboratory monitoring, as well as treatment of hypophosphataemia, remains debatable.

Correction of hypophosphataemia is possible via oral or intravenous route. Intravenous administration of phosphate is not without complications, however. Phosphate may precipitate with calcium. Large intravenous doses of phosphate may cause hypotension and can result in hyperphosphataemia, hypomagnesaemia, and hypocalcaemia. Intravenous therapy is generally recommended in symptomatic hypophosphataemia and where phosphate levels are <0.32 mmol/L. Multiple studies have evaluated the efficacy and safety of intravenous phosphate repletion regimens [16–20]. These studies generally agree that aggressive phosphate supplementation is safe with phosphate doses up to 45 mmol with infusion rates up to 20 mmol/hour. Hyperkalaemia can be prevented by using sodium phosphate instead of potassium phosphate in patients with potassium levels > 4 mmol/L. Moderate hypophosphataemia can be treated by oral supplementation of phosphate. One should keep in mind that active vitamin D is required for intestinal absorption of phosphate. Typical oral supplementation amounts are three times the normal daily intake, with advised doses of 2.5–3.5 g (80–110 mmol) per day, divided over 2–3 doses. Patients who receive feeding after a period of starvation are often phosphate depleted, so additional

phosphate should be added to nutritional preparations. An additional preventive strategy is to slowly build up the caloric intake. The required amount of phosphate cannot be predicted by serum phosphate levels, as phosphate shifts between multiple body compartments.

Hyperphosphataemia

Correction of hyperphosphataemia can be achieved by minimizing the intake of phosphate, increasing renal phosphate excretion, and renal replacement therapy. In the absence of renal failure, phosphate excretion can be increased by means of fluid loading and diuretics. In most patients with hyperphosphataemia associated with renal failure, renal replacement therapy is warranted for reasons other than hyperphosphataemia. Both haemodialysis and haemofiltration effectively remove phosphate from the body.

PART 10.3

Metabolic acidosis and alkalosis

CHAPTER 255

Pathophysiology and causes of metabolic acidosis in the critically ill

Patrick J. Neligan and Clifford S. Deutschman

Key points

- Metabolic acidosis results from any process that decreases the strong ion difference (SID) or increases serum levels of albumin or phosphate.
- Hyperchloraemic acidosis is most often associated with isotonic saline administration. It may reduce splanchnic blood flow and impair renal function.
- Lactic acidosis is associated with global or regional hypoxaemia (type A), stress, catechloamines and/or sepsis (type B). Failure to clear high level of serum lactate, in the presence of acidosis, is associated with poor critical care outcomes.
- Ketoacidosis is associated with hypercatabolism and low intracellular glucose levels.
- Renal acidosis is multifactorial and combines hyperchloraemia, hyperphosphataemia, and dilutional acidosis with the accumulation of a number of protein metabolites.

Introduction

The human body tightly controls the acidity of the intracellular and extracellular spaces as part of a variety of homeostatic systems that maintain transcellular ion pumps. Critical illness is typically characterized by changes in this electrochemical balance, frequently resulting in alterations in extracellular pH. Acidosis (pH <7.35) is the acid-base abnormality most frequently observed in acute critical illness. As the patient's condition becomes more chronic, mixed acid base disorders become evident, and alkalosis secondary to hypoalbuminaemia is frequently present (pH > 7.45) [1].

Metabolic acidosis results from alterations in the water and electrolyte composition of the extracellular fluid. Respiratory and metabolic acidosis often co-exist in critical illness. Metabolic acidosis usually indicates the presence of serious underlying disorder and predict mortality [2]. One multicentre study observed that 6% of critically-ill patients had severe metabolic or mixed acidosis, a finding associated with a 57% ICU mortality rate [3].

Acids and bases

The body is an aqueous environment. All acid–base reactions are directly dependent on the auto-ionization of water molecules into moieties that express H^+ or OH^-, and on the ionization of dissolved salts. In chemistry, an acid is a proton donor and a base is a proton acceptor. Water is an amphiprotic substance—it can act as either a proton donor or proton acceptor, as an acid or a base. The concentration of hydrogen ions in extracellular fluid (the pH) is determined by the water dissociation constant (Kw'), the $PaCO_2$ (effectively H_2CO_3) and the degree of dissociation of all of the fully and partially dissociated ions in that fluid compartment [4]. Strong ions, such as sodium, chloride, potassium, and lactate are fully dissociated at physiological pH. Weak acids such as bicarbonate, albumin, and phosphate are partially dissociated, and the degree of dissociation is itself pH dependent.

When one molecule of hydrochloric acid is added to water, it fully dissociates to release a hydrogen ion (H^+) to water and a chloride anion. Chloride is the proton donor (an acid) and water the proton acceptor. For each Cl^- atom there is an associated hydrogen ion. Due to the need to maintain electrochemical balance, virtually all H^+ are bound to OH^- delivered to water by strong or weak cations, forming water. For example, sodium hydroxide (NaOH) immediately dissociates in water to Na^+ and OH^-. In this scenario, water donates a hydrogen ion to sodium: sodium is a proton acceptor –a base, and water a proton donor—an acid.

$$NaOH + H_2O <-> Na^+ + OH^- + H^+ \quad + OH^- <-> Na^+ + H_3O^+ \qquad \text{[eqn 1]}$$

So,

$$HCl + NaOH + H_2O <-> Na^+ + Cl^- + 2H_2O \qquad \text{[eqn 2]}$$

Strong ion difference

In chemistry, electrical neutrality must always be maintained. All of the hydrogen ions in extracellular fluid derive from strong (fully dissociated) ions, weak (partially dissociated) acids, or carbon dioxide (which reacts, to some degree, with water, yielding H^+ and HCO_3^- -bicarbonate ion—and, with dissociation of bicarbonate, another H^+ and CO_3^{-2}). Electrochemical balance between the non-volatile components of this system is known as the Strong Ion Difference (SID). The SID is difference in total charge carried by all measured strong cations and the charge carried by all measured

Box 255.1 Strong Ion Gap

- The SIDa (apparent SID) = ($[Na^+]$ + $[K^+]$ + $[Mg^{2+}]$ + $[Ca^{2+}]$) – $[Cl^-]$.
- The SIDe (effective) is $[HCO_3^-]$ + [charge on albumin] + [charge on Pi] (in mmol/L).
- Weak acids' degree of ionization is pH dependent, so one must calculate for this:

$$[alb-] = [alb\ g/L] \times (0.123 \times pH - 0.631) \quad \text{[Box eqn 1]}$$

$$[Pi]\ (in\ mg/dL) = [Pi]/10 \times pH - 0.47. \quad \text{[Box eqn 2]}$$

- Strong Ion Gap (SIG) = SIDa–SIDe.

strong anions. The SID is always positive, usually 40-44mEq/L (SIDa—apparent SID, see Box 255.1) as the number of strong cations exceeds the number of strong anions and, because these are charged species, is reflected in a net positive charge. Because the solution must be electrically neutral, this net positive charge must be balanced by an equivalent amount of charge carried by weak acids—albumin, phosphate and bicarbonate (SIDe—effective SID) [5]. In order for there to be a gain in net $[H^+]$, there must be a net gain of anions relative to cations: this can result from excess chloride (hyperchloraemia), a loss of Na^+ (hyponatraemia, dilutional acidosis) accompanied by an increase in H^+, or the generation of metabolic acids at a rate more rapid than their clearance (lactate, ketones, and 'renal acids'). Functionally, in each of these scenarios, there is a reduction in the SID. In a scenario where 10 mEq/L of lactate is present in the extracellular fluid, the SID falls to 34 mEq/L. The strong ion gap (SIG) is SIDa–SIDe, and it reflects unmeasured anions, such as lactate (Box 255.1) [6]. This gap increases by the magnitude of the additional extracellular anions, in this case lactate. The introduction of 10 mEq/L of lactate is associated with an equal quantity of H^+ delivered to water. In the absence of extracellular buffering capacity this would result in a catastrophic fall in extracellular pH; the 'free' hydrogen ions are buffered by bicarbonate molecules, the product is carbon dioxide (CO_2): this induces increased alveolar ventilation and respiratory alkalosis. Effectively, the acid introduced with lactate is converted to CO_2 and excreted. The consequence is a fall in serum HCO_3^- levels, and a reduction in SIDe. In critically-ill patients SIG is usually above zero. This is due to a combination of hypercatabolism with release of large quantities of uric acid, amino acids, organic acids (all anions), and the impact of gelatin (an anion) used for resuscitation.

Metabolic acidosis

Metabolic acidosis results from the accumulation of strong or weak acids in the extracellular fluid (Box 255.2). These acids reflect the presence of certain anions—chloride, lactate, ketone bodies, a variety of difficult-to-measure renal acids, phosphate, and occasionally albumin. Although bicarbonate is a weak acid, its production is associated with whole body CO_2 balance, and its extracellular concentration is determined by the $PaCO_2$: there appears to be no paradigm in which changes in $[HCO_3^-]$can independently influence acid base balance [7]. In effect, the measured bicarbonate

Box 255.2 Causes of metabolic acidosis

Reduced strong ion difference (sid)

***Dilutional acidosis* (↓Na^+:Cl^-)**

- Hypotonic fluid administration.
- Increased osmolar gap:
  - Ethanol.
  - Ethylene glycol poisoning.
- Increased sodium loss: diarrhoea.
- Water overload (acute):
  - Congestive heart failure.
  - Cirrhosis.
  - Acute kidney injury.

***Hyperchloraemia* (↑Cl^-:Na^+)**

- Increased administration: 0.9% NaCl.
- Reduced excretion:
  - Renal tubular acidosis.
  - Ureteric implantation.

Unmeasured anions

- Lactic acidosis:
  - *Type A*—anaerobic glycolysis.
  - *Type B*—aerobic glycolysis.
- Ketoacidosis:
  - Diabetic ketoacidosis.
  - Starvation/alcoholic ketoacidosis.
- 'Renal acidosis':
  - Hyperchloraemia.
  - Hyperphosphataemia.
  - 'Renal acids'.
  - Hyponatraemia.

Increased weak acids

Hyperalbuminaemia

- Albumin administration.
- Cholera.

Hyperphosphataemia

- Reduced clearance—acute kidney injury.
- Increased production:
  - Refeeding syndrome.
  - Tumour lysis syndrome.
  - Rhabdomyolysis.
  - Bowel ischaemia.
  - Neuroleptic malignant syndrome.
- Increased intake:
  - Intravenous.
  - Phosphate enemas.

concentration 'adjusts', **responding** to changes in the other determinants of acid-base balance but almost never **causing** these changes.

Lactic acidosis

Lactic acid is a physiological product of glycolytic metabolism. It is continuously generated by lactate dehydrogenase from pyruvate; the normal lactate to pyruvate ratio is 10–20:1 or less. In anaerobic conditions, such as strenuous exercise, lactate levels may increase dramatically. Lactate is also produced in aerobic conditions. Beta-adrenergic receptor activation, from either stress (increased circulating catecholamines) or catecholamine infusions, increases lacate. Lactate can be metabolized in the liver to carbon dioxide and water or can be used to regenerate glucose (Cori cycle). This first pathway explains why the lactate in Hartmann's solution (Ringer's lactate solution) is functionally equivalent to bicarbonate. Lactic acidosis occurs when the production of lactate is greater than the liver's capacity to clear lactic acidosis. Thus, it may reflect excessive production or inadequate/impaired clearance, most often as a result of liver dysfunction/hypoperfusion.

Measurement of serum lactate concentration is valuable, but elevations do not always indicate the presence of acidosis. A lactate concentration of 2 mmol/L is clinically significant and a level of 5 mmol/L or more is considered severe—if metabolic acidosis is indeed present. Otherwise, in the absence of acidosis, interpreting the clinical implications of elevated serum lactate concentrations are unclear.

Many clinicians identify two types of lactic acidosis. Type A results from a global defect in oxygen delivery, such as occurs in haemorrhagic shock while Type B occurs when acidosis is present despite normal oxygen delivery and tissue perfusion. Type B lactic acidosis is most commonly seen during the aerobic glycolysis that accompanies acute stress or when sepsis, carbon monoxide or cyanide poisoning induce mitochondrial dysfunction. Type B lactic acidosis can result from excess cyanide (associated with Sodium nitroprusside infusion) or biguanides (from metformin use) and hypercatabolic diseases—such as lymphoma, leukaemia, AIDS or diabetic ketoacidosis.

The presence of lactic acidosis is a sensitive marker of the severity of injury. A lactic acidosis that persists for more than 24 hours predicts adverse outcomes [8,9]. This abnormality does not necessarily signify poor tissue perfusion or global hypoxia, and therefore may result in inappropriate therapy. Type A (hypoxia-associated) acidosis is usually, but not always, accompanied by a low mixed venous oxygen saturation (SvO_2), a high lactate, and a very high lactate/pyruvate ratio (>20:1). The presence of an SvO_2 in the normal range does not exclude significant regional hypoperfusion or mitochondrial failure. In this scenario, where acidosis persists despite normal or increased tissue oxygen delivery, regional hypoperfusion such as bowel ischaemia should be considered.

Hyperchloraemic acidosis

The relative ratio of sodium to chloride in the extracellular fluid is approximately 1.4:1. Any reduction in this ratio results in dilutional (hyponatraemic) or hyperchloraemic acidosis. Chloride is the second most abundant extracellular ion, and is active in a variety of systems in the body that depend on chloride channels to generate electrical impulses (i.e. GABA receptors in the central nervous system) or utilize chloride for metabolism (e.g. the parietal cells of the stomach). Hyperchloraemia is caused by excessive administration or inadequate excretion. As sodium and chloride are absorbed in the diet in roughly equimolar concentrations, the kidneys must excrete a relatively greater quantity of chloride than sodium daily.

Diseases that result in reduced chloride excretion, such as renal tubular acidosis, or in chloride reabsorption following excretion (ureteric implantation into the bowel after cystectomy) result in hyperchloraemic acidosis. More commonly, hyperchloraemic acidosis is associated with excessive administration of 0.9% NaCl solution (normal saline). This widely used product contains 154 mmol/L of Na^+ (functionally NaOH) and 154 mmol/L of Cl^- (functionally HCl); therefore, relative to plasma, each administered litre of isotonic saline solution delivers 50 mmol of HCl to extracellular fluid. The immediate impact of this is blunted by dilution of serum albumin (itself a weak acid). Scheingraber and colleagues [10] demonstrated that even relatively small quantities of Saline (30 mL/kg) resulted in a clinically apparent metabolic acidosis.

Is hyperchloraemic acidosis clinically significant? Certainly lactic acidosis, associated with a variety of underlying pathologies, is associated with worse outcomes [11]. Nevertheless, hyperchloraemia may result in clinically significant organ dysfunction. An observational study of 31,000 surgical patients [12] comparing intravenous saline with intravenous balanced salt solutions (BSS) demonstrated significant outcome differences, favouring BSS, including post-operative infections, blood transfusions, and renal failure requiring dialysis. In addition, hyperchloraemia may lead to inappropriate continuation of therapy for treatment of keto- or lactic acidosis.

There is reason to believe that hyperchloraemia may be nephrotoxic—saline infusion has been associated with reduced renal blood flow [13], renal vasoconstriction, reduced glomerular filtration [14], splanchnic hypoperfusion [15], and perhaps an increased risk of contrast nephropathy [16]. Critically-ill patients with sepsis frequently develop hyperchloraemic acidosis that appears to be associated with worse outcomes [17]. In a study of critically-ill patients with various acid base disorders, mortality was highest for lactic acidosis (56%); for strong ion gap (SIG) acidosis it was 39% and for hyperchloraemic acidosis 29% ($p < 0.001$) [11].

Until more data are available, 0.9% NaCl is not recommended as a first line resuscitation fluid for critically-ill patients, in particular those at risk for development of acute kidney injury.

Ketoacidosis

Ketones are an end-product of fat metabolism. Ketones are produced in the mitochondria of liver cells. Fatty acids are beta oxidized to acetyl-coA. Acetyl-CoA normally enters the citric acid (Kreb's) cycle and is metabolized to carbon dioxide and water. However, this process requires insulin, whose release is, in turn, stimulated by an abundance of glucose. In the absence of this hormone, ketones—initially acetoacetate, subsequently beta-hydroxybutyrate and acetone—are produced. Ketosis is seen in starvation, either due to limited food availability, alcoholism, or in carbohydrate limited diets. When the amount of ketones produced exceeds the hepatic clearance rate, ketoacidosis ensues. The most common cause of ketoacidosis is absolute insulin deficiency (as in type 1 diabetes mellitus) or relative insulin deficiency (as occurs in hypercatabolic diabetics who become ill for any reason). Although extracellular glucose levels may be very high, there is intracellular depletion of

glucose due to hypoinsulinaemia. This is less likely to occur in type 2 diabetics, who tend to be hyperinsulinaemic. Ketoacidosis can cause a dramatic fall in pH that may actually produce air hunger. Patients typically develop an osmotic dieresis from hyperglycaemia, and thus develop significant intravascular volume depletion.

Patients with acute ketoacidosis present initially with increased SIG acidosis due to ketones. Subsequently, they develop hyperchloraemic acidosis secondary to treatment with normal saline, the traditional rehydration therapy for diabetic ketoacidosis.

Renal acidosis

Acute kidney injury is characterized by the inability of the nephron to excrete metabolic by-products, primarily protein metabolites, and excess electrolytes. Typically, the patient develops uraemia, hyperkalaemia, hyperphosphaetaemia, hyperchloraemia, and water overload, resulting in hyponatraemia. Hence, the metabolic acidosis associated with kidney injury is multifactorial associated with both measured and unmeasured anions, and haemodilution [18]. Acidosis generally becomes manifest once the GFR falls below 25 mL/min/1.73 m^2.

In early AKI, hyperchloraemia is the major cause of acidosis [19]. Chloride is actively excreted from the nephron in exchange for ammonium (NH_4^+), thus preserving the sodium and potassium levels. Hyperphosphataemia accounts for up to 30% of acidosis. In critically-ill patients, lactate may also contribute. As AKI proceeds, a large variety of metabolites—such as formate, sulphate, urate, oxaloacetate, citrate, fumate, hydroxypropionate, etc., accumulate and are responsible for much of the acidosis. This results in an increased SIG.

Other causes of metabolic acidosis

In the majority of patients that present with metabolic acidosis, the problem is explained by a change in the strong ion difference. However, it is possible to develop acidosis due to an increase in the weak acid concentration. Hyperphosphataemia results from excess administration (occasionally from phosphate containing enemas), reduced excretion (in acute kidney injury) or increased production. This may occur in any situation where there is widespread release of intracellular material: refeeding syndrome, tumour lysis syndrome, rhabdomyolysis, bowel ischaemia or neuroleptic malignant syndrome. Hyperalbuminaemia is rare; it has been reported in cholera but is more likely to be seen as a consequence of excessive intravenous administration of human albumin solution [20].

CHAPTER 256

Management of metabolic acidosis in the critically ill

Patrick J. Neligan and Clifford S. Deutschman

Key points

- Metabolic acidosis (MA) commonly complicates critical illness and is recognized as a fall in arterial pH (<7.4) and a fall in [HCO_3^-].
- The anion gap (AG) is used to distinguish hyperchloraemic versus unmeasured anion (UMA) acidosis. It should be corrected for lactate and albumin.
- Lactic acidosis is commonly due to global or regional tissue hypoperfusion, liver dysfunction, catecholamines, or poisoning. The primary treatment is fluid resuscitation.
- Ketoacidosis is due to hypoinsulinaemia or starvation. The former is treated with isotonic crystalloid and insulin.
- Renal acidosis is treated with renal replacement therapy.

Introduction

Metabolic acidosis is an early indicator of critical illness. Arterial blood is sequentially sampled to identify acidosis, to follow its progress by treating the underlying cause and to prognosticate.

Diagnosis of metabolic acidosis

Metabolic acidosis is associated with a fall in the arterial pH below 7.4. However, due to powerful buffering systems and respiratory compensation, significant acidosis may be present despite a normal range pH. Moreover, in critical illness, several simultaneous acid–base abnormalities may be present, leading to missed or incorrect diagnosis, and potentially inappropriate therapy [1]. Several systems have been introduced for interpreting blood gas results with the objective of teasing out acid–base abnormalities. These can be divided, roughly, into two schools of thought—the traditional observational approach uses the serum bicarbonate level or a mathematical derivative of it (the base deficit) to identify acidosis. An alternative, electrochemical or quantitative approach uses the law of electrical neutrality to identify problems. These approaches are complementary and, in many ways, interchangeable.

Observational approaches: bicarbonate

Bicarbonate is a metabolic derivative of carbon dioxide. Carbon dioxide is hydrated within the erythrocyte to carbonic acid, the hydrogen ion is buffered by haemoglobin and the bicarbonate molecule is ejected from the cell into the extracellular fluid (ECF). This prevents a damaging reduction in pH of venous blood. The body stores a relatively large quantity of bicarbonate in extracellular fluid and the bicarbonate concentration varies in proportion to PCO_2 (Box 256.1). In acute respiratory acidosis, the [HCO_3^-] increases by 1 mEq/L (1 mmol/L) for every 10 mmHg (1.3 kPa) increase in the $PaCO_2$ above 40 mmHg (5.25 kPa). In chronic respiratory acidosis the [HCO_3^-] increases by 4 mEq/L for every 10 mmHg (1.3 kPa) increase in $PaCO_2$ above 40 mmHg (5.25 kPa). Chronic respiratory acidosis is handled by the body by increased intracellular buffering and increased chloride excretion from the kidney, increasing the ECF strong ion difference (SID).

Bicarbonate is a weak acid (pKa = 6.1) that functions as the major extracellular buffer of strong anions. If, for example, 10 mmol/L of lactate is produced and persists in the ECF, in the absence of buffering the pH would drop to life-threatening levels. The majority of the hydrogen ions delivered alongside lactate become bound to HCO_3^-, generating CO_2, activating the respiratory centre, and resulting in increased alveolar ventilation. Conveniently, the [HCO_3^-] falls by an equivalent quantity to the reduction in SID, and for each 1 mEq/L (or mmol/L) fall in [HCO_3^-] there is a 1 mmHg (0.13 kPa) reduction in $PaCO_2$. So, in a patient presenting to the emergency room with a pH < 7.4, a [HCO_3^-] of 14 mEq/L and a $PaCO_2$ of 30 mmHg, will alert the clinician to the presence of excess anions in the extracellular space. The [HCO_3^-] falls because of the anions, not the hydrogen ions, due to the law of mass conservation.

The observational system works well in patients who have normal $PaCO_2$ levels at baseline, but it becomes more complicated in patients who have chronic respiratory failure. In this scenario, a patient may have a significant metabolic acidosis despite a $PaCO_2$ of 40 mmHg [5.3kPa] and [HCO_3^-] of 24 mEq/L.

Anion gap

The anion gap (AG) was introduced in the 1970s to assist clinicians in determining whether the acidosis is associated with hyperchloraemia ('non-gap acidosis') or unmeasured anions ('widened gap acidosis'). UMA may include lactate, ketones, or a variety of metabolic by-products often referred to as 'renal acids.' The AG is calculated by the formula:

$$\text{Anion gap} = ([Na^+] + [K^+]) - ([Cl^-] + [HCO_3^-]) = 4\text{–}18 \text{ mEq/L} \quad \text{[eqn 1]}$$

The 'gap' refers to the charge carried by albumin and phosphate, and is usually approximately 8–18 mEq/L. As the [HCO_3^-] falls

Box 256.1 Observational approach to acid base. Changes in the $[HCO_3^-]$ and $PaCO_2$ associated with various acid-base disturbances: the six rules

Acute respiratory acidosis

$$\text{Expected } [HCO_3^-] = 24 + (PaCO_2 - 40)/10 \quad \text{[Box eqn 1.1]}$$

Chronic respiratory acidosis

$$\text{Expected } [HCO_3^-] = 24 + 4 \times (PaCO_2 - 40)/10 \quad \text{[Box eqn 1.2]}$$

Acute respiratory alkalosis

$$\text{Expected } [HCO_3^-] = 24 - 2 \times (40 - PaCO_2)/10 \quad \text{[Box eqn 1.3]}$$

Chronic respiratory alkalosis

$$\text{Expected } [HCO_3^-] = 24 - 5 \times (40 \times PaCO_2)/10 \quad \text{[Box eqn 1.4]}$$

Metabolic acidosis

$$\text{Expected } PaCO_2 = 1.5\,[HCO_3^-] + 8 \quad \text{[Box eqn 1.5]}$$

Metabolic alkalosis

$$\text{Expected } PaCO_2 = 0.9\,[HCO_3^-] + 9 \quad \text{[Box eqn 1.6]}$$

$[HCO_3^-]$ is represented in mEq/L or mmol/L; $PaCO2$ is represented in mmHg (for kPa divide by 7.5).

irrespective of the cause of acidosis, an increase in the $[Cl^-]$ is associated with a similar fall in $[HCO_3^-]$. The gap remains the same. If unmeasured anions (UMA) are present in the system, then the anion gap appears to widen (as $[HCO_3^-]$ falls, but $[Cl^-]$ remains normal). As the majority of hospitals now directly measure lactate, it is appropriate to add the lactate measurement to the AG:

$$\text{Anion gap (modern)} = \left(\begin{matrix} [Na^+] + [K^+] - ([Cl^-]) \\ + [HCO_3^-] + [\text{lactate}^-] \end{matrix} \right) = 14\text{–}18 \text{ mEq/L} \quad \text{[eqn 2]}$$

Although remarkably popular, the AG is a flawed and frequently misleading calculation when applied to critically-ill patients. Universally, these patients have low serum albumin, and this masks the presence of UMA. Hence, the AG should be corrected for both albumin and lactate [2]:

$$\text{Anion gap corrected } (AG_c) = [(Na^+ + K^+) - (Cl^- + HCO_3^- + \text{lactate}^-)] + [0.25(40 - \text{albumin in g/L})] \quad \text{[eqn 3]}$$

The anion gap is most frequently combined with the traditional, observational approach, as described in Fig. 256.1.

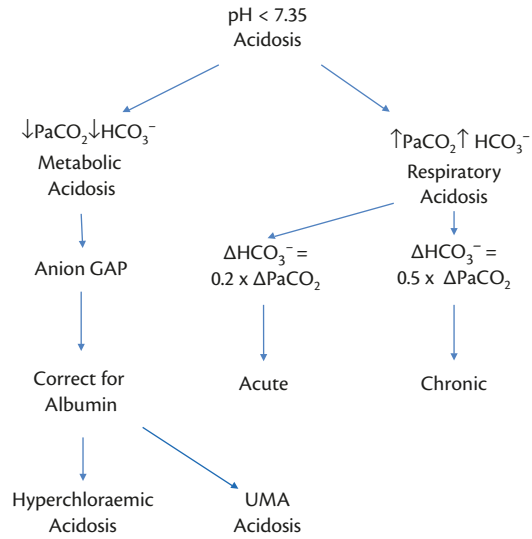

Fig. 256.1 Traditional approach to acid base, combining bicarbonate and the anion gap.

Semi-quantitative approach: base deficit/excess

The base deficit/excess (BDE) was introduced by Siggard–Anderson and colleagues in the 1960s and is often referred to as the 'Copenhagen' approach. The base deficit was an attempt to separate out metabolic acidosis from disorders of CO_2 metabolism/clearance (respiratory acidosis/alkalosis). The base deficit is the amount of strong cation (strong base) required to bring an acidic pH up to 7.4, correcting for a PCO_2 of 40 mmHg and a temperature of 37°C. Originally, the BDE was derived in vitro, but this was limited by changes in CO_2 binding to haemoglobin and referred to the BDE of blood, rather than extracellular fluid (ECF).The Van Slyke Equation facilitated calculation of BDE for whole blood rather than plasma [3].

van Slyke equation

$$BDE = \left\{ \begin{matrix} \left[HCO_3^- \right] - 24.4 + \left(2.3 \times [Hb] + 7.7 \right) \\ \times \left(pH - 7.4 \right) \times 14.83 \times \left(pH - 7.4 \right) \end{matrix} \right\} \times \left(1 - 0.023 \times [Hb] \right) \quad \text{[eqn 4]}$$

The most commonly used formula today is the standard base excess (SBE)—modified to reflect 1/3rd of the normal haemoglobin concentration (blood is only 1/3rd of ECF volume)—the haemoglobin is set at 5 g/dL; SBE is very easy to calculate [4]:

$$SBDE = 0.93 \times \left\{ [HCO_3^-] - 24.4 + 14.83 \times (pH - 7.4) \right\} \quad \text{[eqn 5]}$$

Quantitatively, the standard base deficit (BD) equals the change in the strong ion difference (apparent SID—SID_a) associated with alterations in serum bicarbonate. It is very useful as a rapid screening tool to indicate the presence or absence of a single acid base problem. Moreover, a set of rules (Box 256.2) may be applied to determine the nature of, and respiratory compensation for, the acid base problem. However, in the presence of multiple simultaneous

Box 256.2 The four $PaCO_2$/SBDE rules (SBDE in mmol/L, $PaCO_2$ in mmHg)

- Acute respiratory acidosis and alkalosis: $\Delta SBDE = 0 \times \Delta PaCO_2$.
- Chronic respiratory acidosis: $\Delta SBDE = 0.4 \times \Delta\uparrow PaCO_2$.
- Metabolic acidosis: $\Delta\downarrow PaCO_2 = \Delta SBD$.
- Metabolic alkalosis: $\Delta\uparrow PaCO_2 = 0.6 \times \Delta SE$.

acid base problems, a seemingly normal BDE (–3 to +3) may be misleading.

Electrochemical approaches

Base deficit gap

The base deficit, as calculated, reflects the change in bicarbonate concentration away from normal, corrected for CO_2 and temperature. As such, it measures the response to acidifying or alkalinizing processes. However, as such processes may be multiple and simultaneous, the absolute number of the base deficit or base excess may not accurately reflect strong anion or strong cation gain [5]. It is possible to calculate the impact of sodium, chloride, free water, and albumin on the base deficit-excess (calculated BDE), and subtract that from the measured BDE [6]. The base deficit gap (BDG) [7] should reflect the quantity of unmeasured anions, such as ketones or renal acids, in arterial blood. The BDG should mirror the strong ion gap, and the AGc. There are a number of variations of the calculations for BDG [5–7]. The simplified calculation of Story et al. is most useful (Box 256.3) [6]. They use two equations to calculate the base deficit excess for sodium/chloride/free water (BDE_{NaCl}) and for albumin. A system for using the BDE and the BDG is demonstrated in Fig. 256.2. The 'gap' reflects unmeasured anions, which should be evaluated using a process similar to that demonstrated in Fig. 256.3.

Strong ion gap

The strong ion gap (SIG), in many ways, is a more advanced and accurate version of the AG. It represents a fully quantitative approach to acid base. Like AG, SIG is based on the concept of electrical neutrality [8]. The apparent strong ion difference (SID_a) reflects the difference in charge between all the strong cations minus the strong anions:

$$SID_a = [(Na^+ + Mg^{2+} + Ca^{2+} = K^+) - (Cl^- + A^-)]. \quad \text{[eqn 6]}$$

SID changes quantitatively due to the contraction and dilutional effects associated with loss or gain of extracellular free water. This may be addressed by correcting the chloride concentration for free water (Cl^-_{corr}) and feeding the corrected chloride into the SID_a equation:

$$[Cl^-]_{corr} = [Cl^-]_{observed} \times ([Na^+]_{normal} / [Na^+]_{observed}). \quad \text{[eqn 7]}$$

SID_a is always positive with a magnitude of 40–44 mEq/L. This charge reflects an equivalent quantity of OH^- molecules and is balanced by an equal negative charge carried by weak acids: known as the effective SID (SID_e).

$$SID_e = [HCO_3^-] + [\text{charge on albumin}] + [\text{charge on Pi}]\ (\text{in mmol/L}) \quad \text{[eqn 8]}$$

Weak acids' degree of ionization is pH dependent, so one must adjust for this:

$$[\text{alb}-] = [\text{alb g/L}] \times (0.123 \times pH - 0.631) \quad \text{[eqn 9]}$$

$$[Pi]\ (\text{in mg/dL}) = [Pi]/10 \times pH - 0.47. \quad \text{[eqn 10]}$$

There is a small difference between SID_a and SID_e, the SIG, that quantifies the amount of unmeasured anion present [8].

$$\text{Strong ion gap (SIG)} = SID_a - SID_e \quad \text{[eqn 11]}$$

The 'normal' range for SIG remains unclear: it may be 6–10 mEq/L [1]. In the majority of cases, calculation of SIG is unnecessary as the AG or BDE will reveal the acidosis. In emergency medicine, SIG accurately predicts adverse outcome [9]. However, in ICU, the predictive value of this measure is weaker [10]. It is likely that hypercatabolism associated with critical illness, results in large increases in UMA derived from protein breakdown. Also, succinylated gelatin-based resuscitation fluids (popular in Northern Europe) increase SIG due to the anionic gelatin compound.

Box 256.3 Calculation of base deficit gap

$$BDE_{NaCl} = ([Na+] - [Cl^-]) - 38 \quad \text{[Box eqn 3.1]}$$

$$BDE_{Alb} = 0.25\,(42 - \text{albumin g/L}) \quad \text{[Box eqn 3.2]}$$

$$BDE_{NaCl}{}^{-}BDE_{Alb} = BDE_{calc} \quad \text{[Box eqn 3.3]}$$

$$BDE - BDE_{calc} = BDE\ gap = \text{the effect of unmeasured anions or cations} \quad \text{[Box eqn 3.4]}$$

BDE_{NaCl} component of BDE consequent of sodium concentration, chloride concentration and free water. BDE_{Alb} component of BDE consequent of serum albumin concentration. The serum phosphate concentration does contribute to BDE, but is numerically insignificant. BDE is the base deficit or excess that is derived from the SBE calculation by the blood gas machine.

Treatment of metabolic acidosis

Although acid base disturbances are associated with adverse outcomes, pharmacologically correcting the pH has never been demonstrated to improve outcomes. The use of sodium bicarbonate remains particularly controversial. Sodium bicarbonate expands volume as the 7.5%/8.4% solutions are hypertonic, increases SID due to the administration of sodium without accompanying strong anion, and increases CO_2 generation. Much discussion has focused on bicarbonate inducing intracellular acidosis [11], but this is probably clinically insignificant. In general, treatment of the underlying cause of the acidosis will resolve the problem. Nevertheless, administering sodium-bicarbonate/citrate/acetate solutions in situations

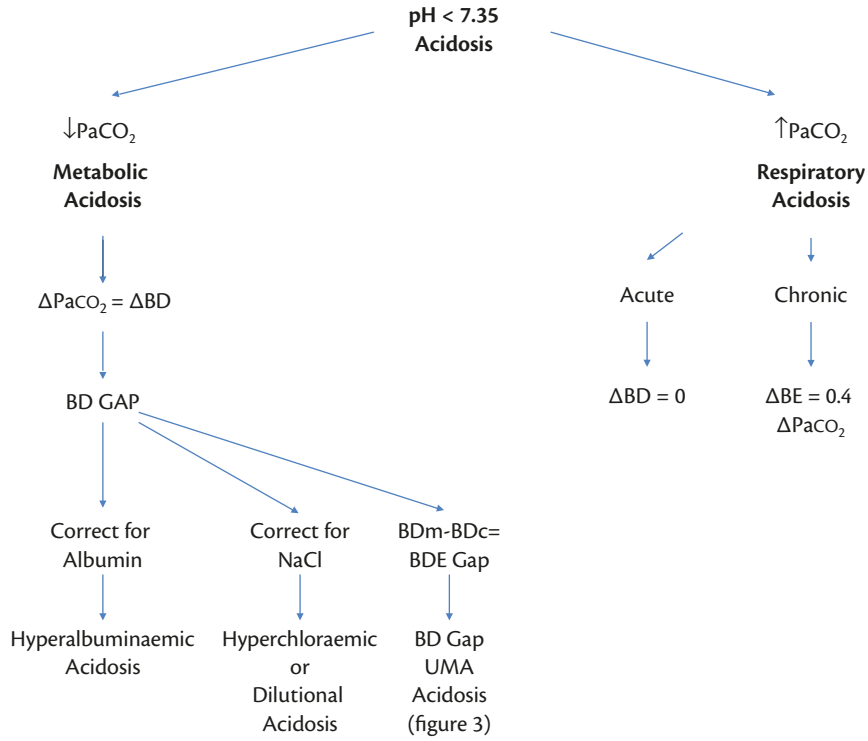

Fig. 256.2 The base deficit-excess approach & the base deficit gap.
BD, base deficit; BE, base excess; BDm, base deficit measured; BDc, base deficit calculated.

such as hyperchloraemic acidosis or renal acidosis (as a bridge to dialysis) reduces symptoms (tachypnoea, headache, etc.).

Hyperchloraemic acidosis

Hyperchloraemic acidosis may result from isotonic 0.9% saline administration, renal tubular acidosis, or ureteric transplantation to the bowel. In patients with normal kidneys, the additional chloride will clear over 2–3 days. However, during the stress response, or in the presence of acute kidney injury or renal tubular problems, resolution may be slow or incomplete. Hyperchloraemic or dilutional acidosis, is treated by increasing the SID of infused fluids, for example by infusing sodium without chloride (e.g. isotonic sodium bicarbonate or sodium acetate solutions).

Lactic acidosis

Serum lactate and arterial pH should be measured early in any critically ill patient. A [lactate] >2 mEq/L is clinically significant and a level of 5 mEq/L is severe in the presence of metabolic acidosis. Isolated hyperlactataemia in the absence of acidosis is of unclear clinical significance.

The presence of a low mixed venous oxygen saturation (SvO_2 <70% or $ScVO_2$ (central vein) <65% with a high lactate, and

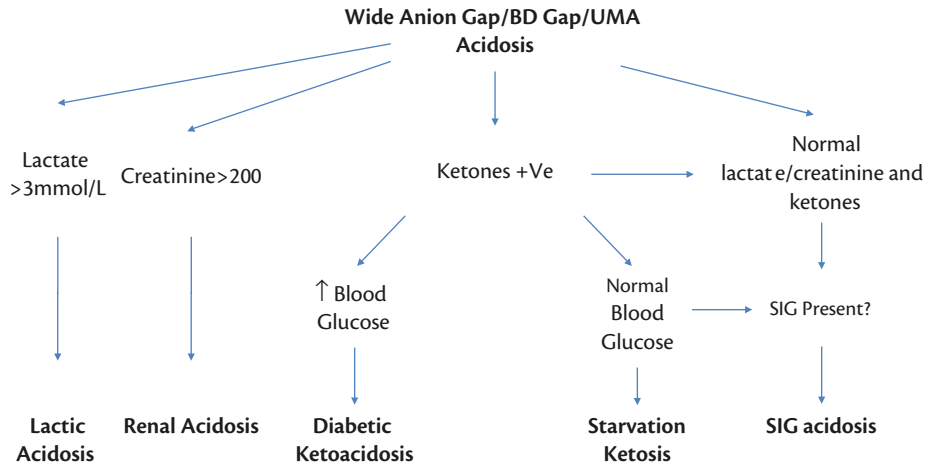

Fig. 256.3 Acidosis associated with unmeasured anions as characterized by a widened corrected anion gap, a base deficit gap (BDG), or a strong ion gap (SIG).

a very high lactate to pyruvate ratio (>20:1) is indicative of type A (hypoxia-associated) acidosis. Patients should be treated with quantitative 'goal'-directed fluid resuscitation, targeting $ScvO_2$, stroke volume, pulse pressure variability etc. The surviving sepsis guidelines (SSG) recommend 30 mL/kg fluid bolus and quantitative haemodynamic measurement [12](survivingsepsis.org).

Following implementation of resuscitation, type A lactic acidosis should begin to resolve and lactate levels should fall. SSG recommends the use of lactate clearance as an endpoint of resuscitation in sepsis [12]. The recommendation is based on data that rapid clearance of lactate has been associated with improved outcomes [13,14]. Better overall perfusion presumably reduces production and increases metabolism of lactate. If lactate does not fall following fluid resuscitation associated with normalization of $ScVO_2$, stroke volume, or other haemodynamic endpoints, clinicians should look for an alternative source of lactate production. This may simply involve turning off epinephrine infusions or may require extensive investigation for sites of regional hypoperfusion, particularly the bowel. In late stage sepsis, high levels of lactate are associated with mitochondrial failure. Patients who fail to clear lactate have worse outcomes [15]. Continued fluid resuscitation despite normalization of stroke volume or $ScVO_2$ for a high lactate, does not benefit the patient, and is likely to lead to pathologies associated with fluid overload, such as ARDS and abdominal compartment syndrome.

Ketoacidosis

Ketoacidosis occurs due to accumulation of fat breakdown products either due to an absolute or relative deficiency of insulin or due to starvation, resulting in low carbohydrate intake. Diabetic ketoacidosis is treated with fluid resuscitation and intravenous insulin. The type of fluid used to resuscitate the patient with DKA is controversial. Hyperchloraemic acidosis has been recognized as a complication of early resuscitation for decades. It is known that in anephric patients NaCl 0.9% increases serum potassium more than lactated Ringers' solution [16]. Modern isotonic balanced salt solutions (BSS) are fully isotonic with plasma, and will not worsen cerebral oedema.

Accumulating data have suggested that BSS may be a superior alternative to saline. In a small randomized study in patients with DKA BSS achieved faster initial resolution of metabolic acidosis and less hyperchloraemia after 24 hours [17]. Potassium levels were lower at 6 and 12 hours in the BSS group. Blood pressure and urinary output was greater in the BSS versus the NS group at 4 and 6 hours, respectively. They also had transiently improved blood pressure profile and urine output. Mahler and colleagues reported higher bicarbonate and lower chloride levels (i.e. less hyperchloraemic acidosis) in 45 patients randomized to NS versus BSS (plasmalyte 148) [18]. Emerging data suggest that NaCl 0.9% may increase the risk of kidney injury [19]. It is likely that BSS will replace NS for early resuscitation of DKA in the future.

Renal acidosis

Continuous renal replacement therapy (CRRT) is used in critical illness where patients are haemodynamically unstable. CRRT resolves the acidosis of acute renal failure by removing strong ions and phosphate [20]. However, metabolic alkalosis may ensue due to the unmasking of metabolic alkalosis due to hypoalbuminaemia. CRRT is not an effective treatment for either type A or type B lactic acidosis.

CHAPTER 257

Pathophysiology, causes, and management of metabolic alkalosis in the critically ill

Serge Brimioulle

Key points

- Metabolic alkalosis is frequent in hospitalized patients, and causes respiratory, cardiovascular, and neurological complications.
- Metabolic alkalosis is generally initiated by alkali administration, digestive losses, and diuretic therapy.
- Metabolic alkalosis is maintained by blood volume depletion, potassium depletion, and chloride depletion.
- Treat metabolic alkalosis by suppressing causative factors, and by giving sodium chloride and potassium chloride.
- If metabolic alkalosis is severe or causes clinical complications, give intravenous HCl.

Introduction

Metabolic alkalosis is the most frequently observed acid-base abnormality in hospitalized patients. In a study of 13,430 acid–base analyses, metabolic alkalosis was identified in 51% of samples with abnormal acid-base status [1]. Metabolic alkalosis causes significant clinical and metabolic complications, and requires early recognition and appropriate management.

Definitions

The term alkalosis refers to abnormal processes decreasing the amount of acid or increasing the amount of alkali in the organism, and thus increasing blood pH. Respiratory alkalosis results from a primary decrease in $PaCO_2$, and metabolic alkalosis from a primary increase in bicarbonate concentration. Alkalaemia refers to a blood pH value above 7.45, without regard to its mode of generation.

Acidosis and alkalosis elicit, in the normal subject, an adaptive response that tends to bring the pH back to its normal value (Table 257.1). Metabolic alkalosis causes a decrease in ventilation and an increase in $PaCO_2$ [2]. Referring to this secondary change as respiratory acidosis should be avoided, because it is a normal compensatory response, and not an abnormal process due to respiratory dysfunction.

Compensatory responses are essentially proportional to the primary acid-base disturbance, and are effective in limiting the change in pH. Respiratory responses are rapid and reach their maximum within hours, whereas renal responses are complete after only 3–5 days. If, for example, $PaCO_2$ rises to 70 mmHg, arterial blood pH first decreases to 7.20 (acute condition), and then progressively increases to reach 7.32 (chronic condition). The correct assessment of compensation therefore requires that the recent history be taken into account. While compensatory responses limit the change in pH, they do not bring the pH back to normal. A pH of 7.40 in a patient with chronic hypercapnia of 70 mmHg should not be interpreted as an appropriate response because of the so-called normal pH, but as a superimposed metabolic alkalosis. In the same way, 'overcompensation' does not occur and must be interpreted as indicating the presence of an additional primary acid–base disturbance.

Table 257.1 Normal compensatory responses to primary acid–base disturbances

Acid–base disturbance	Expected secondary response
Metabolic acidosis	$\Delta PaCO_2 = 1.20\ (0.16) \times \Delta HCO_3^-$
Metabolic alkalosis	$\Delta PaCO_2 = 0.70\ (0.09) \times \Delta HCO_3^-$
Respiratory acidosis, acute	$\Delta HCO_3^- = 0.10\ (0.75) \times \Delta PaCO_2$
Respiratory acidosis, chronic	$\Delta HCO_3^- = 0.35\ (2.60) \times \Delta PaCO_2$
Respiratory alkalosis, acute	$\Delta HCO_3^- = 0.20\ (1.50) \times \Delta PaCO_2$
Respiratory alkalosis, chronic	$\Delta HCO_3^- = 0.40\ (3.00) \times \Delta PaCO_2$

Data from in vivo studies in man or intact animals with an isolated primary acid–base disturbance. The term 'chronic' refers to the delay of 7–11 days required to reach a new steady state. Bicarbonate concentration (HCO_3^-) is expressed in mmol/L and $PaCO_2$ in mmHg or (value in brackets) in kPa.

Data from Adrogue HJ and Madias NE, 'Secondary responses to altered acid-base status: the rules of engagement', *Journal of the American Society of Nephrology*, 2010, **21**, pp. 920–3.

Generation and maintenance

Metabolic alkalosis results from a gain of alkali or a loss of non-respiratory acid [3]. The most common causes are listed in Table 257.2. In health, kidneys are able to excrete large amounts of bicarbonate and reverse alkalosis rapidly. Alkalosis therefore only persists if the kidneys, for any reason, contribute to maintain the bicarbonate excess. The principal factors maintaining alkalosis are

Table 257.2 Causes of metabolic alkalosis

Mechanism	Example
Alkali intake or administration	
Bicarbonate	Treatment of metabolic acidosis
Citrate	Blood transfusions, plasmapheresis
Carbonate	Antacids, milk-alkali syndrome
Acetate	Dialysis, parenteral nutrition
Acid losses, digestive	
Gastric	vomiting, gastric suction
Faecal	Chloride-losing diarrhoea
Acid losses, urinary	
Increased tubular sodium content	Diuretics
Hypercapnia	Post-hypercapnic alkalosis
Hyperaldosteronism	Hypovolaemia, Cushing's syndrome
Non-re-absorbable anions	Penicillin, carbenicillin

chloride depletion, decreased effective blood volume, potassium depletion, and mineralocorticoid stimulation.

Chloride depletion is the most common and most important factor [4]. Decreased glomerular filtration rate is usually observed, but is not universal, at least in some models. The exact mechanisms by which these factors contribute to maintain the alkalosis and their relative importance in different conditions remains to be clarified. In many cases, and particularly in critically-ill patients, several maintenance factors are present and contribute to the typical picture of hypochloraemic hypokalaemic metabolic alkalosis. Identification of maintenance factors is necessary, because they can maintain the alkalosis even when the generating factors have disappeared.

Alkali administration

Isolated alkali ingestion or administration only causes persistent metabolic alkalosis when the absorption is massive and prolonged. Much more commonly, metabolic alkalosis occurs after alkali administration in patients who present or develop oliguric renal failure. Typical situations in critically-ill patients are abundant transfusions of citrated blood for haemorrhagic shock or sodium bicarbonate therapy for metabolic acidosis due to circulatory arrest. Considerable alkalosis may develop when excess lactate is metabolized and administered bicarbonate cannot be eliminated. In patients with renal failure, metabolic alkalosis can also result from the administration of lactate in the haemofiltration replacement fluid.

Digestive loss of acid

Gastric alkalosis occurs when substantial amounts of acid gastric juice are eliminated from the organism by vomiting or gastric suction [3]. Chloride is lost together with hydrogen ions. Bicarbonate generated during acid secretion is not neutralized by more distal buffering in the gut and blood bicarbonate concentration increases above the renal reabsorption ability.

Bicarbonaturia is associated with natriuria, kaliuria, and fluid excretion worsening the gastric electrolyte and fluid losses. Whether, how and how much the chloride, sodium, potassium, and fluid deficits each contribute to the maintenance of the alkalosis has been the subject of much debate. The question is of considerable pathophysiological interest, but of less clinical importance because all the deficits can be corrected concomitantly to reverse the alkalosis.

Diarrhoea due to metabolic defects and villous adenomas can cause metabolic alkalosis due to failure of the colonic mucosa to reabsorb chloride adequately. Diarrhoea with normal chloride concentration can also cause metabolic alkalosis when large fluid, sodium and potassium losses result in sodium and water retention at the expense of hydrogen ion and potassium excretion by the kidney.

Urinary loss of acid

Most diuretics generate metabolic alkalosis by chloride, sodium, potassium, and fluid loss to the urine [4]. Volume contraction, aldosterone secretion, chloride depletion, and potassium depletion all contribute in some way to enhance proximal bicarbonate reabsorption and/or distal proton excretion [3].

Post-hypercapnic alkalosis is a two-step process commonly observed in critically ill patients. First, sustained respiratory acidosis determines a compensatory retention of bicarbonate and a concomitant excretion of chloride by the kidney. If chloride is not available when the hypercapnia is reversed, the bicarbonate excess cannot be eliminated [3]. Such a post-hypercapnic alkalosis commonly occurs when patients with congestive heart failure due to respiratory disease are treated with salt restriction or diuretic therapy.

Mineralocorticoid excess causes mild metabolic alkalosis when isolated, but much more serious alkalosis when potassium depletion is also present [3]. The mechanisms by which both factors combine to generate the alkalosis remain to be fully clarified. Mineralocorticoid excess, potassium depletion, and chloride depletion all contribute to the alkalosis in Bartter's syndrome [3].

Severe isolated potassium depletion has been reported to generate metabolic alkalosis by causing renal chloride wasting [4]. Penicillin and related dugs can generate mild metabolic alkalosis, possibly as non-re-absorbable anions. Hypercalcaemia may be associated with metabolic alkalosis or acidosis.

Clinical manifestations

The compensatory response to metabolic alkalosis is a decrease in ventilation and an increase in $PaCO_2$. Multiple cases of severe hypercapnia, clearly due to metabolic alkalosis, have been reported. Whether the response is or is not always present, and whether its magnitude depends on the cause of the alkalosis or on associated factors has been questioned in numerous studies [2]. It is now accepted that the increase in $PaCO_2$ is proportional to the increase in bicarbonate concentration, and that it is independent of the mode of generation of the alkalosis. $PaCO_2$ normally increases by about 0.7 mmHg for each 1 mmol/L increase in bicarbonate concentration, and can exceed 80 mmHg in severe cases. Hypoxaemia is almost always present, and has generally been attributed to the decreased ventilation and resulting atelectasis. Metabolic alkalosis also inhibits hypoxic pulmonary vasoconstriction [5], which contributes to deteriorate pulmonary gas exchange and to worsening hypoxaemia in patients with respiratory failure [6,7].

Cardiovascular complications mainly consist of various cardiac arrhythmias—supraventricular and ventricular premature beats, supraventricular tachycardia, atrioventricular block, ventricular tachycardia, and fibrillation. The arrhythmias seem to result from the associated potassium depletion, rather than from the increase in pH, and are enhanced by myocardial ischaemia and by digitalis therapy. Alkalosis has a small positive inotropic effect.

Neurological complications generally consist of altered orientation and behaviour, decreased consciousness, and neuromuscular hyperexcitability. Coma and grand mal seizures may occur, but are generally precipitated by concomitant hypovolaemia, hypercapnia, hypoxaemia, or other metabolic disturbances (e.g. hyperammonaemia in hepatic failure). Muscle weakness may occur in presence of severe potassium depletion.

Alkalosis shifts the oxyhaemoglobin dissociation curve to the left, thereby increasing oxygen uptake in the lung and decreasing oxygen release to peripheral tissues [3]. Alkalosis also increases red cell 2,3-DPG concentration, which has an opposite effect and returns the dissociation curve to its original position after 6–8 hours. Alkalosis increases the oxygen consumption, and increases the blood lactate concentration by a pH-induced enzymatic activation. Potassium depletion is almost invariably present in metabolic alkalosis and contributes to its clinical manifestations. Calcium concentration is typically normal, and the hyperexcitability results from decreased calcium ionization or from associated magnesium depletion. Alkalosis enhances the conversion of ammonium ion to ammonia.

Mixed acid–base disorders are common in critically-ill patients and should be actively sought. Particular attention should be paid to the combination of respiratory acidosis and metabolic alkalosis, which is very common, but frequently misdiagnosed when the resulting pH remains close to 7.40. Spontaneous correction is unlikely, since each disturbance enhances the other. Metabolic alkalosis may cause serious alkalaemia when the patient is mechanically ventilated, and serious hypercapnia and hypoxaemia when weaning is attempted.

Diagnosis

Determination of urine electrolyte concentrations helps to identify causal and maintenance factors, and monitors the treatment efficiency. Chloride concentration allows separation of patients into two major groups and prediction of their response to therapy. Urine chloride is generally lower than 10 mmol/L in patients with digestive losses, post-hypercapnic states, and after diuretic therapy [4]. It is typically higher than 50 mmol/L (if chloride intake is preserved) in cases of alkali intake, urinary acid losses, and during diuretic therapy. Metabolic alkalosis is chloride-responsive in the former group, and chloride-resistant in the latter. Urine pH is of little diagnostic value in metabolic alkalosis, particularly in critically-ill patients.

Management

Prevention

Metabolic alkalosis commonly occurs in settings where it could have been anticipated. Prevention of the generating factors is often possible, e.g. by limiting bicarbonate administration in acute metabolic acidosis, by preventing acid losses due to gastric drainage (e.g. proton pump inhibitors), by restricting diuretic administration, or by providing chloride at reversal of sustained hypercapnia. Prevention of the development of maintenance factors may be possible, by providing sufficient amounts of fluids, sodium, potassium, and chloride.

Generating factors

When metabolic alkalosis has developed, initial treatment is, whenever possible, the correction of the underlying disease and elimination of the generating factors. Suppression of further bicarbonate generation or reabsorption may include H2-receptor antagonists [8] or proton pump inhibitors in gastric alkalosis, prostaglandin synthetase inhibitors, or angiotensin-converting enzyme inhibitors in Bartter's syndrome, anti-emetic, and antidiarrhoeal drugs in digestive losses, reduction, or discontinuation of diuretic therapy, etc. Treatment of the underlying disease and elimination of generating factors should always be associated with the identification and reversal of maintenance factors that can maintain the alkalosis, even when generating factors have disappeared.

Maintenance factors

Metabolic alkalosis is always characterized by a chloride deficit. Chloride depletion is typically associated with blood volume and potassium depletion, so that chloride is best administered as sodium chloride and potassium chloride solutions. The blood volume deficit is variable, and sodium chloride should be given until blood volume and natraemia are corrected (as shown by an increase in urine sodium excretion if renal function is normal). The potassium deficit can reach 1000 mmol, and the potassium urinary wasting will persist until the alkalosis is corrected. Potassium chloride should be infused at the rate of 150–300 mmol/day, to restore and maintain a serum potassium concentration above 4 mmol/L.

When given in sufficient amount, sodium chloride and/or potassium chloride solutions generally reverse the alkalosis within a few days. Although mineralocorticoid excess should be identified as a maintenance factor when present, its correction is less important in critically-ill patients because it only causes mild metabolic alkalosis. If reversal of maintenance factors is ineffective or is not possible (e.g. in renal or cardiac failure), or if severe clinical complications require rapid correction, more specific approaches can be considered.

Haemodialysis and haemofiltration

Haemodialysis and peritoneal dialysis, when required because of renal failure, effectively reverse metabolic alkalosis if bicarbonate concentration is decreased and chloride concentration is increased in the dialysate. Similarly, continuous haemofiltration allows treatment of metabolic alkalosis by adapting the composition of solutions used to compensate fluid losses through the membrane. These techniques are not required to correct metabolic alkalosis in the absence of renal failure.

Acetazolamide

Acetazolamide, a carbonic anhydrase inhibitor, is a diuretic drug that enhances renal excretion of water, sodium, potassium, and bicarbonate. Although increased excretion of water, sodium, and potassium are generally unwelcome in metabolic alkalosis, acetazolamide has been proposed as a treatment of alkalosis in patients

Table 257.3 Clinical experience of hydrochloric acid (HCl) infusion in the treatment of metabolic alkalosis: administration modalities and complications

Data from various sources (see references).

with cardiac and respiratory failure. Its diuretic effect may be useful in oedematous cardiac failure, provided potassium losses can be effectively corrected by appropriate intake. It is more hazardous in respiratory failure and particularly in hypercapnic patients. Effects of acetazolamide persist for 24–48 hours, which may be a problem when the drug is found to decrease the pH and not the $PaCO_2$. Acetazolamide inhibits carbonic anhydrase and thus interferes with tissue CO_2 elimination. In COPD patients, it has been shown to cause a sustained and significant increase in the difference between tissue CO_2 tension and $PaCO_2$ [9]. The decrease in $PaCO_2$ reported during acetazolamide therapy thus reflects, at least in part, altered tissue removal rather than improved pulmonary elimination of CO_2. Acetazolamide has been reported to cause haematuria and renal failure. It should be avoided in renal and hepatic failure, and is ineffective in anuric patients.

Acidifying agents

Treatment of metabolic alkalosis with chloride-containing acids has been suggested, but most of these substances have been associated with deleterious side effects. Lysine chloride and arginine chloride can cause hyperglycaemia and hyperkalaemia, and worsen pre-existing renal failure. Ammonium chloride can result in cardiac, respiratory, and neurological complications, especially in cases of rapid administration or patients with renal or hepatic failure. These substances are best avoided in the treatment of metabolic alkalosis.

Hydrochloric acid

Hydrochloric acid (HCl) is proposed as the most efficient way to rapidly and selectively correct the deficits in hydrogen and chloride ions that characterize metabolic alkalosis. Suggested indications for HCl therapy are:

- Serious clinical complications due to the alkalosis (coma, arrhythmias).
- Contraindications to or ineffectiveness of other treatments.
- Severe alkalaemia (arterial pH > 7.55).
- Respiratory failure with hypercapnia and/or hypoxaemia [10].

The efficiency of HCl in reversing alkalosis has been reported in several clinical studies (Table 257.3) [6,10–18].

Pulmonary oedema due to HCl therapy has been reported and attributed to the amount of fluid required to correct the alkalosis. Haemolysis has been reported in animal experiments, but not in clinical series. Vascular and perivascular necrosis have been observed in earlier series, after HCl infusion into a peripheral vein [19]. Extensive tissue necrosis has only been reported after leakage or infusion to extravascular sites [20].

HCl can be infused without complication into the superior vena cava, provided adequate precautions are taken [17]. HCl is prepared in a glass bottle as a 250- or 500-mmol/L solution (25 or 50 mL of 36% HCl in 1 L of sterile water). After very careful verification of the adequate position of the catheter tip on a chest X-ray, the solution is infused at the rate of 1 mL/kg/hour without being mixed to other than electrolytic solutions. Arterial blood gases are measured every 2 hours (500 mmol/L) or 4 hours (250 mmol/L), and the infusion is discontinued when the alkalosis is reversed (i.e. base excess below zero). When rapid correction is required, a 1000 mmol/L solution may be infused at the same rate, while blood gases are measured hourly. After achievement of the HCl infusion, metabolic alkalosis may relapse if generating or maintenance factors have not been corrected.

PART 10.4

Blood glucose control

CHAPTER 258

Pathophysiology of glucose control

Ulrike Madl

Key points

- Hyperglycaemia is a common phenomenon in critically-ill patients, associated with higher morbidity and mortality in different clinical settings.
- Hyperglycaemia exerts negative effects through increased pro-inflammatory mediators, osmotic diuresis, impaired immune function, impaired wound healing, pro-coagulatory effects, endothelial cell dysfunction, increased oxidative stress, causing cell and tissue injury, and adverse cardiovascular effects.
- Both severe and moderate hypoglycaemia are associated with intensive insulin therapy and have been identified as independent risk factors of mortality in critically-ill patients.
- Glucose variability seems to be another independent risk factor influencing mortality in critically-ill patients.
- In critically-ill patients with diabetes negative effects of hyperglycaemia and glucose variability seem to be reduced, depending on glucose control before critical illness.

Stress metabolism and incidence of hyperglycaemia

Hyperglycaemia is a common phenomenon during critical illness. Up to 80–100% of patients develop stress hyperglycaemia during the course of their critical illness independent of diabetes status. This hyperglycaemia was accepted as an adaptive response to injury until many studies linked hyperglycaemia with increased morbidity and mortality in different clinical settings. The stress caused by critical illness or injury disturbs glucose homeostasis and is characterized by hyperglycaemia, glucose intolerance, and peripheral and hepatic insulin resistance with high blood-glucose levels despite high levels of insulin release. Hepatic glucose production is upregulated in the acute phase of critical illness. Increased release of counter regulatory hormones such as glucagon, cortisol, and growth hormone and also cytokines contribute to the enhanced gluconeogenesis [1]. They lead to enhanced lipolysis and increased concentrations of free fatty acids (FFAs) and increased proteolysis. Increased FFA levels also produce dose-dependent insulin resistance in peripheral tissues and serve as a substrate to increase hepatic gluconeogenesis. The hyperglycaemic state caused by these mechanisms is frequently worsened by iatrogenic administration of glucose in the form of parenteral or enteral nutrition or intravenous glucose in critically-ill patients [2].

Furthermore, catecholamines, which are also elevated in acute critical illness, contribute to the disturbed glucose homeostasis by induction of hepatic glycogenolysis and inhibition of glycogenesis [3].

Another factor contributing to hyperglycaemia in critical illness is disturbed glucose uptake mechanisms. Insulin dependent glucose uptake in myocardium, skeletal muscle and adipose tissue by glucose transporter 4 (GLUT 4) is impaired [4]. Moreover, exercise-stimulated skeletal muscle glucose uptake is absent in immobile critically-ill patients. Nevertheless, whole body glucose uptake is increased. Insulin-independent glucose uptake in tissues such as brain and blood cells accounts for this [4,5].

Stress hyperglycaemia

Studies performed in various clinical settings have found an association between stress hyperglycaemia and poor outcome. Several studies identified hyperglycaemia as a major risk factor of mortality and morbidity in critically-ill patients. A large retrospective cohort study including more than 250,000 patients found hyperglycaemia is an independent risk factor for mortality in patients with cardiac disease, sepsis, and respiratory insufficiency. In patients undergoing cardiac surgery, hyperglycaemia is associated with a higher mortality and delayed extubation [6]. In patients with myocardial infarction, congestive heart failure and cardiogenic shock hyperglycaemia was associated with an increased risk of death. In patients with stroke and subarachnoid haemorrhage severe hyperglycaemia is associated with poor clinical outcome and a higher risk of mortality [7].

Several potential mechanisms have been identified that may explain the negative impact of hyperglycaemia:

> Hyperglycaemia negatively influences the immune system. Multiple mechanisms of the hyperglycaemic effect on immune function include: derangement of neutrophil activity, enhanced expression of intercellular adhesion molecules and E-selectins, elevated levels of pro-inflammatory cytokines, and promotion of adherence and sequestration of neutrophils and monocytes in peripheral tissues. Hyperglycaemia also interferes with wound healing by reducing proliferation and migration of fibroblasts and by limiting vasodilatory properties of vascular smooth muscle cells. Moreover, severe hyperglycaemia induces osmotic diuresis, which may result in dehydration and electrolytes loss. [7]

Acute hyperglycaemia also has a negative effect on the myocardium. It can attenuate ischaemic preconditioning of the heart, a protective mechanism for ischaemic injury, possibly by inhibiting activation of ATP-sensitive potassium channels. These activate glycolysis and

may induce cardiac myocyte death through apoptosis or by aggravation of ischaemia-reperfusion cellular injury [7].

In addition, hyperglycaemia has procoagulatory effects and is associated with platelet hyperactivation and hyperaggregation. Increased thromboxane synthesis is related to platelet hyper-reactivity and is tightly regulated by glucose control [7].

Oxidative stress in diabetes

Hyperglycaemia is also associated with the development of increased oxidative stress in diabetes, partly caused by increased mitochondrial superoxide production. Superoxide interacts with nitric oxide (NO) to form peroxynitrite, a reactive oxygen species (ROS) that can modify proteins and alter their function [5]. Oxidative stress represents another modulator of platelet activation, which induces vasoconstriction and platelet hyper-reactivity [7].

Insulin

Insulin exerts several positive effects when administered in acute critical illness, including anti-inflammatory and anabolic effects in addition to glucose control. For example, insulin increases amino acid uptake, lipid synthesis, esterification of fatty acids and decreases proteolysis, lipolysis, and gluconeogenesis [1]. Insulin attenuates counter regulatory hormones, pro-inflammatory transcription factors, and may even inhibit the development of reactive oxidation species. Insulin influences electrolyte homeostasis by decreasing renal sodium excretion and enhancing potassium uptake from the bloodstream into body cells [7]. Strict separation of direct insulin effects and effects mediated by glucose lowering on different tissues and cell systems is difficult.

The main effect of insulin is the stimulation of peripheral glucose uptake via the insulin dependent GLUT-4 in skeletal muscle and adipose tissue. In contrast to this, hepatic insulin resistance cannot be improved by insulin administration, resulting in high gluconeogenesis and low insulin-stimulated glucose uptake and glycogen synthesis [1].

Glucose uptake

The glucose lowering effect can effectively decrease acute glucose toxicity mainly in the insulin independent tissues such as liver, kidney, pancreas, gastrointestinal tract, endothelial cells, neurons, and immune cells. In these tissues, glucose uptake is performed via the insulin independent transporters GLUT-1, -2, and -3, which allow glucose to enter the cells according to the glucose concentration difference [1]. Healthy subjects downregulate the expression of these transporters in the presence of hyperglycaemia in order to protect the cells from glucose overload. However, in critical illness, cytokines upregulate these insulin-independent glucose transporters [8]. This effect may overcome the protective effect of the normal downregulatory response, and consequently result in cellular glucose overload and toxic adverse effects of glycolysis and oxidative phosphorylation, especially in tissues with insulin-independent glucose uptake. Therefore, insulin-dependent glucose uptake via GLUT-4 seems to protect tissues like skeletal muscle or myocardium against uncontrolled glucose overload [2].

In the critically-ill patient, the association between hyperglycaemia and poor outcome is well established. However, trials of glucose control [2] were associated with an increased occurrence of hypoglycaemic events.

Hypoglycaemia

Hypoglycaemia is defined as blood glucose <3.9 mmol/L (70 mg/dL), while severe hypoglycaemia is defined as blood glucose <2.2 mmol/L (40 mg/dL). In healthy individuals, a reduction in blood glucose below 4.44 mmol/L (80 mg/dL) results in inhibition of endogenous insulin production and unblocking of hepatic gluconeogenesis [9]. Further decline of blood glucose below 3.6 mmol/L (65 mg/dL) causes release of glucagon and a further increase in hepatic gluconeogenesis and glycogenolysis. However, in critically-ill patients endogenous glucose production is often impaired. Especially in patients with hepatic failure, adrenal insufficiency during septic shock, renal failure, and patients suffering from severe malnutrition endogenous glucose production may fail. Untreated low blood glucose levels are particularly dangerous for neural cells as they are dependent on glucose supply and glucose from other sources is limited. During severe hypoglycaemia glial glycogen, as well as glial lactate and ketone bodies can serve as an energy source for neurons for a limited time [9].

Brain metabolism

Nevertheless, brain metabolism depends on continuous diffusion of glucose from the blood. Glucose levels in the brain are normally between 0.7 and 2.28 mmol/L (14 and 41 mg/dL) and are directly related to blood glucose levels. Therefore, blood glucose levels below 2 mmol/L (36 mg/dL) result in brain glucose concentration near zero because metabolic requirements exceed supply.

Accordingly, neuroglycopenia first results in functional brain failure with subsequent brain tissue damage due to neuronal cell death in the case of severe and prolonged hypoglycaemia.

Neuronal damage

The pathophysiology of neuronal damage during severe hypoglycaemia is not fully explored yet. However, neuronal death seems to be due to activation of neuronal glutamate receptors, production of reactive oxygen species, DNA damage, neuronal zinc release, activation of poly(ADP-ribose)polymerase-1 and mitochondrial permeability transition, rather than the direct effect of energy failure [1].

Moreover, glucose reperfusion may play a role in hypoglycaemia-induced neuronal cell death [10]. In vitro experiments demonstrated the amount of superoxide production (oxidative stress) and neuronal death were positively correlated with increasing glucose concentrations during the reperfusion period [10]. Hence, in this model, glucose reperfusion after hypoglycaemia was as deleterious as hypoglycaemia itself, implicating the need to avoid over-correction of hypoglycaemia.

Cardiovascular effects

Severe hypoglycaemic events may have cardiovascular effects as well. They may induce cardiac rate and rhythm disturbances, including ventricular tachycardia, atrial fibrillation, and sinus tachy- and bradycardia [9].

Glycaemic control

In all randomized controlled trials investigating the effect of tight glycaemic control in critically-ill patients, intensive insulin therapy was associated with a substantially increased occurrence of hypoglycaemic events (5.1–28.6% in the intervention group) [2,11].

Post-hoc analysis of several trials identified severe hypoglycaemic events as an independent risk factor of mortality, even though there seems to be a difference between iatrogenic and spontaneous hypoglycaemic events with the latter being even more deleterious.

Several observational cohort studies have elucidated the impact of mild hypoglycaemic events (blood glucose < 4.5 mmol/L (81mg/dL)) on outcome [12]. Again, multivariate analysis demonstrated even mild hypoglycaemia was independently associated with increased mortality. Association between mild or moderate hypoglycaemia and mortality persisted even after adjustment for insulin therapy or timing of hypoglycaemic episode. In another analysis hypoglycaemia, was independently associated with increased mortality even after compensating for severity of illness, diagnostic category, diabetic status, mean blood glucose during intensive care unit (ICU) admission, and glycaemic variability [13].

Predisposing factors for the development of hypoglycaemia

Predisposing factors for development of hypoglycaemia include intensive insulin therapy, use of bicarbonate-based substitution fluid during renal replacement therapy, a decrease of nutrition without adjustment of insulin infusion, a prior diagnosis of diabetes mellitus, sepsis, and the need for inotropic support. Other studies identified septic shock, elevated serum creatinine levels >3 mg/dL, mechanical ventilation, severity of disease, medical or non-elective admissions, being female, and being immune-compromised as independent risk factors for the development of severe hypoglycaemic events. Additionally, different glycaemic targets, and differences in monitoring frequency and monitoring technology may also contribute to the development of hypoglycaemic events [9].

Glucose variability

Glycaemic variability, a marker of exogenous glucose regulation, defined as standard deviation, glucose lability index or mean daily blood glucose, was independently associated with mortality in critically-ill patients, independent of the hyper- or hypoglycaemia [14,15]. However, prospective interventional studies have not directly focused on glucose variability in critically-ill patients, since methods of influencing it have not been defined yet. Interestingly, one study proposes the relationship between glycaemic variability and mortality may be even stronger in non-diabetics than in diabetics [16].

The underlying pathophysiology of the harmful effect of elevated glycaemic variability might be the induction of endothelial cell damage and apoptosis by short-time fluctuations of glucose levels. In diabetes mellitus type 2 patients, glycaemic variability was also associated with markers of oxidative stress and mediators of organ dysfunction. Increased oxidative stress and increased monocyte adhesion to endothelial cells may cause endothelial dysfunction and contribute to vascular damage [17].

Finally, in critically-ill patients, glucose complexity has been proposed as a marker of endogenous glucose regulation. Glucose complexity is a dynamic measure of glucose time series and seems to provide more powerful information on endogenous glucose regulation than does conventional glycaemic analysis. In a small number of patients glycaemic profile was shown to be more complex in ICU survivors than in ICU non-survivors. Loss of complexity in glucose time series is significantly associated with higher mortality. This can be explained by the ability of a healthy organism to detect even minor changes in glucose concentration. These changes are promptly followed by endogenous counter regulatory measures leading to a complex glucose profile. In contrast, an impaired regulatory system responds slowly and imprecisely to varying glucose concentrations and therefore displays low glucose complexity. This finding is analagous to the loss of heart rate variability in critically-ill patients, which is associated with a higher mortality [18].

Influence of pre-existing diabetes mellitus

The impact of hyperglycaemia on outcome in critically-ill patients with and without diabetes is different. A diabetic patient with significant hyperglycaemia may be less severely ill than a non-diabetic patient with the same or even a lesser degree of hyperglycaemia. This may be explained by biological adjustment to pre-existing hyperglycaemia. Diabetic patients are used to high glucose levels based on the development of relative insulin resistance, the release of counter regulatory hormones and pro-inflammatory cytokines. Thus, in diabetic critically-ill patients adapted to high glucose levels hyperglycaemia is better tolerated than in non-diabetics [16].

The pathophysiological and molecular background explaining the difference between diabetic and non-diabetic critically-ill patients during hyperglycaemia is not clear yet. The expression of the receptor for advanced glycation end-products (sRAGE) might be involved in different responses of diabetics and non-diabetics to sepsis [16].

In clinical trials, association between hyperglycaemia and outcome is much weaker in diabetic critically-ill patients than in non-diabetic patients. Moreover, response of diabetic critically-ill patients to the normalization of glycaemia compared with non-diabetics is different. In almost all clinical trials, non-diabetics benefitted more from the intervention than did diabetics. Also pre-admission glucose control (HbA1c concentration) in diabetic critically-ill patients seems to play a role in the response to glucose control and mortality. In a retrospective analysis high blood glucose values (>10mmol/L (>180mg/dL)) during the ICU stay were associated with lower mortality in patients with HbA1c >7% compared with patients with good glycaemic control before the ICU stay (HbA1c <7%) [19]. The ACCORD study, showed that aggressive glycaemic control of diabetic patients, resulting in reduction of HbA1c levels from 8.3 to 6.4%, resulted in increased mortality compared with the patients in the control group, who were treated more conservatively [20].

Additionally, the relationship between glucose variability and mortality may be considerably weaker in diabetics than in non-diabetics [16].

Furthermore, glucose complexity was lower in diabetic critically-ill patients compared with non-diabetics. This suggests that the endogenous glucose regulation in diabetic ICU patients is not able to correct alterations of the glucose level as frequently as in non-diabetics [16].

CHAPTER 259

Glycaemic control in critical illness

Simon Finfer

Key points

- Hyperglycaemia, hypoglycaemia, and the degree by which blood glucose fluctuates (blood glucose variability) are all independently associated with increased mortality.
- The optimum target range for blood glucose concentration is not clearly established, current recommendations suggest commencing treatment if blood glucose exceeds 10 mmol/L (180 mg/dL) and continuing treatment when necessary to keep blood glucose in the range of 8–10 mmol/L (144–180 mg/dL).
- Expert opinion on the measurement of blood glucose in critically-ill patients is evolving. Point-of-care glucose analysers (glucometers) are inaccurate. Continuous glucose monitors may be preferable to intermittent measurement, but are not yet in routine clinical use.
- Intensive care units should have a protocol for the management of blood glucose that defines a target range and aims to avoid hyperglycaemia, hypoglycaemia, and excessive blood glucose variability.
- Protocols should address blood sampling (site and frequency), method of measurement of blood glucose concentration, the administration of insulin, avoidance and treatment of hypoglycaemia, and integration of glucose control with feeding and other treatments.

Introduction

In 2001, Van den Berghe and colleagues published research suggesting that targeting normoglycaemia, (blood glucose concentration of 4.4–6.1 mmol/L (80–110 mg/dL)), reduced both morbidity and mortality in patients treated in a surgical ICU [1]. This research radically changed the perception of blood glucose management in critically-ill patients and stimulated a large body of research that has produced a much clearer, but still incomplete, understanding of the complexities of measuring, monitoring, and controlling blood glucose in critically-ill patients. It is now clear that both hypoglycaemia and hyperglycaemia, and the degree by which blood glucose concentration fluctuates (blood glucose variability) are strongly associated with increased risk of death. Strategies for glycaemic control in the intensive care unit (ICU) should seek to avoid all three of these features of dysglycaemia and need to be integrated with other aspects of patient care.

What is the optimum target for blood glucose concentration?

The optimum target for blood glucose concentration is not clearly established. Van den Berghe and colleagues conducted two trials in adults comparing a target of 4.4–6.1 mmol/L; (80–110 mg/dL, normoglycaemia) with a target of 10.0–11.1 mmol/L. In their surgical ICU they found this reduced both mortality and morbidity [1], while, in their medical ICU, only measures of morbidity were reduced [2]. Other investigators have not been able to reproduce these results and a large international multicentre trial found that mortality was significantly lower in patients assigned a target of less than 10 mmol/L than in those where normoglycaemia was targeted [3]. Recent meta-analyses have concluded that targeting normoglycaemia provides no overall mortality benefit in critically-ill patients and consistently increases the risk of severe hypoglycaemia [4,5]. Currently, the American Diabetes Association recommends treating hyperglycaemia when the blood glucose concentration exceeds 10.0 mmol/L and, once insulin treatment is started, targeting a blood glucose concentration of 7.8–10.0 mmol/L [6]. The American College of Physicians recommends similar targets [7].

How and how often should blood glucose be measured?

In most ICUs, and in most trials of intensive glucose control, blood glucose concentration has been measured using point-of-care glucose meters with capillary blood samples being obtained by needlesticks, or with samples from arterial or central venous catheters. Both the use of glucose meters and sampling capillary blood by needle sticks have the potential to introduce unacceptable errors into the measurement of blood glucose concentration [8]; capillary samples also have increased inaccuracy in patients who are shocked or being treated with vasopressors. It is now clear that glucose meters that were not designed for use in ICUs or for regulating insulin infusions are not accurate enough for these purposes, particularly when targeting a narrow range for blood glucose concentration (Fig. 259.1) [9]. Awaiting results of hospital laboratory measurements is generally impractical and, for most ICUs, a readily available accurate blood glucose measurement can best be obtained from a blood gas analyser. Blood samples should be drawn from an arterial catheter whenever possible and arterial catheters should never be flushed with glucose-containing solutions. An alternative for patients without a functioning arterial catheter is to draw blood

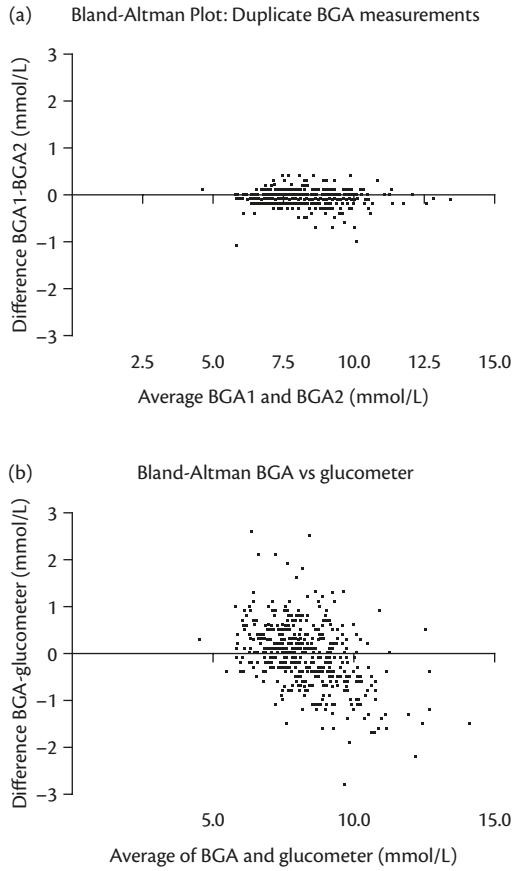

Fig. 259.1 Bland–Altman plots. (a) Blood glucose was analysed twice from the same sample in the same blood gas analyser (BGA). (b) The same sample was analysed in a blood gas analyser and a bedside glucometer.

from a central venous catheter; again, great care must be taken to avoid contamination with glucose-containing fluids, including parenteral nutrition, and to avoid increasing the risk of catheter-related sepsis.

Apart from concerns over inaccuracy, sampling glucose by needlesticks is undesirable as blood glucose concentration should be measured frequently. In critically-ill patients treated with insulin infusions, blood glucose concentration should be checked at least every 2 hours. In unstable patients and during recovery from hypoglycaemia blood glucose concentration should be checked more frequently. In different clinical circumstances, it may be appropriate to measure blood glucose at intervals varying from every 15 minutes to every 2 hours.

Just as continuous monitoring of arterial blood pressure and oxygen saturation are now considered standards of care in ICUs, the optimum solution for monitoring blood glucose may be the use of continuous glucose monitors (cGM). A variety of cGM systems are either in early clinical use or under development. Sensors monitor interstitial or intravascular glucose concentration with the faster response time being advantageous for intravascular monitoring. Initial data from cGM systems suggest blood glucose may fluctuate more widely and more rapidly in critically-ill patients than intermittent monitoring suggests (Fig. 259.2). In future accurate cGM systems should improve blood glucose control and patient safety.

Administration of insulin

As hyperglycaemia is common in critical illness many patients treated in ICUs will be treated with insulin. Patients who are eating or who have intermittent calorie intake should be treated with either oral hypoglycaemic agents or intermittent doses of subcutaneous insulin. Critically-ill patients who are receiving a constant calorie source through enteral or parenteral feeding, and patients who are hyperglycaemic, but not being fed can be treated with a continuous intravenous infusion of short-acting insulin. Insulin infusions should be given via a dedicated port or catheter using an accurate infusion pump or volumetric syringe. Infusion rates to achieve the same blood glucose concentration may vary widely between patients and in the same patient over time as insulin sensitivity and resistance can change with changes in the patient's clinical condition; they are also affected by other treatments. Insulin dosing and control of blood glucose concentration can be unprotocolized where frequency of blood glucose monitoring and changes to insulin dosing are left to the discretion of the individual nurse caring for the patient, or protocolized by use of paper-based or computerized protocols. Paper-based protocols are passive as they rely on the nurse or other individual to measure blood glucose concentration and alter the treatment in response to that measurement. Computerized protocols or computerized decision support systems (CDSS) may also be passive and only give advice when it is requested. The advent of clinical information systems and active decision support means that systems now exist that can require the blood glucose concentration to be measured at set time points, can provide electronic reminders to nurses and other clinicians to measure a patient's blood glucose concentration, and can provide advice on insulin dosing and other treatments to optimize the control of blood glucose. These systems have the potential to improve blood glucose control and patient safety, but are not yet in widespread clinical use and have not yet been proved to improve patient-centred outcomes [10].

The major adverse effect of insulin administration is hypoglycaemia. This is particularly dangerous in sedated patients or those with a reduced level of consciousness as even severe hypoglycaemia may go undetected. Recent data confirm that the occurrence of even moderate hypoglycaemia (blood glucose concentration <3.9 mmol/L or <70 mg/dL) is associated with a significant increase in the risk of death [11]. Risk factors for hypoglycaemia are listed in Box 259.1; common preventable causes of hypoglycaemia include insulin dosing errors, not measuring blood glucose concentration sufficiently frequently, and reducing or stopping feeding without reducing or stopping insulin administration at the same time.

Integration with feeding and other treatments

Critical care treatments other than the administration of insulin affect blood glucose concentration (see Table 259.1). Notable amongst these are the administration of enteral and parenteral nutrition, catecholamines, and corticosteroids.

Feeding

The glycaemic response of critically-ill patients to feeding is not clearly documented or understood. In patients who are unable to

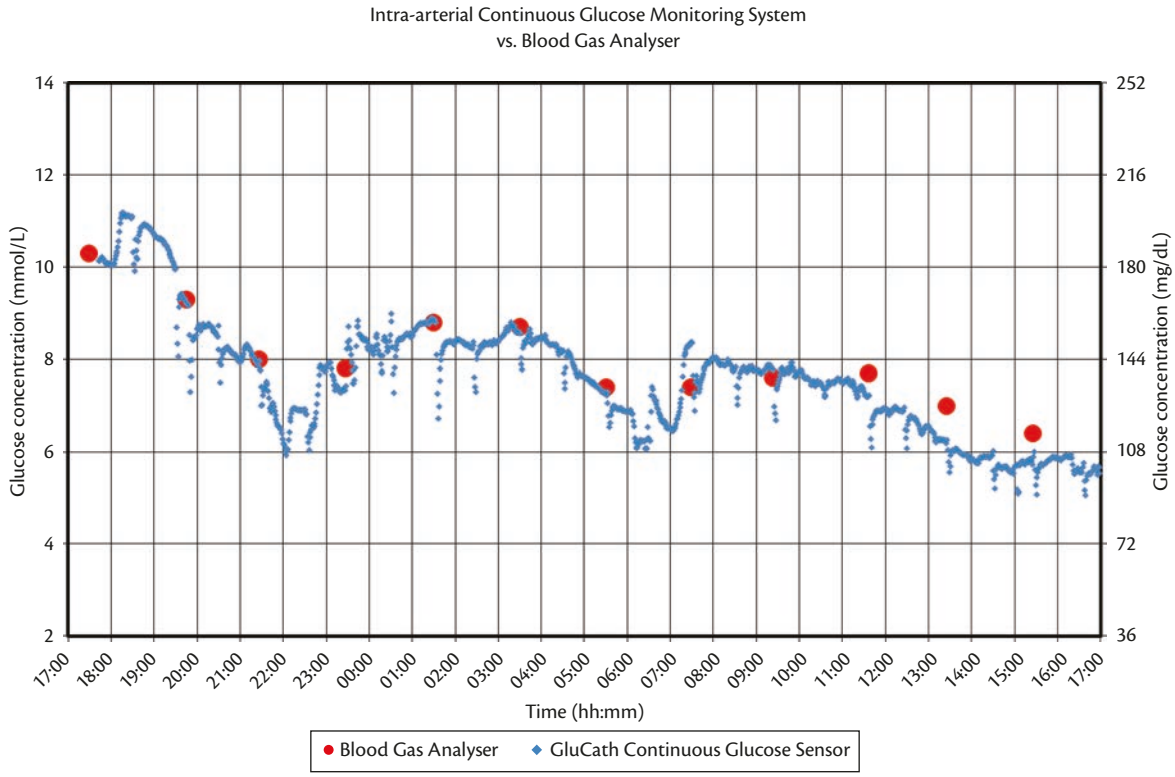

Fig. 259.2 Continuous plot of blood glucose concentration from GluCath® continuous glucose monitoring sensor placed via a radial arterial line. Red dots are simultaneous second hourly measurements using blood drawn from same arterial catheter with blood glucose concentration measured in a Radiometer 800 Flex blood gas analyser.

eat, enteral feeding is preferred over parenteral feeding, and this is most commonly achieved by continuous delivery of feeds through a gastric tube. While the delivery of feed into the stomach can be controlled, the delivery and absorption of feeds in the small intestine is highly variable, and often limited by gastric stasis. Parenteral nutrition can be delivered with greater certainty, but is only recommended for patients with an absolute contraindication to enteral feeding or who have failed a 5–7-day trial of enteral feeding. Stopping or reducing the delivery of feeds (enteral or parenteral) is a common cause of severe hypoglycaemia particularly when

Table 259.1 Common factors affecting blood glucose concentration in critically-ill patients

Factor	Effect
Insulin	Lowers blood glucose in dose-dependent fashion
Enteral nutrition	Blood glucose increases with increased absorption of enteral feeds, may decrease precipitously if feeds stopped and insulin therapy continued
Parenteral nutrition	Blood glucose increases with increased administration of parenteral nutrition , may decrease precipitously if feeds stopped and insulin therapy continued
Catecholamines	Increase insulin resistance, especially with adrenaline
Corticosteroids	Increase insulin resistance in dose-dependent fashion
Therapeutic hypothermia	Decreased metabolic rate may increase blood glucose; glucose may decrease precipitously during rewarming

Box 259.1 Patient- and treatment-related risk factors for hypoglycaemia

Patient risk factors for hypoglycaemia

- Increased age.
- Increase severity of illness score (e.g. APACHE II).
- Lower body mass index (BMI).
- Female sex.
- Medical admission diagnosis.
- Severe sepsis.
- Diabetes mellitus.
- Prior treatment with insulin.
- Prior corticosteroid treatment.
- Vasopressor treatment.
- Targeted intensive glucose control.
- Terminal event in patient dying with or of hepatic failure.

Treatment-related risk factors for severe hypoglycaemia

- Failure to measure blood glucose frequently.
- Stopping or decreasing enteral or parenteral feeding without reducing insulin administration.

- Stopping glucose containing fluid (e.g. peritoneal dialysis) without reducing insulin administration.
- Insulin dosing errors—staff error in dosing.
- Insulin dosing errors in response to inaccurate BG measurement.
- Rewarming from therapeutic hypothermia.

APACHE, acute physiology and chronic health evaluation.

intensive glycaemic control is employed. To reduce glucose variability and the risk of severe hypoglycaemia enteral feeds should be stopped as infrequently as possible. When feeds are stopped or reduced in patients being treated with an insulin infusion the administration of insulin should be reduced or stopped, and blood glucose concentration measured more frequently until it has stabilized.

Other concomitant treatments

Similar consideration should be given to the administration of drugs that influence insulin resistance. This includes treatments commonly used in ICUs, such as catecholamine infusions (particularly adrenaline) and corticosteroids. The blood glucose concentration should be measured with increased frequency when such drugs are given in intermittent dosage or the rate of a continuous infusion is changed substantially.

Other interventions, such as the use of therapeutic hypothermia, also significantly alter metabolic rate and glucose homeostasis. Blood glucose concentration should be measure with increased frequency and insulin treatment supervised closely during rewarming from therapeutic hypothermia as increasing metabolic rate may precipitate severe hypoglycaemia.

Conclusion

Control of blood glucose with the goals of avoiding hyperglycaemia, hypoglycaemia, and excessive blood glucose variability is now established as an important component of the care of critically-ill patients. Future developments will hopefully see the introduction of accurate and continuous monitoring systems leading to better understanding and control of dysglycaemia.

CHAPTER 260

Management of diabetic emergencies in the critically ill

Dieter Mesotten and Sophie Van Cromphaut

Key points

- The initial management of diabetic emergencies is aimed at airway, breathing, and circulation.
- Hospital grade blood glucose meters or blood gas analysers are essential for the safe and effective management of diabetic emergencies.
- Correction of hypovolaemia and electrolyte disturbances should prevail in hyperglycaemic crises. Insulin treatment is a secondary priority.
- Slowly correct hyperglycaemia by continuous, low (physiological) dose insulin therapy.
- Hypoglycaemia is suspected in any case of altered mental status, necessitating immediate treatment with intravenous glucose 50% or intramuscular glucagon 1 mg.

Introduction

The hyperglycaemic emergencies diabetic ketoacidosis (DKA) and hyperglycaemic hyperosmolar state (HHS) are potentially fatal complications of unidentified or uncontrolled diabetes mellitus [1]. The annual incidence of DKA, mainly observed in type 1 diabetes patients, is approximately 4.5 per 10.000 population. The incidence of HHS is estimated to be about 1% of all diabetic admissions, predominantly in type 2 diabetics. The incidence of these hyperglycaemic emergencies continues to rise, but its associated mortality has diminished remarkably due to better understanding of the pathogenesis and the use of evidence-based treatment guidelines [1,2]. DKA remains a leading cause of mortality in children and young adults with type 1 diabetes, and mortality from DKA and HHS remains high in the elderly and patients with severe co-morbid conditions. Prolonged hypoglycaemia is an important side effect of treatment in type 1 and 2 diabetics and is the third life-threatening diabetic emergency [3–5]. Although these conditions infrequently lead to ICU-admission for treatment, the consequences may be grave.

Diabetic emergencies

There is some similarity in the presentation of the three diabetic emergencies (Table 260.1). Hypoglycaemia and DKA can develop acutely, while HHS may develop insidiously over days or weeks. When requiring emergency care, neurological symptoms, such as lethargy, obtundation, and coma in the later stages, are usually in the foreground. As the respiratory and cardiovascular system may also be compromised, a meticulous assessment of the airway, breathing, and circulation (ABC) status, neurological status, and predisposing factors and lead causes has to be done. A comatose patient with a Glasgow Coma Scale of less than 8 always needs airway protection by endotracheal intubation. This should be followed by monitoring of breathing (continuous oxygen saturation and arterial blood gas) and circulation (electrocardiogram (ECG), blood pressure measurement). The use of sedative agents is to be kept to a minimum to allow regular clinical neurological monitoring and to minimize interference with respiratory compensatory mechanisms in the ketoacidotic patient [6]. It is important to look for predisposing factors, such as the type of diabetes mellitus, diabetic medication, as well as factors that may have acutely precipitated the diabetic emergency, such as infection, acute myocardial infarction, or psychiatric problems [1,6]. The blind emergency treatment of a comatose patient with intravenous glucose (25 g: 50 mL of a glucose 50% solution) and 100 mg of thiamine, with/without naloxone and flumazenil, will improve hypoglycaemia, but may complicate the diagnosis of DKA and HHS.

Hyperglycaemic emergencies

Hyperglycaemic diabetic emergencies are associated with a relatively high mortality [1]. In developing countries up to 20% of patients with DKA may die, compared with approximately 5% in the developed world. Mortality in HHS is fairly consistent between 10 and 20%. Patients presenting with a hyperglycaemic emergency rarely die of the hyperglycaemia and the concomitant biochemical disturbances. The underlying diabetes with micro- and macrovascular complications and the precipitating stress factors, such as infection and acute illness are much more important contributors to mortality.

The effective lack of circulating insulin, combined with increased concentrations of counter-regulatory hormones (catecholamines, cortisol, glucagon, and growth hormone) triggers hyperglycaemia and lipolysis in DKA [6]. The same imbalance between insulin and counter-regulatory hormones leads to unrestrained hepatic free fatty acid oxidation in the liver to ketone bodies. The pathogenesis of HHS is more enigmatic. A greater degree of dehydration and some residual endogenous insulin secretion distinguish it from DKA. The latter prevents lipolysis and ketogenesis, but not the development of severe hyperglycaemia.

Table 260.1 Rapid initial assessment of diabetic emergencies

Diabetic keto-acidosis	Hyperglycemic hyperosmolar state	Hypoglycaemia (coma)
History		
DM type 1	DM type 2	DM type 1 or 2
Prodromal illness: 24–72 hours	Prodromal illness: days-weeks	Prodromal illness: hours
Non-compliance	Possible complication of:	Inappropriate caloric intake
Possible infection	Parenteral feeding	Excessive exercise
Weight loss	Drug therapy	Excessive alcohol intake
	Peritoneal or haemodialysis	Drug overdosing: insulin/sulponylureas/meglitinides
		Autonomic neuropathy: hypoglycaemia unawareness
Signs and symptoms		
Polyuria, polydipsia, dehydration	Polyuria and dehydration	Glycaemia < 3,7 mM: autonomic responses
Fruity breath, Kussmaul breathing		Glycaemia < 2,5 mM: neuroglycopenia
Nausea, vomiting, abdominal pain	Serum osmolality > 340 mM: confusion	
Diagnostic criteria		
Ketoacidosis	*Hyperglycaemia and hyperosmolality*	*Hypoglycaemia*
Glycaemia > 13,8 mM*	Glycaemia > 35 mM*	Glycaemia < 2,5 mM
rarely > 40 mM		
Effective serum osmolality variable	Effective serum osmolality > 320 mM*	
pH < 7,3*	pH > 7,2	
Serum HCO_3 < 18 mM*	Serum HCO_3 > 15 mM	
mostly < 15 mM		
Anion gap > 10–12	Anion gap variable	
Urinary and serum ketones: +++	Urinary and serum ketones: minimal	
Deteriorating conscious level	Deteriorating conscious level, seizures	Conscious level: confusion, coma, seizures

Presentation and diagnostic criteria for hyperglycaemic and hypoglycaemic crises.

Effective serum osmolality = 2[measured Na^+(mmol/L) + glycaemia (mg/dL)/18 (mOsm/kg)].

Anion gap = Na^+(mmol/L) – [Cl^- + HCO_3^- (mmol/L)].

Diagnosis, treatment, and management

After Airway–Breathing–Circulation, and diagnosis and treatment of the precipitating factors and complications of hyperglycaemia the management of DKA or HHS should focus on fluid resuscitation, correction of metabolic acidosis, substitution of electrolyte deficits, and finally insulin administration (Fig. 260.1) [1,2,7]. Table 260.2 shows the average fluid and electrolyte loss in DKA and HHS. The fluid loss is caused by osmotic diuresis due to glycosuria. The loss of water exceeds that of sodium. The first priority is to correct the generalized dehydration and hypovolaemia, or shock in severe cases of hyperglycaemic crises. Adequate fluid resuscitation is a prerequisite for the effectiveness of the subsequent insulin therapy. In a shocked patient, the insulin will insufficiently reach the insulin sensitive organs, skeletal muscle, and adipose tissue, which are responsible for glucose uptake. NaCl 0.9%, an isotonic solution, is recommended for severe hypovolaemia and cardiogenic shock (Fig. 260.1). As recent large trials showed no benefit for colloids in fluid resuscitation, their use cannot be supported [8,9]. Aggressive, unmonitored resuscitation with inflexible fluid regimens is dangerous in patients with limited cardiorespiratory capacity. When dehydration is mild, one can start with a 0.45% saline infusion (Fig. 260.1). To further replenish the fluid losses from the interstitial and intracellular space, glucose 5% is given when blood glucose concentrations are decreasing. In this phase, more fixed fluid recipes (150–250 mL/h) can safely be used.

Diabetic ketoacidosis

A hallmark of DKA is an anion gap metabolic acidosis, due to the accumulation of the ketones β-hydroxybutyrate and acetoacetate (Table 260.1). The arterial pH in DKA is less than 7.30 and the anion gap often exceeds 20 mmol/L. Nevertheless, alkali therapy is only necessary when the pH is below 6.90, since metabolic acidosis will be corrected by insulin therapy (Fig. 260.1, Table 260.3). Inappropriate use of bicarbonate will lead to a prolongation of the ketosis, hypernatraemia, hypokalaemia, paradoxical intracellular acidosis, and rebound alkalosis. Obviously, the administration of bicarbonate is not indicated in HHS.

Patients with DKA or HHS always present with profound potassium deficits by urinary loss (Table 260.2). However, serum potassium concentrations are variable (Table 260.3). Rarely, the patient

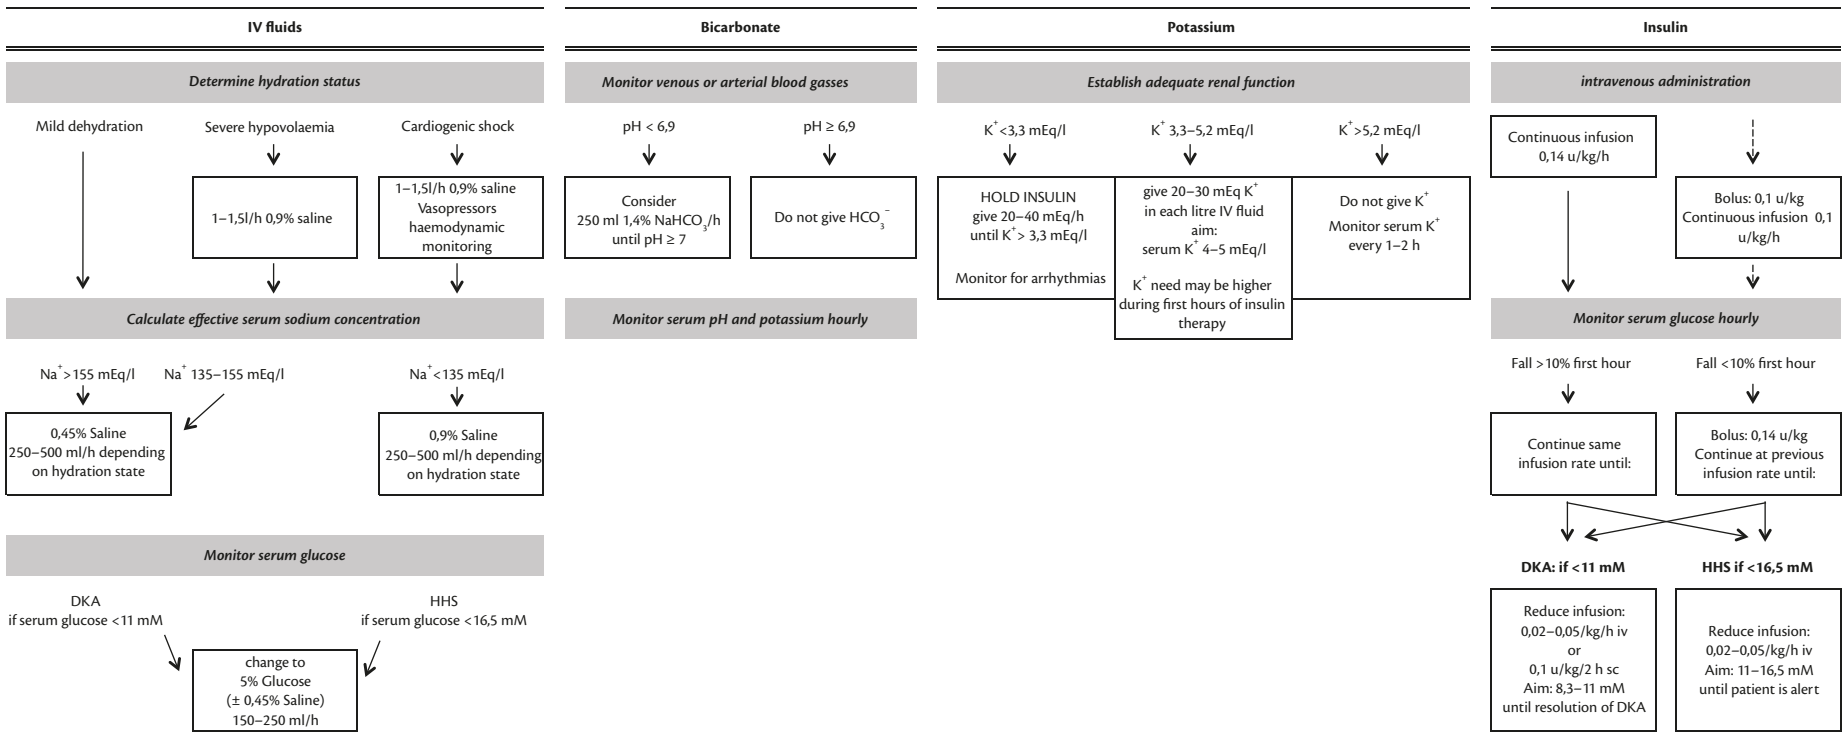

Fig. 260.1 Management of hyperglycaemic crises.

kg, per kg of body weight.

Data from: Nyenwe EA and Kitabchi AE, 'Evidence-based management of hyperglycaemic emergencies in diabetes mellitus', *Diabetes Research and Clinical Practice*, 2011, **94**(3), pp. 340–51; De Beer K et al., 'Diabetic ketoacidosis and hyperglycaemic hyperosmolar syndrome–clinical guidelines', *Nursing in Critical Care*, 2008, **13**(1), pp. 5–11; and Kitabchi AE et al., 'Hyperglycemic crises in adult patients with diabetes', *Diabetes Care*, 2009, **32**(7), pp. 1335–43.

Table 260.2 Typical deficits upon admission for hyperglycaemic crisis

	DKA	HHS
Total water	6 liter	9 liter
Water (ml/kg)	100	100–200
Na^+ (mEq/kg)	7–10	5–13
K^+ (mEq/kg)	3–5	4–6
PO4 (mmol/kg)	5–7	3–7
$Mg2^+$ (mEq/kg)	1–2	1–2

kg = per kg of body weight.

has overt hypokalaemia (<3.3 mmol/L). In this case insulin infusion should not be started until potassium has been properly supplemented and corrected. Usually, normokalaemia and sometimes hyperkalaemia is measured at presentation. Hyperosmolarity, acidosis, and insulin deficiency are driving this relative rise in serum potassium levels, despite the overall potassium depletion (Table 260.3). Impaired kidney function due to the shock may also play a role. As insulin therapy lowers potassium levels, careful monitoring, and timely supplementation is essential. Monitoring includes a continuous ECG and measurements every hour or 2 hours. Supplementation should be started together with the insulin infusion in normokalaemic patients as well. The rate of potassium substitution varies from 10 to 30 mmol/hour. Phosphate and magnesium deficiencies are common in diabetic emergencies (Tables 260.2 and 260.3). Their concentrations should be measured at least daily. However, aggressive magnesium and phosphate supplementation are rarely required.

Hyperglycaemia

Hyperglycaemia is the presenting feature of diabetic hyperglycaemic emergencies [1,2,7,10], but it has developed over days, leaving the cells time to adapt to the hyperosmotic environment. If hyperglycaemia were to be corrected too rapidly without proper attention to volume and electrolyte status, insulin will not only drive glucose, but also water, potassium, magnesium, and phosphate into the cells. This may result in dangerous cell swelling with cerebral oedema, hypokalaemia, hypomagnesaemia, and hypophosphataemia [7]. Hence, management protocols of hyperglycaemic crises have shifted to low-dose insulin regimens and omission of the priming insulin bolus-administration (Fig. 260.1) [1]. The initial drop in blood glucose concentrations is related to the fluid resuscitation, which also restores the insulin sensitivity. Consequently, insulin requirements may change briskly during treatment. It cannot be sufficiently emphasized that blood glucose measurements should be performed hourly until a stable trend becomes obvious. As glucometers for home use are inaccurate in the low and high range, blood glucose measurements ought to be done by hospital grade blood glucose meters [11]. On site, blood gas analysers are preferred since they provide accurate blood glucose measurements, and allow the evaluation of potassium, bicarbonate, ionized calcium levels, and blood gases simultaneously.

Insulin therapy

Insulin therapy should be administered by intravenous, continuous infusion. It is essential to lower the insulin infusion rate when blood glucose levels fall below 11 mmol/L in DKA and below 16.5 mmol/L in HHS. In addition, these thresholds indicate that intravenous fluids should be switched to glucose 5% (Fig. 260.1). Subsequently, blood glucose levels should be maintained between 8 and 10 mmol/L until the resolution of the ketoacidosis or HHS by regular adjustment of insulin and/or glucose 5% infusion. Provided that DKA has resolved

Table 260.3 Electrolyte disorders upon admission and during treatment of hyperglycaemic crises: pitfalls and recommendations

	Upon admission	Response to treatment	Recommendations
Na^+	falsely ↓↓	risk ↑↑	Calculate 'effective' serum Na^+= measured serum Na^+ +1,6 mmol/l for every 5,6 mM glycaemia above 5,6 mM
Cl^-		risk transient metabolic acidosis after resolution of keto-acidosis	Avoid excessive use of isotonic saline: (1) chloride load (2) urinary loss of $NaHCO_3$
K^+	variable: ↓, normal, ↑/↑↑	↓/↓↓	1. Treat life-threatening hyperkalaemia (>6 mM) with bicarbonate 2. Correct severe hypokalaemia before initiation of insulin 3. Resolution of acidosis/insulinopenia will reveal true K^+ deficit: 50–250 mEq 4. Be aware of renal impairment and hyperkalaemia risk
Bicarbonate	↓/↓↓↓	normalization of pH, HCO_3^- and PCO_2	1. Consider bicarbonate only in patients with pH < 6,9 who may deteriorate or whom compensatory mechanisms are stretched to the limits: HCO_3^- < 10 mM or PCO_2 < 12 mmHg 2. Be aware of bicarbonate administration and hypokalaemia risk
Phosphate	normal, ↑/↑↑	↓/↓↓	1. Consider potassium phosphate suppletion: - to prevent cardiac and skeletal muscle weakness and rhabdomyolysis - to reduce Cl-load (1/3 potassium phosphate + 2/3 potassium chloride) 2. Be aware of phosphate therapy and hypocalcaemia risk

Table 260.4 Signs and symptoms according to severity of hypoglycaemia

	Neurogenic	Neuroglycopenic
Glycaemia	< 3, 7 mM	< 2, 5 mM
Pathogenesis	Autonomic response	Brain glucose deprivation
Symptoms	*Cholinergic:* hunger, nausea diaphoresis paresthesias	*Cognitive impairment:* difficult thinking difficult speaking difficult concentrating
	Adrenergic: tremor palpitations, anxiety	*Behavioral changes:* irritability confusion *Psychomotor abnormalities:* blurred vision *Seizures* *Coma*

and the patient is able to eat, a multiple dose subcutaneous insulin regimen can be started. Noteworthy, profound insulinopenia, causing the rare presentation of DKA in type 2 diabetics, is potentially reversible [10]. Hence, part of these patients may be managed with a noninsulin regimen after resolution of DKA [1,10].

As DKA and HHS are hypercoagulable states due to the dehydration and the inflammatory response, it is suggested to initiate prophylactic low molecular weight heparin administration, as in any other critically-ill patient without contraindications [1]. Full therapeutic anticoagulation in HHS is not supported by evidence.

Hypoglycaemia

When unrecognized or inappropriately treated, hypoglycaemia can be associated with increased morbidity and mortality. Most cases of hypoglycaemia are iatrogenic. Insulin and sulfonylurea/meglitinide administration and alcohol intake are the major culprits (Table 260.1) [12,13]. Organ failure can further amplify the risk with these medications or cause spontaneous hypoglycaemia.

Classification

Hypoglycaemia can clinically be classified into severe or mild hypoglycaemia. Severe hypoglycaemia requires third party assistance as the hypoglycaemia episode is associated with coma or seizures, warranting parenteral therapy (intramuscular (im) glucagon or intravenous (iv) glucose). In mild hypoglycaemia the symptoms can be resolved by self-administered ingestion of carbohydrates. It is of note the symptoms of hypoglycaemia, rather than the blood glucose levels are central in the definition (Table 260.4) [3]. This is clinically relevant. In sedated critically-ill patients one can only rely on blood glucose measurements to detect hypoglycaemia (biochemical hypoglycaemia). In the literature, there is a growing consensus that severe biochemical hypoglycaemia is a blood glucose level below 2.2 mmol/L. Mild biochemical hypoglycaemia is variably defined as below 3.3–3.9 mmol/L. In biochemical hypoglycaemia symptoms may or may not be present. In asymptomatic hypoglycaemia the patient has a blood glucose level of less than 3.5 mmol/L without symptoms. A patient with frequent asymptomatic hypoglycaemia episodes has hypoglycaemia unawareness. Hypoglycaemia unawareness largely parallels the hypoglycaemia-associated autonomic failure (HAAF), which is the lack of an appropriate counter-regulatory response during hypoglycaemia. HAAF is associated with a higher risk of severe hypoglycaemia and sudden death in diabetes [3,5]. Recurrent hypoglycaemia episodes shift the glycaemic threshold for neurogenic/autonomic responses to lower blood glucose concentrations (Table 260.4). Therefore, only the neuroglycopenic symptoms will appear when the blood glucose levels are dangerously low and without the counter-regulatory response that would normally increase blood glucose levels. These responses can be restored by rigorously avoiding hypoglycaemia.

Management

The management of hypoglycaemia starts with prevention. Recent guidelines by the Endocrine Society recommend that specific directions for hypoglycaemia avoidance and treatment should be incorporated in hospital glucose management protocols [11]. This includes clear definitions of hypoglycaemia and the implementation of a system to track the frequency of hypoglycaemic events. To prompt immediate therapy the guidelines advise a standardized, hospital-wide, nurse-initiated hypoglycaemia protocol. To minimize the risk for hypoglycaemia, therapy with sulphonylurea, meglitinide, GLP-1, or DPP-4 medication should be discontinued during hospitalization. Blood glucose values should be reviewed daily and insulin therapy should be reassessed when blood glucose levels fall below 5.6 mmol/L. Insulin dose reductions in necessary when blood glucose concentrations are lower than 3.9 mmol/L.

Blood glucose levels below 3.9 mmol/L require treatment. This treatment should be proportional to the depth and the duration of hypoglycaemia [5,11]. Overcorrection should be kept to a minimum as recent data suggest hyperglycaemia during correction, rather than hypoglycaemia causes brain damage. In a conscious patient, 15–20 g rapid-acting carbohydrates, such as glucose tablets or gels, non-diet fizzy drinks and fruit juices should be taken orally. When the glycaemia falls below 2.2 mmol/L in an alert patient, larger amounts of carbohydrates should be administered. If the patient cannot swallow or take oral liquid, iv glucose 50% should be administered (20 mL for mild hypoglycaemia and 25 mL for severe hypoglycaemia). In the case of unconsciousness, one has to administer iv 30–50 mL of glucose 50%. If no iv access is available, 1 mg of glucagon should to be given im immediately. The immediate therapy by bolus administration of glucose needs to be followed by a continuous glucose infusion and frequent blood glucose checks (every 15 minutes) until glycaemia is normalized. This is essential when the hypoglycaemia is caused by sulphonylureas and, to a lesser extent by meglitinide, as they are long acting. If the sulfonylurea-induced hypoglycaemia becomes refractory, the administration of octreotide/somatostatin can be considered.

Endocrine disorders

CHAPTER 261

Pathophysiology and management of adrenal disorders in the critically ill

Bala Venkatesh and Jeremy Cohen

Key points

- The existence of the syndromes of relative adrenal insufficiency, or critical illness-related corticosteroid insufficiency, are debatable.
- In sepsis, there are alterations in plasma cortisol profiles, and corticotrophin responsiveness with marked variability in responses between patients.
- It is probable that the spectrum of plasma and tissue glucocorticoid changes may represent a 'sick euadrenal state' analogous to the sick euthyroid state and may not reflect adrenocortical insufficiency.
- Treatment of acute adrenal crisis should not be delayed for the results of adrenal testing, and should consist of immediate supportive measures, fluid resuscitation, and high-dose intravenous glucocorticoid therapy.
- Admission to intensive care with a primary diagnosis of hyperadrenalism is uncommon. Patients usually present uncontrolled hypertension, electrolyte abnormalities, or encephalopathy.

Introduction

Characterizing the pathophysiology of the adrenal cortex in critical illness has been fraught with controversy and confusion. Some reports suggest 'adrenal insufficiency' directly attributable to critical illness, particularly sepsis. The uncertainty in this area arises from the inability of current tests to identify who is truly glucocorticoid 'deficient' at a cellular level, and requires supplemental glucocorticoid administration. Reports of hyperadrenalism are less common in intensive care practice.

Normal adrenal physiology

Cortisol, the major glucocorticoid synthesized by the adrenal cortex plays a pivotal role in normal metabolism. Secretion is under the control of the hypothalamo-pituitary axis. There are a variety of stimuli to secretion, including stress, tissue damage, cytokine release, hypoxia, hypotension, and hypoglycaemia. These factors act upon the hypothalamus to favour the release of corticotrophin releasing hormone (CRH) and vasopressin. CRH is synthesized in the hypothalamus and carried to the anterior pituitary in portal blood, where it stimulates the secretion of adrenocorticotrophic hormone (ACTH), which in turn stimulates the release of cortisol, mineralocorticoids (principally aldosterone) and androgens from the adrenal cortex (Fig. 261.1).

Free cortisol diffuses passively through the cell membrane. Once inside the cell the actions are profoundly affected by the activity of the 11β-hydroxysteroid dehydrogenase (11β-HSD) enzyme system. This system has two isozymes that have been studied extensively. 11β-HSD1 acts in vivo primarily as a reductase, generating active cortisol from inactive cortisone. By contrast, 11β-HSD2 has dehydrogenase action, inactivating cortisol by conversion to cortisone. The isozymes have differing tissue distributions; 11β-HSD2 is found primarily in mineralocorticoid target tissues such as kidney, sweat glands, and colonic mucosa, where it serves to prevent illicit occupation of the mineralocorticoid receptor by cortisol. 11β-HSD1 has a wide distribution including liver, adipose, and vascular tissues, and while its primary action is reductase, there is some evidence its directionality may be tissue specific (Fig. 261.1) [1].

Cortisol is necessary for the synthesis of adrenergic receptors, normal immune function, wound healing, and vascular tone. The majority of circulating cortisol is bound to corticosteroid-binding globulin (CBG). At normal levels of total plasma cortisol (e.g. 375 nmol/L or 13.5 μg/dL) less than 5% exists as free cortisol in the plasma.

In sepsis and critical illness, the beneficial effects of corticosteroids are thought to be mediated through two mechanisms—immune modulation and cardiovascular modulation. Corticosteroids modulate the transcription of an array of, mainly, nuclear factor-κB (NF- κB) regulated genes that contribute to inflammation. The synthesis of interleukin-1 (IL-1), interleukin-6 (IL-6) and tumour necrosis factor (TNF)-alpha is inhibited, as is inducible cyclo-oxygenase 2 (COX2) and inducible nitric oxide synthase (iNOS) [2].Corticosteroids also enhance the vasoconstrictor response to vasopressor drugs, in particular exogenous catecholamines. They mediate catecholamine release from neural cells and stimulate noradrenaline to adrenaline conversion by the enzyme phenylethanolamine-N-methyltransferase (PNMT) [3].

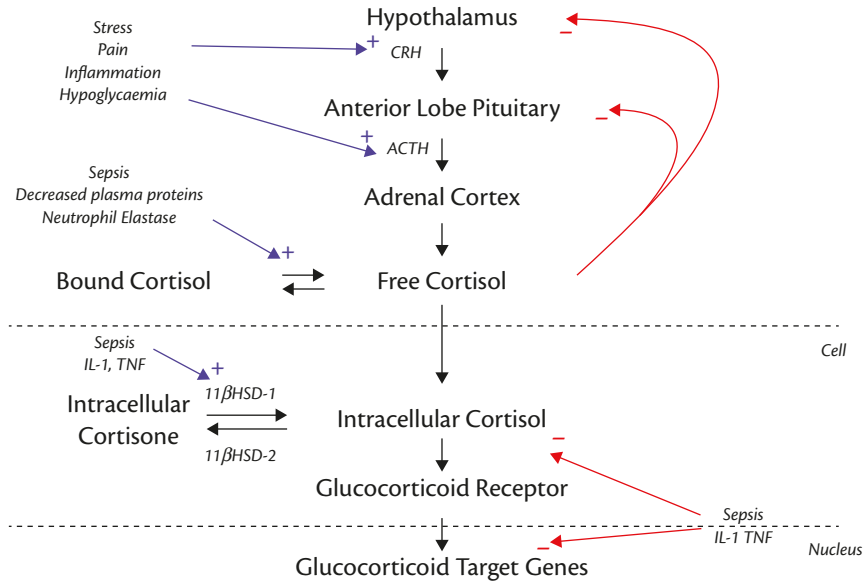

Fig. 261.1 Factors affecting secretion and effect of cortisol.

Normal adrenocortical response to stress

A functioning adrenocortical response appears to be essential for survival from significant stress. Adrenalectomized animals have 100% mortality from induced septic shock [4], and patients with non-functioning adrenal glands require supplemental glucocorticoid treatment during periods of severe illness [5]. Exposure to stress results in cortisol secretion that is transported to the tissues in three fractions. Approximately 80% is closely bound to CBG, 10–15% loosely bound to albumin, and 5–8% as a free fraction. Binding of cortisol to CBG is modulated by temperature, local tissue elastases, including neutrophil elastase, through which inflammatory cells may potentiate cortisol release, and through other tissue factors [6–8]. The relative proportions of cortisol present in these three fractions depend on cortisol levels; for example CBG is saturated at cortisol levels above 500nmol/L although, in sepsis, CBG levels are much reduced due to inhibition of synthesis by inflammatory cytokines such as IL-6 or increased consumption through CBG cleavage by elastases.

Adrenal insufficiency in critical illness

The pivotal role of the hypothalamo-pituitary adrenal axis in the response to critical illness has necessarily resulted in it becoming a focus of research. Structural disruption of the axis results in well recognized clinical sequelae, although the role of functional inadequacy of the system, particularly the need for glucocorticoid supplementation, remains controversial.

Structural inadequacy

The catastrophic consequences of destruction of the adrenal glands were first described by Thomas Addison in 1855. In the western world primary adrenal insufficiency, or Addison's disease, is an uncommon disorder, with an estimated prevalence of 120 per million. However, it remains an important differential diagnosis in the ICU as it can present as refractory circulatory shock, and failure to recognize it may be disastrous.

In adulthood, the commonest cause is autoimmune, but in the intensive care setting, possibilities of adrenal haemorrhage from coagulopathy, sepsis, and infiltration need to be considered. Tuberculosis is the commonest infective cause worldwide, but fungal infections, such as histoplasmosis, coccidiomycosis, and infections with cytomegalovirus (especially in patients with human immunodeficiency virus (HIV)) must be considered. Haemorrhage into the glands is associated with septicaemia, particularly meningococcal (Waterhouse–Friedrichsen syndrome). Secondary adrenal insufficiency is said to occur when there is damage or suppression of the hypothalamus or pituitary. This may occur secondary to tumours, trauma, or cranial irradiation, although the commonest cause is chronic exogenous glucocorticoid administration.

Addison's disease may present with gradual, ill-defined symptoms, including weight loss, anorexia, nausea, generalized weakness, myalgia, and postural hypotension. Hyperpigmentation may occur in areas of the skin exposed to friction, such as palmar creases and oral mucosa. This effect is caused by stimulation of the MC-1 receptor by ACTH and other pro-opiomelanocortin-related peptides, and is not seen in secondary disease.

Acute presentation of adrenal crisis may be precipitated by concurrent infection, surgery or trauma. The cardinal feature is circulatory shock that is refractory to both fluid resuscitation and vasoactive therapy. Diffuse abdominal pain or fever may also be present and this combination can mimic an acute surgical abdomen.

Suggestive features of adrenal crisis include a history of symptomatology consistent with the diagnosis, and demonstration of hyponatraemia, hyperkalaemia, and peripheral blood eosinophilia. A non-anion gap acidosis may be present. Random plasma total cortisol taken during a crisis will be low (below 80 nmol/L), and is diagnostic. Treatment should not be while awaiting the results of adrenal testing, and should consist of immediate supportive measures, fluid resuscitation, and high-dose intravenous glucocorticoid therapy. Hydrocortisone is the steroid of choice as in the doses recommended it also has mineralocorticoid activity A standard dose would be 100 mg hydrocortisone 6-hourly, or as an infusion.

Functional inadequacy

Functional inadequacy of the hypothalamo-pituitary adrenal axis occurring in the setting of critical illness is a more nebulous phenomenon. Pathophysiological changes induced by severe stress may result in a response that is not commensurate with the severity of the stimulus that evoked them. This syndrome is termed 'relative adrenal insufficiency (RAI)' or, more recently, critical illness-related corticosteroid insufficiency (CIRCI) [10,11]. A reduced incremental response to a standard short tetracosactride test performed during critical illness is associated with increased mortality. Additionally, exogenous glucocorticoid administration has been observed to reduce vasopressor requirements. In contrast to primary adrenal insufficiency, patients with CIRCI do not have obvious macroscopic evidence of adrenal gland damage or destruction, and often have high baseline circulating cortisol levels.

While the majority of the studies in this area have focused on patients with septic shock, CIRCI has been described in a wide variety of critical illnesses including liver disease, trauma, burns, and pancreatitis. Diagnosis of CIRCI is based upon the measurement of total plasma cortisol concentrations; either at baseline or following administration of synthetic ACTH. While numerous diagnostic criteria have been proposed in the literature, more recent consensus suggests a threshold of a cortisol increment under 250 nmol/l (9 μg/dL) in response to the short tetracosactride test indicates adrenal insufficiency.

Postulated mechanisms of glucocorticoid insufficiency in sepsis

Several mechanisms have been put forward to explain, why adrenal insufficiency might develop in sepsis [12]. These include impaired CRH and ACTH secretion from necrosis or haemorrhage in the hypothalamus or pituitary from hypotension, and coagulopathy in sepsis, inhibition of ACTH secretion through activation of opiate receptors by fentanyl a commonly used sedative agent, neuronal apoptosis, and cytokine mediated.

Primary adrenal failure from adrenal haemorrhage, adrenalitis from the primary pathogen and pharmacological suppression of cortisol synthesis by drugs used in critical illness are other mechanisms. Altered peripheral cortisol metabolism through the hydroxysteroid dehydrogenase enzyme systems, altered tissue delivery, and tissue glucocorticoid resistance are other mechanisms contributing to hypoadrenalism.

Controversy with the concept of CIRCI

The primary debate around the utility of the CIRCI diagnosis is whether it constitutes an appropriate indication for adjunctive glucocorticoid treatment [13,14]. Conceptually, the possibility of being able to identify and treat patients with a hypofunctioning adrenal axis is extremely appealing. However, studies of glucocorticoid treatment for patients in septic shock based upon the short tetracosactride test (SST) have returned conflicting results. Glucocorticoid treatment based upon the results of the short tetracosactride test has also been advocated in cirrhosis and multiple trauma, but the available studies are small scale and have not been replicated.

Diagnostic criteria

Many different diagnostic criteria based on cortisol responses have been proposed [13,14], the most common of which suggest either a minimum threshold random cortisol measurement during critical illness, or either a minimum peak or minimal response in plasma cortisol following a standard tetracosactride test. **The uncertainty in the diagnosis of RAI** is clearly evident from the widely varying observed incidence in the different studies depending upon which diagnostic criteria are used (Table 261.1) [13]. There are limitations in using total cortisol levels:

- Critically-ill patients appear to have wide plasma cortisol profiles irrespective of the severity of stress. The 'normal' range of cortisol in critical illness is not defined.
- There is marked variability in plasma cortisol profile, such that a random cortisol has limited diagnostic utility.
- There are gender differences in plasma cortisol response to stress.
- A high degree of variability exists between cortisol assays, which may potentially confound the diagnosis of RAI.
- There is marked dissociation between total and free cortisol (the 'bio-active fraction') with respect to 'response to stress'

There are also limitations in using the tetracosactride test:

- The standard 250 μg dose may result in supraphysiological concentrations of corticotrophin and may mask secondary adrenal insufficiency.
- There is marked dissociation between total and free cortisol with respect to tetracosactride stimulation.
- A number of other variables, such as plasma protein concentrations, adrenal blood flow, and body composition impact on the tetracosactride response.

Further issues that complicate the diagnosis of CIRCI have arisen from a greater insight into the changes that occur in glucocorticoid physiology in response to critical illness [13,14]. These include a relative increase in unbound cortisol concentrations, changes in intracellular cortisol metabolism through the activation of the 11β-HSD1 system, and alterations in glucocorticoid receptor expression and glucocorticoid target gene expression induced by the various inflammatory cytokines and stress. Reduced cortisol clearance, potentially as a result of a suppression of 11β-HSD2 activity also appears to be of importance [15]. These changes have the potential to substantially alter glucocorticoid activity in different tissues in a fashion that may not be reflected by circulating plasma cortisol concentrations. Therefore, the identification of patients who may be glucocorticoid deficient at a tissue level remains problematic.

Other dynamic tests for adrenal insufficiency

The insulin tolerance test (ITT) and the metyrapone tests are two other dynamic endocrine investigations which are used in the non-critically-ill patient. They are associated with significant adverse effects and thus have no place in the routine adrenal assessment in the ICU patient. Their role in the critically-ill patient remains to be determined. The glucagon stimulation test is another test of hypothalamo-pituitary adrenal axis integrity and thought to be equivalent to that of the ITT, but little data exist on its usefulness in critical illness.

The free cortisol fraction may represent a more valid measurement of circulating cortisolaemia than total cortisol. Standard

Table 261.1 Diagnostic criteria for adrenal insufficiency in critical illness

Study	Incidence of RAI	Study	Incidence of RAI
Corticotropin response criteria		Peak or baseline cortisol criteria	
Corticotrophin response < 250 nmol/L		**Peak cortisol < 700 nmol/L**	
Rothwell (1991)	40%	Bourne(2003)	40%
Bouachoar (1995)	75%

measurement techniques do not distinguish between the two, so in circumstances where plasma protein levels are abnormal, such as critical illness, measurement of total cortisol concentrations alone may be misleading. Data from trials in critically-ill patients suggest that plasma free cortisol may be superior to total cortisol in assessing adrenocortical function [16].

Hyperadrenalism

Admission to intensive care with a primary diagnosis of hyperadrenalism is uncommon. Moreover diagnosis of hypercortisolism during critical illness is complicated by the fact that patients frequently have raised plasma cortisol levels that are not suppressible by dexamethasone [17]. Patients usually present with one of the manifestations of a steroid storm requiring intensive care support, such as uncontrolled hypertension in pregnancy [18], electrolyte abnormalities, or encephalopathy [19]. Patients with hyperadrenalism may present to the ICU following a laparoscopic adrenalectomy for a cortical adenoma for peri-operative support.

Treatment of these conditions is largely supportive. Medical suppression of cortisol secretion may be undertaken with etomidate infusions; surgical excision of an adenoma, where present, may be the definitive procedure.

CHAPTER 262

Pathophysiology and management of pituitary disorders in the critically ill

Yves Debaveye and Greet Van den Berghe

Key points

- Prompt administration of hydrocortisone, in 'stress dosage', is the single most important acute medical intervention in patients with hypopituitarism.
- Pituitary surgery is often followed by transient abnormalities of antidiuretic hormone secretion and subsequent disorders of water balance (diabetes insipidus and syndrome of inappropriate antidiuretic hormone (SIADH)).
- Diabetes insipidus is hallmarked by an abrupt onset of polyuria, hypernatraemia, and urinary hypotonicity.
- Management of diabetes insipidus includes the correction of free water deficit and the reduction of polyuria with desmopressin.
- Restriction of fluid intake is the first-line treatment for SIADH in patients without hypovolaemia.

Introduction

The pituitary gland is sometimes called the 'master' gland of the endocrine system, because it controls the functions of all other endocrine glands. This makes the pituitary gland quite important, despite its small size.

Hypopituitarism

Hypopituitarism is the clinical syndrome that results from failure of the anterior pituitary gland to secrete one or more of its hormones adequately.

Hypopituitarism can result from intrinsic hypothalamic or pituitary lesions, or extrinsic extrasellar disease that impinges on, infiltrates, or destroys the hypothalamus, pituitary stalk, or pituitary gland [1,2]. All disorders can have an 'organic' or 'functional' origin; the latter has potential for reversibility (Box 262.1).

A critical care specialist may have to deal with hypopituitarism as a recognized pre-existing disease that requires appropriately continued treatment during intercurrent illness, acute exacerbation of an undiagnosed insufficiency evoked by surgery or disease, sequels of recent neurosurgery, cerebral trauma, infection, or shock, or temporary dysfunction induced by the stress of the critical condition itself and/or its therapy.

Clinical manifestations and diagnosis

Symptom presence and severity depends on the amount and rapidity of hormone depletion. Clinical manifestations of hypopituitarism are non-specific and closely match those of the primary deficiency or hypofunctioning of target glands [2]. The most acute clinical presentation occurs with pituitary apoplexy [3,4]. This is caused by sudden haemorrhage or infarction of a pituitary adenoma, and is characterized by headache, visual deficits, ophthalmoplegia, alterations in mental status, and circulatory collapse secondary to acute loss of ACTH with subsequent cortisol deficiency.

The endocrine assessment involves plasma ACTH, cortisol, T4 and T3, IGF-1, FSH, LH, oestradiol, testosterone, and prolactin. Note that TSH is not helpful in making the diagnosis of central hypothyroidism and that growth hormone is not typically measured as its secretion is pulsatile. Plasma electrolytes should also be measured in the initial evaluation as hyponatraemia is present in TSH and ACTH deficiencies, and hypernatraemia may suggest concomitant diabetes insipidus (DI) [2,5]. If visual disturbances occur prompt diagnostic imaging and neurosurgical consultation are mandatory.

Treatment

Acute decompensated patients with suspected hypopituitarism should be admitted to an intensive care unit (ICU) for immediate and adequate treatment that comprises:

- General supportive measures to ensure haemodynamic stability.
- Replacement of the missing hormones.
- Identification and treatment of the causative stressor.

After a diagnostic blood sample has been obtained prompt administration of hydrocortisone, in 'stress dosage', is the single most important acute medical intervention [3,4,6]. Replacement of other hormones is mostly not required in the hyperacute setting. If underlying infection is suspected broad-spectrum antibiotic coverage is advised pending culture results. During treatment, electrolyte and glucose levels must always be carefully monitored and corrected, particularly if concomitant DI is suspected. As absence of cortisol inhibits free water clearance in these patients, glucocorticoid administration may induce or aggravate diabetes insipidus (DI) [2,5].

Box 262.1 Aetiology of hypopituitarism

Hypothalamic

Hypothalamic or central nervous system disease

- Organic:
  - Developmental.
  - Traumatic.
  - Inflammatory.
  - Neoplastic.
  - Idiopathic.
- Functional:
  - Stress.
  - Anorexia nervosa.
  - Renal failure, hepatic failure, uncontrolled DM.
  - Prolonged critical illness.
  - Drugs (dopamine, somatostatin, glucocorticoids, etc.).

Stalk trauma or compression

Pituitary

- Organic.
  - Developmental aplasia or hypoplasia.
  - Traumatic or post-neurosurgical.
  - Inflammatory or infiltrative (infectious or systemic disease).
  - Ischaemic (Sheehan postpartum pituitary necrosis, DM, arteritis, eclampsia).
  - Pituitary apoplexy.
  - Neoplastic, miscellaneous.
- Functional.
  - Drugs (dopamine, somatostatin).

Extrasellar disease

Post-operative management following pituitary surgery

Pituitary surgery (PS), especially transsphenoidal PS, is a commonly performed neurosurgical procedure. All patients require a meticulous multidisciplinary pre-operative evaluation as many patients present with significant pre-operative systemic manifestations, especially patients with Cushing's disease and acromegaly. Ideally, serious systemic disease secondary to pituitary dysfunction should be controlled prior to surgery.

Adenoma specific comorbidities

Acromegalic patients often have macroglossia and hypertrophied soft tissue of the upper airway, making endotracheal intubation potentially difficult and obstructive sleep apnoea (OSA) common in this population [7]. Also, Cushing's disease is associated with OSA and predisposition to difficult intubation, so that narcotics and benzodiazepines should be used with caution.

In both patient groups, there is a high incidence of glucose intolerance or overt diabetes mellitus (DM), arterial hypertension, and ventricular hypertrophy with diastolic dysfunction. As the risk of thromboembolic complications is increased in Cushing's syndrome, peri-operative prophylaxis is warranted. Finally, one should avoid catheterizing the radial artery of an acromegalic patient, as blood flow through the ulnar artery is compromised in up to 50% of patients [8]. It is also imperative that hyperthyroidism is controlled before patients with thyrotropic (thyroid-stimulating hormone (TSH) producing) adenomas undergo surgical resection.

Post-neurosurgical follow-up

Although the majority of these patients do not experience complications, a significant component of post-operative care is devoted to vigilant monitoring for neuroendocrine abnormalities with initiation of appropriate intervention whenever necessary. In addition, awareness is required of other complications inherent to resection of pituitary tumours, such as visual loss, cerebrospinal fluid (CSF) leakage and meningitis (9–12).

All patients should undergo a thorough physical examination repetitively with special attention to cranial nerve function, including assessment of visual acuity, visual fields, and extra-ocular motility. The proximity of cranial nerves II–VI to the pituitary gland makes a post-operative cranial nerve palsy a feared complication. Any new post-operative neurological finding should be addressed with either immediate post-operative imaging or re-exploration in the operating room in case of visual field deficit (9–12).

In addition, patients should be questioned about rhinorrhoea or fluid leakage down the back of the throat. Although some nasal drainage is expected in the post-operative period, suspicious drainage should be further investigated. Drainage may be collected and analysed for the endogenous marker of CSF-leakage, beta-2 transferrin, to confirm or refute the diagnosis [9–12]. Post-operative CSF-leakage is best treated by operative repacking of the defect with autologous adipose tissue.

Meningitis is an infrequent complication of PS. When clinical suspicion is high, empiric broad-spectrum intravenous antibiotic coverage should be started immediately following lumbar puncture (LP). Duration of antibiotics is typically 14 days and adjustments are guided by LP cultures and sensitivity results. It is recommended that at least one repeat LP is performed to document clearing of CSF and appropriate response to antibiotic administration.

The most common post-PS complaint is headache, which may be treated with paracetamol, non-steroidal anti-inflammatory drugs and narcotics [12]. Narcotics should be used with care in patients with OSA.

Routine pharmacological post-operative nausea and vomiting (PONV) prophylaxis is advisable as nearly 40% of patients experience PONV and because of the detrimental effect of vomiting on intracranial pressure [12].

Peri-operative corticosteroid administration

At most centres, patients who undergo PS are given hydrocortisone 50–100 mg every 6–8 h intravenously for several days before being gradually weaned [9,11]. This is often not necessary and post-operative corticoid supplementation is rarely

required beyond the first 24 hours. In a more modern approach, patients receive peri-operative hydrocortisone, 50 mg every 6 hours, with the last peri-operative dose given on the morning of post-operative day 1. During the mornings of post-operative days 2 and 3, serum cortisol levels are assessed. Patients with two consecutive cortisol values ≤8 μg/dL should receive hydrocortisone replacement treatment. Patients who are already receiving corticosteroid replacement pre-operatively should have gradual dose reduction to their replacement dose during their hospitalization [10–12].

Patients with Cushing's disease are managed somewhat differently. Traditionally, dexamethasone is preferred because it does not interfere with post-operative endogenous cortisol assays [9]. However, recent publications advise avoiding all peri-operative corticosteroid administration [10–12]. Instead they obtain serum cortisol levels every 6 hours post-operatively to document laboratory evidence of disease remission. Patients should be monitored closely for clinical signs of hypocortisolaemia, including malaise, nausea, tachycardia, hypotension, and hypothermia, which in general does not appear until 24–36 hours post-operatively. Hydrocortisone is withheld until patients have hypocortisolaemia symptoms with low serum cortisol levels (usually <2μg/dL). If hypocortisolaemia does not develop, consideration is given to prompt surgical re-exploration. This approach is only possible if the hospital laboratory is able to report serum cortisol levels rapidly (<1 hour) [10–12].

Box 262.2 Causes of diabetes insipidus

Central

- Familial.
- Neurosurgery.
- Neurotrauma.
- Tumours: craniopharyngioma, hypothalamic glioma, metastatic carcinoma, meningioma, lymphoma.
- Intracranial hypertension.
- Brain death.
- Infections: cerebral abscess, meningitis, encephalitis, tuberculosis.
- Infiltrations: sarcoidosis, hystiocytosis X, haemochromatosis.
- Vascular: aneurysm, haemorrhage, thrombosis.
- Autoimmune disorder.
- Idiopathic.

Nephrogenic

- Familial.
- Hypercalcaemia.
- Hypokalaemia.
- Drugs: lithium, cidofovir, foscarnet, amphotericin, glibenclamide, demeclocycline.
- Amyloidosis, Sjögren syndrome.
- Sickle cell disease/trait.
- Post-obstructive polyuria.
- Pregnancy (placental production of vasopressinase).
- Idiopathic.

Other anterior hormone assessment

Although the pituitary thyroid axis may be disrupted at the time of PS, patients without pre-operative hypothyroidism should not be screened in the immediate post-operative period. Patients with known pre-operative hypothyroidism continue their pre-operative replacement therapy.

Post-operative assessment of growth hormone and gonadal function is also reserved for a later post-operative visit by the endocrinologist [9].

Disorders of water balance

Abnormalities of antidiuretic hormone (ADH) secretion and subsequent disorders of water balance are among the most common complications of patients undergoing PS [9–12].

Post-operative DI typically manifests in the first 24–48 hours after surgery. DI is observed in up to one-third of patients and is almost always transient. Since the majority of post-PS patients have an intact thirst mechanism, they are able to keep up with ongoing urinary losses and development of hypernatraemia is rather uncommon post-PS. When desmopressin is administered, a single dose may be sufficient and close monitoring of urine output and serum electrolytes is mandatory to avoid 'overshoot' hypernatraemia. For early detection of DI, it is recommended that urinary output and osmolality (or specific gravity) be measured routinely after PS [9–12].

It is important to distinguish DI from other causes of post-operative polyuria (Box 262.2). Note that acromegalic patients often have robust physiological diuresis after successful tumour resection, and early treatment with desmopressin should be avoided.

Hyponatraemia due to syndrome of inappropriate antidiuretic hormone secretion (SIADH) is observed in up to 25% of patients who underwent PS [9,10]. In SIADH, an injured posterior pituitary continues to secrete ADH regardless of plasma osmolality. If patients continue to drink or are administrated intravenous (iv) fluids, free water intake exceeds free water excretion while the kidney's ability to handle sodium remains intact. It is characterized by hyponatraemia (<135mmol/L), hypo-osmolality (<280mOsm/L), and inappropriately concentrated urine (> serum osmolality) in a setting of euvolaemia and normal renal, adrenal, and thyroid function [9,10,12].

The diagnosis of SIADH is mostly biochemical. However, symptoms such as headache, dizziness, nausea, vomiting, and altered mental status and seizures may arise if the onset of hyponatraemia is particularly rapid.

When making a diagnosis of SIADH, it is important to distinguish other causes of hyponatraemia, especially those associated with PS, such as hypocortisolism, hypothyroidism, and DM. Perhaps the most important clue to distinguish SIADH from other causes of hyponatraemia is the time frame in which it occurs. SIADH typically becomes manifest a week after surgery, which is much later than the other conditions described [5,9,10,12–15].

Restriction of fluid intake is the first-line treatment for SIADH in patients without hypovolaemia. In patients with severe (<120 mmol/L), symptomatic hyponatraemia hypertonic saline (3 or 1.8%) can be added to fluid restriction in order to restore serum sodium quickly, remembering only partial restoration is required. Excessive rapid correction (>0.5–1mmol/L/hour) should be avoided to prevent the rare, but serious complication of central pontine myelinolysis. In cases of severe or resistant hyponatraemia urea (iv or by mouth (po)) may be considered as adjunct therapy.

Diabetes insipidus

Vasopressin or ADH is secreted by the posterior pituitary. ADH increases water permeability in distal renal tubules and collecting ducts, resulting in an enhanced water reabsorption and urine concentration [5,13–16]. Consequently, insufficient production of ADH (central DI) or inadequate response of the renal tubules to ADH (nephrogenic DI) results in excretion of large volumes of hypotonic fluid (Box 262.3). This inability to conserve water is primarily reflected by polyuria (>2 mL/kg/hour), that does not decrease with reduction in fluid intake, and polydipsia. The main laboratory finding in critically-ill patients with DI is hypernatraemia.

In alert patients with an unimpaired thirst mechanism the polyuria and polydipsia are inconvenient, but not detrimental as these patients are able to drink sufficient amounts of water to maintain normal serum osmolality [5,13–16]. Most critically-ill patients, however, do not sense and/or cannot respond to thirst, and will rapidly develop dehydration, hyperosmolality, and hypernatraemia.

Clinical features and diagnosis

The hallmark of DI is an abrupt onset of polyuria. Because polyuria is not specific to DI, it is essential to exclude other causes of polyuria (Box 262.3) before treatment is initiated. Note that primary polydipsia, a classically cited possible cause of hypo-osmotic polyuria, is essentially excluded in the setting of hypernatraemia and plasma hyperosmolality.

Box 262.3 Causes of polyuria in the ICU

- Excessive fluid administration.
- Diuretic drugs.
- Primary polydipsia.
- Osmotic diuresis:
  - Mannitol.
  - Hyperglycaemia.
  - Intravenous contrast agent myogloburia.
  - Post-obstructive diuresis.
  - Recovery phase of acute kidney injury.
- Diabetes insipidus:
  - Central.
  - Nephrogenic.
- Post-tumour resection in acromegalic patients.

The classical diagnostic test of DI, the water deprivation test, should not be used in the ICU-setting as most critically-ill patients with DI are already hypernatraemic, and deliberate induction of hypovolaemia is potentially dangerous, since it may provoke haemodynamic instability. The diagnosis of DI in critically-ill patients can be made by demonstrating plasma hyperosmolality (≥295 mOsm/kg) and hypernatraemia (mostly ≥145 mmol/L) in the face of hypo-osmolar (usually ≤250 mOsm/kg) polyuria.

Treatment

Mild cases of DI can often be managed by adequate fluid replacement, in the form of glucose-containing water solutions to correct the loss of free water. Use of saline solutions is inappropriate as it represents an unnecessary solute load that further increases renal water loss. Careful routine monitoring of body weight, plasma sodium and osmolality, and fluid input and urinary output are essential. Collectively, these data provide serial information regarding fluid balance and allow adaptation of treatment when necessary.

Other electrolytes, such as potassium, magnesium, and phosphate, should be evaluated, since deficiencies can develop rapidly in polyuric patients and monitoring allows timely titrated replacement.

In patients with excessive polyuria administration of the synthetic ADH-analog desmopressin may be necessary to prevent the development of significant volume contraction and hyperosmolarity with severe hypernatraemia. Desmopressin, typically dosed at 1–2 μg subcutaneous or iv bd, is safer than vasopressin, as it lacks undesirable pressor effects.

Careful monitoring of fluid balance is essential because of the possibility of 'breakthrough' polyuria at a low desmopressin dose, and the risk of fluid overload and hyponatraemia at higher doses. Excessive infusion of hypotonic (5% glucose) fluid in the setting of demopressin-driven antidiuresis carries a high risk of profound hyponatraemia. An increase of urine output (hypo-osmotic polyuria) should be tolerated before administration of the next desmopressin dose. Maintenance of hypotonic fluid replacement should be switched from iv to po as soon as the patient is able to sense thirst and drink adequate amounts of water. Indeed, if the patient's thirst mechanism is intact, this is the best guide for adequate water replacement, while avoiding over-replacement.

Patients with nephrogenic DI do not, or only partially, respond to desmopressin [13,16]. In adults, a urinary concentrating disability severe enough to produce polyuria due to nephrogenic DI is most often due to hypercalcaemia or chronic lithium use. Therapy includes discontinuation of the causative drug and correction of the underlying disorder. Normalization of plasma calcium concentrations usually ameliorate polyuria in hypercalcaemic patients. In contrast, lithium-induced renal DI is frequently irreversible if the patient already has a notable renal concentrating defect.

Thiazide diuretics (such as hydrochlorothiazide 12.5–25 mg, od or bd) may diminish the degree of polyuria via volume contraction and enhanced tubular water reabsorption.

CHAPTER 263

Pathophysiology and management of thyroid disorders in the critically ill

Michael O'Dwyer and David Watson

Key points

- Thyroid hormones act on most tissues via nuclear T_3 receptors.
- Thyroid hormones stimulate oxygen consumption and heat production, influence cell growth, and maturation (central nervous system, bone) and modulate metabolism (carbohydrates, lipids, proteins, drugs).
- Treatment for presumed thyroid disease frequently has to be initiated before the results of diagnostic tests are available.
- Treatment of hyperthyroidism should result in the reduction of serum thyroid hormone levels and their action on peripheral tissues with concurrent treatment of the precipitating event.
- In severe hypothyroidism the choice of thyroid hormone (thyroxine or triiodothyronine), optimal dosing, and the route of administration remain controversial.

Basic pathophysiology

The primary function of the thyroid gland is to produce tetraiodothyronine (T_4) and triiodothyronine (T_3) from iodide and tyrosine. While this pathway is the sole endogenous source of T_4, the majority of T_3 is derived from peripheral conversion of T_4 to T_3 in the liver and kidneys. This conversion is frequently inhibited by physiological stressors such as severe trauma and critical illness [1]. In addition, calcitonin produced by the thyroid parafollicular cells regulates calcium levels.

The half-life of T_4 is approximately 7 days and that of T_3 is approximately 24 hours. Both hormones are highly protein bound with the free hormones (FT_3 and FT_4) having physiological effect. The greater effect attributed to T_3 is largely explained by the relatively greater amount of FT_3 compared with FT_4 (0.4% versus 0.04% of the T_3 and T_4, respectively) [2]. The ultimate effect of free hormone binding to intracellular receptors is an increase in cellular energy output. These receptors are particularly abundant in cells of the heart, brain, and liver, where they are involved in the regulation of basal metabolism and heat production.

Thyroid-stimulating hormone (TSH), from the anterior pituitary, controls the production and release of thyroid hormones. Levels of TSH are in turn regulated by levels of FT_3 and FT_4 and also by hypothalamic thyrotropin-releasing hormone (TRH), which is itself regulated by higher neural centres and by feedback from circulating thyroid hormone levels [3].

The incidence of recognized thyroid disease remains under 5% in western populations. Thyroid crises are rarer still, yet untreated or poorly managed thyroid storm and myxoedema coma are frequently fatal.

Hyperthyroidism

Hyperthyroidism is a clinical syndrome caused by exposure of the body tissues to excess circulating levels of FT_3 and FT_4. Table 263.1 shows the cause of most cases.

Graves' disease

Graves' disease is an autoimmune condition associated with diffuse thyroid enlargement, opthalmopathy and proptosis, and pretibial myxoedema. The binding of IgG thyroid stimulating antibodies to the TSH receptor stimulates thyroid hormone production. The pathogenesis of the opthalmopathy and dermopathy is also believed to be immunologically mediated. Although the disease trigger has yet to be definitively identified, the frequent sudden presentation in middle age suggests an infective aetiology coupled with a genetic predisposition [4].

Toxic multinodular goitre and solitary nodule

In some patients a simple diffuse goitre may progress over decades, stimulated by thyroid-growth immunoglobulins, to a multinodular goitre with areas of autonomous function. Hyperthyroidism then develops in middle or old age.

A toxic solitary nodule is a follicular adenoma, which autonomously secretes thyroid hormones, while inhibiting TSH secretion, which causes subsequent atrophy of the rest of the gland [5].

Excess administration of iodide

While large amounts of available iodide usually inhibit hormone production through a negative feedback mechanism it may paradoxically induce hyperthyroidism, particularly in patients who are relatively iodide deficient. Iodide excess may come from dietary supplements or medication (e.g. antitussive agents, amiodorone, or radio-angiographic contrast agents). This paradoxical hyperthyroidism is termed the Jod–Basedow effect [6].

Table 263.1 Causes of hyperthyroidism

Common causes (>90% of cases)	Rare causes
◆ Graves' disease	◆ Excess pituitary secretion of TSH
◆ Toxic multinodular goitre	◆ Metastatic differentiated thyroid carcinoma
◆ Toxic solitary nodule	◆ Ovarian teratoma-containing thyroid tissue
◆ Overdose of thyroid hormones	◆ Intrinsic thyroid-stimulating activity of human chorionic gonadotropin in hydatid form mole and choriocarcinoma
	◆ Excess administration of iodide

Thyrotoxic crisis (thyroid storm)

A thyrotoxic crisis is a life-threatening increase in the severity of the clinical features of hyperthyroidism. This is most commonly precipitated by infection in a known hyperthyroid patient who is inadequately controlled by antithyroid drugs or alternatively has unrecognized Graves' disease. It may also be precipitated by surgery (particularly subtotal thyroidectomy in an inadequately prepared patient), trauma, labour, or iodine therapy. FT_3 and FT_4 are usually elevated although levels do not always correlate with severity of illness. TSH is usually undetectable.

Clinical presentation

Cardiorespiratory features

Thyroid hormones exert their cardiac effects directly via specific nuclear receptors and also through central activation of the sympathoadrenal system. The increased basal metabolic rate, frequently exacerbated by pyrexia due to impaired thermoregulation, is associated with an increase in oxygen consumption and carbon dioxide production, and a hyperdynamic circulation. Consequently, patients are at risk of developing arrhythmias and myocardial ischaemia, while concurrent respiratory muscle weakness may lead to respiratory failure.

Neuromuscular features

An excess of thyroid hormones affects the concentration and distribution of assorted neurotransmitters. The resultant neurological features include severe agitation, psychosis, irritability, tremor, delirium, stupor, and seizures.

Proximal muscle weakness is common and may be the dominant manifestation in some individuals.

When present, dysphagia is usually secondary to weakness of the striated muscles of the pharynx as a consequence of hyperthyroidism-induced myopathy. Ocular muscle involvement results in ophthalmoplegia.

Gastrointestinal features

Patients with hyperthyroidism have a high incidence of gastrointestinal hypermotility. Gastritis is frequent and associated with malabsorption. This may complicate management with oral medications.

Rarely, jaundice can be a sign of an associated fulminant hepatic necrosis.

Electrolyte and haematological abnormalities

Hypercalcemia is observed in up to 15% of cases and can be life-threatening. Similarly, hypomagnesaemia and hypokalaemia are frequently observed.

Haematological manifestations include anaemia, thrombocytopenia, and eosinophilia with lymphocytosis.

Management

Although the diagnosis of a thyrotoxic crisis is largely clinical, response to treatment can be monitored both clinically and by falling T_3 levels.

Treatment strategies involve the following principals:

- Control the effects of circulating T_3 and T_4.
- Acutely reduce the synthesis and secretion of thyroid hormones and prevent peripheral conversion of T_4 to T_3.
- Treat the precipitating cause.

General/supportive measures

Supplemental oxygen and intravenous fluids should be administered following principals common to all critically-ill patients.

Some medications, such as salicylates and furosemide, should be avoided. Salicylates, sometimes used to limit pyrexia, displace thyroid hormones from their binding proteins. Furosemide has a similar effect.

Gastric lavage and activated charcoal may be of use in cases of witnessed, recent thyroid hormone overdose [7]. Cholestyramine may increase faecal elimination of the hormone.

Plasma exchange, charcoal haemoperfusion and dantrolene are all reported treatment strategies, but remain controversial [8].

Specific antithyroid treatments

Both propylthiouracil and carmbimazole impede the formation of thyroid hormone and prevent peripheral conversion of T_4 to T_3 [9]. Disadvantages include the lack of a parenteral preparation for these drugs, and also the development of bone marrow depression and a transient leucopenia.

Oral potassium iodide or Lugol's iodine are effective treatments, but their administration should be delayed for approximately 1 hour following the first dose of propylthiouracil. This is to minimize the possibility of excessive hormone release following iodination. Intravenous iodine preparations can be easily prepared.

Recently, radiographic contrast dyes, such as sodium ipodate, which contains iodine have been suggested as superior agents as they may also directly diminish the cardiotoxic effects of thyroid hormones. In addition, they potently inhibit the peripheral conversion of T_4 to T_3 and it is now suggested these are the iodine preparations of choice [10].

If patients are known to be sensitive to iodine then lithium carbonate should be considered as it has a similar mechanism of action [11]. Therapeutic drug monitoring is essential.

Cardiovascular management

Propranolol blocks the β-adrenoreceptor effects of thyroxine, impairs conversion of T_4 to T_3 and also inhibits release of thyroid hormone. β1 adrenergic selective antagonists, such as atenolol or the ultrashort-acting β blocker esmolol may be indicated in cases of cardiac insufficiency or airflow limitation.

Digoxin may prove useful in the treatment of rapid atrial fibrillation, particularly in amiodorone-induced thyrotoxicosis, but should be preceded by the correction of hypokalaemia. Dosage is affected by the accelerated metabolism of digoxin in thyrotoxicosis. Conversely, these patients are more sensitive to warfarin because vitamin K-dependent clotting factors are metabolized more rapidly.

Although amiodorone can cause hyperthyroidism it can control the acute arrhythmias observed in this setting and can additionally inhibit the peripheral deiodination of T_4 to T_3 [12]. Verapamil may also be useful in this setting to reduce the ventricular rate.

Steroids are also usually administered since relative hypoadrenalism may be present in severe hyperthyroidism due to the accelerated metabolism of cortisol. Glucocorticoids can also reduce the conversion of T_4 to T_3.

Ongoing management

The response to treatment of a thyrotoxic crisis should be monitored by recording clinical vital signs of sympathetic drive as well as regular serum T_3 estimations. Hyperthyroidism is usually brought under control after approximately 10 days and the iodide preparations and β blockers may then be withdrawn. Patients may subsequently be maintained on oral carbimazole.

Sick euthyroid syndrome

In critical illness abnormal thyroid function tests are frequently reported in the setting of a non-thyroidal illness and patients are described as having sick euthyroid syndrome. Many abnormalities of thyroid hormones are described but the most prominent are low T_3 and elevated reverse T_3. TSH and T_4 are affected to varying degrees. As the severity of the illness increases T_3 and T_4 fall.

Treatment with exogenous thyroid hormones is controversial with little data to guide clinicians [13].

Hypothyroidism

Deficiency of thyroid hormones may result in a broad range of presentations with a spectrum of illness that varies from an asymptomatic disease process through to coma with multisystem involvement. Predominantly, it is a primary process whereby the thyroid gland fails to produce adequate thyroid hormone. The most common cause is autoimmune thyroid disease (Hashimoto thyroiditis). Although less common, it can also be secondary to inadequate production of TSH or TRH.

Clinical presentation

Cardiorespiratory features

Bradycardia results from a reduction in basal metabolism accompanied by loss of thyroid hormone stimulation of cardiac pacemaker cells. Catecholamine levels are usually normal but there is reduced sensitivity to their actions resulting in reduced myocardial contractility [14]. T_4 deficiency contributes to this as it is a myocardial growth factor. However, chronic peripheral vasoconstriction, necessary to maintain normal body core temperature, leads invariably to diastolic hypertension [15].

Pericardial effusion is commonly described and contributes to the low voltage observed on an ECG. Accompanying ECG abnormalities include long QT interval and flattened or inverted T waves.

Cardiac ischaemia, partially due to altered lipid metabolism, is frequent in hypothyroidism and may become clinically apparent during thyroid hormone replacement therapy [16].

Sleep apnoea syndrome, when present, is usually of mixed origin with a reduction of central drive in conjunction with tongue enlargement, which contributes to an obstructive picture.

Neurological features

Somnolence, lethargy, coma, and seizures are features of myxoedema coma. Associated hyponatraemia may exacerbate these features.

Gastrointestinal features

Hypothyroidism frequently slows gastric emptying and inhibits motor activity of the small intestine and colon. Intestinal absorption of drugs is not always preserved [17].

Haematological features and electrolyte abnormalities

Normocytic anaemia is common and may be due to decreased erythropoietin production.

The total leukocyte count rarely exceeds 10,000, even if infection is the precipitating event. The presence of band cells indicates probable sepsis.

Increased fibrinolytic activity with high plasminogen and reduced activation of the plasminogen inhibitor may play a role in haemorrhage associated with severe hypothyroidism.

Dilutional hyponatraemia is a constant feature of myxoedema coma as high plasma levels of vasopressin lead to water retention.

Musculoskeletal features

Muscle contraction and relaxation are slowed in hypothyroidism and high plasma levels of muscle derived enzymes (transaminases, creatine phosphokinase and lactic dehydrogenase) are frequently observed.

1,25-OH vitamin D concentrations are increased, leading to decreased calciuria, which may partly explain the hypercalcaemia occasionally described in severely hypothyroid patients.

Dermatological features

Peripheral vasoconstriction and decreased cutaneous metabolism result in a cold, dry, and pale skin. There is thinning of the epidermis and deep wrinkles are present. Hair is scarce and grows slowly. However, only 40% of hypothyroid patients display the typical cutaneous infiltration.

Carbohydrate metabolism

The risk of severe and prolonged hypoglycaemia is high in hypothyroidism. Insulin clearance is reduced, and sensitivity to endogenous or exogenous insulin is increased. Gluconeogenesis is also decreased.

Myxoedema coma/crisis

Myxoedema coma is a rare yet life-threatening medical emergency. It usually presents as altered mental status and defective thermoregulation with a precipitating event usually in an elderly patient. The precipitant is often infection, but climate-induced hypothermia and drug therapy are also well described [18].

Successful management requires early diagnosis and prompt appropriate therapeutic measures.

Diagnosis of myxoedema coma

Clinical suspicion should trigger initiation of specific treatment. Baseline blood samples should be obtained for assays of TSH, FT_3, FT_4, and cortisol. The diagnosis is confirmed in the presence of elevated plasma TSH, and dramatic reduction of both FT_3 and FT_4.

Hypothermia

Passive rewarming using blankets and warm ambient temperature is usual. If patients are rewarmed too aggressively peripheral vasodilatation can precipitate cardiovascular collapse.

Cardiovascular assistance

Hypotension indicates an unfavourable prognosis as hypothyroidism is usually associated with mild diastolic hypertension. Myocardial infarction, gastrointestinal blood loss, and aggressive rewarming should not be overlooked as causes of hypotension. Echocardiography and troponin levels may help to make a definite diagnosis of myocardial dysfunction as levels of muscular enzymes are increased in hypothyroid patients and ECG abnormalities are also common even in the absence of myocardial dysfunction.

Caution is needed in treating congestive heart failure. There is a substantial risk of overdose when administering digitalis, diuretics, and afterload-reducing agents in patients with hypothyroidism.

Vasoactive drugs are ineffective until thyroid hormone and possibly glucocorticoids are replaced. They may, in fact, prove to be disadvantageous by precipitating dangerous arrhythmias.

Fluids and electrolytes

Fluid status should be monitored closely and intravenous glucose or normal saline administered if appropriate. As a dilutional hyponatraemia is usually present water restriction should be instituted first. Hypertonic saline followed by furosemide may be necessary in severe hyponatraemia.

Antibiotic therapy

Infection is a common precipitating cause of myxoedema coma. Diagnosis is difficult because elevation of leukocyte count and fever is rare. However, left shift and band formation usually signify infection.

Hormonal therapy

Steroid therapy

The possibility of coexistent adrenal insufficiency (Schmidt's syndrome) mandates intravenous empiric hydrocortisone treatment until baseline cortisol results are reported [19].

Thyroid hormone therapy

Thyroid hormone replacement treatment must begin promptly, often before confirmatory test results. As impaired gastrointestinal absorption can potentially be a feature of the disease process intravenous therapy is usual but not universal.

Choice of thyroid hormone (T_4, T_3, or both) and optimal dosage remain controversial [20]. To exert full biological effect, T_4 must be converted into T_3 by an enzymatic step involving 5'-deiodinase. In critically-ill patients or those on medications, such as amiodorone T_3 administration, may be advisable due to reduced 5'-deiodinase activity. However, T_3 can induce too rapid an increase in oxygen consumption adversely affecting cardiovascular and respiratory functions [16]. Although inconsistent, some observational studies have described an association between large doses of T_3 and increased mortality.

One treatment regimen is to use an intravenous loading dose of T_4 followed by a maintenance intravenous dose until the patient is able to take oral medications. Additional intravenous T_3 may be considered. The benefits of a loading dose and ongoing high dosing of T_4 plus the concurrent use of T_3 should be weighed against the cardiovascular risk, particularly in elderly patients.

Monitoring serum concentrations of TSH, FT_3, and FT_4 is not clinically useful during ICU treatment, but demonstrates a rapid increase of plasma FT_4 and a slower increase of FT_3, whereas TSH levels decrease only after a few weeks. The goal of maintenance treatment is to normalize TSH levels, a process which may take several months.

CHAPTER 264

Pathophysiology and management of functional endocrine tumours in the critically ill

Sara Nikravan and Frederick Mihm

Key points

- Carcinoid tumours may secrete bioactive products that can lead to carcinoid syndrome and valvular heart disease with right heart failure.
- Carcinoid shock and bronchospasm can be precipitated or worsened by use of beta-adrenergic agents.
- Pheochromocytomas are rare and potentially lethal catecholamine secreting tumours. They mimic or co-exist with more common diseases making recognition challenging.
- Extreme blood pressure lability during pheochromocytoma manipulation and shock after removal can be dramatic.
- Neuroglycopenic patients with increased systemic insulin levels should be evaluated for insulinoma, while being aggressively treated for hypoglycaemia in a monitored setting.

Carcinoid tumours

Carcinoid tumours are rare, well-differentiated neuroendocrine tumours of the aerodigestive tract. They can produce as many as 40 different secretory amine and polypeptides including serotonin, histamine, tachykinins, kallikrein, and prostaglandins [1,2]. Tumours are classified based on their origins of embryonic division with most functional carcinoid tumours originating from the midgut.

Pathophysiology

Most patients are asymptomatic with tumours discovered incidentally, typically in the appendix. Carcinoid syndrome occurs in 20–30% of carcinoid patients [3]. The liver inactivates bioactive products in the portal system, so gastrointestinal carcinoid tumours only cause carcinoid syndrome with widespread liver metastases, unlike bronchial and extra-intestinal tumours. The syndrome includes flushing, mostly on the face, neck, and upper chest in a serpiginous pattern [4]. The facial flush can appear very similar to a lupus rash (see Fig. 264.1). Most events are spontaneous, but can be provoked by eating, alcohol, defaecation, liver manipulation, stress, exposure to catecholamines, cardiopulmonary bypass, and general anaesthesia. Severe flushing, generalized vasodilation, and capillary damage can cause profound hypotension and tachycardia. Moderate to severe bronchospasm may also occur. These episodic events can be life-threatening, resulting in carcinoid crisis and shock, particularly if mismanaged. Other serious problems can result from local tumour manifestations, such as bleeding, intestinal obstruction, and/or perforation [2].

Diagnosis

The diagnosis is usually well established before severe decompensation requiring intensive care unit (ICU) admission. Laboratory confirmation can be made with a 24-hour urine collection for 5-hydroxyindoleacetic acid (5-HIAA) secretion, the end product of serotonin metabolism. Chromogranin A is a glycoprotein stored in the secretory granules of neuroendocrine cells and is elevated in >80% of carcinoid syndrome patients. Levels of this marker correlate with disease activity and tumour burden [5].

About 50% of patients with carcinoid syndrome develop carcinoid heart disease, presumably related to the release of vasoactive substances (serotonin, substance P) into the venous circulation, ultimately affecting the right heart and right heart valves. Patients will present with significant dyspnoea and fatigue, lower extremity oedema, and other signs of right heart failure. Constant exposure of these substances has been correlated to plaque formation on the endocardial surfaces of the heart leading to right heart valvular lesions (tricuspid > pulmonary), restrictive cardiomyopathy, constrictive pericarditis, pericardial effusion, and hypoxia secondary to intra-atrial shunting in the presence of a patent foramen ovale, which can develop as the disease progresses. Left heart valve lesions are generally not observed because the lungs actively metabolize serotonin (70% first pass). However, left-sided valvular lesions can

Fig. 264.1 Carcinoid rash associated with peri-operative carcinoid shock.

be observed with bronchial carcinoids and in patients who develop a patent foramen ovale, an independent mortality risk factor [5]. Median survival after diagnosis of carcinoid heart disease has improved from 1.5 to 4.4 years, and may be related to better selection of patients for valve surgery and better treatment strategies, particularly somatostatin [5].

Treatment

Somatostatin can be highly effective in treating carcinoid shock. It is a tetradecapeptide hormone, widely distributed throughout the CNS and peripheral nervous system, gastrointestinal tract, and pancreatic D cells. Somatostatin results in potent inhibition of hormone excretion (growth hormone (GH), thyroid-stimulating hormone (TSH), glucagon, insulin, prolactin, adrenocorticotropic hormone (ACTH), secretin, pancreozymin, vasoactive intestinal peptide (VIP), pancreatic polypeptide (PP), Gastrin), digestive enzymes (pepsin, pancreatic enzymes), while also decreasing intestinal motility and absorption (e.g. glucose). Analogs such as octreotide have a longer half-life and bind to somatostatin receptors on tumour cells, inhibiting the release of bioactive amines. They may also inhibit tumour growth [6]. Rare side effects include nausea, abdominal discomfort, and steatorrhoea. Most importantly, when given in acute settings, transient severe bradycardia and third degree heart block have been reported [7].

Pre- and intra-operative treatment with octreotide is crucial for protection against carcinoid crisis that can develop secondary to anaesthesia and/or tumour manipulation [8]. Intra-operative blood pressure lability can be supported by a 100 mg octreotide bolus or infusion (100 mg/hour). If carcinoid crisis does ensue, it is often refractory to fluid administration alone and, notably, can be exacerbated by administering beta-adrenergic agonists (including by inhalation) and/or calcium. The use of a pure alpha agonist, such as phenylephrine or a non-adrenergic drug like vasopressin, is recommended together with ongoing assessment of fluid requirements, as fluid sequestration may be dramatic. Since tricuspid regurgitation is common, beware of over-estimating CVP and subsequently under-resuscitating the patient. Drugs such as xylocaine and anti-cholinergic agents (ipratroprium) may be used for bronchospasm. If the patient is mechanically ventilated, it is vital to increase expiratory time to avoid breath-stacking and auto-PEEP.

Pheochromocytoma

Pheochromocytomas and catecholamine secreting paragangliomas (extra-adrenal pheochromocytomas) are rare tumours that arise from chromaffin cells of the adrenal medulla and sympathetic ganglia. If unrecognized and left untreated, they are almost certainly lethal. Approximately 95% of these tumours are located in the abdomen, 85–90% of which are intra-adrenal. About 10% are malignant. These tumours often go undiagnosed with vague paroxysmal symptoms. While they can occur at any age, pheochromocytomas most often develop in the 4th and 5th decades of life [9].

Pathophysiology

Pheochromocytomas can secrete a combination of norepinephrine, epinephrine, and very rarely, dopamine in a sustained or paroxysmal fashion. Patients can present with the classic triad of headaches, sweating, and tachycardia/palpitations. They most often have sustained or paroxysmal hypertension that can lead to hypovolaemia. This may cause orthostatic hypotension in some patients. Reflex bradycardia has also been described. Rarely, hypertension is absent, particularly in familial pheochromocytoma [9]. While symptoms can occur spontaneously, they can be precipitated by a number of factors, such as tumour palpation, trauma, exertion, valsalva, anxiety, pain, tyramine-containing foods or beverages, intubation, and induction of anaesthesia. Medications such as metoclopramide, phenothiazines, droperidol, amytriptiline, adrenocorticotropic hormone, glucagon, histamine, and illicit drugs, such as cocaine can also induce attacks. Hypercatecholaminaemia can cause significant weight loss, constipation or pseudo-obstruction, bowel ischaemia, all of the complications of severe sustained hypertension, and acute myocarditis (direct cardiac toxic effect of catecholamines) [9,10].

Diagnosis

The cumulative presence of headaches, sweating, and palpitations in the setting of hypertension makes the diagnosis likely. Patients with episodic symptoms may not be observed during catecholamine surges nor diagnosed with hypertension [11].

Besides clinical symptoms, certain routine laboratory findings raise the suspicion of pheochromocytoma. Hyperglycaemia in the absence of diabetes mellitus, hypertriglyceridaemia, and an unexplained elevated haematocrit (secondary to hypovolaemia and/or erythropoietin secretion from the tumour) may occur. Presence of lactic acidosis in the absence of shock may be noted as a result of persistent secretion of epinephrine. Pheochromocytoma may mimic many diseases, or rarely, co-exist with other disease processes (e.g. aortic dissection, thyrotoxicosis, etc.) [12]. Apparent hypotension occurs in the setting of extreme vasoconstriction. The patient is thought to be hypotensive because of an inability to measure blood pressure accurately when, in fact, they are experiencing a hypertensive crisis. Presenting features are varied and include, e.g. pulmonary oedema, congestive heart failure, angina or myocardial infarction, recurrent ventricular tachycardia, and lactic acidosis. There may be cardiomyopathy, peripheral vascular disease, gastrointestinal bleeding, hypertensive complications, or seizures.

Metanephrine and normetanephrine are formed by catecholamine metabolism inside the tumour. Diagnostic tests include plasma

fractionated metanephrines (normetanephrine and metanephrine) and catecholamines in addition to 24-hour urine excretion of free catecholamines, metanephrines, and vanillyl mandelic acid (VMA), the end product of catecholamine metabolism. Some recommend obtaining samples when patients are at a basal state, but this should not delay diagnosis in an unstable patient where pheochromocytoma is considered. Certain medications such as tricyclic antidepressants, levodopa, and other antipsychotics can interfere with laboratory interpretation. In many cases, these medications cannot be discontinued so diagnostic imaging should be used. Either CT or MRI is a reasonable first choice diagnostic imaging modality. Both suppression (clonidine) and provocative (histamine, metoclopramide, glucagon) testing have been used in the past, but are considered unnecessary and potentially dangerous. If diagnosis seems likely despite negative imaging, 123-I-metaiodobenzylguanidine (MIBG) scintigraphy can be used. MIBG is a norepinephrine-like compound that is taken up by adrenergic tissue, helping to detect presence of tumour(s). Diagnostic needle biopsy is dangerous and not recommended [13].

In pregnancy, pheochromocytoma can be distinguished from pre-eclampsia by tachyarrhythmias, hypertension before the 3rd trimester, and the lack of proteinuria.

Once diagnosed, it is important to evaluate the patient for evidence of catecholamine-induced cardiomyopathy, acute/chronic myocarditis, and/or any end organ damage. Appropriate diagnostics for heart disease include electrocardiogram (ECG), cardiac enzymes, and resting cardiography (not a stress/exercise study).

Treatment

Since resection of these tumours is high risk, patients must be diligently managed in the peri-operative period. Pre-operative preparation includes sufficient alpha-adrenergic blockage prior to surgery, allowing for hypertension control, organ recovery, and volume re-expansion. Current first line therapy is phenoxybenzamine, a long-acting, irreversible, non-selective alpha-adrenergic blocking agent that is usually initiated at 10–20 mg/day orally and increased in 10 mg divided intervals every 3–4 days as necessary for blood pressure control. Some patients might require >300 mg/day, and several weeks may be necessary to achieve proper blockade. The end points are resolution of episodic symptoms and hypertensive swings, with blood pressure in the normal to near normal range. Side effects include orthostasis, nasal stuffiness, and fatigue. Although there are different practice patterns, the conservative approach would place the timing of surgery 7–14 days after achieving proper blockade. One study suggests the risk of all peri-operative complications is reduced if pre-operative systolic BP ≤ 140 mmHg [14]. If the patient has any end organ damage (cardiomyopathy, myocarditis, renal failure, etc.), surgery should be delayed until organ recovery has occurred.

Beta-blockade is not necessary in most patients and should not be arbitrarily used. Since cardiovascular collapse is a major risk during the peri-operative period, avoiding unnecessary negative inotropic drugs is desirable. Additionally, pheochromocytoma patients with cardiomyopathy or myocarditis recover with the use of alpha-blockade alone, making the use of beta-blockade for myocardial remodeling unnecessary. Beta-blockade should be started for persistent tachycardia (not transient tachycardia with orthostasis). Most importantly, beta-blockade should not be used as part of the antihypertensive regimen. It has long been emphasized that beta-blockers should be avoided before adequate alpha-blockade, as inhibition of peripheral vasodilation, negative inotropy, inhibition of catecholamine metabolism, and subsequent unopposed alpha-adrenergic stimulation could lead to catastrophic vasoconstriction and morbidity/mortality. While this position is generally true, there are rare exceptions, e.g. if tachyarrhythmia is the primary problem.

Calcium channel blockers can also be used as adjuncts to control hypertension. They do not appear to completely prevent hemodynamic lability, but have been associated with low morbidity and mortality [15]. Catecholamine synthesis inhibition with metyrosine can effectively reduce catecholamine excretion by 50–80%. Unfortunately, it is not universally used for patients with resectable tumours because of significant side effects (sedation, diarrhoea, depression, confusion, crystalluria, extrapyramidal reactions) and dangerous rebound effects with abrupt drug cessation; cardiac arrest being the most extreme reported consequence.

Fluid management pre-operatively does not need to be aggressive. Placing the patient on high volume intravenous fluids 24 hours before surgery is no longer recommended. Instead, volume deficits are replaced gradually as blood pressure normalizes during the 2 or more weeks of pre-operative alpha-blockade. In addition, there is significant heterogeneity of blood volume deficits among pheochromocytoma patients and is such that further fluid resuscitation can be achieved more safely in the operating room, when the patient is invasively monitored and continuously assessed.

While laparoscopic resection of intra-adrenal tumours of less than 6 cm is usually preferred, paragangliomas, and tumours of larger size may need open resection. Unless the margins of disease are resectable, there is no definitive cure for the treatment of malignant pheochromocytoma. If possible, metastatic lesions should be removed. Surgical intervention in unresectable malignant tumours is undertaken for symptom improvement and prolonged survival [16].

In pregnancy factors such as tumour location, size of the fetus, and co-morbidities should be considered. Successful antepartum laparoscopic tumour removal has been reported in seven cases [17].

Understanding intra-operative management is key to post-operative care. Invasive monitoring during the surgical procedure is used for the risk of acute hypertensive crisis and arrhythmias secondary to induction, intubation, and tumour manipulation, as well as shock once the tumour is removed. Sudden cardiac arrest has been reported in 2–4% of patients, some cases occurring with induction of anaesthesia [14]. A 'central' arterial catheter (femoral or axillary) should be placed to measure blood pressure accurately during acute vasoconstriction, in addition to continuous $ScvO_2$/SvO_2 and cardiac output monitoring. Invasive catheters should be placed before induction of anaesthesia. Acute hypertensive episodes during direct tumour manipulation are expected despite adequate pre-operative preparation and proper anaesthetic technique, including adjunct epidural anaesthesia. Risk factors for intra-operative haemodynamic lability include tumour size >4 cm, higher pre-operative catecholamine concentrations, and >10 mmHg postural blood pressure drop after adequate alpha-blockade [18] and the magnitude of tumour manipulation that occurs during resection. Management of hypertensive crisis involves administration of rapidly-acting vasodilators through a central venous catheter.

Table 264.1 Treating hypertensive crisis. Titratable, short-acting medications (**bold**) are preferred

		Onset	Duration
Nitroprusside	NO donor	1	3–5 minutes
Nitroglycerin	NO donor	2–5	5–10 minutes
Fenoldopam	DA_1 agonist	4–5	<10 minutes
Clevidipine	Ca channel blocker	3–5	10 minutes
Esmolol	β_1 blocker	3–5	10 minutes
Phentolamine	α_1 α_2 blocker	15	1 hour
Nicardipine	Ca channel blocker	1–5	3–6 hours
Labetalol	β_1 β_2 α_1 blocker	≤5	3–6 hours
Urapidil	α_1 blocker	10	3–4 hours

Data from Cooper ZA and Mihm FG, 'Blood pressure control with fenoldopam during excision of a pheochromocytoma', *Anesthesiology*, 1999, **91**(2), pp. 558–60.

Nitroprusside, nitroglycerin, fenoldopam, and clevidipine share the desirable features of fast onset and offset (Table 264.1) [19]. Agents like phentolamine and nicardipine have been listed for comparison, but are not considered ideal agents for the rapidly changing physiology observed in the critical care setting. Esmolol is appropriate as an adjuvant to control tachycardia, but not hypertension. Magnesium sulphate has also been used to help control blood pressure, but there are limits to its use because of side effects (e.g. muscle relaxation). In some patients multiple agents may be necessary.

Box 264.1 Hypotension after pheochromocytoma tumour removal

- Reduced endogenous catecholamines.
- Receptor down regulation.
- Residual α receptor blockade.
- Residual β receptor blockade.
- Exogenous vasodilators.
- Vena caval compression (surgical retraction).
- Hypovolaemia.
- Adrenal insufficiency (in setting of bilateral adrenalectomy).
- Anaesthetic depth.
- Regional block (epidural-induced sympathectomy).
- Vasopressin deficiency.

Shock may develop immediately after removal of the tumour resulting in the need for post-operative vasopressors/inotropes. In some cases, hypotension develops less precipitously several hours after surgery. After adequate fluid resuscitation, if the patient appears vasoplegic (normal stroke volume/cardiac output, but low arterial pressure), vasopressin is recommended to avoid competing with residual alpha-blockade. If the patient has low cardiac output despite fluid resuscitation, epinephrine is recommended. Multiple causes of the hypotension may play a part in an individual patient (Box 264.1).

Patients should also be monitored post-operatively for hypoglycaemia, a complication noted after removal of catecholamine inhibition of insulin secretion. After tumour resection, it can take up to 1 week for normalization of catecholamine levels, as excess catecholamines leech out of storage granules throughout the body. Patients who remain hypertensive may have residual tumour (unlikely) or essential hypertension that will respond to conventional treatment.

Insulinoma

These rare, mostly benign pancreatic islet cell tumours can lead to profound hypoglycaemia. One cohort study reported a 6% incidence of insulinoma in the setting of multiple endocrine neoplasia (MEN) type I [20].

Patients present with neuroglycopenic symptoms such as confusion and amnesia, lethargy or loss of consciousness, and visual changes, in addition to palpitations, diaphoresis, and tremulousness. Most patients have fasting hypoglycaemia, but can also present with post-prandial hypoglycaemia [20]. They are often misdiagnosed with psychiatric or neurological disorders, such as seizures. If left untreated, patients face the risks of profound hypoglycaemia, coma, and death.

High serum insulin levels during episodes of hypoglycaemia confirms the diagnosis. Imaging techniques can be used to localize the tumour [20]. Initial treatment includes correction of hypoglycaemia with frequent glycaemic and neurological checks until surgical resection can be arranged. Up to 1200 mg of diazoxide in divided doses can be used to decrease insulin secretion while planning for tumour removal.

SECTION 11

The haematological system

PART 11.1

Laboratory monitoring

CHAPTER 265

The blood cells and blood count

Tyler J. Albert and Erik R. Swenson

Key points

- A blood smear is a rapid, reliable, and inexpensive test to examine the functional status of the bone marrow during cytopenic states.
- Haematopoiesis originates from the pluripotent stem cell, which undergoes replication, proliferation, and differentiation, giving rise to cells of the erythroid, myeloid, and lymphoid series, as well as megakaryocytes, the precursors to platelets.
- Red blood cells (RBCs) have a normal lifespan of only 120 days, requiring constant erythropoiesis with the essential factors being iron, zinc, folate, and vitamin B12, under the influence of erythropoietin, thyroxine, androgens, cortisol, and catecholamines. Many aspects of critical illness reduce the circulating lifespan of red cells.
- The white blood count represents a summation of several circulating cell types that have independent kinetics and regulation, each deriving from the haematopoietic stem cell, and together form the critical components of both the innate and adaptive immune systems.
- Platelets are not only integral to haemostasis, but aid our inflammatory and immune responses, help maintain vascular integrity, and contribute to wound healing.

Normal physiology

Blood is a dynamic fluid consisting of cellular and plasma components undergoing constant regeneration and recycling. The cellular components, including red blood cells (RBCs), white blood cells (WBCs), and platelets, all originate from the bone marrow, with plasma proteins primarily being synthesized in the liver. In the steady state, the bone marrow has an enormous production capacity, with an estimated production of more than 200 billion RBC, 10 billion WBC, and 400 billion platelets each day. Like most physiological systems, the concentrations of these components are tightly regulated within narrow limits under normal conditions (Table 265.1). In the critically-ill population, however, the haematological abnormalities frequently recognized are predominantly quantitative, with qualitative defects being less common, but nonetheless important. Likewise, these haematological abnormalities are thought to be due to non-haematological single- or multiple-organ pathology. Acquired defects are much more common than congenital defects, and multiple abnormalities of both cellular and haemostatic components are more frequent than the single defects usually identified in routine haematological practice. A rapid, reliable and inexpensive method of examining haematological disorders is the peripheral blood smear, which allows practitioners to assess the functional status of the bone marrow, especially during cytopenic states [1].

Anatomically, the cellular components comprise cells in circulating blood, bone marrow, lymph nodes, and the spleen. RBCs are primarily concerned with oxygen and carbon dioxide transport, WBC with immunity and infection control, and platelets with maintaining vascular integrity and haemostasis. The haemostatic system is responsible for maintaining blood fluidity and, at the same time, prevents blood loss by initiating rapid, localized, and appropriate blood clotting at sites of vascular damage. This system is complex, comprising both cellular and plasma elements, i.e. platelets, coagulation, and fibrinolytic cascades, the natural intrinsic and extrinsic pathways of anticoagulation, and the vascular endothelium.

Haematopoiesis, the process by which RBCs, WBCs, and platelets are produced, occurs in adults within the marrow spaces of the bones of the axial skeleton. Haematopoiesis originates from the pluripotent stem cell, which has the capacity to maintain stem cell

Table 265.1 Normal haematological indices

Haemoglobin (g/dL)	M	13.0–16.5
	F	11.5–15.5
Haematocrit	M	0.40–0.50
	F	0.37–0.47
Red blood cells ($\times 10^{12}$/L)	M	3.8–5.6
	F	3.4–5.2
Mean corpuscular volume (fl)		84–99
Reticulocytes ($\times 10^{9}$/L)		20–70 (0.5–1.6%)
Red cell mass (mL/kg)	M	25–35
	F	20–30
Plasma volume (mL/kg)		35–45
White blood cells ($\times 10^{9}$/L)	Total	4.0–10.15
	Neutrophils	2.0–8.0
	Lymphocytes	1.0–4.0
	Monocytes	0.1–0.8

numbers through replication and proliferation. Furthermore, the stem cell is able to undergo differentiation, giving rise to cells of the erythroid, myeloid, and lymphoid series, as well as megakaryocytes, the precursors to platelets (Fig. 265.1).

Development and differentiation of haemopoietic stem cells is under the control of glycoprotein cytokines, which operate in a paracrine or endocrine fashion. These act at early, intermediate, and late stages of cell differentiation, target cell responsiveness depends upon both cytokine production, and expression of specific receptors on the target cells. Early-acting cytokines include stem cell factor and interleukin 3, while cytokines acting on more differentiated cells include granulocyte colony-stimulating factor (G-CSF), granulocyte-macrophage colony-stimulating factor (GM-CSF), thrombopoietin, platelet growth factor, and erythropoietin, produced in the kidney and controlling erythropoiesis. Availability of human recombinant forms of these proteins has resulted in their usage in the treatment of anaemic and neutropenic states under some circumstances. There are also inhibitory cytokines (e.g. tumour necrosis factor, transforming growth factor, and probably, interleukin 2), which act in a negative regulatory manner to inhibit haematopoiesis. These are implicated in pathological conditions resulting in the suppression of haematopoiesis, in particular the anaemia of chronic disease.

Red blood cells

Erythrocytes are the most common circulating haemopoietic cells. The precursor forms within the marrow are nucleated, but when released into the peripheral blood, they no longer contain a nucleus or mitochondria. Red cells have a finite lifespan of around 120 days, at which time they are destroyed primarily in the reticuloendothelial system. Red cells recently released from the bone marrow contain trace amounts of ribonucleic acid (RNA) that can be stained with supravital stains and recognized as reticulocytes. The reticulocyte count can give a vital insight into the synthetic function of the marrow. Red cell numbers can be decreased by loss from the body (haemorrhage), failure of synthesis due to primary marrow disease or deficiency of iron, vitamin B12, and folate, depressed erythropoiesis in the anaemia of chronic disease, and premature red cell destruction (haemolysis). Measurement of haemoglobin concentration depends not only on the number of red cells present and their individual haemoglobin content, but also on the plasma volume in which they are distributed. A diminished plasma volume will spuriously elevate haemoglobin, and depletion of red cells and haemoglobin will be masked if there is concomitant loss of plasma volume. Consequently, measurement of plasma volume and red cell mass using isotopic techniques can sometimes be highly informative.

The efficient blood transport of oxygen and carbon dioxide is critically dependent upon the O_2, CO_2, and H^+ binding properties of haemoglobin (Hb). These are facilitated by the enzyme carbonic anhydrase, RBC specific membrane and cytoplasmic proteins, and by the unique intracellular RBC environment, including the modulation of Hb-O_2 affinity by 2,3-diphosphoglycerate (2,3-DPG) and maintenance of redox state stability. Packaging the majority of the blood's O_2 and CO_2 transport capacity in the RBC reduces the effective viscosity of blood by two-thirds in comparison to a cell-free medium of equivalent transport capacity and prevents loss of haemoglobin, carbonic anhydrase, and 2,3-DPG via glomerular filtration. RBCs also have potent anti-oxidant capacity, enhance haemostasis by directing platelets towards the vessel wall, and minimize haemoglobin–nitric oxide (NO) scavenging by sequestrating Hb away from direct contact with the endothelium of resistance arterioles. Finally, RBCs contribute to microcirculatory vasoregulation by both haemoglobin-independent and haemoglobin saturation-dependent vasodilator release [2].

RBC rheology contributes to vasoregulation, particularly at the microvascular level [3]. In addition to tissue and endothelial cell contributions to vascular tone, mediated in part by tissue oxygenation, rheology has an influence on vascular tone by altering wall shear stress and nitric oxide generation, as well as homogenizing flow distribution at capillary branch points. Local blood flow and metabolic demand are matched by three recently identified mechanisms involving RBCs and haemoglobin. First, bioactive NO is produced in proportion to the concentration of deoxyhaemoglobin acting as a nitrite reductase [4]. Secondly, NO is bound by oxyhaemoglobin in the lungs and released by deoxyhaemoglobin in the tissues, mediated by reversible allosteric S-nitrosylation of beta chain cystein-93 in haemoglobin [5]. Thirdly, mechanical deformation of RBCs and desaturation of haemoglobin initiates vasodilation by release of ATP, which binds to endothelial cell purinergic receptors and stimulates NO synthesis [6]. The redundancy of these mechanisms highlights the probable critical contribution of healthy

RBCs to active vasoregulation at the microvascular level. However, this function may be compromised both by anaemia and by pathological RBC changes occurring in critical illness and during storage of allogeneic blood [2].

With a lifespan of only 120 days, caused by accumulative radical oxygen species (ROS)-mediated damage and age-related loss of intrinsic antioxidant defences [7], there must be a constant production of new RBCs. The essential factors for erythropoiesis include iron, zinc, folate, and vitamin B12, under the influence of erythropoietin, thyroxine, androgens, cortisol, and catecholamines. RBC formation occurs at a basal rate of 15–20 mL/day under steady-state conditions, and upwards of 200 mL/day after haemolysis or heavy blood loss in iron-replete healthy persons [8]. Normal RBC ageing leads to changes in membrane characteristics (reduced fluidity and deformability), loss of volume and surface area, increased cell density and viscosity, and deleterious alterations in the intracellular milieu (decreased ATP and 2,3-DPG, and lowered hexokinase and glucose-6-phosphate dehydrogenase activity). These lead to a fall in cellular energy level, increased Hb-oxygen affinity, reduced repair of oxidant injury and diminished ability of cells to deform normally during microvascular transit [9]. These changes also mark RBCs for removal by the spleen and reticuloendothelial system (RES). Alterations in rheology with normal ageing may occur even sooner in the lifespan of the RBC in critically-ill patients, and have been shown to be associated with poor outcomes [10]. In many regards, these changes in red cell characteristics occur when red cells are stored for transfusion purposes and likely account for the markedly shorter lifespan of these cells when transfused [2].

Other determinants of RBC survival include the premature death of mature RBCs (eryptosis), and removal of RBCs just released from the marrow (neocytolysis). Eryptosis is thought to be partially triggered by excessive oxidant RBC injury, among other stressors, and is inhibited by EPO, which thus extends the life span of circulating RBCs [11]. This apoptosis-like process is characterized by a cascade of biochemical and biomechanical changes, leading to cell shrinkage, dysregulation of normal membrane asymmetry with exposure of normally sequestered phosphatidylserine on the outer membrane leaflet, and the formation of membrane blebs and microparticles. Phosphatidylserine marks cells for engulfment by macrophages and may carry important downstream effects related to inflammation, coagulation, cell signalling, and/or immune modulation. Conversely, excessive eryptosis may lead to the development of anaemia [12]. Neocytolysis is a physiological process first noted in the study of anaemia that develops during spaceflight (microgravity) and of polycythaemia correction with descent from high altitude; as both processes develop too rapidly to be solely accounted for by reduced erythropoiesis. This regulation of red cell mass by selectively removing young circulating erythrocytes is initiated by a sudden fall in EPO levels allows for fine control of the number of circulating erythrocytes under steady-state conditions and relatively rapid adaptation to new environments or conditions, where polycythaemia would no longer be advantageous [13]. Eryptosis and neocytolysis, negatively regulated by EPO and acting at different points in the life span of the RBC, provide flexibility in regulating total red cell mass [2].

White blood cells

The white blood count represents a summation of several circulating cell types that have independent kinetics and regulation, each deriving from the haematopoietic stem cell, together forming the critical components of both the innate and adaptive immune systems. WBC are divided into five groups—neutrophils, monocytes, eosinophils, basophils (collectively referred to as the myeloid cells), and lymphocytes.

Neutrophils, which form the majority of WBC, have a relatively short half-life of about 6 hours and function primarily as a defence mechanism against pathogenic bacteria. The differentiation of stem cells into mature neutrophils takes approximately 3 weeks, but this period can be compressed in the case of stress or under the influence of cytokines such as G-CSF. During this time the cell progresses through a number of identifiable stages: myeloblast, promyelocyte, myelocyte, metamyelocyte, band, and ultimately neutrophil. Throughout this progression there is condensation of the nucleus, with mature neutrophils having segmented nuclei (thus the origination of the term polymorphonuclear leukocyte (PMN) as a synonym for a neutrophil). Additionally, there is a concurrent reduction of the nuclear-to-cytoplasm ratio and increasing cytoplasmic granularity. A significant portion of neutrophils are in a marginated (loosely adherent to the vascular wall), rather than circulating pool, which can be rapidly mobilized, leading to the rapid development of a neutrophilic leukoyctosis following physiological stress, infection, trauma, burns, and any state of increased sympathetic nervous system or increased glucocorticoid activity.

Lymphocytes, the next most populous WBC, are an integral part of the body's humoral and cellular immune system. Lymphocytes are responsible for adaptive immunity, meaning the capacity to recognize foreign proteins and pathogens in the absence of prior exposure in order to amplify specific responses to those pathogens, retaining a memory so that subsequent challenges are met with a more rapid and vigorous response. Lymphocytes can be divided into three major sublineages—B cells, T cells, and natural killer cells, each of which can be readily identified by monoclonal antibodies to characteristic surface antigens. B cells are particularly important in the humoral immune response, producing immunoglobulin proteins, which serve as receptors for antigen on the cell surface and are secreted as antibodies. T cells are primarily involved in the cellular immune response, as they bear T cell antigen receptor proteins on their surface and play diverse roles in coordinating immune responses and directly killing virus-infected cells. It is becoming increasingly clear that B and T cells must act together for efficient functioning of the body's immune system. Natural killer (NK) cells, making up a small percentage of circulating lymphocytes and can destroy target cells without adaptive specificity for foreign antigens. About 70% of blood lymphocytes are T cells, 10–15% B cells, with the remaining cells being unidentifiable or NK cells. Lymphyocytosis, an increase in circulating lymphocytes, can be a reactive response as in the setting of a viral or bacterial infection, or a clonal process, such as with a lymphoproliferative malignancy.

Eosinophils, basophils, and monocyte/macrophages make up the remaining WBCs, each of which is differentiated from myeloid precursor cells as mentioned previously. Eosinophilic differentiation parallels that of neutrophils, although eosinophils can be easily recognized by their large, red-staining granules with minimally-segmented, bi-lobed nuclei. Normally present in small numbers (less than 5% of WBCs), eosinophila can occur with various allergic states and in response to many parasitic infections. Basophils, comprising less than 1% of total WBCs, have very large,

blue-staining granules covering the cell with receptors for IgE on their surface. When an antigen-IgE interaction takes place the basophil releases histamine from its granules, which can lead to rhinitis, bronchospasm and angioedema. Basophilic leukocytosis is a rare condition most often associated with myeloproliferative disorders. Monocytes, the largest cells normally seen in the blood, have a distinctive folded nucleus with a greyish-blue cytoplasm replete with vacuoles. They are known to participate in host defence at several levels, migrating into inflammatory sites where they are further differentiated into macrophages, which then phagocytize any opsonized organisms.

Platelets

Platelets are highly organized and structured anucleate cells of myeloid origin that circulate in a resting state in the blood. The cells themselves are small and discoid-shaped, with a diameter between 1.5 and 3 μm, although younger platelets tend to be much larger. In response to activating signals, the quiescent platelet phenotype changes and these versatile effectors of host defence perform major haemostatic, inflammatory, and reparative functions [14]. They express specific surface glycoproteins allowing them to bind to adhesive endothelial, subendothelial, and plasma proteins. They can undergo adhesion, aggregation, and subsequently a release reaction, which liberates the contents of granules contained within their cytoplasm, resulting in augmentation of the aggregation reaction. Activated platelets also provide a negatively charged phospholipid surface upon which proteins of the coagulation cascade can assemble. Although they are individually very small, aggregated platelets form a platelet plug, which can block vascular defects and precipitate a stabilizing fibrin mesh over the top. To perform this task efficiently, platelets need to be present in sufficient numbers and have normal function. The normal platelet count in an adult is 150,000–400,000/μL, with two-thirds of platelets circulating in the blood and one-third sequestered in the spleen. The lifespan of a platelet in the circulation is 9–10 days, but in cases of accelerated destruction this can be much shorter, in some cases only minutes to hours, leading to severe thrombocytopenia. Normal haemostasis, assuming normal platelet function, is maintained with platelet counts above 50,000/μL; diminution below this level results in a progressively prolonged bleeding time. At levels below 10,000–20,000/μL there is a much heightened risk of spontaneous haemorrhage.

While platelets are the chief effector cells in haemostasis, they are known to play important roles in other functions as well, including promoting inflammatory and immune responses, maintaining vascular integrity, and contributing to wound healing. Platelets have been shown to recruit leukocytes and progenitor cells to sites of vascular injury and inflammation. They store, produce, and release pro- and anti-inflammatory, and angiogenic factors and microparticles into the circulation, and they spur thrombin generation. In experimental models these function have been shown to contribute to atherosclerosis, sepsis, hepatitis, vascular restenosis, acute lung injury, and transplant rejection [15].

CHAPTER 266

Coagulation monitoring

Gerhardus J. A. J. M. Kuiper and Hugo ten Cate

Key points

- Knowledge of the coagulation and fibrinolysis cascade, and the interaction with and function of platelets is imperative for haemostasis monitoring and interpreting the laboratory results obtained.
- Primary haemostasis is dependent on platelet levels and function, while in secondary haemostasis fibrin formation is the ultimate goal with thrombin as its central controlling enzyme.
- Fibrinolysis is the breakdown of the fibrin mesh, a process regulated in part by thrombin.
- Point-of-care (POC) monitoring of haemostasis can be done with an array of devices each with its pros and cons. The main advantage over conventional laboratory assessment is that POC monitoring can be done at the bedside and with a shorter turnaround time.
- Acquired haemostasis disorders and the use of (oral) anticoagulants, antiplatelet, or prohaemostatic drugs are frequently seen in patients on the intensive care unit. Monitoring of these patients should be based on both classical and novel haemostasis monitoring techniques.

Haemostasis: platelets and the coagulation and fibrinolysis cascade

Haemostasis is a dynamic process between blood constituents and the vessel wall required to stop bleeding after vessel wall damage (Fig. 266.1). The involvement of platelets is classically described as primary haemostasis, while the coagulation proteins are responsible for secondary haemostasis. The breakdown of a blood clot is mediated by so-called fibrinolysis [1].

Platelets have several receptors for the activation of platelets, the adherence to collagen, and the aggregation with other platelets. In vivo, vessel wall damage exposes collagen to platelets, to which they can adhere through glycoproteins including the GPIb receptor with von Willebrand factor (vWF) as a co-factor. Other activators are thrombin, arachidonic acid, epinephrine, and adenosine diphosphate (ADP). Upon activation, platelets aggregate via GPIIb/IIIa receptors with other platelets through fibrinogen and vWF.

Vessel wall damage also exposes tissue factor (TF). Coagulation factor VII (FVII) is activated by TF and this complex can activate factor X (FX), with FV as its cofactor, in order to convert prothrombin into thrombin. This is classically described as the extrinsic route. Activation of the intrinsic route is achieved by contact activation via negatively charged surfaces in vitro and by compounds like polyphosphates in vivo. Activated FXII starts an intrinsic cascade through activation of FXI, which yields activated FIX. FIXa, with FVIIIa as its cofactor, activates FX and this again leads to prothrombin conversion. Thrombin stimulates fibrin and FXIIIa formation, which stabilizes fibrin via cross-links. Thrombin as the central coagulation enzyme has pro-, as well as anticoagulant properties, thereby balancing the haemostatic system. Thrombomodulin (TM), an endothelial receptor, binds thrombin and hereby inactivates thrombin's procoagulant properties. Protein C, activated via this thrombin–thrombomodulin complex, can inactivate FVa and FVIIIa. Circulating antithrombin attenuates thrombin formation by neutralizing FXa and thrombin, while tissue factor pathway inhibitor (TFPI) inactivates FXa when in complex with TF-FVIIa.

The fibrin mesh is degraded by plasmin, resulting from the action of tissue-type plasminogen activator (tPA), released from endothelial cells, on plasminogen. Likewise, urokinase is a potent fibrinolysis activator. Thrombin inhibits fibrinolysis via thrombin activatable fibrinolysis inhibitor (TAFI) when bound to TM, while platelets secrete plasminogen activator inhibitor (PAI)-1 and 2, which inhibit tPA and urokinase, respectively. Fibrin is degraded into fragments called fibrin degradation products (FDP's). D-dimer is an FDP in which the cross-link is still present.

Classical coagulation monitoring

In primary haemostasis testing various laboratory assays are adopted to reflect the function of platelets. In short, for effective primary haemostasis, a sufficient number of functional platelets need to be present in the body. First of all, a platelet count is indispensable, however, this does not adequately reflect the function of the respective platelets. Mean platelet volume (MPV) gives information on the volume of the platelets, reflecting the turnover of platelets and their reactivity. A high MPV could indicate a high platelet turnover due to increased production of platelets from bone marrow-derived megakaryocytes. A low MPV is usually an indication of less reactive platelets or due to splenic sequestration. The gold standard in platelet function testing is light transmission aggregometry (LTA). The test needs, however, a sufficient number of platelets to be reliable, while interpretation of the results is merely based on expertise, rather than specific cut-off values. The bleeding time test (the Ivy method), being the only in vivo platelet function test, is poorly reproducible. A prolonged bleeding time could indicate a platelet dysfunction. However, a normal test does not rule out a platelet disorder.

For monitoring secondary haemostasis the prothrombin time (PT), activated partial thromboplastin time (aPTT), thrombin time (TT), and reptilase time (RT) reflect disorders in specific steps of the coagulation cascade. The PT is activated by adding TF, the aPTT

by a contact activator. The international normalized ratio (INR) is a ratio of the PT of the local laboratory compared with a standardized reference PT. Prolonged PT and aPTT test are normally accompanied by a bleeding tendency (Table 266.1), although the presence of the lupus anticoagulant, which is an antibody, is paradoxically associated with a thrombotic tendency. An aPTT prolongation due to FXII deficiency does not exert in a bleeding or thrombotic tendency. The TT is measured by directly adding thrombin to plasma, which triggers fibrin formation. The TT is thus sensitive to fibrinogen, but also to FDP's (which themselves inhibit fibrin polymerization) and to heparin therapy. RT is similar to TT, but insensitive to heparin. Lastly, levels and activities can also be measured for each separate coagulation factor.

Fibrinolysis is frequently monitored by measuring d-dimer levels (or FDP's), fibrinogen levels, and the euglobulin clot lysis time. Excessive clot breakdown will result in low fibrinogen levels and high d-dimer or FDP levels. D-dimer has a low specificity, thereby making it only suitable to exclude (ongoing) fibrinolysis for the diagnosis in patients. Fibrinogen, as an acute phase protein, can be elevated in a wide variety of diseases. The euglobulin clot lysis time is an elaborate test in which the overall lysis potential of a formed clot can be quantified. A shortened euglobulin clot lysis time is an indication of potential hyperfibrinolysis.

Point-of-care coagulation monitoring

Point-of-care monitoring (POC) provides simple, rapid bedside testing for various laboratory tests. In coagulation monitoring the activated clotting time (ACT), a viscoelasticity measuring technique (TEG, ROTEM, or Sonoclot systems), and platelet function tests are widely-used, whole blood tests for coagulation monitoring.

In the ACT test, native whole blood is activated via the intrinsic pathway by either kaolin or celite. The time to form a clot is the ACT given in seconds. The ACT is used in cardiothoracic surgery to monitor unfractionated heparin therapy and its reversal by protamine sulphate. The ACT is less sensitive to therapy with low molecular weight heparins and insensitive to pentasaccharide therapy [2].

The TEG (thromboelastography) and ROTEM (rotational thromboelastometry) systems are the most widely used whole blood viscoelasticity devices, together with the Sonoclot [3]. The basic principle is that citrate anticoagulated whole blood is activated after recalcification with either an extrinsic or intrinsic activator in a measuring cuvette. While the blood starts to clot, the device measures the strength of the clot formed and plots the strength at each point in time in a graph. Each device has its own parameters, but all three display the time till the fibrin clot starts to form, the

Table 266.1 Causes of PT and aPTT test abnormalities

PT (extrinsic pathway)	aPTT (intrinsic pathway)	Possible cause
Prolonged	Normal	FVII deficiency or inhibitor
		Vitamin K deficiency or vitamin K antagonist therapy
		Liver disease
Normal	Prolonged	FVIII, FIX, and FXI deficiencies or inhibitors (haemophilia A/B/C)
		FXII, prekallikrein, or HMW kininogen deficiencies or FXII inhibitor
		Von Willebrand disease
		Heparin therapy
		Lupus anticoagulant
Prolonged	Prolonged	FX, FV, prothrombin, and fibrinogen deficiencies or inhibitors
		Disseminated intravascular coagulation, trauma-induced coagulopathy
		Combined VKA and heparin therapy

maximum clot strength achieved, and the time it takes to dissolve the formed clot [3]. For instance, the maximum clot strength is the resultant of both platelets and fibrin involved in the formed clot. The decline of the maximum clot strength is again influenced by both platelets (clot retraction) and fibrin (fibrinolysis) [4]. Each system has its own specific measuring principle, its own nomenclature, and (dis)advantages compared with the other two. The consequence is that, thus far, results cannot be interchanged between systems [3,5]. Correlations between some viscoelasticity parameters and standard coagulation tests are fairly good, making the need for standard coagulation tests redundant in certain scenarios [3].

Other POC tests are specially developed for platelet function measuring in whole blood [6]. All these operate according to the same basic principle—whole blood is put in a measuring cuvette and the platelet receptors are then activated by a reagent, aggregating the platelets. This alteration of the platelets is detected by the device. However, normal haematocrit and platelet levels are imperative for platelet function testing either by POC or LTA [7].

Coagulation monitoring in critical care diseases

Coagulation disorders seen in critical care are classically divided into bleeding, thrombosis, or a combination. Monitoring of the three disorders is highlighted in the following paragraphs.

Trauma-induced coagulopathy (TIC) is often referred to as consisting of a lethal triad. Massively bleeding trauma patients present with hypothermia and acidosis. Fluid resuscitation leads to a dilutional coagulopathy completing the triad [8]. This is further aggravated by endothelial damage, releasing tPA and thrombomodulin in abundance, resulting in anticoagulation and hyperfibrinolysis [9]. Classic laboratory coagulation tests for TIC include PT, aPTT, platelet count, and fibrinogen levels. The first coagulation factor to fall below a critical value is fibrinogen [8]. In colloid use fibrinogen levels are overestimated and platelet function is impaired [10]. Low platelet counts in TIC hinder platelet function testing. The use of viscoelasticity measurements in trauma or massive transfusion cases is advocated by many, although evidence for a favourable outcome is thus far scarce [11].

A mixed bleeding-thrombosis condition is DIC (disseminated intravascular coagulation). In overt DIC excess thrombin is produced, resulting in microvascular thrombosis due to failure of the natural anticoagulant mechanisms. This condition can be accompanied by bleeding due to a depletion of coagulation proteins and platelets [12]. In the early phase of DIC, fibrinolysis is often impaired due to high PAI-1 levels, while hyperfibrinolysis is present in late DIC. The diagnosis is based on classical coagulation tests incorporated in a scoring system [13]. Subsequent monitoring should focus on platelet levels and function over time, on the fibrinogen levels, and PT during DIC. Viscoelasticity measurements could help in monitoring hypo- or hyperfibrinolysis.

Haemolysis, **e**levated **l**iver enzymes and **l**ow **p**latelets (HELLP) is a syndrome complicating around 0.5% of all pregnancies. Monitoring for the presence of DIC and MPV, as a marker for platelet function and consumption, together with platelet levels and POC platelet function testing is advocated [14].

Coagulation monitoring in medication use

Antiplatelet and (oral) anticoagulant drugs are frequently used on the ICU or by patients at home. The effect of antiplatelet drugs can be monitored with platelet function tests, either by LTA or POC [6]. Vitamin K antagonist monitoring and dose-adjustment is done via the INR. Heparin treatment can be monitored by measuring anti-FXa levels for any type of heparin including pentasaccharides, while aPTT is only suitable in unfractionated heparin use [2]. A complication of heparin administration is HIT (heparin-induced thrombocytopenia). In HIT suspected patients, the 4T's scoring system followed by specialized laboratory analysis is applied [15]. New oral anticoagulants (NOACs) are emerging on the market targeted at inhibiting thrombin or FXa. It is advocated that monitoring is unnecessary, although in clinical practice there is growing demand for laboratory tests to monitor these NOACs, certainly in critical situations [16]. For screening in acute situations, some of the conventional coagulation tests may still be useful, provided that the reagents are sufficiently sensitive. For quantitative measurement, specific anti-FXa-based chromogenic assays (Xa-directed NOACs) or thrombin sensitive clotting methods (for thrombin-directed NOAC) should be used [17].

In TIC and in the peri-operative setting prohaemostatic therapy can be given in many forms [18]. Monitoring of prohaemostatic therapy is focused on platelet levels and function, fibrinogen levels, classical coagulation tests, and viscoelasticity measurements. Fibrinogen levels can decline rapidly due to thrombolytic therapy in stroke or venous embolism, resulting in an acquired bleeding tendency.

PART 11.2

Haematological therapies

CHAPTER 267

Blood product therapy in the ICU

Lirong Qu and Darrell J. Triulzi

Key points

- Avoid unnecessary transfusion through adhering to the evidence-based transfusion guidelines. A restrictive red blood cell (RBC) transfusion strategy (haemoglobin < 7 g/dL) is recommended for haemodynamically stable patients in the critical care setting.
- Optimal haemoglobin threshold for patients with acute coronary syndrome has yet to be determined.
- Plasma transfusion for an invasive procedure has not been shown to be of benefit in patients with international normalized ratio <2.0.
- The target platelet count for a bleeding patient or for an invasive procedure is 50,000/dL.
- The risk of transfusion transmitted human immunodeficiency virus (HIV) and hepatitis C virus (HCV) or hepatitis B virus infections is less than 1 in a million; other risks such as transfusion-associated circulatory overload (TACO) and, to a lesser extent, transfusion-related acute lung injury (TRALI), are much more common.

Introduction

Blood transfusion is a frequent intervention in critically-ill patients. Major progress has been made in blood safety over the last two decades. This chapter will provide a brief updates on the evidence-based indications for blood product transfusion, as well as its attendant risks.

Anaemia in intensive care settings

Anaemia is prevalent in the critically ill patients. Its etiology is multifactorial including a shortened life span for the circulating RBC and diminished RBC production (1). The body responds to anaemia by employing compensatory mechanisms such as increase cardiac output, increased tissue oxygen extraction, right-shift of oxyhaemoglobin disassociation curve via increased 2,3 DPG in the red cells, and increased red cell production. Although there is an association between anaemia and poor outcomes in patient with various chronic diseases, it remains uncertain as to whether anaemia is an independent predictor of poor outcomes or merely a marker of severity of underlying condition (1). The optional management of anaemia in critically ill patients is a topic of much controversy and ongoing research.

Blood components

Currently, whole blood is processed into blood components (RBC, platelets, and plasma) so that each component can be stored at its optimal condition and patients receive only the specific blood components they need. Automatic cell separation (apheresis) technology can also be used to collect red cells, platelets, and/or plasma. A single apheresis platelets (single donor platelets) collection or 4–5 units of pooled platelets contains sufficient numbers of platelets for a therapeutic dose in an adult patient.

The shelf-life of RBC component is determined by the anticoagulant and preservative used. The most commonly used additive solution (ADSOL®) allows for up to 42 days of storage at 4°C (1–6°C) for RBC. The volume is approximately 350 mL of which 200 mL is red cells (haematocrit around 60%). In an average-size adult, transfusion of 1 unit RBC is expected to increase the haemoglobin by 1 g/dL or haematocrit by 3%. Platelets are stored at 20–24°C with constant agitation for a maximum of 5 days. Four to five units of whole blood-derived platelets or one apheresis platelets can increase platelet count by 20,000–40,000/μL in a stable patient. Fresh frozen plasma (FFP) is frozen and stored at –18°C within 8 hours of collection. Upon ordering, it is thawed at 37°C over 25 minutes and then stored at 4°C for 24 hours. FFP has a volume of 220 mL and contains 'normal' level of all coagulation factors. Thawed plasma is similar to FFP, but can be stored up to 5 days at 1–6°C and is clinically interchangeable with FFP. Cryoprecipitate is made from FFP and is a concentrated source of fibrinogen, each unit containing approximately 450 mg of fibrinogen.

Leukocyte-reduced blood components

White blood cells (WBCs) in the blood components can mediate adverse effects. White cells are removed primarily by filtration or apheresis processing. Leukocyte-reduction filters remove 3–5 logs (99.9–99.999%) of WBCs from whole blood-derived RBCs and platelet components. Leukoreduction can be performed before the component is stored (prestorage leukoreduction) or at the time blood is issued for transfusion (post-storage leukoreduction). Components collected by apheresis technology are leukoreduced as part of the collection. The benefits of leukocyte-reduced blood components include:

- Prevention or decrease of the incidence of HLA allo-immunization (and platelet refractoriness).
- Reduction of the incidence of febrile non-haemolytic transfusion reactions.

- Reduction of transfusion-transmitted WBC-associated viruses, such as cytomegalovirus and Epstein–Barr virus [1].

Other potential benefits, such as avoiding immunomodulatory effects of transfusion, remain controversial.

Evidenced-based blood component therapy

RBC transfusion

RBC should be transfused with the goal of improving tissue oxygenation in the context of anaemia or acute blood loss. Over one-third of all intensive care unit (ICU) patients receive transfusion; 70% if the ICU stay is longer than 1 week [2]. Many observational studies show an association between transfusion and poor clinical outcomes in hospitalized patients. In a systematic literature review of 45 observational studies including 272,596 critically-ill patients, RBC transfusion did not demonstrate efficacy in improving morbidity and mortality, although the study has the inherent limitations of an observational study, namely patient selection bias [3].

The best evidence for the threshold for RBC transfusion in the critical care setting is mainly based on the landmark randomized controlled trial (RCT) Transfusion Requirements in Critical Care (TRICC) trial in which patients assigned to a restrictive transfusion strategy (haemoglobin <7 g/dL) had similar mortality rates compared with patients assigned to a liberal transfusion strategy (haemoglobin <10 g/dL). The mortality was lower in the restrictive strategy group in patients who were younger than 55 years old and less ill (Acute Physiology and Chronic Health Evaluation score <20). The patients in the restrictive group also had lower multiple-organ-dysfunction scores, myocardial infarction, and pulmonary oedema [4]. In cardiac surgery patients, the RCT called the Transfusion Requirements After Cardiac Surgery (TRACS) trial compared a restrictive (haematocrit <24%) with a liberal (haematocrit <30%) transfusion strategy, and showed no difference in the composite 30-day mortality and morbidity (cardiogenic shock, acute respiratory distress syndrome, and acute kidney injury) between the two groups [5]. In the RCT FOCUS (Transfusion Trigger Trial for Functional Outcomes in Cardiovascular Patients Undergoing Surgical Hip Fracture Repair), patients with cardiovascular disease or cardiovascular risk factors who underwent repair of hip fracture were post-operatively randomly assigned to a liberal transfusion strategy (haemoglobulin threshold of 10 g/dL) or a restrictive transfusion strategy (symptomatic anaemia or haemoglobulin threshold of 8 g/dL) [6]. There was no difference in overall mortality and functional recovery. More recently, an RCT in 998 patients with septic shock compared a haemoglobin trigger of 7 g/dL versus 9 g/dL and found no difference in 90-day mortality [7].These RCTs support the safety of a restrictive transfusion policy and do not support the observational study findings of increased mortality in more heavily transfused patients compared with those transfused with a restrictive strategy. In a recently published Clinical Practice Guidelines for RBC transfusion from the AABB (formerly, the American Association of Blood Banks), four recommendations were made based on the quality of evidence from clinical trial data [8]. The clinical data were based on a systemic review of literature from 1950 to February of 2011 including the previously mentioned RCTs. The recommendations were:

- Strong recommendations for adhering to a restrictive transfusion strategy (7–8 g/dL) in hospitalized, stable patients (high-quality evidence).
- Suggests (weak recommendation) adhering to a restrictive strategy in hospitalized patients with pre-existing cardiovascular disease, and considering transfusion for symptoms or a haemoglobin of 8 g/dL or less (moderate-quality evidence).
- Cannot recommend for or against a liberal or restrictive transfusion threshold for patients with acute coronary syndrome (very low-quality evidence)
- Suggests (weak recommendation) that transfusion decisions be influenced by symptoms we well as haemoglobin level (low-quality evidence) [8].

RBC storage lesion

Stored RBC undergoes metabolic and structural changes including decrease in intracellular adenosine triphosphate (ATP) and 2,3-diphosphoglycerate (2,3-DPG), increase in extracellular concentration of potassium and changes in morphology. In the USA, the mean storage period for RBC transfused to ICU patients ranged from 16 to 21 days [2]. Recently, concerns over the age of transfused RBC have been raised as a contributing factor to morbidity and mortality [9]. A review of more than 20 studies in adult patients concluded that it is difficult to assign a causal relationship between the age of transfused RBC and adverse clinical outcomes [10]. Two large multicenter randomized clinical trials including the ABLE (**a**ge of **bl**ood **e**valuation) study in ICU patients in Canada and the RECESS (red cell storage duration) study of cardiac surgery patients in the USA have recently been reported [11,12]. Both studies failed to show a difference in patient outcomes between those transfused with fresher units versus those transfused with older units. These studies suggest that, although red cells show in vitro changes with storage, these changes are not associated with adverse clinical effects.

Platelet transfusion

Platelets are used to treat (therapeutic) or prevent (prophylaxis) bleeding due to deficiencies in platelet number or function. In patient with active bleeding or planned surgical procedures, platelet transfusions are indicated for platelet count of below 50,000/μL. Higher counts may be needed for bleeding at critical anatomic locations such as neurological or ophthalmological surgery. In non-bleeding stable patients with hypoproliferative thrombocytopenia, prophylactic transfusion for a platelet count of below 10,000/μl is indicated to prevent spontaneous bleeding [13]. In patients with high risk for spontaneous bleeding due to risk factors such as high fever, sepsis, disseminated intravascular coagulation (DIC), or splenomegaly, prophylactic transfusions for platelet count of below 20,000/uL is a reasonable approach.

The expected response to a platelet transfusion is an increment of 20-40,000/μL, 1–4 hours after the transfusion [13]. Patients with poor responses should be evaluated for immune refractoriness due to HLA-antibodies. HLA-matched or cross-match compatible platelets can achieve successful responses in the majority of patients who are HLA alloimmunized. Leukoreduction can be used to prevent platelet refractoriness due to HLA allo-immunization.

Plasma transfusion

Plasma transfusions are indicated for patients who are bleeding or undergoing invasive procedures with multiple coagulation factors deficiencies. Each unit of plasma is 220 mL and the recommended

dose is 15–20 mL/kg. Plasma transfusion for an invasive procedure has not been shown to be of benefit in patients with INR <2.0 and would probably have minimal or no effect on the INR [13].

Urgent and massive transfusion

Urgent transfusion refers to the administration of blood products before the pre-transfusion compatibility testing is completed. In patients with an unknown blood type, group O RBCs and group AB plasma products should be used. Rh-negative RBCs should be used for children and females with childbearing potential, to avoid the possible sensitization to the D antigen.

Massive transfusion refers to the replacement of more than one patient's blood volume within 24 hours. Transfusion of large amounts of cold, citrated blood products can lead to hypothermia, dilutional coagulopathy, and acid–base imbalance. Blood warmers may be used. The use of all blood components should be ideally guided by laboratory results. However, in trauma and massive transfusion setting, it may be necessary to empirically transfuse before laboratory results are available. Many hospitals have trauma transfusion protocols in which a predetermined plasma:RBC ratio is transfused. Platelet counts should be maintained >50,000/μl and cryoprecipitate should be given to maintain the fibrinogen level above 100 mg/dL. Whole blood clotting assays, such as thromboelastography (TEG) and rotational TEG (RoTEG) can be used to guide transfusion therapy in trauma and massive transfusion settings [13].

Adverse effects of blood transfusion

Major improvements have been made in blood safety over the last 20 years, particularly with the implementation of direct methods of viral detection using nucleic acid testing. The risk of HIV and HCV transmission through blood transfusion is less than 1 in a million [14,15]. (Table 267.1). While the risk of known viruses has become minimal, non-infectious risks are now the most common causes of transfusion related morbidity and mortality including TRALI, TACO, and acute haemolytic reactions.

Acute haemolytic transfusion reactions are caused by immune-mediated lysis of transfusion red cells via complement activation (intravascular haemolysis). Symptoms/signs include fever, chills, haemoglobulinaemia, haemoglobulinuria, shock, and DIC. The most common cause is infusion of ABO-incompatible blood due to human clerical error. Treatments include hydration, diuretics, blood pressure support, and treatment of DIC if present. Careful patient identification at the time of pretransfusion specimen collection and blood administration are keys in preventing acute haemolysis caused by ABO-incompatible transfusions [13]. With approximately 13.5 million RBC transfused each year in the USA, the estimated risk of death due to haemolysis is 1 in 1,250,000 (or 8 per 10 million RBC units) [6].

Febrile non-haemolytic transfusion reactions (FNHTR) are characterized by fever (≥1°C elevation), which may be accompanied by chills, rigors, hypertension, tachycardia, and dyspnoea without another clinical explanation. Leukocytes and cytokines released by leukocytes in the blood components are the primary cause of FNHTR, which has been reported to occur in approximately 0.5% of RBC or platelet transfusions. Leukoreduction (especially when performed prior to storage) has been shown to reduce the incidence of FNHTR to RBC and platelet transfusion. FNHTRs can be treated with antipyretics [13].

Allergic reactions to plasma proteins are characterized by a histamine-mediated urticarial rash occurring in 1–3% of transfused patients. In mild localized allergic reactions, transfusion can be temporarily stopped and the patient treated with antihistamines. If symptoms resolve, the transfusion can be restarted slowly with close observation. Future similar reactions can be prevented with pretransfusion medications using antihistamines and if the reaction was more severe, steroids 30–60 minutes before the start of the transfusion. Anaphylactic reactions to blood products are rare, occurring in patients with antibodies again plasma proteins such as IgA, haptoglobin, or complement (C4). Patients with severe allergic or anaphylactic reactions should be treated with fluid resuscitation, epinephrine, and steroids. Washed cellular blood components (RBCs and platelets) are indicated. Patients with anaphylactic reaction due to IgA deficiency should receive IgA deficiency plasma which can be obtained through rare-donor registry [13].

TRALI is manifested as new onset of dyspnoea, hypoxia, and non-carcinogenic bilateral pulmonary oedema associated with transfusion without another cause. It is an inflammatory process due to a proposed two-step mechanism:.

- Predisposing clinical event (including trauma or infection) leading to endothelial and neutrophil priming.
- Transfusion of biological response modifiers (including antibodies to human leukocytes and neutrophil antigens).

This leads to activation of neutrophils and complement in the pulmonary vasculature resulting in capillary leakage syndrome [13]. Treatment is supportive with oxygen and mechanical ventilation. With the recognition of the roles of donor HLA antibodies in the pathogenesis of TRALI, blood centres have implemented strategies to reduce TRALI risk using plasma from low risk donors. As a result, the incidence of TRALI has declined by more than 60%. The rate of TRALI in 2009 was 0.81 (95% CI: 0.44–1.49) per 10,000 transfused blood components according a large prospective study [16].

Transfusion-associated circulatory overload (TACO) is cardiogenic pulmonary oedema due to the rapid and/or excessive transfusion of blood products to a patient with limited/compromised cardiac reserve. Treatments include diuresis and supportive cardiopulmonary care. The estimated incidence of TACO is 1–4% [8].

Bacterial contamination of blood components is a rare, but serious complication. Patients may experience high fever, chills/rigors, and even shock. Aggressive therapy and broad-spectrum antibiotics

Table 267.1 Risks of transfusion-transmitted viral infections

Viruses	Estimated risk in USA
Human immunodeficiency virus (HIV)	1:1,467,000
Hepatitis C virus (HCV)	1:1,149,000
Hepatitis B virus (HBV)	1:843,000 to 1:1,208,000

Data from Carson JL et al., 2012, 'Red Blood Cell Transfusion: A Clinical Practice Guideline From the AABB', *Annals of Internal Medicine*, **157**, 49–58; Zou S et al., 2010, 'Prevalence, incidence, and residual risk of human immunodeficiency virus and hepatitis C virus infections among United States blood donors since the introduction of nucleic acid testing', *Transfusion*, **50**, pp. 1495–504; and Vamvakas EC and Blajchman MA, 2009, 'Transfusion-related mortality: the ongoing risks of allogeneic blood transfusion and the available strategies for their prevention', *Blood*, **113**, pp. 3406–17.

should be started if a septic reaction is suspected. The implicated component should be sent for culture. Blood cultures should also be draw from the patient.

Alternative to blood transfusion

Several strategies can be used to reduce allogeneic blood product transfusions. Blood salvage during surgery and immediate post-post-operative period is gaining traction as a strategy for reducing blood transfusion. Strategies for reducing iatrogenic blood loss include the use of small-volume phlebotomy tube, elimination of redundant, and unnecessary laboratory testing, and the use of POC testing and non-invasive testing. Antifibrinolytic agents, such as tranexamic acid and epsilon-aminocaproic acid, have been used to decrease blood loss in cardiac surgery setting, control bleeding in patients on extracorporeal membrane oxygenation (ECMO), and in the management of thrombocytopenic bleeding. The available data on erythropoietin (EPO) indicates that it does not improve survival in critically-ill patients. There may be increased risk for thrombotic complications [13]. There are no safe and effective haemoglobin-based oxygen carriers to replace blood.

CHAPTER 268

Apheresis in the ICU

Marion Sternbach

Key points

- Apheresis means selective removal of either cellular or harmful molecular elements from blood.
- Instruments are based mostly on density centrifugation, less on specific column adsorption or membrane filtration.
- Plasmapheresis for noxious molecules uses albumin 5% most frequently. Fresh frozen plasma (FFP) is used therapeutically only in thrombotic micro-angiopathies.
- Critical care therapies may interfere or be interfered by plasmapheresis. Careful monitoring during and after apheresis cannot be over emphasized.
- Indication for plasmapheresis in haematological disorders proved as effective by RCT are only for thrombotic micro-angiopathies.

Definition

Apheresis is derived from Greek and means 'to remove'. Initially, it was used in situations like life-threatening neutropenia or hyperviscosity states. It involves separation of blood cellular elements or plasma from cellular elements, and occasionally removing harmful molecules from the plasma, returning purified plasma to the patient.

Instrumentation

Most apheresis machines are based on the principle of continuous or intermittent density centrifugation. Some instruments have attached devices for selective column adsorption or membrane filtration for specific molecules, like antibodies or antigen-antibody complexes.

Physical and biochemical principles of therapeutic plasma exchange

Plasma exchange removes harmful molecules from the circulation, but stimulates their resynthesis through feedback to lymphocytes and plasma cells. Therefore, plasma exchange has to be performed repeatedly. The rate of synthesis of some molecules can decrease if appropriate therapy is administered following plasma exchange. For steady equilibrium, 1 or 1.5 plasma volume removal will effectively deplete the body of ≥2/3 of the targeted molecule and 100% is removed by the fourth session [1]. Ions re-equilibrate very fast, while most non-immunoglobulin proteins recover within 72 hours [1].

Blood and plasma volume calculations

These can be calculated from a person's weight, gender, red cell volume, and muscle mass. Muscular people have a higher total blood volume (TBV) than obese persons.

During apheresis procedures extracorporeal blood volume should never exceed 15% of TBV to avoid hypovolaemia. Different instruments have different extracorporeal volumes varying between 150 and 500 mL. Therefore, small persons and children may not be able to tolerate a large extracorporeal volume. In such cases, the instruments can be primed with albumin 5% or a colloid solution.

Replacement fluids for plasma exchange

Albumin 5% with saline is the most common fluid. Fresh frozen plasma (FFP) or cryo-poor plasma are used only for thrombotic thrombocytopenic purpura (TTP), haemolytic uraemic syndrome (HUS), and for hypofibrinogenaemia. Hypocalcaemia due to citrate and albumin infusion is an important consideration. Adverse effects of hypocalcaemia, depending on its level, are far reaching from inhibition of haemostasis to neuromuscular symptoms and signs up to seizures and cardiac arrhythmias [2]. Citrate levels will rise in addition to anticoagulation at ratios 1 part citrate to 10–14 parts of blood, by infusion of FFP containing citrate (CPD). On the other hand albumin will bind Ca^{2+} too. The body's parathormone will try to compensate by elevating Ca^{2+} levels. It rises fast, levels off, and decreases later during the procedure [3,4]. Higher concentration of citrate, as well as rate of its infusion and duration of the procedure will worsen hypocalcaemia.

Pathophysiology of apheresis

Therapeutic plasma exchange (TPE) depletes the body of immunoglobulins and coagulation factors. However, rapid resynthesis occurs due to negative feedback.

During thrombapheresis lymphocyte depletion also occurs because of their vicinity during density centrifugation. Lymphocytes that are long lived are not easily replaced by the lymphatic system.

For vascular access, peripheral antecubital veins are preferred as they typically permit a blood flow of 60–120 mL/min and completion of a TPE in about 3 hours. Major cell collections take longer and require more invasive access, such as subclavian or jugular vein with rigid double lumen catheters. Central venous catheters are considered potentially dangerous because of possible clotting and septic complications.

Bleeding due to apheresis is rare, unless one is facing underlying DIC with septicaemia, hepatic coagulopathies, or vitamin K

depletion due to broad spectrum antibiotics and starvation. In such cases, replacement fluid may have to include FFP and vitamin K.

During and immediately following the procedure, the prothrombin time (PT) and partial thromboplastin time (PTT) may be prolonged, and platelets and fibrinogen may fall, but clinical haemorrhage is rare, and abnormalities usually resolve in 24 hours.

Adverse effects

Adverse events occur in 4–5% of cases, especially in first time procedures, as shown in a large US review [1]. These events include fluid overload or hypovolaemia, unintentional removal of drugs from the circulation, citrate-induced hypocalcaemia and alkalosis, vaso-vagal reactions, allergic reactions, and some specific drug interactions. Careful monitoring of fluid status and consideration of drug redosing are therefore important. To avoid hypocalcaemia, consider using the lowest ratio of citrate to blood that prevents clotting. With early signs or symptoms of hypocalcaemia, consider reducing the blood flow to 50 mL/min. Treatment with oral calcium may be useful, but more severe cases require intravenous (iv) calcium gluconate, and aphersis should be put on hold. Allergic reactions are typically to hydroxyethyl starch (HES), plasma or the ethylene dioxide in the tubing. Typical drug interactions relate to the blunting of physiological responses to volume shifts by drugs, such as beta blockers or calcium channel blockers.

Therapeutic plasma exchange in haematological disorders

TPE is most commonly indicated, and most clearly demonstrated to be efficacious, in select haematological disorders, such as thrombotic thrombocytopenic purpura (TTP)/haemolytic uraemic syndrome (HUS) [5]. Thrombotic micro-angiopathies present with micro-angiopathic haemolytic anaemia, thrombocytopenia, and microthrombi due to platelet aggregation in small arterioles in kidneys, brain, heart, and in pregnancy even in the liver.

They comprise TTP, HUS, and HELLP (haemolysis, elevated liver enzymes, low platelets in pregnancy). Depending on the predominance of the brain versus kidney, the disease is coined either TTP or HUS. In overlap symptomatology it is called TTP/HUS [6]. A similar micro-angiopathy occurs in pregnancy, usually in the third trimester, known as HELLP, life-threatening to both mother and fetus. Immediate delivery is here indicated. If the condition does not resolve spontaneously post-partum, TPE is indicated with FFP or cryo-poor plasma.

The pathogenesis of thrombotic micro-angiopathies has been elucidated to be due in part to deficiency of ADAMTS 13, a metalloprotease cleaving ultra large von Willebrand multimers, originating in the endothelium, causing microthrombi through platelet aggregation. This deficiency may be either congenital or acquired due to antibodies to ADAMTS 13. TPE with FFP replaces at least in part the deficient enzyme. TPE with cryo-poor FFP is devoid of von Willebrand multimers, which ought to make it more efficacious. This has not been proven unequivocally to date.

Moshkovwitz's classic 'pentad' of haemolysis, low platelets, neurological symptoms and signs (from headaches to palsies and seizures), renal failure, and fever is not always present. The presence of micro-angiopathic haemolytic anaemia and thrombocytopenia establish the likely diagnosis of TTP/HUS and justify the start of TPE, since this disease has a very high mortality in the absence of plasma exchange. If TPE cannot be started right away, infusion of FFP should be considered. Renal involvement may start with proteinuria, haemoglobinuria and haematuria and may end up with dialysis dependent uraemia. Early TPE may prevent this latter. *E. coli* with enterotoxin or *Shigella* are frequent aetiologies of HUS. Laboratory features are schistocytes and fragmented red blood cells, thrombocytopenia, elevated lactate dehydrogenase and unconjugated bilirubin, elevated creatinine. Usually PT, PTT, fibrinogen, and thrombin time are within normal limits. Direct antiglobulin test (Direct Coombs') is negative. These parameters need to be monitored before and after daily TPE of 1–1.5 volume.

The average number of apheresis procedures to achieve lasting remission is 16. Mortality has dropped from 80% to less than 20%, but relapses after 1 month to years amount to 20% [7]. There are also cases with refractory TTP/HUS in 10–22% of patients. They will require repeat plasma exchanges and may benefit from anti-platelet drugs and splenectomy [8], as well as immune suppressant drugs, like vincristine, cyclosporin A, cyclophosphamide and rituximab (anti-CD20 monoclonal antibody), most successful [9].

Platelet transfusions may be harmful in TTP, 'fuelling the fire' of thrombotic micro-angiopathy. However, red cell transfusions may become necessary in severe haemolytic anaemias, either during or following plasmapheresis. Rock et al. showed in a randomized controlled trial (RCT) [5] comparing TPE with FFP infusion, the superiority of TPE with survivals of 78 versus 63%, respectively. The response rate was also faster in the TPE group by day 9, 82 versus 49% in the FFP infusion group. The average number of TPE required was 15.8, including tapering with five treatments over 2 weeks.

Adult HUS is more severe than the paediatric, epidemic variety associated with *E. coli* verotoxin (O-157 H:7) or *Shigella* with diarrhoea at the outset. Adults may suffer from enterocolitis, neurological manifestations, liver impairment, pancreatitis, and even cardiac ischaemia with severe renal failure, requiring dialysis. Histology of renal biopsies in these patients show platelet aggregates, with von Willebrand Factor, thrombin in the glomeruli with fibrin deposits and widening of the glomeruli. HUS has usually somewhat higher platelets, over 31,000/μl. TPE has not been established as the most efficacious treatment. ADAMTS 13 may be normal or somewhat reduced in HUS.

HELLP occurs in 10% of women with severe pre-eclampsia, but may appear also post-partum or continue after delivery. Presenting symptoms are abdominal pains, nausea, oedemas with haemolysis, thrombocytopenia, liver dysfunction. Maternal mortality is about 1%, infant mortality goes as high as 10–20% due to placental ischaemia and possible abruption. Delivery should be performed as soon as possible. Post-partum recovery occurs usually within 6 days. In the presence of severe ongoing thrombocytopenia and organ dysfunctions plasma exchange may be helpful and, occasionally, all abnormalities have reverted to normal after a couple of procedures. ADAMTS 13 is usually reduced in the third trimester of pregnancy and no useful marker.

Autoimmune haemolytic anaemia with warm antibodies

Plasma exchange is rarely first line therapy in this disease. Autoimmune haemolytic anaemia (AIHA) may be 'idiopathic',

due to underlying autoimmune disease, like systemic lupus erythematosus or lymphoproliferative disorders. Its symptoms are fatigue and dyspnoea, conspicuous signs pallor, icterus, and splenomegaly. The peripheral blood film shows anaemia with spherocytosis, polychromasia, and investigations detect a positive direct antiglobulin test (DAT) or Direct Coombs' test often directed against an Rh system component and an elevated unconjugated (indirect) bilirubin. Since warm antibodies (IgG = immunoglobulin G) are widely distributed intra- and extravascular, TPE is not very helpful and should only be used in cases of fulminant AIHA, where conventional therapy with steroids given intravenous immunoglobulin (IVIg), cyclophosphamide, and splenectomy have failed.

Cold antibody haemolytic anaemia

This may be also 'idiopathic', associated with lymphoproliferative disorders, *Mycoplasma* pneumonia, viral diseases, like Hepatitis B, infectious mononucleosis or *Varicella*. Symptoms and signs are due to red blood cell (RBC) sludging coated by IGM antibodies with acral cyanosis of fingers, toes, ears and nose. Haemolysis occurs largely intravascularly, since IGM fixes complement. The specificity of the antibody is usually anti-I, occasionally IH or IGM dissociates itself in a warmer environment at 37°C from the RBC. The C3b-coated RBCs flowing through the liver, fix C3d (which is a C3b inhibitor), emerging more resistant to haemolysis. Thermal amplitude of these IGM antibodies determines the severity of the clinical manifestations. Cold antibody haemolytic anaemia CAHA respond poorly or not at all to steroids. Immune suppression by cyclophosphamide, azathioprine recently to rituximab (anti-CD20 monoclonal Antibody) [4,10] have been more successful.

IGM, a very large molecule is mostly intravascular and lends itself to very efficient removal by plasma exchange. One to one-and-a-half plasma volume removed, will remove up to 90% of the circulating IGM, provided the blood and fluids are maintained at 37°C, using a blood warming coil.

Immune thrombocytopenia

Is in adults a similar autoimmune disease to AIHA, starting out insidiously—in children it may follow viral infections. The auto-antibody is directed against the membrane glycoproteins on the platelet GIIb IIIa and less to GIb9. It presents with haemorrhagic symptoms of different degrees, petechiae, purpura, ecchymoses, and often active bleeding. The blood film shows scant platelets, but large, often giant young ones. The bone marrow is replete of megakaryocytes, young, and hypoploid with no pathology. TPE is not included in the newest guidelines of the American Society of Hematology (ASH) being currently developed for immune thrombocytopenia (ITP). Correct therapy of ITP in adults includes steroids, followed by IVIg 1.0 g/kg. If that fails, immune suppression with rituximab before or after splenectomy has shown success. If all fails TPE has been used by Bussell followed by large dose IVIg in a few refractory cases [11].

Post-transfusion purpura

This is a rare syndrome, more frequently seen in females, presenting as severe thrombocytopenia, 10,000–20,000/μl within 5–14 days usually following red cell transfusion. The pathogenesis is due to previous sensitization to a specific platelet antigen PLA1 during pregnancy, which persists in the recipient. The antigen, absent in the recipient is being transfused with the red cells, adsorbed to the recipient's platelets and then reacting with the specific (Immunoglobulin G (IgG) antibody to PLA1. Thus the platelets are destroyed as 'innocent bystanders'. Post-transfusion purpura PTP responds usually dramatically to IVIg [4]. TPE has been used successfully in cases of failure due to IVIg [12]. Haemostasis should be closely monitored during and after plasmapheresis, since dilutional coagulopathies may occur and FFP may have to be used as replacement fluid.

Coagulation factor inhibitors (allo- and autoantibodies)

Allo-antibodies against Factor VIII in haemophiliacs occur in 15–20% of this population. Autoantibodies against this appear spontaneously in SLE, pregnancy, and may be a presenting symptom or sign in lymphoproliferative disorders. Immune suppressive therapy with corticosteroids, cyclophosphamide, and rituximab have been used for eradication of the autoantibody. 'Bypassing coagulation factors' with activated Factor VII, have been used in severe, life-threatening haemorrhage. Porcine Factor VIII can be used successfully, though cross-reacting antibodies with the porcine Factor VIII may also develop.

Slocombe described successful plasma exchange in a haemophiliac with alloantibodies to Factor VIII and post-operative haemorrhage: fourteen daily 4.0 l. exchanges reduced the antibody by 90% [13]. TPE followed by immune suppression with steroids, and cyclophosphamide and Factor VIII infusion resulted in good control of haemorrhage [14]. Central catheters in such bleeding patients should be, if possible, avoided. Currently anti-Factor VIII inhibitors can be successfully treated by column adsorption.

Hyperviscosity syndromes

Occur in lymphoproliferative disorders with IGM monoclonal antibody hyperproduction. These are large molecules of 900,000 Dalton present in 50–70% of patients with Waldenstrom's macroglobulinaemia. These large, intravascular molecules cause hypervolaemia due to their colloid osmotic pressure. They also surround and coat the red cells lowering their 'zeta' (electro-negative repealing) potential, thus causing sludging in the microcirculation in the brain and eyes. Symptoms consist of headaches, dizziness, somnolence, nystagmus, stupor, and if untreated, lead to coma. Eye grounds show sausage-shaped veins, poor pulsations, haemorrhages, and retinal exudates. When plasma viscosity reaches four times that of water (Ostwald units), symptoms may appear, over 8 Ostwald units, manifestations become severe. Impaired platelet function and fibrin polymerization may result in a coagulopathy. TPE results in immediate and dramatic improvement of symptoms, since one volume exchange removes 90% of the intravascular immunoglobulin. Chemotherapy is very important as mainstay, since TPE stimulates through its IGM removal 'feedback' resynthesis of IGM by lymphocytes. ASFA and AABB classify hyperviscosity as category II indication for TPE.

Myeloma with renal failure

Myeloma is classified by the WHO as a lymphoplasmacytoid lymphoproliferative disease, often evolving from a monoclonal gammopathy at a rate of 1% per year. Its characteristics are a monoclonal immunoglobulin expansion due to neoplastic plasma cell proliferation, which cause through osteoclastic activity very painful osteolytic lesions. Anaemia due mostly to bone marrow infiltration by plasma cells, but often, in part, also due to the accompanying renal failure.

Renal impairment progressing to severe renal failure requiring haemodialysis is multifactorial. Good hydration and occasional haemodialysis may be required to reverse or improve renal failure to enable appropriate chemotherapy. TPE has been used in myeloma renal disease in RCT with variable success. Where TPE was compared with its absence, but where one arm consisted of TPE, chemotherapy, and haemodialysis, while the control arm had no TPE, but peritoneal dialysis the outcomes were good favouring TPE significantly with improved renal function (creatinine < 2.5 mg/dL), marked decrease of light chain proteinuria and significantly improved survival, 66% in the TPE group, versus 28% in the control arm [15]. TPE was not shown to be superior to conventional chemotherapy in a small study of patients with multiple myeloma [16].

Cryoglobulinaemia

Encompasses diverse groups of immunoglobulins with a low thermal amplitude, which causes their precipitation at even room temperature:

- **Type 1**: monoclonal proteins seen with myeloma.
- **Type 2**: mixed cryoglobulins, monoclonal IGM, and polyclonal IGG, as seen in autoimmune diseases, like rheumatoid arthritis, scleroderma, or leucocytoclastic vasculitis.
- **Type 3**: antigen-polyclonal immunoglobulin complexes, associated with glomerulonephritis, polyarthralgias, and skin ulcerations.

Pathogenetic therapy comprises steroids, (except in hepatitis C) and immune suppression [17]. TPE as adjuvant therapy has a salutary effect on symptoms, clinical signs and a protective effect on renal function [18].

Cytapheresis in the critical care setting

Cytapheresis implies selective removal of blood cell types from the buffy coat, separable by density centrifugation. This has become possible over the years through highly sophisticated cell separators, electronic cell size recognition and computerized programming. Centrifugal force and speed in the separation chamber allows for collection of platelets from the upper most layer of the buffy coat, mononuclear cells (MNC): lymphocytes, blasts, monocytes from the lower layer and polymorphonuclears (PMN) from the deepest layer of the buffy coat. This latter can be enhanced by hydroxyethyl starch (HES), causing rouleaux formation of red cells, thus separating the PMN more visibly from the RBCs and harvesting larger numbers.

The intended number of cells to be removed is not easily predictable:

- Blood volumes calculated may be underestimated.
- Cells may be recruited also from bone marrow and large spleens.
- Leukaemic blasts may have different sedimentation density than expected [19].

Therefore it is recommended to monitor harvested cell numbers during cytapheresis procedures until the desired number has been collected. In therapeutic cell depletions one should achieve optimally 30–50% collection of the harmful elements.

Therapeutic plateletpheresis (thrombapheresis)

Is indicated in rare cases of myeloproliferative neoplasias (MPN), such as chronic myelogenous leukaemia (CML) and essential thrombocythaemia (ET) with platelet counts of 100–10^{-9}/L (over 1 million per µl) with clinical evidence of haemorrhagic or thrombosing tendency, and only until chemotherapeutic agents (e.g. hydroxyurea or anagrelide) have started to lower platelets. Thrombosis may be venous like in Budd–Chiari syndrome or arterial in stroke, gastrointestinal haemorrhages can be severe and life-threatening.

Therapeutic leukapheresis

This is performed in leukaemia with high blast counts of over 100,000/µl because of leucostasis, impending or ongoing tumour lysis syndrome and high mortality.

Table 268.1 ASFA and AABB indication categories for therapeutic apheresis in hematologic diseases and dysproteinemias

Disease	ASFA/AABB Category
ABO-incompatible marrow transplant	II
Aplastic Anemia	III
Autoimmune hemolytic anemia	III
Coagulation Factor Inhibitor	II
Cryoglobulinemia	II
HELLP syndrome (postpartum)	NR
Hemolytic uremic syndrome	III
Hyperviscosity syndrome/multiple myeloma	II
Immune Thrombocytopenic Purpura	II*
Posttransfusion purpura	I
Pure red cell aplasia	III
Red cell alloimmunization	III
Thrombotic thrombocytopenic purpura	I

*This disorder is only ranked in context of staphylococcal protein A immune adsorption. NR, Disorder not ranked by AABB or ASFA; HELLP, hemolysis, elevated liver enzymes, low platelets; Category I, standard acceptable therapy; Category II, available evidence suggests efficacy; Category III, available evidence inconclusive; Category IV, ineffective in controlled trials.

From: THERAPEUTIC APHERESIS, A Physician's Handbook 1-st Edition 2005 AABB and ASFA,Editor: Bruce C. McLeod, MD. Reproduced with permission of the Editor and Publishers.

Clinical leucostasis manifestations are microvascular sludging in brain and eyes, as well as in the pulmonary circulation in acute leukaemia. In CML priapism has been seen on occasion. The causes of leucostasis are multifactorial, of which hyperviscosity is the least important, while reduced deformability, cytokine secretion, inter-adherence of mostly myeloblasts are essential [19,20]. Hyperleucocytosis has a poor prognosis at presentation. It parallels hyperuricaemia and unless treated promptly, leads to tumour lysis syndrome. Therefore, it should be dealt with by apheresis, before initiating definitive chemotherapy, thus making it an urgent indication.

The risk of introducing a central venous line in patients with severe thrombocytopenia or even coagulopathies in acute promyelocytic leukaemia and acute monocytic leukaemia has to be weighed against the benefits of leukapheresis. The extent and number of leukapheresis procedures to prevent tumour lysis syndrome is unknown. Removal of large number of blasts, will also remove significant amounts of plasma, therefore fluid replacement is essential. Efficiency of cell removal is increased by HES addition as sedimenting agent and volume expander. Cell counts should be monitored, during procedures, as well as volume status and urinary output.

PART 11.3

Disordered coagulation

CHAPTER 269

Pathophysiology of disordered coagulation

Simon Stanworth and Stuart McKechnie

Key points

- The integrity of haemostasis is maintained by complex interactions between the vascular endothelium, the coagulation cascade, anticoagulant mechanisms, the fibrinolytic system, platelets, leucocytes, inflammatory mediators, and blood flow dynamics.
- Dysregulation of haemostasis is common in critically-ill patients, and may result from infection, trauma, haemorrhage, inflammation, organ dysfunction or drug therapy.
- Dysregulation of haemostasis may present as bleeding or thrombosis, although complex patterns of coagulopathy, where both bleeding and pro-thrombotic tendencies co-exist, are well recognized in critical illness.
- The laboratory tests of APTT and PT were developed to investigate coagulation factor deficiencies in patients with a known bleeding history, and their limited significance and applied clinical value in predicting bleeding (or thrombotic) risk in critically-ill patients is well recognised.
- The diversity of mechanisms and interactions between coagulation pathways and inflammation is considered with reference to two different clinical settings, sepsis, and trauma.

Normal haemostasis

Haemostasis *in vivo* results from the complex interplay of vascular endothelium, platelets, a series of soluble coagulation factors known as the coagulation cascade, anticoagulation mechanisms and the fibrinolytic system. The key points of haemostasis are summarized in the following sections and in Fig. 269.1.

Primary haemostasis

This refers to the generation of a platelet plug. Injury of the vascular endothelium results in vascular endothelial contraction and exposure of underlying collagen. Circulating platelets bind to the exposed collagen via collagen-specific glycoprotein surface receptors. Von Willebrand factor (vWF), released from endothelial cells and platelets, also attaches to the exposed subendothelium. This is followed by interactions between platelets and vWF mediated by specific glycoprotein receptors (e.g. gpIIb/IIIa) on the platelet surface. Platelet activation then occurs. Platelets change shape and start to secrete a variety of pro-coagulant factors (e.g. adenosine diphosphate (ADP), calcium, serotonin, fibrinogen, lysosomal enzymes, and platelet factor 4) at the site of injury. The arachidonic acid pathway is also stimulated by platelet activation resulting in formation of thromboxane A_2 (TXA_2). The interaction of platelets with vWF, released enzymes, ADP, and TXA_2 promote platelet aggregation and the formation of a platelet plug. This temporarily seals the breach in the endothelium at the site of injury and provides a surface for the procoagulant reactions of secondary haemostasis.

Secondary haemostasis

This refers to the formation of a stable fibrin clot by activation of an integrated cascade of enzymatic reactions. Initiation of coagulation occurs when circulating factor VII (FVII) is exposed to tissue factor (TF) in subendothelial tissues, resulting in formation of a TF-FVIIa complex. Through its action on Factors IX and X, and the formation of the tenase (FIXa and its cofactor FVIIIa) and prothrombinase (FXa and its cofactor FVa) complexes, the TF-FVIIa complex leads to the generation of thrombin. Thrombin cleaves fibrinogen to fibrin, the ultimate step in the coagulation chain reaction. Fibrin monomers link together, polymerizing to form fibrils that are then cross-linked by Factor XIIIa-mediated covalent bond formation to form a stable fibrin clot.

Thrombin

The protease **thrombin** plays a key role in haemostasis, including activation of platelets and clotting factors (V, VIII, and XIII), activation of anti-coagulant factors (protein C) and interaction with pathways of fibrinolysis (in particular by activation of plasminogen activator inhibitor type 1 (PAI-1) and thrombin-activatable fibrinolysis inhibitor (TAFI)).

Anticoagulant control

Natural **anticoagulants** control thrombin generation and other steps of the clotting cascade. Principal anticoagulant pathways include tissue factor pathway inhibitor (TFPI), which inhibits the FVIIa-TF complex, antithrombin (AT, also known as antithrombin III), which inhibits thrombin (and other activated clotting factors) and activated protein C, which, with its co-factor protein S, inhibits activated factors V and VIII. Protein C also attenuates tPA inhibition, increasing plasmin generation and fibrinolysis.

Fibrinolysis

This is a normal homeostatic mechanism following vascular injury, ensuring that fibrin clot formation remains localized to the site of injury. The fibrinolytic system contains an inactive pro-enzyme,

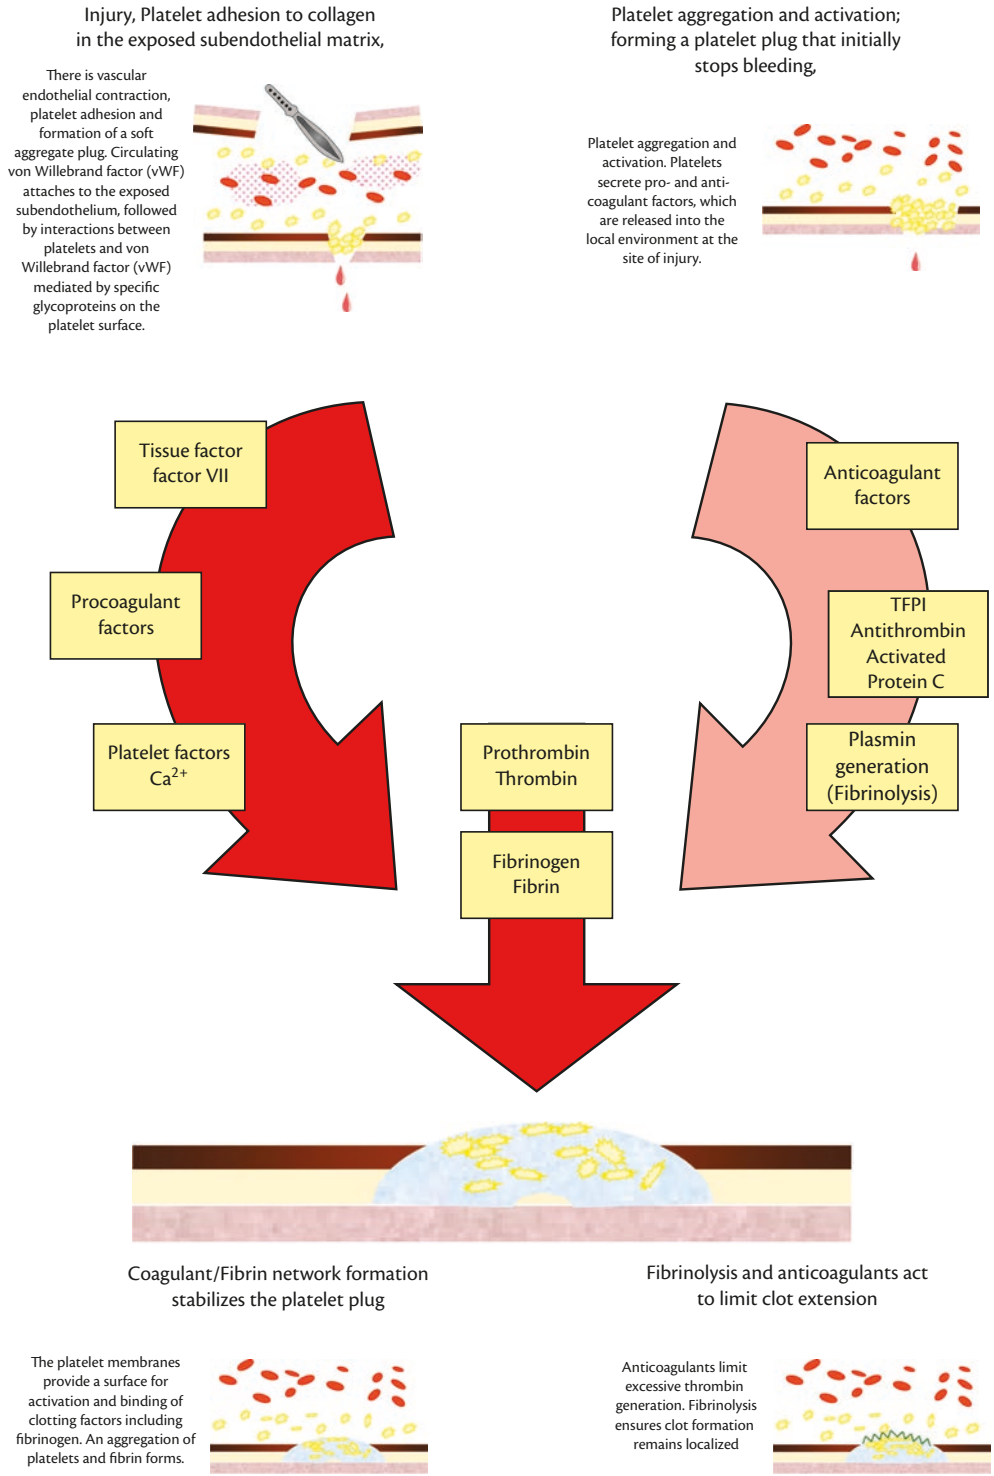

Fig. 269.1 An illustration of the pathways of haemostasis *in vivo*.

plasminogen, which is converted to plasmin by tissue plasminogen activator (tPA). tPA is released from the endothelium in response to a variety of stimuli including trauma, thrombin, and venous stasis. tPA binds to fibrin and converts clot-bound plasminogen to plasmin. Plasmin degrades fibrin and fibrinogen into a number of soluble fibrin degradation products. Plasmin activity is inhibited by α_2-antiplasmin and the therapeutic agent tranexamic acid. Fibrinolysis is also inhibited by thrombin-activatable fibrinolysis inhibitor (TAFI).

Vascular endothelium

The **vascular endothelium** plays an important role in maintaining haemostasis. Under normal conditions, endothelial cells form a regulated antithrombotic interface between the blood and tissues

by synthesizing a number of anticoagulants, including nitric oxide, thrombomodulin, prostacyclin, and glycosoaminoglycans. Injury exposes subendothelial collagen leading to the local expression of tissue factor and the localized sequence of haemostatic events described. However, widespread changes in endothelial cell function and tissue factor expression can occur in response to circulating cytokines (e.g. IL-8, TNF, IL-1, and IL-6) and/or bacterial endotoxin rendering the endothelial surface procoagulant.

Molecular pathophysiology

The structural domains of many proteins involved in haemostasis have been characterized. These typically include multiple functional units, presumably derived from common ancestral genes, which are responsible for key steps of synthesis, post-translational processing (vitamin K dependent procoagulant factors), membrane binding, and enzyme function. The first coagulation factor gene to be cloned and characterized in the early 1980s was Factor IX, the deficiency of which leads to haemophilia. Factor IX is a much smaller gene than factor VIII, and this is one reason why gene transfer has been reported and tested first for Factor IX deficiency, including the recent documentation that dose-dependent increases in FIX can be achieved and sustained in humans by gene therapy [1]. Von Willebrand disease is the commonest inherited bleeding disorder causing primary haemostatic defects, with a gene prevalence of around 1%. Many different mutations have been identified across the large number of exons of the vWF gene.

While inherited causes of bleeding appear to be often related to single gene abnormalities, thrombotic tendencies appear to reflect more complex interactions between acquired factors and multiple genes. Inherited thrombophilia describes patients with genetic defects that predispose them to thrombosis. The hereditary thrombotic disorders include deficiencies of anticoagulants (anti-thrombin, protein C, protein S), and mutations in selected genes, such as factor V Leiden, and a prothrombin gene mutation. Although the prevalence of some of these thrombophiliac mutations is common in populations, the relative risk for venous thrombosis is often not significantly increased. The co-inheritance of other genetic factors (some as yet unidentified), or contributions of acquired, or environmental risk factors (e.g. advancing age, atherosclerosis, malignancy, and trauma) is likely to be highly relevant and this will particularly apply for admissions to critical care.

Laboratory tests of disordered coagulation

The term disordered coagulation or coagulopathy is often used synonymously with abnormalities in standard laboratory coagulation test results, most frequently the platelet count, activated partial thromboplastin time (APTT) and prothrombin time (PT). Abnormalities of these tests (**laboratory-defined** coagulopathy) are common in hospital practice. In some patients, the abnormal results are largely incidental to the reason for admission to critical care (e.g. mild inherited 'deficiencies' of coagulation factors or the presence of lupus anticoagulant). However, the clinical significance of abnormal laboratory tests often remains unclear. The laboratory tests of APTT and PT were developed to investigate coagulation factor deficiencies in patients with a known bleeding history, and their significance and applied clinical value in predicting bleeding (or thrombotic) risk in critically-ill patients remains debatable [2]. Both PT and APTT results are dependent on reagent and laboratory quality controls and may be abnormal for a number of reasons not associated with bleeding risk, including normal variation of coagulation factor levels, or the presence of a lupus anticoagulant, or as part of an acute phase response. Coagulation results also vary in sensitivity with reduced levels of different coagulation factor levels. For example, the APTT will be significantly prolonged with only small reductions in the levels of some intrinsic coagulation factors, and the PT, in particular, is sensitive to mild (but not clinically significant) deficiencies of multiple pro-coagulants, as is often seen in clinical practice, for example liver disease [3].

Many laboratories report the international normalized ratio (INR), but the INR was developed to monitor warfarin therapy by standardizing PT results to account for different sensitivities of thromboplastins in the laboratory. The extrapolation of PT to INR is really only valid for those patients stably anticoagulated with vitamin K antagonists, and may not be a valid measure of coagulation for many patients in critical care. An INR of 1.5 is not equivalent to a PT of 1.5× midpoint of reference range, although it may approximate to this measure as the ISI value (a measure of 'quality' of the laboratory coagulant reagents) moves closer to a standard of 1.0. A study by Deitcher (2002) showed that over the INR range of 1.3–1.9 inclusive, mean factor levels ranged from 31 to 65% (FII), 40 to 70% (FV), and 22 to 60% (FVII). All of these levels are consistent with adequate concentrations of factors to support haemostasis in most clinical settings.

Newer global tests of haemostasis may provide a more clinically meaningful assessment of overall haemostatic competence. These include tests to assess endogenous thrombin generation potential (e.g. thrombin generation tests) or visco-elastic techniques such as thromboelastography (TEG) and thromboelastometry (TEM).

Features of disordered coagulation in critical care

Disordered coagulation in critical illness occurs as a consequence of multiple haemostatic abnormalities (Table 269.1), and may present clinically as bleeding or thrombosis [5]. Clinical bleeding ranges from minor localized bleeding (e.g. bleeding from vascular access sites), to microvascular bleeding, major haemorrhage (e.g. gastrointestinal haemorrhage resulting in shock) or bleeding in a critical site (e.g. intracranial haemorrhage). Using a structured bleeding assessment tool, a group in Canada reported rates of bleeding in 100 consecutive patients admitted to ICU [6]. Bleeding, often minor, occurred in the majority (90%) of patients, with one in five patients experiencing a major bleed. A decrease in platelet count and prolonged PT were independent risk factors for major bleeding in this observational study, the use of prophylactic anticoagulation was not.

In a prospective multicentre study (ISOC-1), of all sequentially admitted patients to UK general intensive care units (ICUs), around 30% of patients had or developed a prolonged PT (defined pragmatically as an INR >1.5) [7,8]. Most INR abnormalities appeared minor and short-lived, with ~70% of worst INR values in the range 1.6–2.5. Patients with PT prolongation in this study were more likely to have sepsis, be older, female, have higher APACHE II scores, chronic liver disease, and dialysis-dependent renal failure. PT prolongation was also associated with increased risk of death. For the purposes of this study, clinically significant haemorrhage during a 24-hour period was defined as estimated total cumulative blood loss >300 mL (one unit of red blood cells) or bleeding from a critical site, e.g. intracranial bleed. Clinically significant

Table 269.1 Haemostatic abnormalities in critically-ill patients

Disease	Haemostasis
Liver disease	◆ All clotting factors decreased except factor VIII and vWF ◆ Decreased AT, PC, PS ◆ Decreased platelet count ◆ Platelet dysfunction ◆ Dysfibrinogenaemia ◆ Increased fibrinolysis (rare) ◆ DIC (in patients with acute hepatic failure)
Renal failure	◆ Major abnormality is platelet dysfunction ◆ Decreased clotting factors rare in the absence of uremic enteritis, liver disease, or DIC ◆ AT deficiency in nephrotic syndrome
Cardiopulmonary bypass surgery	◆ Platelet function defect (the most common and relates to duration of surgery) ◆ Over-heparinization is common; this causes increased APTT but bleeding is rare ◆ Decreased fibrinogen ◆ Decreased factors II, V, VII, X, XI ◆ DIC
Severe head injury	◆ Increased FDPs ◆ DIC
Massive transfusion	◆ Decreased procoagulant factors (see text) ◆ Acute traumatic coagulopathy ◆ Iatrogenic dilutional coagulopathy ◆ DIC
Warfarin	◆ Decreased factors II, VII, IX, X ◆ Decreased PS, PC
Heparin	◆ LMWH Inhibits action of Xa; heparin inhibits other factors ◆ Thrombocytopenia (rare, unless HITT)
Thrombolytic agents	◆ Increased plasmin, FDPs ◆ Decreased fibrinogen
DIC	◆ Decreased pro and anti-coagulant factors ◆ Decreased fibrinogen ◆ Decreased platelets ◆ Increased FDPs

vWF, von Willibrand factor; AT, Antithrombin; PC, Protein C; PS, Protein S; DIC, Disseminated intravascular coagulation; APTT, Activated partial thromboplatin time; FDP, Fibrin degradation product; LMWH, Low molecular weight heparin; HITT, Heparin induced thrombocytopoenia and thrombosis.

haemorrhage was recorded most frequently affecting the gastrointestinal tract, chest, and abdominal cavity, and occurred in 258 out of 1923 (13%) patient admissions. There was no association with the degree of INR derangement and the occurrence of haemorrhage (10.2 versus 9.2%), including major haemorrhage (6.4 versus 6.8%) in this study.

Haemostatic disturbance should not be considered in terms of coagulation pathways in isolation. Thrombocytopenia in critically-ill patients is a well-recognized independent risk factor for death, and the prevalence of mild ($<150 \times 10^9$/L) and severe ($<50 \times 10^9$/L) thrombocytopenia in adult ICU patients is reported at around 40 and 8%, respectively. In the ISOC-1 study, the period prevalence of severe thrombocytopenia ($<50 \times 10^9$/L) for the entire ICU stay was 13.7% when the 24 hours prior to admission was also included [9]. 35.4% of patients who experienced severe thrombocytopenia died in ICU. During their ICU stay, patients with severe thrombocytopenia were more likely to experience an episode of clinically significant bleeding. There was wide variation in platelet transfusion use, and patients commonly received platelet transfusions on days without clinically significant haemorrhage.

Thromboembolism, most notably deep vein thrombosis (DVT) and pulmonary embolus (PE), is an important cause of morbidity and mortality in critically-ill patients. In addition to clot formation in the macrocirculation, the development of a prothrombotic tendency and thrombosis in the microcirculation is increasingly recognized as central to the pathogenesis of organ dysfunction in several conditions, including sepsis, trauma, and DIC, for example. Whilst bleeding is often (but not always) clinically apparent, thrombosis (particularly in the microcirculation) may be clinically occult. Compounding this, standard laboratory tests of coagulation (PT, APTT, platelet count, D-dimers) have less value in defining thrombotic risk. Significant thrombosis is likely to be under-diagnosed as a result. Although observational studies report a large range of incidence (1–31%), DVT is present in around 2% of admissions to critical care and thought to occur in 5–10% of patients following admission, even those on prophylactic anticoagulation. The most significant risk factors associated with DVT appear to be a previous history of DVT, renal failure and vasopressor therapy. Pulmonary embolus was radiologically confirmed in 0.5% of critically-ill patients in one large multicentre observational study, but post-mortem examination suggests the incidence of PE may be significantly higher (20–27%).

Pathophysiology of disordered coagulation in critical care

The pathophysiology of the coagulopathy occurring in sepsis and trauma, is considered here in more detail. Disseminated intravascular coagulation is described elsewhere.

Inflammation and sepsis

Studies of specific markers of coagulation activity, such as activated clotting factor assays, suggest that systemic inflammation triggers widespread activation of coagulation, with pro-inflammatory cytokines activating procoagulant pathways and downregulating anticoagulant pathways [10]. The net result of this interaction between inflammatory and coagulation pathways in sepsis are widespread thrombin generation, intravascular fibrin deposition, and a consumptive coagulopathy. Reduced levels of coagulation factors and thrombocytopenia may result in increased bleeding risk in patients with systemic inflammation [11], whilst microvascular fibrin deposition and thrombosis has been implicated in the pathogenesis of organ dysfunction.

Pro-inflammatory cytokines (notably IL-6) markedly increase the expression of tissue factor (TF) by circulating monocytes and this appears to play a central role in inflammation-induced activation of coagulation. Exposure of TF to blood results in the formation of the TF-FVIIa complex, activation of Factor X, and the conversion of prothrombin to thrombin. In animal models, inhibition of both IL-6 and TF has been shown to inhibit inflammation-induced

thrombin generation, as has infusion of recombinant tissue factor pathway inhibitor (TFPI) to achieve TFPI concentrations above physiologically normal levels in humans.

Three important anticoagulant pathways regulate procoagulant activity—antithrombin (AT), protein C, and TFPI. Systemic inflammation has an inhibitory effect on all three anticoagulant pathways.

Antithrombin inhibits thrombin, with AT activity significantly enhanced under normal conditions by heparin-like glycosaminoglycan cofactors on the endothelial surface. Circulating AT levels are significantly reduced in severe inflammation as a result of increased consumption (secondary to ongoing thrombin generation), degradation by neutrophil elastase, and reduced synthesis. Pro-inflammatory cytokines also inhibit endothelial glycosaminoglycan synthesis, reducing AT activity.

Activated protein C has antithrombotic (inactivation of Factors Va and VIIIa), antifibrinolytic (inhibition of plasminogen activator inhibitor type 1 (PAI-1)) and anti-inflammatory properties (reduced inflammatory and endothelial cell release of IL-1, IL-6, and TNF-α; downregulation of vascular adhesion molecules). Diminished activity in the protein C pathway has long been implicated as having a central role in the coagulopathy and pathogenesis of microvascular injury in sepsis. The circulating zymogen protein C is converted to activated protein C when it binds to thrombin. Protein C activation is greatly enhanced by endothelial protein C receptors (EPCRs) and thrombomodulin. Levels of protein C are reduced in sepsis as a result of increased degradation and reduced synthesis. Additionally, activation of protein C is inhibited by pro-inflammatory mediator (IL-1β, TNF-α) induced downregulation of thrombomodulin and EPCRs. Anti-coagulant activity of the protein C pathway is further decreased by reduced levels of protein S, a cofactor of protein C in the inactivation of Factors Va and VIIIa.

Increased understanding of the haemostatic changes in sepsis, most notably deficiencies in the activated protein C and AT anti-coagulant pathways, has informed the design of several recent clinical studies. To date, there is little evidence that administration of recombinant activated protein C or antithrombin to correct deficiencies improves outcome in severe sepsis. These studies are discussed in more detail in other chapters.

Trauma

In 2003, large observational studies reported that approximately one-quarter of all trauma patients had a coagulopathy on hospital admission [12]. Coagulopathy was evident in patients who had received little or no intravenous fluid therapy, and has subsequently been reported 'on-scene' (within 45 minutes) following injury. There is little current consensus about a definition of acute traumatic coagulopathy (ATC), but identifying patients with ATC is clinically important, because these patients have poorer outcomes.

In the past, trauma-induced coagulopathy was considered to be largely caused by dilution of coagulation factors (following administration of intravenous fluids or red blood cells), and exacerbated by consumption, acidosis, and hypothermia. The prevention of the 'lethal triad' of coagulopathy, acidosis, and hypothermia has become central to the management of military trauma in recent years emphasizing this interrelationship.

Several broad models may mechanistically explain traumatic coagulopathy [13]. One proposes that ATC results from the combined effects of tissue injury and hypoperfusion leading to protein C activation. Activated protein C causes the breakdown of Factors Va and VIIIa resulting in reduced thrombin generation and systemic anticoagulation. Activated protein C also inhibits PAI-1, thereby promoting fibrinolysis. Recent observational patient data confirm low clotting factor values, including low protein C values, in coagulopathic trauma patients, with the lowest values seen in Factor V. The second model suggests that tissue damage per se leads to excess tissue factor exposure, activation of coagulation, and consumption of clotting factors in a DIC-like manner. Fibrinolysis occurs not by PAI-1 inhibition, but by release of t-PA from the endothelium as a direct result of hypoxia and cell activation. However, unlike true DIC, pathological evidence of inappropriate widespread thromboses is not evident in traumatic injury.

Both hypotheses highlight the important role of fibrinolysis in ATC. Further evidence for the clinical significance of fibrinolysis comes from CRASH-2, a large multi-centre randomized controlled trial, which indicated that administration of the anti-fibrinolytic tranexamic acid within 3 hours of injury reduced mortality in patients with or at risk of significant bleeding following trauma.

CHAPTER 270

Disseminated intravascular coagulation in the critically ill

Marcel Levi and Marcus J. Schultz

Key points

- Disseminated intravascular coagulation (DIC) is a syndrome characterized by a systemic activation of coagulation leading to the intravascular deposition of fibrin in the (micro)vasculature, and the simultaneous consumption of coagulation factors and platelets.
- The relevance of the occurrence of microvascular thrombosis as a consequence of DIC is underscored by pathological, experimental, and clinical findings, demonstrating a link between DIC and organ dysfunction.
- DIC is not a disease in itself, but a complication of a variety of disorders, including sepsis, severe trauma, pregnancy complications, cancer, and systemic inflammatory states.
- The diagnosis of DIC can be made using a combination of widely available tests and may be helpful in guiding the selection of patients that require specific interventions in the coagulation system.
- The cornerstone of DIC treatment is treatment of the underlying disorder. Supportive strategies are tailored on the current insight in the pathogenesis of DIC and include anticoagulant strategies (e.g. directed at tissue factor) and strategies to restore physiological anticoagulant pathways (such as activated protein C concentrate).

Introduction

In virtually all critically-ill patients some degree of coagulation activation may be detected. In many cases, this activation of coagulation will not lead to clinical complications and will not even be detected by routine laboratory tests, but can only be measured with sensitive molecular markers for activation of coagulation factors and pathways [1]. However, if activation of coagulation is sufficiently strong, the platelet count may decrease and global clotting times may become prolonged. In its extreme form, systemic activation of coagulation is known as disseminated intravascular coagulation (DIC). DIC is characterized by the simultaneous occurrence of widespread (micro)vascular thrombosis, thereby compromising blood supply to various organs, which may contribute to organ failure [2,3]. Because of ongoing activation of the coagulation system and other factors, such as impaired synthesis and increased degradation of coagulation proteins and protease inhibitors, consumption of clotting factors and platelets may occur, resulting in bleeding from various sites.

Epidemiology and diagnosis

In clinical studies DIC has shown to be an independent predictor of organ failure and mortality [4]. In addition to microvascular thrombosis and organ dysfunction, coagulation abnormalities may have other harmful consequences. Critically-ill patients with a platelet count of $<50 \times 10^9$/L have a 4–5-fold higher risk for bleeding as those with higher platelet counts [5]. Although the overall risk of intracerebral bleeding in patients in the ICU is less than 0.5%, up to 88% of patients with this complication have platelet counts less than 100×10^9/L. In particular, thrombocytopenia that persists more than 4 days after ICU admission, or 50% of greater decrease in platelet count during the ICU stay is associated with a 4–6-fold increase in mortality.

Thrombocytopenia or a rapidly declining platelet count is an important diagnostic hallmark of DIC. However, the specificity and sensitivity of thrombocytopenia for the diagnosis of DIC is limited [5]. A platelet count of $<100 \times 10^9$/L is seen in 50–60% of DIC patients, whereas 10–15% of patients have a platelet count $<50 \times 10^9$/L. In surgical or trauma patients with DIC, over 80% of patients have platelet counts less than 100×10^9/L. On the other hand, in consecutive critically-ill patients with thromboctypenia, only 35% had DIC [5].

Consumption of coagulation factors leads to low levels of coagulation factors in patients with DIC. In addition, impaired synthesis, for example, due to impaired liver function or a vitamin K deficiency, and loss of coagulation proteins, due to massive bleeding, may play a role in DIC as well. The low level of coagulation factors is reflected by prolonged coagulation screening tests, such as the prothrombin time (PT) or the activated partial thromboplastin time (APTT). A prolonged PT or APTT occurs in 14–28% of intensive care patients, but is present in more than 95% of patients with DIC.

Measurement of fibrinogen has been widely advocated as a useful tool for the diagnosis of DIC, but is not in fact very helpful in the diagnosis of DIC in most cases. Fibrinogen acts as an acute-phase reactant and despite ongoing consumption plasma levels can remain well within the normal range for a long period of time. In a consecutive series of patients the sensitivity of a low fibrinogen level for the diagnosis of DIC was only 28% and hypofibrinogenaemia was detected in very severe cases of DIC only.

Plasma levels of fibrin split products (such as D-dimer) are frequently used for the diagnosis of DIC. Fibrin split products are detectable in 42% of a consecutive series of intensive care patients, in 80% of trauma patients and in 99% of patients with sepsis and

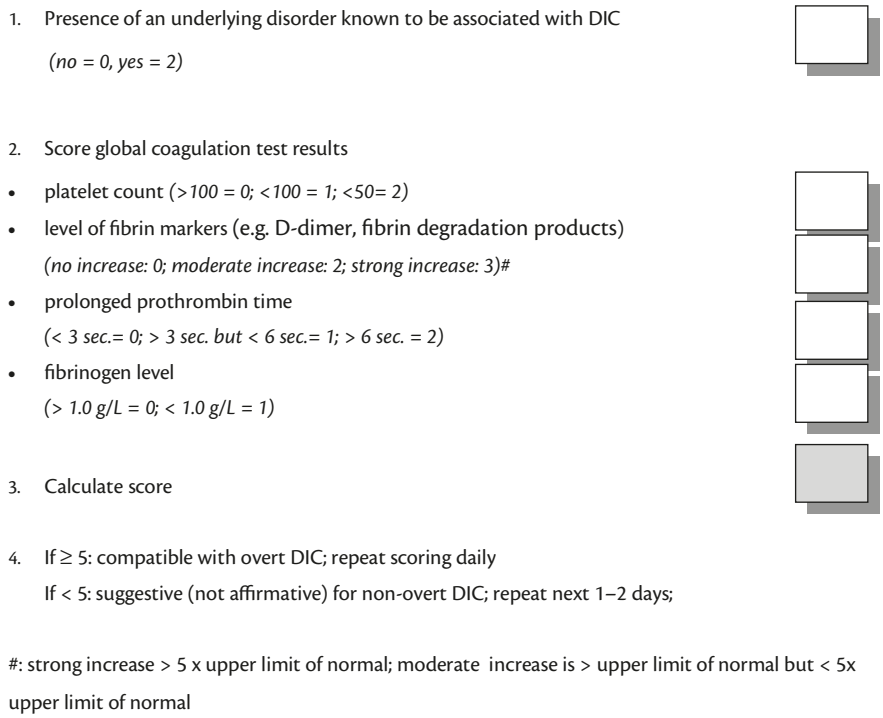

Fig. 270.1 Diagnostic algorithm for the diagnosis of overt DIC.
Reproduced from Taylor FB et al., 'Towards Definition, Clinical and Laboratory Criteria, and a Scoring System for Disseminated Intravascular Coagulation* On behalf of the Scientific Subcommittee on Disseminated Intravascular Coagulation (DIC) of the ISTH', *Thrombosis and Haemostasis*, **86**(5), pp. 1327–30, with permission from Schattaeur Publishers.

DIC. Most of the available assays for fibrin degradation products (FDP's) poorly discriminate between degradation products of cross-linked fibrin and fibrinogen degradation, which may cause spuriously high results. The specificity of high levels of fibrin degradation products is limited and many other conditions, such as trauma, recent surgery, inflammation or venous thromboembolism, are associated with elevated FDP's or D-dimer.

Plasma levels of physiological coagulation inhibitors, such as protein C or antithrombin may be useful indicators of ongoing coagulation activation [6]. Low levels of these coagulation inhibitors are found in 40–60% of critically-ill patients and in 90% of DIC patients.

Thromboelastography (TEG) is a method that has been developed decades ago and provides an overall picture of ex vivo coagulation. Modern techniques, such as rotational thromboelastography (ROTEM), enable bedside performance of this test and has become popular recently in acute care settings [7]. The theoretical advantage of TEG over conventional coagulation assays is that is provides an idea of platelet function, as well as fibrinolytic activity. There are no systematic studies on the diagnostic accuracy of TEG for the diagnosis of DIC, although the test may be useful for assessing the global status of the coagulation system in critically-ill patients.

For the diagnosis of overt DIC a simple scoring system has been developed (Fig. 270.1) [8]. The score can be calculated based on routinely available laboratory tests, i.e. platelet count, prothrombin time (or international normalized ratio), a fibrin-related marker (usually D-dimer), and fibrinogen. Tentatively, a score of 5 or more is compatible with DIC. Prospective studies show that the sensitivity of the DIC score is 93%, and the specificity is 98%. Studies in series of patients with specific underlying disorders causing DIC (e.g. cancer patients or patients with obstetric complications) show similar results. The severity of DIC according to this scoring system is related to the mortality in patients with sepsis [4].

Underlying causes of DIC

DIC is always secondary to an underlying disorder (Box 270.1).

Infection and sepsis

Severe systemic infections and/or sepsis are among the most common causes of DIC. Immunocompromised patients, asplenic patients whose ability to clear bacteria (particularly pneumococci) is impaired, and newborns whose anticoagulant systems are immature are particularly prone to infection-induced DIC. Infections may be superimposed on trauma or malignancies, which themselves are potential triggers of DIC. Clinically overt DIC occurs in 30–50% of patients with Gram-negative or Gram-positive sepsis, but also in infections with non-bacterial pathogens, such as viruses, protozoa (malaria), and fungi. An extreme form of DIC is represented by purpura fulminans, a severe, often lethal form of DIC in which extensive areas of the skin over the extremities and buttocks undergo haemorrhagic necrosis.

DIC in trauma and burns

Extensive exposure of damaged tissue (including tissue factor (TF)) to the blood circulation and haemorrhagic shock probably are the most immediate triggers of DIC in trauma. An alternative hypothesis is that cytokines play a pivotal role in the occurrence of DIC in trauma patients [9]. Bleeding, laboratory tests indicative of DIC, and vascular microthrombi in biopsies of undamaged skin have been described in patients with extensive burns. Kinetic studies with labelled fibrinogen and labelled platelets disclosed that, in

Box 270.1 Clinical conditions that are most frequently complicated by DIC

- Sepsis/severe infection.
- Trauma/burn/heatstroke.
- Malignancy:
  - Solid tumours.
  - Acute leukaemia.
- Obstetrical conditions:
  - Amniotic fluid embolism.
  - Abruptio placentae.
  - HELLP (haemolysis, elevated liver enzymes, low platelet) syndrome.
- Vascular abnormalities:
  - Kasabach–Merrit syndrome.
  - Other vascular malformations.
  - Aortic aneurysms.
- Severe allergic/toxic reactions.
- Severe immunological reactions (e.g. transfusion reaction).

Reproduced from Taylor FB et al., 'Towards Definition, Clinical and Laboratory Criteria, and a Scoring System for Disseminated Intravascular Coagulation* On behalf of the Scientific Subcommittee on Disseminated Intravascular Coagulation (DIC) of the ISTH', *Thrombosis and Haemostasis*, **86**(5), pp. 1327–30, with permission from Schattaeur Publishers.

addition to systemic consumption of haemostatic factors, significant local consumption occurs in burned areas.

DIC in obstetric calamities

Placental abruption is a leading cause of perinatal death [10]. The severe haemostatic failure accompanying abruptio placentae is the result of acute DIC emanating from the introduction of large amounts of TF into the blood circulation from the damaged placenta and uterus. Amniotic fluid has been shown to be able to activate coagulation in vitro, and the degree of placental separation correlates with the extent of DIC, suggesting that leakage of thromboplastin-like material from the placental system is responsible for the occurrence of DIC.

DIC in malignancy

Patients with solid tumours are vulnerable to risk factors and additional triggers of DIC that can aggravate thromboembolism and bleeding. Solid tumour cells can express different procoagulant molecules including tissue factor and cancer procoagulant (CP), a cysteine protease with factor X activating properties. Numerous reports on DIC and fibrinolysis complicating the course of acute leukaemias have been published. In 161 consecutive patients presenting with acute myeloid leukaemia, DIC was diagnosed in 52 (32%). In acute lymphoblastic leukaemia, DIC was diagnosed in 15–20% [11]. Some reports indicate that the incidence of DIC in acute leukaemia patients might further increase during remission induction with chemotherapy. In patients with acute promyelocytic leukaemia (APL), DIC is present in more than 90% of patients at the time of diagnosis or after initiation of remission induction.

DIC with vascular disorders

Rarely, vascular anomalies can trigger DIC. With some large aortic aneurysms, localized consumption of platelets and fibrinogen can produce coagulation abnormalities and bleeding. In a series of patients with aortic aneurysms, 40% had elevated levels of FDPs, but only 4% had laboratory evidence of DIC or bleeding. Kasabach and Merritt were the first to describe bleeding in association with giant cavernous haemangiomas, benign tumours found in newborns or children, and can evolve into convoluted masses of abnormal vascular channels that sequester, and consume platelets and fibrinogen.

DIC with toxic reactions or snake bites

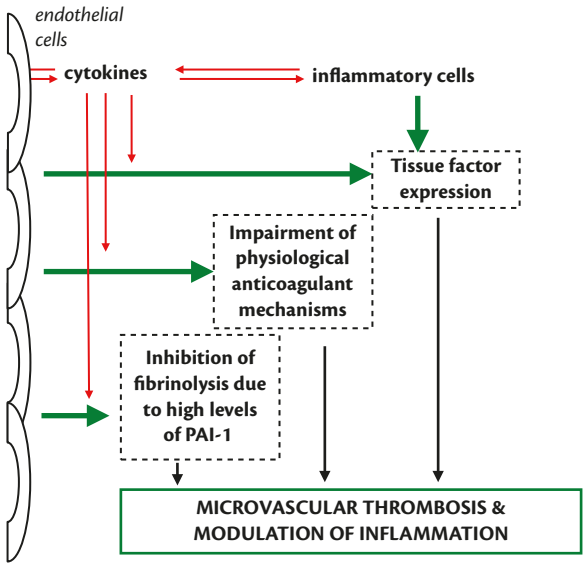
The venom of certain snakes, particularly vipers and rattlesnakes, can produce a coagulopathy similar to that of DIC [12]. Interestingly, victims of snake bites rarely have excessive bleeding or thromboembolism despite the abnormal coagulation tests and DIC-like picture.

Pathophysiology

In recent years, the molecular mechanisms of coagulation pathways have been defined (Fig. 270.2). The most important mediators that orchestrate the imbalance of the coagulation system in DIC are cytokines [13]. The initiation of coagulation activation leading to thrombin generation in DIC is mediated exclusively by the tissue factor/factor VII(a) pathway. Despite the potent initiation of coagulation by tissue factor, the activation of coagulation cannot be propagated if physiological anticoagulant pathways function properly. However, in DIC all major natural anticoagulant pathways (i.e. antithrombin III, the protein C system, and tissue factor pathway inhibitor (TFPI)) appear to be impaired [14]. Plasma levels of antithrombin III, the most important inhibitor of thrombin, are markedly reduced during DIC, due to a combination of consumption, degradation by elastase from activated neutrophils, and impaired synthesis. A significant depression of the protein C system may further compromise an adequate regulation of activated coagulation. This impaired function of the protein C system is caused by a combination of impaired protein synthesis, cytokine-mediated downregulation of endothelial thrombomodulin, and a fall in the concentration of the free fraction of protein S (the essential co-factor of protein C), resulting in reduced activation of protein C [15]. There seems to be an imbalance of TFPI function in relation to the increased tissue factor-dependent activation of coagulation. Finally, and importantly, experimental and clinical studies indicate that during DIC the fibrinolytic system is largely suppressed at the time of maximal activation of coagulation. This inhibition of fibrinolysis is caused by a sustained rise in the plasma level of plasminogen activator inhibitor-1 (PAI-1), the principal inhibitor of the fibrinolytic system.

Management

Adequate management of patients with DIC depends on vigorous treatment of the underlying disorder to alleviate or remove the inciting injurious cause. In addition of intensive support of vital



Pathways involved in the activation of coagulation in DIC. Both perturbed endothelial cells and activated mononuclear cells may produce proinflammatory cytokines that induce tissue factor expression, thereby initiating coagulation. In addition, downregulation of physiological anticoagulant mechanisms and inhibition of fibrinolysis promotes intravascular fibrin deposition. PAI-1: plasminogen activator inhibitor, type 1.

Fig. 270.2 Pathogenesis of disseminated intravascular coagulation.

functions, supportive treatment aimed at the coagulopathy may be helpful.

Platelet and plasma transfusion

Low levels of platelets and coagulation factors may increase the risk of bleeding. However, plasma or platelet substitution therapy should not be instituted on the basis of laboratory results alone; it is indicated only in patients with active bleeding and in those requiring an invasive procedure or are at risk for bleeding complications. The presumed efficacy of treatment with plasma, fibrinogen concentrate, cryoprecipitate, or platelets is not based on randomized controlled trials, but appears to be rational therapy in bleeding patients or in patients at risk of bleeding who have a significant depletion of these haemostatic factors. Replacement therapy for thrombocytopenia should consist of 5–10 U platelet concentrate to raise the platelet count to 20–30 $\times$ 10^9/L and, in cases in patients who need an invasive procedure, to 50 $\times$ 10^9/L.

Anticoagulant treatment

Heparin therapy in patients with DIC remains controversial. Experimental studies have shown that heparin can at least partly inhibit the activation of coagulation in DIC. However, a beneficial effect of heparin on clinically important outcome events in patients with DIC has not definitively been demonstrated in controlled clinical trials. Also, the safety of heparin treatment is debatable in DIC patients who are prone to bleeding. A large trial in patients with severe sepsis showed a slight, but non-significant benefit, of low dose heparin on 28-day mortality in patients with severe sepsis who were also treated with activated protein C and no major safety concerns [16]. There is general consensus that administration of heparin is beneficial in some categories of DIC, such as metastatic carcinomas, purpura fulminans, and aortic aneurysm (prior to resection). Heparin also is indicated for treating thromboembolic complications in large vessels and before surgery in patients with chronic DIC. Apart from all these considerations, current guidelines dictate the universal use of prophylactic doses of heparin or low molecular weight heparin to prevent venous thromboembolic events in critically-ill patients [17].

Recombinant human soluble thrombomodulin binds to thrombin to form a complex that inactivates thrombin's coagulant activity and activates protein C, and thus, is a potential drug for the treatment of patients with DIC. In a phase III randomized double-blind clinical trial in patients with DIC, administration of the soluble thrombomodulin had a significantly better effect on bleeding manifestations and coagulation parameters than heparin. Currently, ongoing trials with soluble thrombomodulin focus on DIC, organ failure, and mortality rate.

Physiological anticoagulant factor concentrates

Restoration of the levels of physiological anticoagulants in DIC may be a rational approach. In several small clinical trials, use of very high doses of AT concentrate showed even a modest reduction in mortality, however, without being statistically significant. A large-scale, multicenter, randomized controlled trial also showed no significant reduction in mortality of patients with sepsis [18]. Interestingly, post-hoc subgroup analyses of the latter study indicated some benefit in patients who did not receive concomitant heparin, but this observation needs validation.

A randomized controlled phase III trial of recombinant human activated protein C (APC) in patients with severe sepsis was prematurely stopped because of efficacy in reducing mortality in these patients [19]. Interestingly, patients who had DIC according to international criteria benefited more from the therapy with APC than patients who did not have overt DIC [4]. However, meta-analyses of published literature concluded that the basis for treatment with APC, even in patients with a high disease severity, was not very strong. A recently completed placebo-controlled trial in patients with severe sepsis and septic shock was prematurely stopped due to the lack of any significant benefit of APC. Subsequently, the manufacturer of APC has decided to withdraw the product from the market.

Fibrinolytic inhibitors

Most guidelines recommend against the use of anti-fibrinolytic agents, such as ε-aminocaproic acid or tranexamic acid, in patients with DIC. This is because these drugs block already suppressed endogenous fibrinolysis, and may further compromise tissue perfusion. However, in patients with DIC accompanied by primary fibrino(geno)lysis, as in some cases of acute promyelocytic leukaemia, giant cavernous haemangioma, heat stroke, and metastatic carcinoma of the prostate, the use of fibrinolytic inhibitors can be considered if the patient has profuse bleeding that does not respond to replacement therapy.

- Presence of an underlying disorder known to be associated with DIC (**no = 0, yes = 2**).
- Score global coagulation test results:
  - Platelet count (**>100 = 0; <100 = 1; <50 = 2**).
  - Level of fibrin markers (e.g. D-dimer, fibrin degradation products) (**no increase: 0; moderate increase: 2; strong increase: 3**)#.

- Prolonged prothrombin time (**<3 seconds = 0; >3 seconds, but <6 seconds = 1; >6 seconds = 2**).
- Fibrinogen level (> **1.0 g/L = 0;** < **1.0 g/L = 1**).

◆ Calculate score.

◆ If ≥5: compatible with overt DIC; repeat scoring daily.

If <5 is suggestive (not affirmative) for non-overt DIC, repeat next 1–2 days; # indicates strong increase >5× upper limit of normal; moderate increase is > upper limit of normal but <5× upper limit of normal.

Pathways involved in the activation of coagulation in DIC. Both perturbed endothelial cells and activated mononuclear cells may produce pro-inflammatory cytokines that induce tissue factor expression, thereby initiating coagulation. In addition, downregulation of physiological anticoagulant mechanisms and inhibition of fibrinolysis promotes intravascular fibrin deposition.

CHAPTER 271

Prevention and management of thrombosis in the critically ill

Chee M. Chan and Andrew F. Shorr

Key points

- The incidence of venous thromboembolism (VTE) in the critically-ill patient is extremely high and ranges between 13 and 24% in the general medical ICU patient.
- Unfractionated heparin (UFH) and low molecular weight heparin (LMWH) significantly decreases incidence of deep vein thrombosis (DVT) in critically-ill patients.
- Chemical thromboprophylaxis is preferred over mechanical DVT prophylaxis in the intensive care unit.
- LMWH is more effective at reducing the incidence of DVT among trauma and ischaemic stroke patients.
- The primary modality for managing VTE is prevention.

Introduction

Critically-ill patients face a heightened risk of venous thromboembolism (VTE) for multiple reasons. Typically, they suffer from conditions that lead to the features that encompass all three principles of Virchow's triad relative to thromboembolic disease. For example, they have disturbed blood flow because they are immobile, they have injured vascular endothelium due to multiple procedures, and they have alterations in the constitution of their blood (i.e. sepsis, inflammation). Furthermore, the underlying condition, itself leading to critical illness, can also represent an independent risk factor for VTE. These syndromes include, but are not limited to, acute respiratory failure, trauma, sepsis, and congestive heart failure.

More concerning, critically-ill patients necessarily lack the cardiopulmonary reserve required to tolerate a VTE, particularly a pulmonary embolus (PE). Conversely, since these patients are often both at increased risk for bleeding and are less tolerant of bleeding should it occur, the intensivist must carefully weigh the risk:benefit ratio regarding use of full dose anticoagulation.

Epidemiology of VTE in the ICU

The incidence of DVT varies among the heterogeneous ICU population and depends upon the reason for admission. Among the general medical ICU population, the incidence of DVT ranges between 13 and 24% in the first week of admission when using various imaging modalities to screen for DVT [1,2]. Moser and colleagues performed a prospective observational study among 34 patients admitted to a respiratory ICU [2]. Of the 23 subjects who had screening radiofibrinogen leg scans within the first week, 13% were found to have a DVT. In a similar study evaluating the incidence of DVT in a mixed medical-surgical critical care population, approximately 30% of subjects developed a DVT during the course of critical illness as determined using screening lower extremity Doppler examinations [1]. Of the 261 subjects enrolled, 2.7% were found to have a DVT within 48 hours of admission to the ICU, which demonstrates the hypercoagulability of these subjects. In trauma patients, the incidence of DVT is even more worrisome. Geerts documented the presence of DVT in 58% of 716 major trauma patients with the use of serial impedance plethysmography and lower extremity contrast venography [3]. Finally, among acute stroke patients, the incidence of DVT is as high as 70% with 1–2% succumbing to a fatal PE [4–6].

The incidence of PE is difficult to assess in the ICU. The current diagnostic modalities pose a challenge for screening and quantifying the incidence of disease. The inability of the intubated patient to make a conscious inspiratory effort limits the utility of ventilation-perfusion scintigraphy (V/Q scan). The increased risk of contrast nephropathy from computed tomography (CT) of the chest with PE protocol in a population already at higher risk for renal impairment hampers the ability to screen for PE in the ICU. Therefore, most knowledge regarding the prevalence of PE in the ICU derives from autopsy data. In post-mortem studies of ICU subjects, incidental PEs are found in approximately 7–27% with 1–3% of these PE felt to have caused demise [7]. However, autopsy data has substantial flaws and are subject to selection bias. Autopsies are mostly performed when the aetiology of death is unknown and, as such, only about 6–8% of critically-ill patients who die will have an autopsy [8]. Without knowing the cause of death in all subjects who die in the ICU, it is difficult to estimate the true mortality rate from PE in this patient population. Furthermore, since there is a high discrepancy rate between pre- and post-mortem diagnoses (20–40%) among critically-ill patients, one must be sceptical about diagnostic accuracy in this setting [7]. Specifically, PE remains one of the top three misdiagnosed diseases in the ICU, which re-emphasizes the need to prevent the condition.

Management of VTE among critical care subjects

The use of and choice for thromboprophylaxis in critical care patients is a complex topic. The heterogeneity of the ICU population with regards to the risk for thrombosis must be carefully

weighed against the risk of bleeding associated with anticoagulant options for prevention. There are two broad categories for thromboprophylaxis—mechanical and chemical. Mechanical VTE prophylaxis is generally reserved for those who are at high risk of VTE, but chemical prophylaxis is contraindicated. These individuals include those who are actively bleeding, those considered high risk for bleeding, and those with profound thrombocytopenia. Since the literature base for the efficacy of mechanical thromboprophylaxis in the ICU setting is particularly narrow, the initiation of pharmacological therapies must constantly be re-evaluated.

Five randomized controlled trials (RCTs) have been performed to assess the use of mechanical DVT prophylaxis in the critical care population [9–13]. Four of the five studies involved trauma patients, while the last study involved subjects with acute myocardial infarctions. In a pooled analysis of these five studies, 811 subjects were randomized to mechanical thromboprophylaxis versus another form of prophylaxis (placebo, another mechanical device, or a chemical agent, low molecular weight heparin (LMWH)) [14]. Due to these varying comparison groups, only two studies were pooled in a recent meta-analysis. To summarize, 562 subjects were randomized to pneumatic compression devices versus LMWH. LMWH was found to be superior and patients given mechanical prophylaxis were more than twice as likely to suffer a DVT (odds ratio: 2.37; 95% confidence interval [CI]: 0.57–9.9). In the study involving patients with acute myocardial infarctions ($n = 80$), graduated compression stockings had better efficacy at preventing DVT compared with placebo (0 versus 10%, $p = 0.003$) [9]. Given the scarcity of quality data supporting the use of mechanical thromboprophylaxis in the critically-ill patient, the preferred modality for VTE prophylaxis remains chemical options [15].

Several pharmacological therapies are recommended for the use of VTE prophylaxis in the critically ill; these include unfractionated heparin (UFH) and LMWH. While other agents are available for VTE prophylaxis, such as fondaparinux, rivaroxaban, and dabigatran, these agents have not yet been studied in the ICU patient population. Only a few randomized controlled trials have been performed to assess the safety and efficacy of chemical thromboprophylaxis in the ICU. About 223 mechanically-ventilated patients with chronic obstructive pulmonary disease were randomized to nadoparin, a LMWH, versus placebo [16]. Doppler ultrasonography was performed upon enrolment into the study, weekly, and when clinically indicated. All subjects also had a venography study performed at completion, after early discontinuation, or as confirmatory testing after a positive or indeterminant Doppler ultrasound study. The incidence of DVT was significantly lower for nadoparin compared to placebo (15.5 versus 28.2%, $p = 0.045$). There was no difference in the rate of adverse events, which included major and minor bleeding, and thrombocytopenia. In another RCT, 3746 critically-ill medical-surgical patients were randomized to either dalteparin 5000 U od or UFH 5000 U bd [17]. The incidence of DVT served as the primary outcome and was assessed within 2 days after admission and then twice weekly using Doppler ultrasonography. Secondary outcomes included the incidence of symptomatic PE and the development of major bleeding. Within the first two days of admission, 3.5% of subjects who received dalteparin already had a DVT, while 3.4% in the UFH group had a DVT. The incidence of DVT was also similar between groups (5.2% for dalteparin versus 5.8% for UFH, $p = 0.57$) using bi-weekly testing. However, those in the dalteparin group had fewer clinically significant PE compared with the UFH group (1.2 versus 2.0%, $p = 0.02$). Major bleeding was similar between groups (5.5% for dalteparin and 5.6% for UFH, $p = 0.98$). There was no correlation between renal function and bleeding with either agent. Thus, the rate of VTE is low in the presence of thromboprophylaxis for medical-surgical critical care patients. These studies demonstrate that chemical thromboprophylaxis is efficacious and safe in decreasing the incidence of DVT when compared with placebo. Overall, UFH and LMWH were similarly effective and safe in preventing VTE as a combined endpoint.

One must be cautious, however, about the interpretation of these studies. Screening for DVT with the use of Doppler ultrasonography has never been validated in the critical care setting and may therefore lead to over- or underdiagnosis of DVT. Additionally, there is uncertainty regarding the clinical significance of DVTs that are found incidentally. Patel and colleagues determined that the rate of symptomatic DVT and PE were only 1.0% (95% CI: 0.8–1.2) and 0.5% (95% CI: 0.4ƨ0.6%), respectively [18]. These incidence rates are substantially lower compared with the rate of asymptomatic VTE diagnosed when using screening tests. This study illustrates that VTE is underdiagnosed in the ICU and clinicians must be vigilant in identifying signs and symptoms of VTE in the ICU.

In combination, this data demonstrates that pharmacological therapy for VTE prophylaxis is safe and efficacious. Given the risks associated with the development of DVT and the risks associated with full dose anticoagulation in the ICU patient population, the best current management for DVT remains prevention. For these reasons, the American College of Chest Physicians recommends that early, thoughtful initiation of thromboprophylaxis upon admission to the ICU is imperative and that chemical prophylaxis is preferred to mechanical when the risk of bleeding is tolerable [15].

VTE prophylaxis in trauma patients

Trauma patients are at substantial risk for DVT with an incidence of 25–65% [19]. One RCT of 344 consecutive trauma patients randomized to the LMWH, enoxaparin 30 mg bd, versus UFH 5000 U bd for thromboprophylaxis has been performed to assess the efficacy and safety of these agents [3]. Leg venography was performed between 10 and 14 days after enrolment and when clinically indicated. The primary outcome was the incidence of DVT. The use of LMWH decreased the incidence of DVT compared to UFH (31 versus 44%, $p = 0.014$) with a relative risk reduction of 30% (95% CI: 4–50%). The incidence of proximal DVT was also lower in the LMWH group (6%) compared with UFH (15%) with a 58% risk reduction (95% CI: 12–87%). The risk for major bleeding was similar between groups. Thus, the high rate of DVT in this patient population mandates the consideration of chemical thromboprophylaxis when the risk of bleeding is acceptable.

VTE prophylaxis in ischaemic stroke

The risk for VTE in patients with acute ischaemic stroke can be as high as 70% [4–6]. Few studies have assessed the efficacy and safety of VTE prophylaxis in this patient population. In a meta-analysis pooling 2028 ischaemic stroke patients, the efficacy and safety of LMWH was compared to UFH for VTE prophylaxis [20]. Based on this meta-analysis, LMWH reduced the occurrence of DVT compared with UFH with an odds ratio of 0.54 (95% CI: 0.41–0.70). There were no differences in major bleeding, intracranial haemorrhage, and overall mortality between groups.

Conclusion

Prevention is the primary modality for managing VTE in the ICU. Although data are sparse, there is clear evidence that chemical thromboprophylaxis is the most effective means of preventing VTE. Newer evidence demonstrates that these agents are also safe with minimal to no increased risk for bleeding. In patients at particularly high risk for DVT in the ICU, mechanical devices should be used to prevent DVT until pharmacological agents can be initiated.

CHAPTER 272

Thrombocytopenia in the critically ill

Jaimal Kothari and Marie Scully

Key points

- Sepsis and disseminated intravascular coagulation are the commonest causes of thrombocytopenia in the intensive care unit.
- Always assess the platelet count in combination with laboratory clotting parameters.
- Consumption, sequestration, impaired production, increased destruction, and haemodilution are the primary pathological mechanisms for thrombocytopenia, and in practice, a number of the mechanisms overlap and are implicated in critically-ill patients.
- Heparin-induced thrombocytopenia is a rare, but highly thrombogenic condition that needs prompt diagnosis and action.
- There are standardized platelet thresholds that should generally be followed when considering the need for platelet transfusions.

Introduction

The multiple co-morbidities of patients in intensive care make thrombocytopenia very common. It is typically, but essentially arbitrarily defined as a platelet count of $<150 \times 10^9$/L, with severe thrombocytopenia being $<50 \times 10^9$/L.

It is estimated that 35-45% of ICU patients have thrombocytopenia with between 5-20% severely thrombocytopenic [1–3]. The prevalence of thrombocytopenia is 20–30% of ICU admissions and a similar number of patients develop thrombocytopenia during their ICU admission. It is rarer for patients to be severely thrombocytopenic at admission to ICU, with one recent series showing it to be approximately 6% [4].

An understanding of the aetiology is crucial, allowing specific interventions as required, together with a global appreciation of how thrombocytopenia interacts with the multiple other haemostatic and mechanisms that define the bleeding risk, which is a daily consideration in many ICU patients.

Platelet count dynamics in ICU

The bone marrow produces approximately 150 billion platelets per day, and the average lifespan of a single unit is 7–10 days. In any disease process, the balance between production and consumption is altered, and this is especially notable in acutely sick patients. It is not uncommon to see a decrease in the platelet count on the first few days after admission to the ICU, especially in patients who have undergone surgery. The platelet nadir tends to occur 1–4 days post-surgery, with the count then tending to increase to the presurgery level, before a rebound thrombocytosis is often seen. This is in keeping with an initial consumptive/dilutional effect and subsequent increases above the normal range due to the normal physiological response to reduced platelet counts, where an increased thrombopoeitin leads to stimulation of megakaryocytes. In medical patients, a complex interplay of factors can lead to more unpredictable and labile counts, and are more likely to be thrombocytopenic on admission.

Thrombocytopenia and platelet dynamics as a prognostic factor

There is evidence that thrombocytopenia per se is associated with adverse outcomes. This is understandable as severely-ill patients have multifactorial mechanisms underlying their thrombocytopenia and critically unwell patients with thrombocytopenia who are admitted to the ITU have higher values on validated scoring systems used to stratify disease severity (e.g. MODS and APACHE) [5], compared with patients who are admitted with normal platelet counts. It has also been shown that the dynamics of platelet recovery—i.e. a blunted or absent rise in the platelet count after the initial decrease is associated with prolonged ICU stays and excess mortality. One series has shown that mortality in patients with thrombocytopenia ($< 150 \times 10^9$/L) at day 4 was 33%, compared with 66% at day 14 and mortality in normal counts [6].

Causes

There are five main mechanisms contributing to thrombocytopenia. Typically, in the intensive care unit (ICU) setting there is interplay of more than one:

- Haemodilution.
- Increased consumption.
- Increased platelet destruction.
- Reduced production.
- Increased sequestration.

Haemodilution (associated with bleeding) and consumption (typically associated with disseminated intravascular coagulation (DIC)/tissue trauma and sepsis) are the commonest reasons

for a low platelet count in the ICU, and it is normal to have at least two or three of the mechanisms involved at any particular time. Major haemorrhage can often lead to a partly dilutional and partly consumptive thrombocytopenia if product replacement does not include the judicious use of fresh frozen plasma and platelets.

Pseudothrombocytopenia

Pseudothrombocytopenia should also always be considered as a potential confounding factor. This is an in vitro phenomenon typically caused by either activation of the sample in the tube with clots or aggregates in ethylenediaminetraacetic acid (EDTA)-anticoagulated blood. Pseudothrombocytopenia is especially common in patients treated with GPIIb/IIIa antagonists, and this phenomenon is almost as frequently seen as true thrombocytopenia [7].

Sepsis and DIC

Sepsis and DIC are by the far the commonest causes of thrombocytopenia seen in the ICU, with significant overlap between both pathologies. The severity of sepsis does correlate with the magnitude of the platelet drop, and from a recent series, approximately 75% of septic episodes are associated with thrombocytopenia, and that as the count drops, the mean platelet volume (MPV) increases [8]. It is not uncommon for a moderate thrombocytopenia to be caused by sepsis alone, but when the count drops to less than 50×10^9/L, disseminated intravascular coagulation (DIC) is often present [9].

In the septic state, consumption, impaired production, and sequestration are all involved to a greater or lesser extent. They can all be involved at the endothelial cell surface as result of extensive and well understood interaction between platelets and the endothelium. Increased consumption can be associated with the sepsis itself, together with haemophagocytosis and, importantly, DIC. DIC is a frequent clinical problem in the acutely-ill patient—a syndrome caused by the systemic intravascular activation of the clotting system that leads to the generation of thrombin (the most potent in vivo activator of platelets) and formation of microvascular thrombi. Platelet counts in DIC can rapidly drop in association with the characteristic other abnormalities in laboratory clotting tests (raised prothrombin time (PT), raised activated partial thromboplastin time (APTT), raised D-dimers and fibrin degradation products (FDPs). Laboratory evidence of DIC is not always associated with bleeding, and an isolated thrombocytopenia can be the first evidence of impending DIC. The key mantra of managing DIC is to treat the underlying cause.

Drug-induced thrombocytopenia

Drug-induced thrombocytopenia is an important aetiology not to miss, but can be difficult to pin-point as patients are often on multiple medications, and there are so many alternative explanations for thrombocytopenia in this patient group. Drugs can cause thrombocytopenia via a number of mechanisms, but the commonest cause is an immune-mediated idiosyncratic reaction. Typically with the immune form, the thrombocytopenia only occurs in the presence of the drug, and the timing is highly significant. On removal of the drug, the rapid recovery of the count is evidence for the drug being the cause. Drug induced thrombocytopenia may also be a direct myelosuppressive action on the bone marrow.

Rarer causes of thrombocytopenia in the intensive care unit

Post-transfusion purpura

This is an immune condition, most commonly caused by platelet allo-antibodies against the human platelet antigen HPA-1a. Post-transfusion purpura (PTP) should be considered if the patient received blood transfusions in the previous two weeks. Typically, PTP affects woman who during pregnancy, developed an antibody against the HPA-1a. Transfusion then leads to an immune response, which boosts anti-HPA-1a, which then destroy the patient's own platelets. Treating with intravenous immunoglobulin is effective.

Heparin-induced thrombocytopenia

Commonly tested for, but rarely found, this is a diagnosis not to be missed. It has an incidence of approximately 0.5% in ICU patients [10]. Heparin-induced thrombocytopenia (HIT) is caused by an immune-mediated adverse drug reaction caused by the development of IgG antibodies directed against platelet factor 4/heparin complexes that form on the surface of platelets. The antibody/antigen interaction leads to the activation of platelets, and vascular endothelium, leading to thrombin generation, and the development of potentially devastating venous/arterial thromboses and thrombocytopenia. HIT is at least 10 times more common in patients taking unfractionated heparin and more common in women who have undergone surgery, typically orthopaedics or cardiothoracic. Thrombocytopenia and thromboembolism are common in intensive care units without HIT, and therefore diagnosis of HIT requires a combination of appropriate clinical suspicion and the use of sensitive laboratory tests when appropriate. The '4Ts' scoring system, introduced by Warkentin and Heddle, gives a validated probability score on the basis of the nature of the thrombocytopenia (the percentage drop, and nadir), the timing of the thrombocytopenia, whether a thrombosis has formed and whether there is a potential alternative cause for thrombocytopenia. Following a confirmed case of HIT/or a high clinical suspicion prior to confirmation (even in the absence of new thrombosis)—all heparin must be stopped **immediately**. Anticoagulation is required to counteract the highly thrombogenic environment with alternative agents.

Micro-angiopathic haemolysis

Patients with thrombotic thrombocytopenic purpura (TTP) or haemolytic uraemic syndrome (HUS) are characterized by the presence of severe thrombocytopenia, micro-angiopathic haemolytic anaemia and end organ damage (typically brain/heart in TTP) and more kidney related damage in HUS, which can often require renal replacement therapy. These patients are often admitted to ITU for organ support and for the initiation/continuation of definitive treatment. In TTP the dysfunction/absence of the cleaving metalinoproteinase ADAMTS 13 (via an immune autoantibody, or in some cases the congenital absence of enzyme) leads to the accumulation of ultra-large von Willebrand multimers, and the activation of the clotting system with a consumptive coagulopathy and the development of intravascular thrombi, leading to the end organ damage. The mainstay of treatment is plasma exchange, with new evidence for immune suppression by Rituximab (a monoclonal anti-CD20 antibody) in acquired TTP [11]. Platelet transfusions are contraindicated in TTP, with exogenous platelets merely feeding the thrombogenic environment. Drugs are rarely implicated in the development of a TTP-like state, and in these cases, cessation

of the drug is key intervention. Laboratory findings that are suggestive of TTP/HUS are anaemia with a reticulocytosis, raised LDH, thrombocytopenia and a blood film showing evidence of red cell fragments, sometimes described as schistocytes. It should be noted that red cell fragments are also seen on the blood film of patients with DIC, and one of the key discriminating laboratory features being normal clotting times in TTP/HUS.

Immune thrombocytopenia

This is not typically seen as an isolated cause of thrombocytopenia in intensive care, but remains on the differential—an immune mediated peripheral destruction of platelets not associated with production failure. First-line treatments include corticosteroids or intravenous immunoglobulins.

Platelet counts, bleeding, and transfusions

ICUs are amongst the highest users of platelet pools in hospitals. Transfusion practice is widespread with marked variation in triggers and targets. This is partly explained by the lack of a convincing evidence base in this area, and a lack of appreciation of what a 'safe' platelet count is. The absolute platelet count is an independent risk factor for bleeding, however, impaired platelet function is also implicated, together with the other multiple interacting factors that control bleeding risk at any point in time—intervention type, local anatomical factors, hyperfibrinolysis, and DIC. It is rare for patients with platelet counts >10×10^9/L to bleed because of their thrombocytopenia alone and factors above are likely to be involved. The complexity of individual cases in the ICU together with the constant need for interventions (e.g. central lines, tracheostomies) and anticoagulation (for haemofiltration, prophylaxis, or treatment of thromboembolic disease) require a higher threshold and may lead to numerous platelet transfusions. There is not a good evidence base for transfusion triggers in this population, and what is deemed 'safe' varies. However, clinicians need a pragmatic guide to how and when platelet transfusions should be given. A single adult pool of platelets generally contains 240×10^9 platelets, and an increment of at least 10×10^9/L is expected, although the actual increment can be very variable. Multiply transfused patients can develop HLA-antibodies, and the transfusion of HLA-matched platelets helps ensure that immune-mediated destruction does not occur. National and international guidelines exist to guide clinicians, and one such guideline is highlighted in Table 272.1.

Table 272.1 Platelet thresholds and transfusion

Intervention type/clinical problem	Transfuse platelets if count below
Bone marrow failure/following chemotherapy, without bleeding	10×10^9/L
Active sepsis/low risk procedure (e.g. endoscopy/bronchoscopy)	20×10^9/L
Major surgery or procedure with high risk of bleeding (e.g. tracheostomy), lumbar puncture	50×10^9/L
Neurosurgery or high risk of bleeding into critical sites	100×10^9/L

Data from British Committee for Standards in Haematology and Blood Transfusion Taskforce, 'Guidelines for the use of platelet transfusions', *British Journal of Haematology*, 2003, **122**(1), pp.10–23.

Further well designed, randomized trials examining the risks of bleeding and platelet thresholds are needed to improve the evidence base in this area, and such studies are already being carried out in neonates [13]. Another area of uncertainty and variation within platelet transfusion practice is within dysfunctional platelets—acquired abnormalities usually due to antiplatelet agents. When these patients bleed, platelet transfusion is often of value in providing functional ability.

Anti-coagulating patients with thrombocytopenia

Superimposed thrombocytopenia can make formal anticoagulation risky, with differing practice to what platelet count is safe for full anticoagulation. Practice is generally not evidence based, with some units preferring an absolute platelet count of 50×10^9/L, below which all anticoagulation is withheld. Using unfractionated heparin allows a more rapid 'switch-off' of anticoagulation effect, but in practice there tends to be greater use of split-dose low molecular weight heparin, with dosing adjusted in relation to the absolute platelet count.

Conclusion

The multifactorial nature of thrombocytopenia in critically-unwell patients means that a logical approach is required to diagnose the cause(s), allowing timely aetiology-specific interventions, specifically to treat underlying pathologies and minimize bleeding risk.

PART 11.4

Disorders of the blood cells

CHAPTER 273

Pathophysiology and management of anaemia in the critically ill

Timothy Walsh

Key points

- Anaemia is prevalent among the critically ill, especially during prolonged critical illness.
- Aetiology is multifactorial, including iatrogenic blood loss (especially blood sampling), reduced red cell lifespan, and impaired erythropoiesis.
- Most patients tolerate a haemoglobin concentration as low as 70–80 g/L without adverse effects on clinical outcome.
- Red cell transfusions have an uncertain risk-to-benefit profile in the critically ill, and should be restricted to bleeding patients, or non-bleeding patients requiring transfusion to maintain a haemoglobin concentration >70 g/L.
- Recombinant erythropoietin is not licensed for treating the anaemia of critical illness; parenteral iron therapy requires further evaluation before introduction into routine care.

Definition of anaemia

Anaemia is a haemoglobin concentration (Hb) below expected population values, when age, gender, pregnancy, and certain environmental factors, such as altitude, are taken into account. It results in a reduction in red cell mass and a decrease in the oxygen-carrying capacity of the blood. The World Health Organization (WHO) defines anaemia as a haemoglobin <130 g/dL (haematocrit <39%) for adult males and < 120 g/L (haematocrit <36%) for adult non-pregnant females. The WHO has further classified anaemia as mild (95–109 g/L), moderate (80–94 g/L), severe (65–79 g/L), and life-threatening (<65 g/L).

Prevalence of anaemia during critical illness

The prevalence of anaemia among critically-ill patients is high, but depends on patient case mix and the blood transfusion practice employed. More consistent use of restrictive Hb transfusion triggers, typically 70–90 g/L since publication of the Transfusion Requirements In Critical Care (TRICC) study [1], have enabled prevalence attributable to critical illness to be more accurately estimated. At ICU admission 10–15% of patients have a history of chronic anaemia, but typically the first Hb measured indicates anaemia in 60–70% of patients and 20–30% have a Hb <100 g/L [2]. Anaemia is associated with greater illness severity and older age.

During early ICU stay Hb decreases progressively in many patients, typically by 0.1–5 g/L/day in ICU, until clinicians intervene with blood transfusions. Consequently, the prevalence of anaemia increases with duration of ICU stay and typically 70–80% of patients are anaemic at ICU discharge, with 20–30% having Hb values <90 g/L [3]. Local blood transfusion policies will strongly influence anaemia severity in longer stay patients, but typically mean Hb concentrations among ICU populations are 90-100 g/L. Longer ICU stay and greater organ dysfunction are associated with more severe anaemia at ICU discharge.

Anaemia frequently persists for many weeks following ICU discharge and is often present when patients are discharged from acute care facilities [3]. Recovery occurs much slower than in otherwise healthy individuals suffering acute anaemia following blood loss and 10–30% of patients remain anaemic for at least 3 months [4]. The importance of anaemia to functional recovery is unknown.

Anaemia and outcome

Anaemia is associated with adverse outcomes during critical illness, including failure of liberation from mechanical ventilation, myocardial ischaemia and infarction, and increased risk of death. As anaemia is most prevalent in patients with greatest illness severity and longest intensive care unit (ICU) stays, it is uncertain whether this association is causative or simply an epiphenomenon. Importantly, the association does not imply that interventions to modify anaemia will improve outcomes and the risk to benefit profile of interventions to treat anaemia requires further evaluation. The heterogeneity of critical care populations also means that similar treatment effects cannot be assumed for all patient groups.

Aetiology of anaemia during critical illness

Important factors contributing to anaemia during critical illness are summarized in Fig. 273.1.

Haemodilution

Haemodilution contributes to the rapid decrease in Hb described during early ICU treatment, as a result of resuscitation with fluids

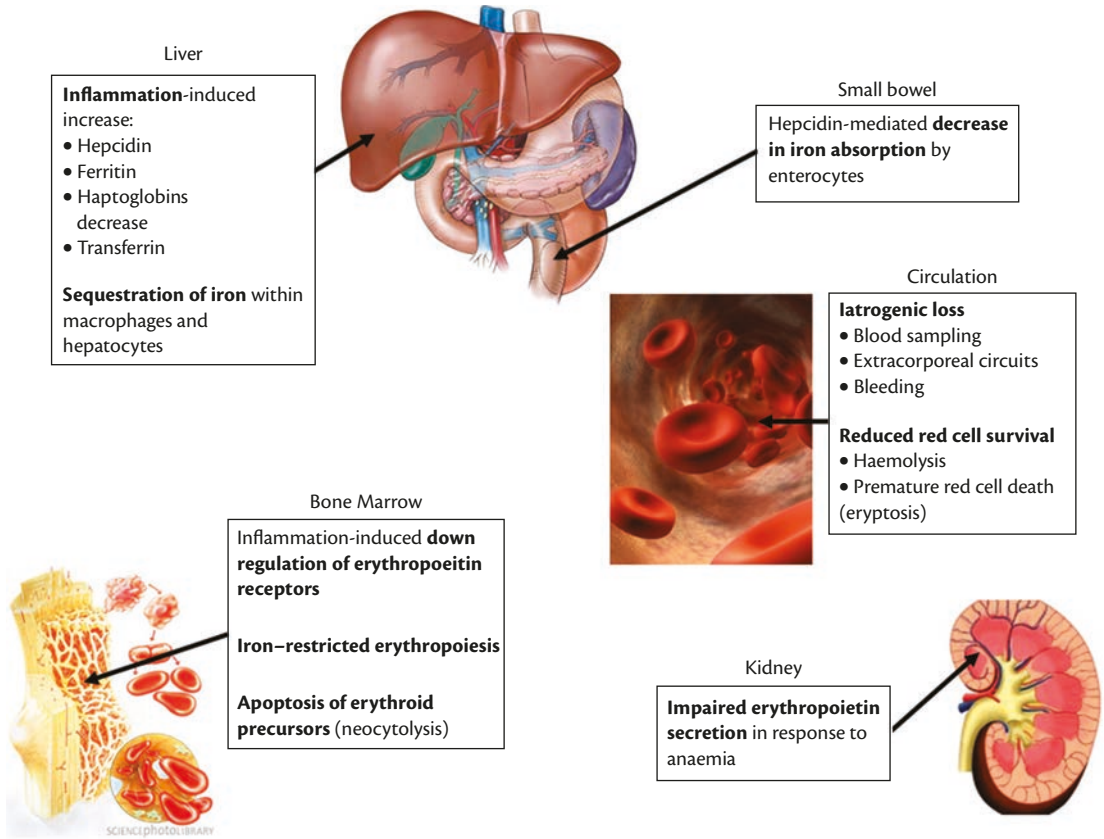

Fig. 273.1 Pathogenesis of anaemia during critical illness.

to expand intravascular volume. Modest haemodilution can cause anaemia without decreasing red cell mass or, importantly, oxygen carrying capacity.

Red cell loss

Iatrogenic blood loss

Blood loss is a significant cause of anaemia in ICU patients. Diagnostic blood sampling typically amounts to 30–40 mL/day, and accounted for approximately 30% of blood transfusion requirements prior to the introduction of blood conservation measures [2]. Sampling volumes are highest for sicker patients, such as those requiring advanced respiratory support or renal replacement therapy who require frequent monitoring of gas exchange or blood coagulation. Several strategies are effective at reducing blood sampling, including the use of paediatric sampling tubes [5] and collection systems that enable the return of dead space volumes from arterial sampling lines [6]. Local protocols to limit sampling frequency will also significantly decrease iatrogenic blood loss. Other sources of iatrogenic blood loss include haemofiltration circuits and other extracorporeal systems.

Haemorrhage

There are many potential sources of bleeding in critically-ill patients. The contribution of stress ulceration is probably small with modern resuscitation and stress ulcer prophylaxis. About 20% of ICU patients experience at least one episode of significant bleeding during ICU stay, and between 20 and 50% of all blood transfusions administered during ICU treatment are associated with clinically significant bleeding [7].

Reduced red cell survival

It is likely that critical illness, and sepsis in particular, reduces RBC lifespan [2]. Premature death of mature RBCs (termed eryptosis, a type of cellular apoptosis) is thought to be triggered, in part, by oxidant injury and other inflammatory processes, which are features of most critical illnesses. Inflammatory mediators, such as TNF-α and IL-1, decrease erythrocyte survival time in other settings, and induce premature apoptosis among RBCs. Cell injury causes changes including phosphatidylserine exposure on RBC membranes, which marks cells for engulfment by macrophages. Another process, neocytolysis, is the selective removal of young circulating RBCs, and is associated with rapid reductions in plasma levels of erythropoietin (EPO). Although a pathophysiological rationale exists for both eryptosis and neocytolysis their relative importance to critical illness anaemia is currently unknown.

Increased haemolysis is also likely during critical illness, especially in association with extracorporeal circuits, but is difficult to demonstrate clinically. Serum haptoglobins are positive acute phase proteins; consequently, their utility as biomarkers of haemolysis is limited unless severe haemolytic anaemia is present.

Reduced red cell production

The essential factors for normal erythropoiesis include iron, zinc, folate, and vitamin B12, under the influence of erythropoietin (EPO), thyroxine, androgens, cortisol, and catecholamines. Metabolism of all of these is affected by critical illness. In health RBC formation occurs at a basal rate of 15–20 mL/day under

steady-state conditions, increasing to >200 mL/day after haemolysis or heavy blood loss in iron-replete healthy individuals.

Anaemic critically-ill patients typically have a normochromic normocytic anaemia [7]. Reticulocyte counts are low compared with the healthy response to anaemia suggesting impaired erythropoiesis. This pattern is similar to the anaemia of chronic disease, which is frequently associated with inflammatory illness [8]. The typical biochemical parameters observed in anaemic critically-ill patients are shown in Table 273.1.

Iron metabolism

ICU patients typically have a low serum iron, total iron binding capacity, serum transferrin, transferrin saturation, and serum iron/total iron binding capacity ratio [7]. Serum ferritin concentration is usually normal or increased, a pattern typical of inflammatory conditions. Ferritin synthesis increases and transferrin decreases, because these are, respectively, positive and negative acute phase proteins. The net result is a transfer of iron into storage form (ferritin) within macrophages and hepatocytes, which reduces plasma transferrin saturation and serum iron. The iron regulatory protein hepcidin plays a key role in these processes [8]; it is upregulated when body iron stores are replete and downregulated during iron deficiency. Hepcidin decreases duodenal iron uptake and release of iron into the circulation by enterocytes, and prevents release of storage iron from macrophages and hepatocytes. Inflammation induces upregulation of hepcidin irrespective of iron status, which effectively reduces the availability of iron for RBC production. This iron-restricted erythropoiesis, also sometimes termed functional iron deficiency, results in impaired RBC production despite adequate total body iron stores. Several parameters are associated with functional iron deficiency, including a reduced reticulocyte haemoglobin concentration (CHR) and increased percentage hypochromic red cells in peripheral blood, both of which have been demonstrated in the critically ill [6]. Transferrin receptors are shed into the circulation as soluble molecules (sTFR) when erythropoiesis is increased or during significant iron deficiency, but concentrations of sTFR are normal in most anaemic critically-ill patients [4,7]. Taken together, these data indicate that the most critically-ill patients do not have an absolute iron deficiency, but many have a functional iron deficiency resulting from inflammation-mediated sequestration of iron within macrophages and hepatocytes. The resulting iron-restricted erythropoiesis may contribute to anaemia, especially when the duration of critical illness is prolonged. The difficulties diagnosing iron deficiency during critical illness make an accurate estimation of prevalence challenging, but is estimated to affect 10–20% of anaemic patients. It has been suggested that a reduced hepcidin concentration can be used to identify iron-deficiency during critical illness [9].

Table 273.1 Biochemical characteristics of anaemia in critically-ill patients

	Change in relation to healthy state
Serum iron	↓
Total iron binding capacity	↓
Serum iron/total iron binding capacity ratio	↓
Ferritin	↑
Transferrin	↓
Transferrin saturation	↓
Soluble transferrin receptor concentration	N
Percentage hypochromic red cells	N/↑
Vitamin B12 and folate	N
Erythropoietin concentration	N/slight increase
Hepcidin concentration	↑

N, normal range.

B12 and folate metabolism

Vitamin B12 or folate deficiency is rare in critically-ill patients, and has been demonstrated in <5% of ICU patients [2,7].

Endogenous erythropoietin response

The normal response to anaemia is to increase EPO release from the kidneys. Critically-ill patients have inappropriately low EPO concentrations for their degree of anaemia [2,7]. The blunted EPO response probably results from inhibition of the *EPO* gene by inflammatory cytokines and direct renal injury. Some drugs commonly used in critical care also reduce EPO release in response to anaemia, such as angiotensin-converting enzyme inhibitors and beta-blockers. Downregulation of EPO receptors on marrow red cell precursor cells may also contribute to blunted erythropoiesis.

Abnormal red blood cell maturation

Inflammatory cytokines such as tumour necrosis factor α, interleukin-1 and interleukin-6 directly inhibit red cell formation, and other circulating factors such as interferon γ can induce apoptosis of erythroid precursors, which could be important during critical illness [2,7]. These factors, together with a relative EPO deficiency, downregulation of EPO receptors, and decreased iron availability are likely explanations for the poor erythroid response during critical illness.

Management of anaemia

Reduction of red cell loss

Decreasing iatrogenic blood loss by reducing sampling frequency, sample volumes, and systems that allow re-infusion of dead space from lines can reduce anaemia severity [2,5,6].

Red cell transfusion

The treatment with greatest efficacy for increasing haemoglobin concentration is red cell transfusion. However, evidence from physiological studies and randomized trials indicates that anaemia is well-tolerated by the majority of critically-ill patients, despite the risk of inadequate oxygen delivery, increased tissue oxygen requirements, and impaired oxygen extraction [2,7]. Stored red cell transfusions have potential risks, including pro-inflammatory effects, immunomodulation, and increased infection [10,11]. Decreased deformability, greater endothelial adherence, and impaired oxygen release also mean that stored red cells are less effective oxygen transporters than circulating autologous cells [10,11]. These factors may explain the association between red cell transfusion and adverse patient outcomes in many cohort studies, and in some randomized trials, and questions the risk-to-benefit balance of red

cell transfusion to treat anaemia during critical illness [12]. Based on available evidence a default haemoglobin transfusion trigger of 70 g/L is justified in haemodynamically-stable non-bleeding patients [13,14]. Factors that support using higher transfusion triggers include the presence of tissue hypoxia (elevated lactate concentration), chronic ischaemic heart disease, acute coronary syndromes, delayed liberation from mechanical ventilation, and acute neurological injury. The quality of evidence to guide practice in these situations is poor. The lack of high quality evidence or physiological measures to assess adequacy of organ perfusion within individual patients mean clinician judgement strongly influences clinical decision-making in these situations. Most guidelines suggest a haemoglobin transfusion trigger of between 70 and 90 g/L for critically-ill anaemic patients, reassessing patients after each red cell unit [13,14]. Recently published trials have found no evidence to support a transfusion trigger >70 g/L for patients with septic shock [15], but some evidence of benefit from more liberal transfusion triggers after cardiac surgery [16]. A large trial using clinician-determined transfusion decisions found no evidence of benefit from using exclusively fresher RBCs (stored on average 6.1 days) with standard issue RBCs (stored on average 22 days) for critically ill patients [17].

EPO therapy

Relative EPO deficiency and impaired erythropoeisis provide a physiological rationale for pharmacotherapy with exogenous EPO during critical illness. Epoetin alfa (or any erythropoiesis stimulating agents) is not currently licensed for use to treat the anaemia of critical illness, but several trials have evaluated its efficacy and effectiveness [18]. The three largest trials were industry sponsored (EPO-1, EPO-2, and EPO-3), and had varying sample size, inclusion criteria, and intervention regimens (dose of erythropoietin; dose and route of iron therapy) [18,19]. A key difference was the progressive adoption of more restrictive haemoglobin transfusion triggers with each trial, decreasing from a mean of 90 g/L (EPO-1) to 80 g/L (EPO-3). Although EPO-1 and EPO-2 showed a small reduction in transfusion requirements, there was no transfusion-sparing effect in EPO-3 (the largest trial). Thrombotic events also occurred more frequently with EPO therapy in EPO-3, possibly in association with failure to provide thromboprophylaxis. Based on this evidence EPO therapy is not recommended to treat the anaemia of critical illness. A sub-group analysis of the EPO-3 trial indicated an association between EPO therapy and improved survival in trauma patients [19]. It is hypothesized that EPO might have cytoprotective effects, but these are likely mediated through different receptors (EPO-BCR receptor) rather than any link to anaemia (erythropoietic effect mediated via EPO-R receptors) [2].

Iron therapy

Evidence from animal and experimental studies suggests that greater iron availability may promote infection and exogenous therapy may induce oxidative stress [20]. There is no high quality evidence to support this association in humans, but it is a possible evolutionary explanation for iron sequestration within reticulo-endothelial cells, reduced intestinal iron absorption, during inflammatory illnesses and infections. Increased hepcidin concentrations during inflammatory illness decrease intestinal iron absorption, suggesting that parenteral iron therapy is required to effectively treat functional iron deficiency. Parenteral iron preparations vary, and each has documented risks, including anaphylaxis. The risk to benefit profile of enteral and parenteral iron in anaemic critically-ill patients has not been investigated in large clinical trials in critically-ill humans. The difficulty diagnosing iron-deficient erythropoiesis during critical illness also makes this challenging. Routine administration of iron therapy to treat anaemia is not currently recommended by any route during critical illness. Ongoing and future trials may provide evidence to guide practice.

Conclusion

Anaemia is a prevalent feature of critical illness, with multiple aetiology. During long-term critical illness anaemia results mainly from iatrogenic blood loss and impaired erythropoiesis. Anaemia is well-tolerated by most critically-ill patients, and blood transfusions in non-bleeding patients are rarely indicated if the Hb is greater than 80–90 g/L. EPO is not licensed for use to treat the anaemia of critical illness; parenteral iron therapy requires further evaluation before introduction into routine practice.

CHAPTER 274

Pathophysiology and management of neutropenia in the critically ill

Benoit Champigneulle and Frédéric Pène

Key points

- Neutropenia is a common side-effect of most chemotherapy regimens and is defined by an absolute neutrophil count <500/mm^3.
- Profound (<100 neutrophils/mm^3) and prolonged (>7 days) neutropenia carry the highest risk for severe bacterial and invasive fungal infections.
- Febrile neutropenia imposes urgent empirical antibiotic therapy.
- The choice of the initial antimicrobial regimen should involve the presence of complications such as pneumonia or severe sepsis as well as the risk assessment of Gram-positive and fungal infections.
- The outcome of critically-ill cancer patients including neutropenic patients has markedly improved over the last two decades.

Introduction

Neutropenia is defined as an absolute neutrophil count <500 cells/mm^3, but also includes situations when neutrophil count is predicted to drop within a few days. The spectrum of infections encountered during neutropenia relies on the critical role of phagocytic cells in host defence against bacteria and fungi. Therefore, neutropenia, especially when profound and prolonged, represents a major risk factor for severe bacterial and invasive fungal infections. Common sources of infections include the lung, the gastrointestinal tract, soft tissues, and indwelling catheters. In addition, some patients may experience respiratory status deterioration at the time of neutropenia recovery due to pulmonary influx of activated neutrophils. Whatever the initial clinical presentation, the risk for rapid clinical deterioration of febrile neutropenic patients underlies the concept of urgent antimicrobial empirical treatment. The present chapter aims at discussing the particularities of neutropenic patients in the intensive care unit (ICU).

Aetiologies and mechanisms of neutropenia in the ICU

The leading mechanism of neutropenia is related to chemotherapy- and radiotherapy-induced myelotoxicity that also often accounts for thrombocytopenia and anaemia. The type and dosing of cytostatic drugs as well as the extent of radiation field and dosimetry determine the depth and duration of neutropenia. Patients with solid tumours usually exhibit moderate and short (<7 days) neutropenia. In contrast, patients with acute leukaemia, high-grade lymphoma and haematopoietic stem cell transplantation (HSCT) exhibit profound (<100 neutrophils/mm^3) and prolonged neutropenia. In this setting, the mechanism of neutropenia is obvious and does not require additional investigations. However, bone marrow explorations may provide useful prognostic information in critically-ill patients for whom neutropenia recovery is urgently expected. Bone marrow may exhibit granulocytes progenitors suggestive of neutropenia recovery within a few days, or may conversely appear empty or invaded by malignant cells.

Neutropenia can also result from bone marrow involvement by haematological malignancies or by solid tumour metastasis or from associated mechanisms such as haemophagocytosis or bone marrow necrosis. Non-malignant disorders can also present with neutropenia, including aplastic anaemia, drug-induced agranulocytosis, auto-immune neutropenia or vitamin deficiency. Various infections can be responsible for neutropenia, either by bone marrow involvement (dengue virus, leishmaniosis), haemophagocytic lymphohistiocytosis (tuberculosis), or by granulopoiesis exhaustion with maturation blockade that typically occurs in severe pneumococcal infections. Diagnosis relies on the presence of associated cytopenias, cytological examination of blood smears and most often bone marrow exploration by sternal puncture or biopsy. Neutropenia may occasionally result from peripheral mechanisms, such as auto-immune destruction of neutrophils.

Epidemiology of infections in neutropenic patients

The depth and duration of neutropenia are the critical factors that determine the development of infections. Profound and prolonged neutropenia observed during acute leukaemia induction and intensive conditioning regimen of HSCT carry the highest risk of bacterial and invasive fungal infections. The risk of febrile neutropenia is increased by disruption of anatomical barriers, such as indwelling catheters, mucositis, and enterocolitis. Herpes simplex virus reactivation may also contribute to oral mucosal damage in this setting.

In addition, many anticancer treatments affect B- and T-cell immunity, and lymphopenia represents an independent risk factor of infections during neutropenia.

Numerous interventional studies and observational surveys have delineated the trends in microbiological epidemiology of febrile neutropenia over time. Of note, these data are based on blood cultures that are retrieved positive in less than one-third of febrile episodes, owing to low bacterial inocula or early administration of broad-spectrum antibiotics. Until the mid-eighties, Gram-negative bacilli including enterobacteriaceae and *Pseudomonas aeruginosa* were the most frequent pathogens encountered in febrile neutropenic episodes. Since then, Gram-positive cocci have become predominant as a consequence of severe mucosal damage induced by intensive chemotherapy, the increasing use of indwelling vascular access, gut decontamination with absorbable or non-absorbable antibiotics and treatment with anti-acid drugs [1,2]. Coagulase-negative staphylococci are the most frequent isolates in febrile neutropenic patients, although the distinction between infection and blood culture contamination is often unclear. Importantly, virulent pathogens, such as Gram-negative bacilli, streptococci, and *Staphylococcus aureus* account for most documented episodes of severe sepsis and septic shock in neutropenic patients [3,4]. Furthermore, polymicrobial infections represent a significant proportion of documented infections in neutropenic patients with gastrointestinal and soft tissue infections.

Invasive fungal infections also concur to severe complications in neutropenic patients [4]. The common clinical presentation of invasive candidiasis in neutropenic patients is candidaemia from digestive or cutaneous origin. Alternatively, hepatosplenic candidiasis may occur after neutropenia recovery as a manifestation of immune reconstitution syndrome towards previous occult candidaemia. Invasive aspergillosis typically affects patients with prolonged neutropenia or long-term corticosteroid treatment. The diagnosis of pulmonary aspergillosis is most often presumptive and based on retrieval of the fungus in respiratory samples, positive galactomannan antigen and CT-scan findings with nodules surrounded by the round-glass opacities, also known as the halo sign. Screening by galactomannan antigen assay is limited by false-positive results induced by beta-lactams or food, but retains a good performance in neutropenic patients [5]. Finally, neutropenia is also a risk factor for emergent fungal infections such as mucormycosis that are not covered by recent antifungal drugs such as echinocandins and voriconazole.

Outcome of neutropenic patients in the ICU

Over the last two decades, a number of studies reported an improvement in the outcome of cancer patients in the ICU including those with neutropenia. Several factors accounted for this trend through advances in both antitumoural treatments and supportive care. Close collaborations between haematologist/oncologists and intensivists resulted in better selection of patients likely to benefit from intensive care, early detection of organ failures, and early admission to the ICU in order to prevent further deterioration. Specifically, recent advances in care of severe sepsis and septic shock were associated with a dramatic improvement in survival of non-neutropenic and neutropenic patients [3,4,6].

Although neutropenia was previously associated with poor outcome, recent data suggest it is no longer a risk factor of mortality in critically-ill cancer patients [4,7,8]. Conversely, some neutropenic patients with recent intravenous chemotherapy or allogeneic HSCT recipients during engraftment period may even fare better than non-neutropenic counterparts [9,10]. As an explanation, infections that largely account for organ failures in neutropenic patients are likely to be controlled by antimicrobials treatment and forthcoming reversal of immunosuppression through neutropenia recovery. Therefore, admission to the ICU of neutropenic patients should no longer be considered as a terminal event, but as an integral part of supportive care in the curative process of the underlying disease.

Antimicrobial treatments in neutropenic patients

Principles of antibiotic treatment

The principles ruling antimicrobials management in febrile neutropenia have been formally summarized by the recently updated guidelines of the Infectious Diseases Society of America [11]. Early initiation of empirical antibiotic therapy represents the cornerstone of the treatment of febrile neutropenia. However, practical modalities may differ according to the clinical presentation and to the risk assessment for specific pathogens. High-risk patients include those with anticipated prolonged and profound neutropenia and/or significant co-morbid conditions, including hypotension, pneumonia, new-onset abdominal pain, and neurological changes, and therefore include virtually all neutropenic patients in the ICU. Therefore, the initial antibiotic regimen in critically-ill neutropenic patients should provide a broad coverage against Gram-negative and -positive bacteria through antibiotic combination.

The initial antibiotic regimen is based on broad-spectrum beta-lactams with anti-pseudomonal activity, including piperacillin-tazobactam, ceftazidime, cefepime, and carbapenems, and should take into account the presumed source of infection, the presence of risk factors for Gram-positive cocci, previous drug-induced allergy, and local patterns of antibiotic resistance. The widespread emergence of multiresistant bacteria is also a matter of concern in neutropenic patients as a consequence of multiple courses of antibiotics prior to ICU admission. Digestive colonisation or previous infections caused by extended-spectrum beta-lactamase enterobacteriaceae, multiresistant *Pseudomonas aeruginosa*, meticillin-resistant *Staphylococcus aureus*, and vancomycin-resistant *Enterococci* should be carefully tracked in the medical file.

Addition of other antimicrobials (aminoglycosides, fluoroquinolones, and/or vancomycin) has been recommended in order to broaden the antibiotic spectrum and/or to improve bactericidal activity in patients with pneumonia or haemodynamic instability. Aminoglycosides are highly bactericidal antibiotics, which display synergism with beta-lactams. Although a number of studies did not retrieve any overall benefit to aminoglycosides in febrile neutropenia, antibiotic combination with beta-lactams, and aminoglycosides may improve outcome in Gram-negative bacteraemia and severe sepsis [3,12]. Most beta-lactams provide excellent coverage against viridans streptococci or meticillin-susceptible *Staphylococcus aureus*. However, suspicion of resistant Gram-positive cocci or the use of ceftazidime or aztreonam, which retain poor activity against Gram-positive bacteria may indicate empirical treatment with vancomycin. Linezolid

represents a valuable alternative to vancomycin, although delayed recovery of neutropenia may be of concern in these patients [13]. Step-down of antibiotic regimen should be considered after 48 hours in the light of bacterial documentation. However, maintenance of a broad spectrum beta-lactam is advocated until neutropenia recovery in order to prevent sepsis recurrence with Gram-negative bacteria. Gram-negative bacteraemia, most especially those related to *Pseudomonas aeruginosa*, may indicate a combination antibiotic therapy with aminoglycosides [12]. Specific coverage for Gram-positive organisms may be stopped if no evidence of such infection [14].

Antibiotic pharmacokinetics

Neutropenic patients display some pharmacokinetic particularities of beta-lactams, aminoglycosides and glycopeptides that should be taken into account in order to optimize the efficacy of antibiotic treatment [15]. Beta-lactams are time-dependent antibiotics requiring that serum concentrations exceed the minimal inhibitory concentration (MIC) of the causative bacteria for most of the dosing interval. In neutropenic patients, increased volumes of distribution and the risk of too low trough levels require shorter dosing intervals or even continuous infusion for short-life beta-lactams in order to prevent bacterial regrowth. Glycopeptides are also time-dependent antibiotics with increased volume of distribution and shorter elimination half-life. The use of higher doses of glycopeptides is recommended more highly in neutropenic patients than in non-neutropenic ones, as is monitoring of trough levels. Alternatively, efficient and durable concentrations of vancomycin are better achieved with continuous infusion. Aminoglycosides are highly bactericidal concentration-dependent antibiotics for which the efficacy is dependent on a high ratio between concentration peak and MIC of the causative pathogen. Pharmacokinetic changes of aminoglycosides in neutropenic patients include increased distribution volumes and increased clearance rates. Therefore, several studies documented that achievement of high aminoglycoside concentrations required once-daily dosing regimen that also appeared to be less nephrotoxic than multiple daily schedules.

Antifungal treatments

Prolonged and profound neutropenia is a major risk factor of invasive fungal infections. High-risk neutropenic patients with persistent or recurrent fever after 5–7 days of antibiotics should be considered for investigation of invasive fungal infection and empirical antifungal treatment. Echinocandins and amphotericin are currently approved for empirical treatment of febrile neutropenia [16,17]. Lipid formulations of amphotericin are preferred to amphotericin deoxycholate in critically-ill neutropenic patients owing to the frequency of renal dysfunction and/or concurrent use of nephrotoxic drugs [16].

Special features of ICU management in neutropenic patients

Protective measures

The prevention of acquisition of exogenous bacteria or fungi is a major challenge in hospitalized neutropenic patients, especially in the ICU environment, where the risk of transmission of multiresistant micro-organisms is high. In haematology units, data from the literature support the simultaneous application of isolation in a single room, standard barrier precautions (cap, gown, gloves, mask), high-efficiency particulate air filtration, and clean or even sterile food. In addition, antibacterial and antifungal digestive decontamination has been used in very high risk patients with HSCT or acute leukaemia induction. In the ICU, the need for stringent protective measures should be balanced with the necessity of a close watch being kept on critically-ill patients. Neutropenic patients should be applied simple preventive measures including geographic isolation and standard barrier precautions. Air filtration is recommended, but remains restricted to recent units.

Source control measures

In addition to antibiotic treatment, some sources of infections may require surgical treatment, such as extensive debridement of infected tissues in cellulitis. Management of neutropenic enterocolitis is preferentially conservative, but uncontrolled septic shock or evidence of intestinal perforation or obstruction indicates surgical resection of necrotic or perforated bowel. Without any doubt, the expected benefits of source control on septic shock overcome the potential risks of surgery in neutropenic patients.

Central lines are major sources of bloodstream infections in neutropenic patients. Causing micro-organisms include coagulase-negative staphylococci, *Staphylococcus aureus* and *Candida* species, but also aerobic Gram-negative bacilli. A catheter-related infection is suggested by shorter time-to-positivity >120 minutes of blood cultures drawn from the device as compared with simultaneous blood cultures drawn from peripheral vein. Bloodstream infections due to virulent pathogens such as *S. aureus*, fungi or Gram-negative bacilli usually impose urgent catheter removal. Nevertheless, catheters may represent an occult source of infection despite negative blood cultures. Accordingly, systematic removal of catheters has been independently associated with improved survival in neutropenic patients with severe sepsis without evidence of alternative source of infection [3].

Management of organ failures

Management of organ failures in neutropenic patients is generally similar to that of non-neutropenic ones. Nonetheless, the ventilatory management of acute respiratory failure may differ with respect to specific indications of non-invasive ventilation (NIV) in this population. Indeed, NIV has been shown to decrease the intubation rate and the eventual ICU mortality in non-neutropenic and neutropenic immunocompromised patients with hypoxaemic respiratory failure [18]. Of note, NIV is best applied in non-terminal respiratory failure, implicating early detection of patients likely to benefit from it. However, the reluctance to intubate such high-risk patients should not lead to disregard the contraindications for NIV such as end stage acute respiratory failure or extra-respiratory failures.

Immune defence restoration

The poor outcome of severely-infected neutropenic patients prompted some therapeutic strategies aimed to restore the number and functions of neutrophils, including treatment with granulopoiesis-stimulating agents and granulocyte transfusion. Granulocyte colony-stimulating factor (G-CSF) is a haematopoietic growth factor that promotes the production of neutrophils

from bone marrow progenitors and enhances their antimicrobial activity. Prophylactic use of G-CSF has been able to shorten duration of neutropenia with an eventual decrease in the risk of febrile episodes, and is now considered for chemotherapy-treated patients with a high risk (>20%) of febrile neutropenia. The use of G-CSF as an adjunctive therapy of febrile neutropenia did not result in improved outcomes although a meta-analysis reported a possible decrease in infection-related mortality [19]. The use of G-CSF in critically-ill neutropenic patients neither reduced the time to neutrophil recovery nor improved survival [7], nor has been associated with deterioration of respiratory status at the time of neutropenia recovery related to lung infiltration by activated neutrophils [20]. Transfusion of granulocytes collected by leukapheresis from G-CSF-stimulated healthy donors has been proposed as a supportive treatment in patients with neutropenia or neutrophil dysfunction experiencing severe infections. The efficacy of this procedure remains questionable, and it is associated with side effects such as transfusion-associated lung injury and anti-HLA immunization. Whenever indicated, it should anyway be restricted to patients with forthcoming neutropenia recovery and progressive infections clearly linked to defective pathogen clearance (necrotic cellulitis, invasive fungal infections). To date, uncertainties about the real efficacy and the potential adverse side effects of G-CSF and granulocytes transfusion argue against their routine application in critically ill neutropenic patients.

CHAPTER 275

Sickle crisis in the critically ill

Shilpa Jain and Mark T. Gladwin

Key points

- Sickle cell disease (SCD) crises are precipitated by an acute occlusion of microvessels, which can lead to end organ ischaemia reperfusion injury and acute haemolysis.
- Acute fat emboli syndrome, acute lung injury (the acute chest syndrome), acute pulmonary hypertension and cor pulmonale, haemorrhagic and occlusive stroke, and systemic infection represent the most common life-threatening complications observed in current ICU practice.
- General principles of management in all patients admitted to the critical care unit are hydration, antibiotics, pain control, and maintenance of oxygenation and ventilation.
- Red blood cell transfusion therapy is the treatment of choice for most complications of sickle cell disease requiring intensive care management. Transfusion of sickle negative, leukoreduced red blood cells, phenotypically matched for Rhesus and Kell antigens is the minimum standard of care in sickle cell disease patients as they have a high incidence of red blood cell alloimmunization.
- SCD poses an increased risk of sudden death in patients, probably related to the high incidence of chronic pulmonary hypertension and haemodynamic deterioration in the acute setting.

Introduction

Sickle cell disease (SCD) is the most common haemoglobinopathy in the world, affecting nearly 275,000 babies born annually [1]. It is caused by a single nucleotide substitution in the beta-globin gene, valine for glutamic acid, resulting in a mutant haemoglobin S (HbS) molecule. When deoxygenated, HbS has an exposed hydrophobic valine residue that binds to other HbS molecules leading to the formation of insoluble polymers within the red blood cells (RBCs). This causes a structural damage to the membrane of the RBCs, which become sickle-shaped, rigid, hyperadhesive, and prone to haemolysis. It also impairs their passage through the microvessels causing end organ ischaemia and necrosis. Sickling is precipitated by hypoxia, acidosis, hypothermia, dehydration, and inflammatory adhesive events between RBCs, white blood cells (WBCs), and the endothelium.

Sickle cell disease is inherited as an autosomal recessive disorder with homozygotes (SS) or compound heterozygotes (haemoglobin SC, and Sbeta thalassaemia) demonstrating haemolytic anaemia and low levels of vaso-occlusion at steady state. Individuals with one sickle cell gene (AS or sickle trait) are usually asymptomatic. Acute occlusion of microvessels results in events called vaso-occlusive crises (VOC), represented by severe pain and acute organ injury. These further exacerbate already present end-organ complications which are becoming common with the increasing lifespan of the SCD patients. The most frequent problems for which a SCD patient is seen in a critical care setting are listed below, and reviewed subsequently:

- Acute chest syndrome.
- Haemolytic transfusion reactions.
- Sepsis (most commonly related to central line infections).
- Pulmonary hypertension and right heart failure.
- Multi-organ failure.

Acute chest syndrome

Acute chest syndrome (AChS) frequently develops in SCD patients post-operatively, and after hospitalization for acute VOC [2]. Diagnosis is established by the finding of a new segmental pulmonary infiltrate, excluding atelectasis, along with some or all of the following symptoms: cough, chest pain, fever (>38.5°C), hypoxia, and dyspnoea (Fig. 275.1) [3]. Laboratory findings include leukocytosis (mean WBC, 23,000 cells/μl), increased haemolysis, and drop in Hb and platelet counts (~1 g/dL and <200,000/mm^3, respectively) [3]. Risk factors identified for respiratory failure are decreased platelet count, multilobar disease, cardiac disease likely representing pulmonary hypertension (PH), and neurologic complications [3].

Acute chest syndrome is essentially a form of acute lung injury similar to ARDS, which results from a vicious cycle of lung infarction by bone marrow fat emboli and *in situ* sickle cell vaso-occlusion, infection, and atelectasis that produce ventilation–perfusion mismatch, hypoxaemia, and often acute increases in pulmonary and right ventricular pressures. The major identifiable aetiologies of AChS that promote the above-listed mechanisms are listed below in order of frequency [2]:

- Respiratory infections from chlamydia, mycoplasma, respiratory syncytial virus, *Staphylococcus aureus, Streptococcus pneumoniae*, and other pathogens in decreasing order of frequency [2]. Influenza also produces severe seasonal outbreaks of AChS .
- Pulmonary fat embolism syndrome caused by bone marrow necrosis following severe vaso-occlusion in the bone marrow. Fat emboli in the lung vasculature are metabolized to free fatty acids, including secretory phospholipase A2, which mediate alveolar inflammation and endothelial injury [4]. Oil red O-positive

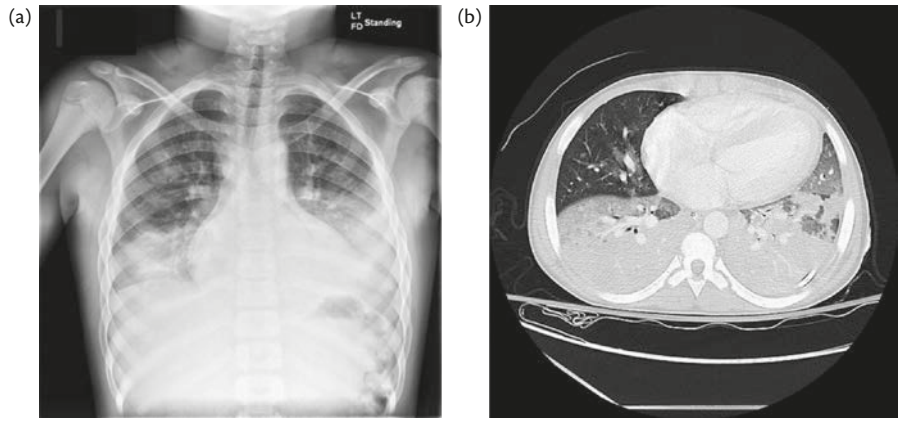

Fig. 275.1 A 14-year-old boy with sickle cell disease and acute chest syndrome. (a) Chest X-ray bilbasilar infiltrates and a moderate-sized left pleural effusion. (b) Chest CT of the same patient showing multifocal bilateral consolidations.

fat-laden macrophages in bronchoalveolar lavage (BAL) or induced sputum are diagnostic [2].

- Costal or sternal infarction resulting in splinting and consequently hypoventilation and atelectasis, and pooling of secretions at lung bases which predisposes to ventilation-perfusion mismatch and hypoxia.
- Pulmonary infarction from in situ sickle cell vaso-occlusion as a result of increased adhesion of sickled RBCs to the endothelium.
- Pulmonary embolism (PE) or in situ thrombosis may also occur in small subset of patients [5].

Haemolytic transfusion reactions

Haemolytic transfusion reactions (HTR) occur as a complication of RBC allo-immunization following blood transfusions, and is reported to occur in 19–47% of SCD adults in USA [6]. The high risk of allo-immunization is related to the differences in RBC antigen expression between African-American SCD patients, and the predominantly Caucasian blood donor pool, leading to antibody formation against Rh (C,E), Kell (K1), Kidd (Jk^b), MNSs (S), and Duffy (Fy^a). Rarely, HTR in SCD can occur in the absence of detectable antibodies from other mechanisms, such as macrophage mediated erythrophagocytosis [7].

Haemolytic transfusion reactions can result in severe life-threatening anaemia and can present acutely or delayed (2 days to 2 weeks). Delayed HTR is caused by re-exposure to red cell alloantigens, producing an anamnestic immune response. This stimulates the formation of previously low-titre antibodies which were below the limits of detection during standard cross-matching procedures. In extreme cases, a hyperhaemolytic crisis may ensue as a result of delayed HTR and is defined by development of more severe anaemia than was present prior to transfusion. This occurs as a result of 'bystander haemolysis' of self and transfused RBCs, suppressed erythropoiesis, and autoantibody formation.

Diagnosis is a challenge, and requires a high degree of suspicion as symptoms are similar to those of acute VOC. Laboratory evaluation shows evidence of haemolysis, haemoglobinuria, and marked reticulocytopenia initially, with reticulocytosis heralding recovery. Direct antiglobulin test (DAT) is positive unless the antibody titres have decreased to undetectable levels between transfusions. Serial CBC with reticulocyte count and Hb electrophoresis to look for disappearance of transfused HbA donor RBCs may aid in diagnosis.

Sepsis

Sepsis in SCD occurs secondary to impaired immunity from splenic, complement, and neutrophil dysfunction. Patients are particularly susceptible to encapsulated organisms (*Streptococcus pneumoniae, Salmonella* species, *Haemophilus influenza*), although their incidence has decreased markedly with the use of vaccinations and penicillin prophylaxis. Effects of infection such as fever, hypoxia, acidosis, dehydration, and increased WBC counts, can trigger a cascade of events leading to vaso-occlusive events. Pathological effects of SCD correlate to the following sources and specific pathogens:

- The most common source of infection is intravenous catheters placed for antibiotic infusions, erythrocytapheresis, chronic blood transfusion, or haemodialysis. Commonly isolated organisms are *Staphylococcus aureus* and skin flora.
- **Osteomyelitis**: haematogenous spread of *Salmonella typhimurium* and less frequently *Staphylococcus* aureus and enteric Gram-negative bacilli. This complication is seen almost exclusively in children.
- **Biliary tract**: anaerobes.
- **Urinary tract infections**: *Escherichia coli* and other Gram negative enteric organisms.
- **Lung**: typical and atypical bacteria.
- **Iron overload**: *Yersinia enterocolitia* causing fever, diarrhoea, and symptoms mimicking acute appendicitis.
- **Recurrent hospitalizations and exposure to multiple antibiotics**: nosocomial infections and colonization with resistant organisms such as methicillin-resistant *Staphylococcus aureus* (MRSA).

Pulmonary hypertension

Pulmonary hypertension (PH) is an emerging cause of morbidity and mortality, associated with a 10-fold increased risk for early death [8,9].The prevalence of PH is approximately 10% in adult SCD patients, based on right heart catheterization screening

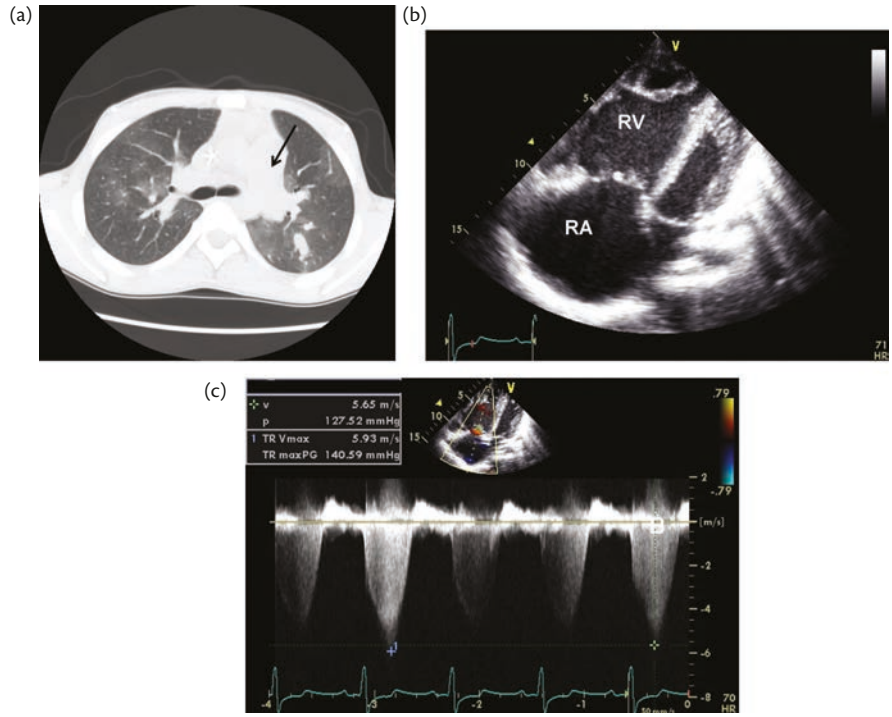

Fig. 275.2 Patient with Sickle Cell Disease and Pulmonary Hypertension. (a) CT of the chest showing dilation of main pulmonary artery (black arrow) and mosaic perfusion in both lobes of the lungs. (b) A four-chamber view of the heart shows right ventricular (RV) and right atrial (RA) dilatation. Right ventricular wall thickness is increased consistent with right ventricular hypertrophy. There is flattening of the interventricular septum indicative of pulmonary hypertension. (c) A Doppler echocardiographic tracing shows peak tricuspid regurgitant-jet-velocity to be 5.9 m/second. With an assumed right atrial pressure of 15 mmHg, the estimated pulmonary artery systolic pressure is 154 mmHg. This constitutes severe pulmonary hypertension.

studies, and is defined by a mean pulmonary artery pressure greater than or equal to 25 mm Hg [10–12]. A central event in the pathogenesis of PH is acute and chronic haemolytic anaemia. Chronic vascular exposure to haemolysate and cell free plasma haemoglobin scavenges nitric oxide (NO) and generates reactive oxygen species that contributes to the development of a progressive systemic and pulmonary vasculopathy. Risk factors for PH include increased lactate dehydrogenate (capturing increased intensity of haemolytic anaemia), liver and renal dysfunction, increasing age, iron overload, systolic hypertension, and left ventricular diastolic dysfunction [13].

Echocardiographic assessments of tricuspid regurgitant (TR) jet velocity and right heart function are convenient and non-invasive screening assessments for PH and should be performed in all patients admitted to the ICU, since pulmonary pressures can rise acutely during severe VOC or AChS [14,15]. Pulmonary hypertension and right heart failure (cor pulmonale) complicates approximately 13% of patients with the acute chest syndrome and portends a worse prognosis [15] (Fig. 275.2).

Acute multi-organ failure syndrome

Acute Multi-organ failure syndrome (AMOFS) involves severe dysfunction of at least two major organ systems (kidney, lung, liver) during an acute painful VOC. It is diagnosed when the following criteria are present: serum creatinine >2 mg/dL; ALT and total bilirubin >5× normal; direct bilirubin >2× normal; prothrombin time >3 seconds; acute pulmonary infiltrate and hypoxia [16]. Patients can present with fever, rapid fall in Hb and platelet count, non-focal encephalopathy, rhabdomyolysis, and sudden syncope. Necrosis of bone marrow can result in fat emboli, and rarely myocardial ischaemia. Thrombotic thrombocytopenic purpura (TTP) can mimic AMOFS in its presentation, but is difficult to diagnose in SCD because of higher von Willebrand antigen levels as compared with ADAMTS13 levels at baseline, with the latter further decreasing during VOC [17]. In TTP, coagulation studies are usually normal and if abnormal should raise the suspicion of disseminated intravascular coagulation (DIC).

General principles of management of SCD complications

The ultimate goal of treatment of SCD-related complications is to prevent HbS polymerization or to remove and replace sickle RBCs. Major approaches to general management, applicable to most patients, are primarily supportive and based on the pathophysiology of the disease as listed in Table 275.1.

Guidelines for transfusion

A SCD patient admitted to an ICU for almost any reason requires a blood transfusion, simple or exchange, and the following guidelines should be followed:

- Sickle negative, leukocyte reduced, at least Rh (ABO, C, D, E), and Kell matched
- Extended phenotype matching in patients with history of allo-immunization

Table 275.1 General management principles to prevent haemoglobin S (HbS) polymerization in sickle cell disease based on pathophysiology

Pathophysiology	Goal	Therapy
Limit HbS deoxygenation	Reduce tissue hypoxia	◆ Supplemental oxygen ◆ Incentive spirometry (10 puffs every 2 hours while awake), BiPAP or assisted breathing to improve ventilation
	Increase HbS oxygen affinity	◆ Prevent acidosis with adequate ventilation ◆ Antipyretics for fever
Limit erythrocyte-leukocyte adhesion in the microvasculature	Reduce inflammation	◆ Treat infections (encapsulated organisms, atypical, viral) ◆ Analgesia (NSAIDs + opioids, patient-controlled)
Reduce red cell HbS concentration	Reduce RBC dehydration and vaso-occlusion	Hydration with hypotonic iv fluids: (dextrose 5% + ½ normal saline at 1 – 1.5 × maintenance); reduce to 0.75 × maintenance in AChS to avoid pulmonary oedema
	Increase HbA concentration	Transfusion of normal red blood cells
	Increase HbF concentration	Pharmacological therapy (hydroxyurea)

HbS, sickle haemoglobin; HbA, adult haemoglobin; HbF, fetal haemoglobin; RBC, red blood cell; NSAIDs, non-steroidal anti-inflammatory drugs; AChS, acute chest syndrome.

- Goal is to increase the Hb concentration to 10–11 g/dL or decrease HbS <30% with exchange.
- Post-transfusion Hb to not exceed 11 g/dL to avoid hyperviscosity, and more vaso-occlusion.
- Exchange transfusion if baseline Hb >10g/dL, AMOFS, AChS with severe respiratory distress, concurrent stroke or a worsening clinical condition despite simple transfusion.

A recommended and straight forward approach is to rapidly transfuse to a post-transfusion Hb target of 10–11 g/dL and then maintain it at that level with daily simple transfusions of 1–2 units as needed. This will maintain haemoglobin S levels at less than 20–30% while the patient recovers from multi-organ injury.

Management of specific complications

In addition to instituting supportive care (Table 275.1), specific guidelines pertaining to each of the complications are discussed in the following sections.

Acute chest syndrome

- Empiric coverage for typical and atypical bacteria with third-generation cephalosporins or quinolones, macrolides, and vancomycin especially for MRSA in severely-ill patients. In the influenza season, empiric treatment with antiviral medication oseltamivir should be included.
- Early and aggressive RBC transfusions result in immediate improvements in arterial Hb oxygen saturations and in the A-a O_2 gradient. It has been noted in observational trials that simple transfusion of 2–4 units is as effective as performing exchange transfusion [18]. However, the goal should be to reduce Hb S levels rapidly to less than 20–30%.
- If a patient does not improve with supportive care and empiric antibiotics, consider diagnostic bronchoscopy with BAL, CT imaging to evaluate for other sources of infection and possible pleuracentesis if large effusions present.
- Management of PE follows the guidelines for the general population although the role of anticoagulation for in situ thrombosis is unknown.
- The effectiveness of vasodilators such as inhaled nitric oxide has not been fully ascertained, but clearly does not reduce the severity of VOC [19].
- Two major comorbidities, asthma and PH, are highly prevalent in SCD patients with AChS and can worsen the outcome.
  - **Airway hyperreactivity**: use of bronchodilator therapy every 4 hours. Routine corticosteroid therapy is controversial in SCD patients as its use has been associated with rebound pain crisis and hospitalization. It is our practice to only use corticosteroids in patients that have received transfusion therapy.
  - **Pulmonary hypertension**: Doppler-echocardiogram should be performed in every patient admitted to the ICU with AChS to diagnose right ventricular failure.

Haemolytic transfusion reactions

It is important to avoid additional transfusions as they may exacerbate the ongoing haemolysis, unless there is evidence of haemodynamic compromise from the acute anaemia. In this case transfusions should be given along with immune modulators to suppress the activity of macrophages. There is anecdotal evidence that high dose corticosteroids and intravenous (iv) immunoglobulins (IVIg) are beneficial in this setting, although both treatments have SCD-specific relative contraindications. Particular attention should be made to maintenance of hydration with iv fluids to avoid haemoglobinaemia-associated renal damage. Complete RBC phenotyping should be undertaken in case of an emergency, but it is important to highlight that during hyperhaemolytic crises, haemolysis may occur in spite of the infusion of fully cross-matched compatible blood.

There are anecdotal reports of the successful use of rituximab, a monoclonal antibody against the CD20 antigen on B-cells, prior to subsequent transfusions to reduce auto-antibody formation and further hyperhaemolytic reactions.

Sepsis

Supportive care for septic shock follows the same guidelines instituted for the general population. Central lines should be removed, broad-spectrum antibiotics administered, and sources of infection determined with therapy tailored accordingly.

Pulmonary hypertension

Detailed management of PH is discussed elsewhere. Patients with right heart failure (cor pulmonale) should receive exchange transfusion to increased mixed venous oxygen saturations and prevent pulmonary vaso-occlusion. Right heart catheterization, therapy with inotropes to increase right heart function, and iv epoprostenol

may be required to increase cardiac output and acutely lower pulmonary vascular resistance, and pressures. A multicenter, placebo-controlled trial of treatment of PH in SCD using oral sildenafil, phosphodiesterase 5-inhibitor was prematurely stopped because of increased hospitalization rate from pain in the sildenafil group. This drug is no longer considered a first-line therapy for PH in SCD [20]. Other agents used for PH include endothelin receptor antagonists, bosentan, and ambrisentan.

Acute multi-organ failure syndrome

Prompt initiation of transfusion therapy or exchange transfusion should be undertaken to improve tissue oxygenation and perfusion, and to aid in recovery of organ function. If TTP is strongly suspected, plasmapheresis should be promptly instituted in tandem with exchange transfusion, for rapid resolution of symptoms.

SECTION 12

The skin and connective tissue

PART 12.1

Skin and connective tissue disorders

CHAPTER 276

Assessment and management of dermatological problems in the critically ill

Richard Groves

Key points

- Important primary dermatological conditions that require intensive care management include erythroderma, toxic epidermal necrolysis/Stevens Johnson syndrome, widespread drug eruptions and blistering disorders with extensive skin involvement.
- Drug reaction with eosinophilia and systemic symptoms may affect multiple organ systems and death may ensue from hepatic necrosis. Treatment of severe cases includes steroids and/or immunosuppression.
- Acute generalized exanthematous pustulosis occurs rapidly following exposure to causative drugs and is generally self-limiting, although associated with secondary infection.
- Toxic epidermal necrolysis, Stevens–Johnson syndrome and widespread erythema multiforme represent a continuum of severe skin reactions associated with significant mortality and morbidity.
- Treatment of extensive skin disease requires expert nursing care in order to mitigate the consequences of skin failure.

Introduction

Although dermatology is generally considered to be an outpatient specialty, relating to conditions of low acuity, a wide array of skin problems can present in the critically-ill patient. Some may reflect pre-existing disease (psoriasis, for example, affects 2% of the general population and so will be seen in many acutely unwell patients and be unconnected with their acute illness); some may occur as a consequence of treatment, for example, drug eruptions, and a small fraction will represent severe or extensive primary skin disease that is best managed in a critical care setting.

The spectrum of dermatological disease in critical care

A number of studies have reviewed dermatological presentations in critical care settings in different countries [1–3]. A survey in the UK suggested that primary dermatological diagnoses account for around 0.5% of ICU admissions [3], although dermatological conditions were present in 9.3% ICU patients identified in a recent prospective study [4] and reviews of dermatological consults in ICU suggest that many were for infectious complications of ICU admission (candida intertrigo, cellulitis, herpes simplex/zoster) [1].

Important primary dermatological conditions that require intensive care management include erythroderma, toxic epidermal necrolysis/Stevens–Johnson syndrome (TEN/SJS), widespread drug eruptions and blistering disorders with extensive skin involvement.

General approach to the assessment and management of the patient with skin disease in intensive care

Skin disease diagnosis and management can be confusing for the non-specialist and, in the critical care context, will be best achieved by a team-based approach with input from medical dermatologists, dermatology specialist nurses and colleagues in critical care.

A methodical approach will often provide useful pointers, and taking a good history is the first step. Does the patient have a history of skin problems? Are they currently using any prescribed topical medication? Is there a family history of skin problems? What is the chronology of the skin problem in relation to the patients other medical problems? Has any new medication been started recently? If it has, when exactly?

When examining the patient, a number of factors will require evaluation in order to define the potential severity of the eruption. Estimation of the extent of the skin involvement can conveniently be done using the rule of 9s. Evaluation of the integrity of the skin is also crucial—are there blisters or erosions? Is there mucosal involvement? Thinking about the principal lesion (papules, pustules, vesicles, bullae) will aid in identifying the potential pathology and in communication with dermatological colleagues.

All patients with extensive skin disease will require expert nursing care in order to mitigate the consequences of skin failure. Thus, low-friction beds, non-adherent primary dressings, careful attention to prevention of infection, temperature regulation, fluid management, and so on are critical.

Erythroderma

Erythroderma is generally defined as a state in which there is >90% skin area involvement with an inflammatory process. The

skin is typically red (erythematous), and may be scaly or exudative. Remember that in black skin erythema can be hard to assess. Erythroderma should be regarded as a situation of general skin failure, where the skin fails to perform its normal functions of protection against infection (barrier and immunological), temperature control and fluid regulation (preventing and regulating losses). Therapy is primarily supportive and intensive care is often required. Although erythroderma has traditionally been associated with a high mortality, with modern intervention mortality is low [5].

Erythroderma is a final common pathway for various inflammatory dermatoses including psoriasis, eczema (of all sorts), drug eruptions and cutaneous T-cell lymphoma (see Table 276.1). Associated clinical features (for example, psoriatic nail dystrophy) or the patient's past dermatological history may point to the underlying diagnosis, but erythroderma due to any of the potential underlying diagnoses may appear remarkably similar clinically.

Histopathology of the skin may be helpful in the elucidation of some causes of erythroderma, most particularly pemphigus foliaceus and cutaneous T-cell lymphoma. Diagnostic features may be seen in patients with eczema (spongiosis) or psoriasis (papillomatosis, thinning of the suprapapillary plate), but often only non-specific changes are seen. Repeat biopsies may eventually show features more typical of the underlying diagnosis and should be considered if an underlying cause remains elusive. Blood investigations are generally unhelpful in identifying the cause (for example, eosinophilia can be seen in atopic eczema, drug eruptions, and in acute psoriasis) though Sezary cells are suggestive of a cutaneous lymphoma.

Initial assessment of the erythrodermic patient should focus on the general state of the patient, including electrolyte balance, nutritional status and signs of infection. Management is supportive, with liberal bland topical applications in the early stages of therapy. Topical steroids and tar are, in general, avoided as they may destablize psoriasis and provoke a pustular flare. Once a diagnosis is established, and the initial acute inflammatory state improves, specific systemic therapy can be introduced according to the underlying diagnosis. Thus, in eczematous states, systemic steroids may be of benefit and in psoriasis agents such as ciclosporin, acitretin or anti-TNF therapy can be considered.

Table 276.1 Causes of erythroderma

Condition	Prevalence (%)
Eczema of various types	40.0
Psoriasis	25.0
Drugs	10.0
Lymphoma and leukaemias	15.0
Hereditary disorders	1.0
Other skin diseases: ◆ Lichen planus, dermatophytosis ◆ Crusted scabies, Pemphigus foliaceus ◆ Dermatomyositis	1.0
Unknown	8.0

Drug eruptions

Drug eruptions can be seen either as a coincidental finding in patients in an intensive care setting or as the primary reason for admission. Numerous morphological changes can occur, although most drug eruptions seen in ICU are relatively trivial, generally exanthematous and frequently secondary to antibiotic drugs. These reactions are self-limiting, as long as the offending drug is withdrawn. Toxic epidermal necrolysis is generally drug-induced and is considered later in this chapter. Two additional reactions can be more severe and are dealt with in more detail here.

Drug reaction with eosinophilia and systemic symptoms

Drug reaction with eosinophilia and systemic symptoms (DRESS) [6,7] is a potentially life-threatening adverse drug reaction with a mortality rate of around 10%. It is characterized by skin changes, most usually a morbilliform (measles-like) rash, in association with liver, renal, and other systemic organ involvement. Mortality occurs particularly as a result of liver involvement.

DRESS represents a severe hypersensitivity reaction and has been described in association with a wide variety of medication, especially anticonvulsant drugs [8]. Immunosuppression may play a role, and recent evidence suggests that human herpes virus-6 (HHV-6) infection may predispose to the eruption [9]. Interestingly, some human leukocyte antigen (HLA) types are over-represented in DRESS patients suggesting a potential genetic predisposition [9].

Onset of DRESS is typically delayed following first exposure to the drug, generally by 2–6 weeks. Patients are often febrile and develop a morbilliform rash typically initially affecting the face, sometimes with significant associated oedema. The eruption may take differing morphological forms, and an erythema multiforme-like change has been associated with a poorer outcome [8]. Mucositis may occur in ~30% patients [6].

Multiple organ systems may be affected in DRESS, with lymphadenopathy, haematological changes (eosinophilia, leukocytosis), kidney, lung, endocrine, neurological and cardiac involvement reported. The principal cause of mortality is hepatic involvement, initially transaminitis, which may progress to fulminating hepatic necrosis requiring hepatic transplantation.

Once DRESS is recognized, immediate withdrawal of the probable offending drug is required. Mild cases may resolve spontaneously, but where there is evidence of internal organ involvement, systemic steroids are generally required, typically oral prednisolone 1 mg/kg/day or intravenous (iv) methylprednisolone [7,10]. Prolonged tapering may be required over several months in order to prevent relapse. In patients resistant to the effects of steroids other interventions have been used including ciclosporin, IVIg, cyclophosphamide, as well as antivirals such as valganciclovir in order to prevent or minimize complications relating to HHV-6 reactivation. Patients may require multi-organ support and intensive skin care nursing in the acute phase.

In some patients it may be unclear which of a number of drugs is responsible. In this situation challenge patch testing or lymphocyte stimulation assays following recovery can provide pointers to the potential culprit. Unfortunately false negative results are recognized with both approaches and thus positive results tend to be of more help than negative ones.

Acute generalized exanthematous pustulosis

Acute generalized exanthematous pustulosis (AGEP) [11] is a relatively uncommon reaction characterized by fever and pruritus followed by the appearance of multiple tiny sterile pustules, often most marked in the flexures. Women seem to be more often affected than men. Internal organ involvement is uncommon, although renal and hepatic dysfunction have been reported. Associated mortality of 5% seems to relate particularly to secondary infection in the elderly. Some patients with DRESS will present with pustulation and this differential diagnosis must be borne in mind.

Unlike DRESS, AGEP occurs rapidly following exposure to the causative drug, typically within 48 hours. Many drugs have been reported to cause the eruption with penicillins, antimalarials, terbinafine, and diltiazem being amongst the most frequent.

The principal differential diagnosis is acute pustular psoriasis. Skin histology in AGEP shows subcorneal pustule formation, but the typical features of psoriasis are absent. Following resolution, epicutaneous patch testing to the offending drug may provoke inflammation and, in some patients, pustule formation at the site of application.

AGEP is generally self-limiting (assuming withdrawal of the causative drug) and it remains to be established whether topical or systemic steroid therapy hastens resolution.

Toxic epidermal necrolysis/Stevens–Johnson syndrome

TEN, SJS, and widespread erythema multiforme represent a continuum of severe skin reactions in which there is extensive keratinocyte cell death in the epidermis leading to blistering, erosion, and skin failure. TEN and SJS in particular are associated with significant mortality and morbidity.

Definition

Erythema multiforme major, SJS, and TEN are all characterized by similar pathological changes, with necrosis/apoptosis of epidermal keratinocytes, either individually or affecting the full thickness of the epidermis, in association with a perivascular inflammatory cell infiltrate in the dermis. Histological features vary depending on the site of biopsy and it's timing in relation to the evolution of a lesion.

Erythema multiforme lesions are typically a concentric circular erythema, but as the name implies, may take multiple forms. Lesions are typically acral or over extensor prominences. In SJS, there is generally mucosal involvement (mouth, eyes, genitalia) together with EM-type lesions affecting less than 10% body surface area (BSA). TEN is defined as more than 30% BSA involvement and TEN/SJS overlap having 10–30% BSA affected.

Causes

The overwhelming majority of cases of TEN occur as a result of drug hypersensitivity, although infection (for example, mycoplasma) may also precipitate the reaction. SJS is more commonly related to infection, most notably herpes simplex and mycoplasma. All patients with suspected TEN or SJS should undergo forensic analysis of recent drug exposure: the ALDEN algorithm has been developed to assist with this [12]. TEN typically occurs 1–8 weeks following drug exposure, with mean time of onset between 6 days and 2 weeks. Common drug culprits are listed in Box 276.1.

Box 276.1 Drugs commonly implicated in TEN

- **Allopurinol**
- **Aminopenicillins**
- **Carbamazepine**
- **Cephalosporins**
- **Cotrimoxazole**
- **Lamotrigine**
- **Nevirapine**
- **Oxicam**
- **NSAIDs**
- **Phenobarbital**
- **Phenytoin**
- **Quinolones**
- **Sulfasalazine**

Clinical features

The characteristic feature of TEN is the development of widespread denudation of the dermis with sheets of epidermal separation. There is frequently a prodrome of general malaise, fever, and rash, which may be morbilliform or with features of erythema multiforme. The skin is typically tender and pain is prominent. Mucosal ulceration occurs in the majority of patients with TEN, affecting the mouth, eyes, and genitalia. It is important to remember that the erosive process may also affect the respiratory mucosa, and ARDS has been documented, with lung function abnormalities in up to 25% patients.

Pathophysiology

The key pathological change in TEN and SJS is apoptosis within the epidermis, potentially mediated by granzyme B, perforin, granulysin, and fas/fas ligand interactions [13]. There is increasing evidence for involvement of CD8+ve cytotoxic T-cells, which can be found in blister fluid and in the dermis of affected skin. Interestingly, a number of recent studies have demonstrated a relationship between MHC class I status and drug hypersensitivity reactions. Thus in some populations (notably Han Chinese) a strong relationship exists between anticonvulsant reactions and the presence of HLA B*1502, whereas patients with TEN secondary to allopurinol have a higher frequency of HLA-B*5801. Because of the potential severity of skin reactions such as TEN, genetic testing should be considered prior to commencing treatment in those groups where strong genetic relationships have been demonstrated [14].

Prognosis

TEN is associated with a mortality of ~25% at 6 weeks and 34% at 1 year [15]. Principal causes of death are sepsis, respiratory failure, and gastrointestinal bleeding. In order to guide prognosis the severity of illness **score** for **TEN** (SCORTEN) scale has been developed and validated in a number of studies [16,17]. Seven variables (see Box 276.2 and Table 276.2) are scored for presence or absence and the number of positive variables relates directly to outcomes. SCORTEN values on the third day of hospital admission seem to have the best predictive value.

Patients who survive the acute phase of TEN are at risk of multiple sequelae, including cutaneous scarring and dyspigmentation, eye, respiratory, genitourinary, and psychological problems. Multidisciplinary involvement at an early stage may minimize these and provide a framework for subsequent management.

Management

General measures and wound care

The most important therapeutic intervention in TEN is identification and withdrawal of the precipitating drug. Identification is not

Box 276.2 SCORTEN variables

- **Age >40 years**: heart rate >120 bpm.
- **Bicarbonate <20 mmol/L**: comorbid malignancy.
- **Epidermal detachment > 10%**: urea > 10 mmol/L.
- Glucose >14 mmol/L.

Data from Bastuji-Garin S et al., 'SCORTEN: a severity-of-illness score for toxic epidermal necrolysis', *Journal Investigative Dermatology*, 2000, **115**(2), pp. 149–53.

always easy and withdrawal of all potentially culprit drugs is mandatory. Unfortunately, diagnostic sensitivity testing (for example, by lymphocyte proliferation or cytokine release assays) is of little value in the acute situation.

TEN represents a situation of acute skin failure, with loss of most of the normal functions of the skin and consequent risks of infection, fluid loss, loss of temperature control, and so-on. Expert nursing care, such as will be available in a specialized dermatological or burns centre is advisable. Most patients will require nursing in an ICU setting. Non-adherent primary dressings such as silicone mesh will minimize damage to newly re-epithelialized skin at dressing changes. Many absorbent secondary dressings are available, some in garment-shaped configurations that give increased patient comfort. Liberal use of emollients will minimize shearing damage to the skin and patients should be nursed on a friction-reducing mattress.

Systemic therapy

Corticosteroids have been used to variable effect. Although for many years their use was thought to be associated with adverse outcomes, particularly from infection, some recent studies have suggested a possible beneficial effect [18]. At present however there is no consensus as to how or when they may be of benefit.

Intravenous immunoglobulin has been widely used in the management of TEN, initially because of its inhibitory effect on fas/fas ligand interactions [19]. Since then, many studies have been reported [20], with variable benefit. Unfortunately none of these has been controlled and, as with steroids, there is no consensus on appropriate use. Whilst IVIG might not have the potential adverse effects on healing or infection of steroids, it is expensive and in short supply.

Table 276.2 SCORTEN mortality

Number of positive variables	Mortality
0–1	3.2%
2	12.2%
3	35.5%
4	58.3%
5–7	90%

Data from Bastuji-Garin S et al., 'SCORTEN: a severity-of-illness score for toxic epidermal necrolysis', *Journal Investigative Dermatology*, 2000, **115**(2), pp. 149–53.

Other interventions have been reported in small numbers of patients, including ciclosporin, plasmapheresis and TNF inhibitors, but there is currently insufficient evidence to recommend their routine use.

Conclusion

Dermatological problems occur frequently in the critical care setting. Many are minor and relate to drug sensitivities that resolve following drug withdrawal. Others however are life-threatening but, with a carefully coordinated multidisciplinary approach involving dermatologists, intensivists, organ specialists and specialist nurses should now have a much improved long-term outcome.

CHAPTER 277

Vasculitis in the critically ill

Karina A. Keogh

Key points

- The vasculitic syndromes are a heterogeneous group of rare disorders characterized by degrees of inflammation and necrosis of blood vessels with a wide variety of clinical manifestations.
- These syndromes were previously associated with a very high mortality, but significant gains in mortality have been seen with current immunosuppressive therapy.
- Vasculitis is frequently diagnosed for the first time during an intensive care unit (ICU) admission.
- Vasculitis in the ICU is most commonly an anti-neutrophil cytoplasmic antibodies (ANCA)-associated vasculitis.
- ICU admission may be for end-organ damage from the disease process itself, or may be for a treatment complication, most commonly severe infection in an immunocompromised host.

Introduction

The vasculitic syndromes are a heterogeneous group of rare disorders characterized by degrees of inflammation and necrosis of blood vessels with a wide variety of clinical manifestations. The pathological process may affect the arteries, veins, and capillaries of any organ. The majority of primary vasculitis syndromes have no known aetiological factors. Secondary vasculitis can be seen in collagen vascular disease, immunological disorders, and infections, e.g. hepatitis B and C.

A number of nomenclature systems have been developed, primarily for research purposes. The American College of Rheumatology (ACR) 1990 diagnostic criteria, classifies the primary vasculitides based on the size of blood vessels involved (aorta and major branches, and equivalent veins) [1]. The Chapel Hill Consensus Conference (CHCC) definitions [2], similarly divide on the basis of blood vessel size. Unlike the ACR criteria, CHCC definitions define microscopic polyangiitis (MPA) as a distinct entity. The European Medicines Agency algorithm [3] also incorporates ANCA, and the latest iteration of the CHCC definition takes into account the recent move away from 'honorific' names for syndromes, towards more descriptive names. These recently accepted more descriptive names for vasculitic syndromes are used throughout this chapter, and an updated list of the primary vasculitides is outlined in Box 277.1. Differential diagnoses typically consists of infection, collagen vascular disease, sarcoidosis, and malignancy.

Intensive care admission is most commonly required for vasculitis involving small blood vessels, including capillaries. The three most common forms of systemic small vessel vasculitides are granulomatosis with polyangiitis (GPA) (Wegener's), microscopic polyangiitis (MPA), and eosinophilic granulomatosis with polyangiitis (EGPA) (Churg–Strauss syndrome). These three conditions are associated with antineutrophil cytoplasmic antibodies (ANCA) and are referred to as the ANCA-associated vasculitides [4,5]. Non-vasculitic manifestations may also be present, such as pulmonary nodules secondary to necrotizing granulomatous inflammation in GPA.

Standard treatment consists of corticosteroids and cytotoxic drugs [6]. ICU admission is typically for end organ damage secondary to inflammation, or because of side effects from the cytotoxic therapies, particularly infection. Overall, there has been a dramatic improvement in prognosis for these conditions since the introduction of cyclophosphamide in the late 1970s, previously rapidly fatal diseases now have 5-year survivals of 80%. ICU admission is associated with a worse prognosis. In one French cohort of 210 patients with primary vasculitides there were 26 ICU admissions over a 20-year period [7]. In 77% the reason for admission was active vasculitis, and in almost half, this was the initial presentation of the disease. The in-ICU mortality was 15% (n = 4), primarily from infectious complications. After a mean follow-up of 31.4 ± 29.2 months, the overall mortality rate was 39% (n = 10).

Small vessel vasculitis

Granulomatosis with polyangiitis (Wegener's)

GPA is a systemic vasculitis characterized by necrotizing granulomatous vasculitis of the respiratory tract, kidneys, and other organs. Alveolar haemorrhage and renal involvement with focal segmental glomerulonephritis are severe manifestations of GPA. The term 'limited Wegener's granulomatosis' has been used to describe disease that is not life- or organ-threatening. Morphological characteristics of GPA include necrotizing granulomas, fibrinoid necrosis, micro-abscesses, focal vasculitis, and thrombosis. GPA, the most common form of vasculitis to involve the lung has a prevalence of up to 63 per million, and an annual incidence of 10 per million

The mean age at onset of symptoms of Wegener's granulomatosis is approximately 45 years; the male to female ratio is 2:1. Patients may initially present with non-specific symptoms including fever, malaise, weight loss, arthralgias, and myalgias. Other frequent disease manifestations are: skin (40–50%), eyes (43%), arthralgias (58%), and arthritis (28%), and neurological involvement in (25%). The cardiovascular system may also be involved.

Upper airway disease, which is present in over 85% of patients, manifests as rhinorrhoea with purulent or bloody nasal discharge,

Box 277.1 Classification of the primary systemic vasculitides based on the size of the blood

- Vessel involvement.
- **Large vessel:**
  - Takayasu's arteritis.
  - Giant cell arteritis.
- **Medium-sized vessel**:
  - Kawasaki's disease.
  - Polyarteritis nodosa (PAN).
- **Small vessel—ANCA-associated vasculitis**:
  - Granulomatosis with polyangiitis (GPA) (Wegener's).
  - Microscopic polyangiitis (MPA).
  - Eosinophilic granulomatosis with polyangiitis (EGPA) (Churg–Strauss syndrome).
- **Small Vessel—Immune Complex Small Vessel Vasculitis**:
  - Anti-glomerular basement membrane (anti-GBM) disease.
  - Cryoglobulinaemic vasculitis.
  - IgA vasculitis (Henoch–Schönlein purpura).
  - Hypocomplementemic urticarial vasculitis.
- **Variable vessel vasculitis**: Behcet's disease.

nasal mucosal drying, and crust formation, epistaxis. Paranasal sinus involvement leading to deep facial pain, nasal septal perforation, and ulceration of the vomer are important signs. Destruction of the nasal cartilages resulting in 'saddle-nose deformity' is usually a subacute or chronic complication.

Laryngeal and tracheal ulcerated lesions which are present in 30% of untreated patients Subglottic stenosis develops in 5–8% of treated patients. The symptoms caused by subglottic stenosis are usually insidious in onset. Inspiratory and expiratory flow-volume loops may be useful in assessing the impairment of upper airway function, as well as in the follow-up of these patients. Laryngeal involvement may lead to a more difficult intubation, often requiring a smaller endobronchial tube. Surgical dilatation and less commonly tracheostomy may be required.

Microscopic polyangiitis

MPA is a separate entity, with similar vasculitic manifestations to GPA—pauci-immune necrotizing and crescentic glomerulonephritis, and alveolar haemorrhage. By definition there is no granulomatous inflammation, and the upper airway complications seen in Wegener's granulomatosis are not seen. Both GPA and MPA have similar clinical courses and therefore in clinical trials are typically grouped together. They respond similarly to immunosuppressive treatment.

Investigation

Both GPA and MPA are associated with ANCA [8]. These antibodies react with antigens in neutrophil granules, resulting in two staining patterns on indirect immunofluorescence. The C-ANCA pattern demonstrates granular staining in the cytoplasm while the P-ANCA pattern is staining in a perinuclear distribution. The target antigen for cANCA is almost always protease 3 (PR-3). This C-ANCA/PR3 pattern is found in 80–95% of patients with GPA, and up to 40% of patients with MPA. P-ANCA most commonly targets MPO (myeloperoxidase), however, there are a large number of other antigens with which it reacts including many different neutrophil granule and cytoplasmic components, as well as infection-related antigens, (e.g. bactericidal permeability increasing protein (BPI)). The P-ANCA/MPO pattern is seen in 40–80% of patients with MPA (and also Churg–Strauss syndrome), but is less specific for the ANCA-associated vasculitidies. P-ANCA positivity may also be seen in rheumatoid arthritis, ulcerative colitis, Crohn's disease, autoimmune chronic active hepatitis, primary biliary cirrhosis, and sclerosing cholangitis.

Laboratory testing in GPA and MPA may also reveal the following non-specific findings—normochromic normocytic anaemia, mild leukocytosis, mild thrombocytosis, elevated erythrocyte sedimentation rate (often above 100 mm/hour). On urinalysis, abnormalities such as haematuria, proteinuria, and red cell casts are observed in 80% of patients. Pulmonary function tests, particularly flow-volume curves, are helpful in assessing major airway involvement in GPA. In the setting of neurological symptoms an electromyogram may suggest a vasculitic aetiology. Ideally, the diagnosis would be confirmed with a biopsy, although in cases with classical symptomatology, particularly when supported by appropriate serology, it is not always necessary. A tissue diagnosis is not required to fulfil either the ACR criteria or the definitions of the CHCC. When a biopsy is necessary, it should be taken from the most accessible involved organ, such as the skin. In GPA an upper airway biopsy is often diagnostic. The role of transbronchial biopsy in the diagnosis of pulmonary vasculitis is limited, whereas open lung biopsy has a much higher yield.

Treatment

The primary treatment of severe GPA or MPA vasculitis is a combination of corticosteroids and cytotoxic agents [9]. Corticosteroids are typically initially given as methylprednisolone 1 g/day × 3 days, followed by 1 mg/kg/day of prednisone until the disease is controlled, then a slow taper over 3–6 months. The standard induction agent for severe disease over the last 40 years has been oral cyclophosphamide (standard dose 2 mg/kg/day orally, maximum 200 mg/day) [10], followed by a less toxic remission maintenance agent, typically azathioprine or methotrexate, continued for 2 years [11]. This regimen induces remission in >90%, however, is associated with significant toxicity. In one study, 54% of patients treated, developed a serious infection. Other side effects are bladder toxicity, malignancy, and infertility. In an attempt to limit this toxicity, intermittent pulsed (intravenous) dosing has been studied. This leads to a lower total dose of cyclophosphamide administered, with comparable efficacy of inducing remission, but presumably less toxicity [12]. An alternative, distinctly different agent rituximab has also recently been approved for the treatment of severe ANCA-associated vasculitis, on the basis of multicentre randomized trials indicating that rituximab is as efficacious as cyclophosphamide in inducing remission [13,14]. The standard vasculitis rituximab treatment regimen is 375 mg/m^2 weekly × 4 weeks. Rituximab likely has a more favourable side effect profile than cyclophosphamide, in particular it does not have the same negative effects on fertility. There

is, however, a risk with rituximab use of multifocal progressive leukoencephalopathy, a very rare irreversible dementia, thought to be secondary to the reactivation of the John Cunningham (JC) virus in the brain. Major relapses necessitate a return to an induction therapy regimen.

A large multicentre randomized study has also supported a role for plasma exchange in patients with acute renal failure secondary to ANCA-associated vasculitis, with a creatinine greater than 4 mg/dL [15]. Plasma exchange is also often considered in alveolar haemorrhage, requiring mechanical ventilation. A large multicentre study is currently underway to address the efficacy of plasma exchange in this setting.

Patients receiving long-term steroids should also receive prophylaxis against osteoporosis including calcium, vitamin D, and bisphosphonates, as indicated. Prophylaxis against pneumocystis jiroveci should be considered in any patient on chronic immunosuppressive therapy or corticosteroids in excess of 20 mg/day. Active vasculitis is also associated with a greater risk of thromboembolic disease, thus DVT prophylaxis should ideally be given in the ICU, balancing the risk of clot with the potential risk of severe bleeding in this patient population.

Eosinophilic granulomatosis with polyangiitis (Churg–Strauss syndrome)

EGPA, also previously known as allergic granulomatosis and angiitis, is the third ANCA-associated vasculitis, although ANCA positivity is typically only seen in 50% of patients. EGPA vasculitic manifestations are typically not as severe as those seen in GPA and MPA, and EGPA has distinct eosinophilic manifestions, therefore EGPA has typically been studied separately in clinical trials. Greater than 95% of patients have asthma. Nasal symptoms such as allergic rhinitis, nasal polyps, nasal mucosal crusting, and septal perforation are seen in over 70% of patients. Hypereosinophilia in peripheral blood, tissue eosinophilia, and elevation of serum IgE are common. Other causes of hypereosinophlia need to be ruled out, including hypereosinophlic syndrome secondary to a bone marrow disorder, and parasitic infection. The classic pathological findings are granulomatous or non-granulomatous angiitis and extravascular necrotizing granulomas, usually with eosinophilic infiltrates

Chest radiographic abnormalities are present in over 60% of patients, and include patchy and occasionally diffuse alveolar-interstitial infiltrates in the perihilar area. Pulmonary nodules +/– cavitation may be seen. Alveolar haemorrhage is very uncommon. Renal involvement is seen in 25%, but the need for renal replacement therapy is rare. One of the leading causes of morbidity/mortality is cardiac involvement with eosinophilic infiltration of the myocardium. These patients may require intensive care for vasculitic manifestations, eosinophilic manifestations (particularly cardiac, eosinophilic pneumonia), or for asthma management. The use of several medications has been associated with the development of EGPA, most notably the leukotriene-modifying agents, although it may be simply, that the use of these agents lead to a reduction in system corticosteroid use, which allows for the 'unmasking' of forme fruste Churg–Strauss syndrome (CSS).

Severity has classically been defined based on a five factor score (FFS), based on the presence or absence of five clinical features—cardiac involvement, gastrointestinal involvement, renal insufficiency (creatinine >1.58 mg/dL), proteinuria (>1 g/day), central nervous system involvement.

The primary therapy for EGPA is corticosteroids. If severe manifestations, typically denoted by a five factor score >1, treat as for the other ANCA-associated vasculitis. There are no large randomized treatment trials in EGPA, but small non- randomized studies support the use of cyclophosphamide in severe disease. There is also some evidence suggesting efficacy of rituximab in EGPA. The anti-IL 5 agent mepolizumab has also shown promise [16].

Anti-glomerular basement membrane (anti-GBM) disease

Anti-glomerular basement membrane (anti-GBM) disease was previously known as Goodpasture's disease. This is a rarer cause of 'pulmonary-renal syndrome' with alveolar haemorrhage and glomerulonephritis associated with autoantibodies that target the glomerular and pulmonary basement membranes. Treatment consists of prednisone and cyclophosphamide, similar to the ANCA-associated vasculitides, in conjunction with plasmaphoresis. The use of plasmaphoresis is based on a small randomized trial of 17 patients (where the best correlation with outcome was the severity of renal disease on entry, rather than treatment group), biological plausibility regarding benefit of rapid reduction in anti-GBM levels, and the improved morbidity and mortality with plasmaphoresis, compared to historic rates [17].

Medium vessel vasculitis

Polyarteritis nodosa

This medium vessel vasculitis, affecting primarily medium-sized muscular arteries, and occasionally small muscular arteries, is rare with a prevalence of 2–33/million, and may be associated with hepatitis B or C infection, or hairy cell leukaemia. Many patients who would previously been classified as having polyarteritis nodosa (PAN) are now classified as having MPA. While any organ may be affected, pulmonary involvement is rare. If a diagnostic biopsy cannot easily be obtained. Angiography can be helpful in making the diagnosis; multiple micro-aneurysms may be seen in the renal, hepatic, or mesenteric circulation. Severe manifestations such as renal insufficiency, mesenteric artery ischaemia, and mononeuritis multiplex, are treated with high dose corticosteroids and cyclophosphamide, as outlined for GPA. When there is underlying hepatitis, it is important that antivirals are used in conjunction with immunosuppression.

Large vessel vasculitis

Giant cell arteritis
