Giant cell arteritis, also known as temporal arteritis, cranial arteritis, and granulomatous arteritis is a large vessel vasculitis. The characteristic histological findings are lymphocytic infiltration with fragmentation of the internal elastic lamina, granulomatous inflammation, histiocytes, and multinucleated giant cells. The classic pathological features of giant cell arteritis are seen in approximately 60% of temporal artery biopsies. Giant cell arteritis may be seen in association with polymyalgia rheumatica, the relationship between these two entities remains uncertain. Giant cell arteritis usually affects persons in middle age or older individuals. There are no specific laboratory tests available to diagnose giant cell arteritis,

even though moderate elevation of erythrocyte sedimentation rate is common.

The onset of arteritis and blindness may be sudden, but usually the clinical illness is gradual in onset, with the development of non-specific systemic symptoms, such as low grade fever, malaise, and weight loss. Headache, variable, but often severe, is the most common symptom in giant cell arteritis. These may be followed by more specific symptoms like jaw claudication and sudden loss of vision. Amaurosis fugax is observed in 20% and visual loss in 10%.

Pulmonary complications of giant cell arteritis occur in approximately 10% of patients, and may be the presenting symptoms. They included cough, sore throat, and hoarseness. A population-based study of patients with giant cell arteritis noted respiratory symptoms in up to 30%. It should be considered in any older patient with a new cough or throat pain without obvious cause. Small airways disease has been observed in 46.2% of patients with giant cell arteritis, although the abnormalities have not been significantly different from controls. Chest radiograph abnormalities consist of pulmonary nodules, interstitial infiltrates, occlusion, and aneurysms of pulmonary artery.

Virtually all patients respond favourably to systemic corticosteroids at an initial dose of 1 mg/kg/day. Chronic low-dose therapy is required to maintain remission in most patients.

Takayasu's arteritis

Takayasu's arteritis, is a term synonymous with pulseless disease, aortic arch syndrome, or reversed coarctation. The aorta and its main branches are primarily involved. Histological features include continuous or patchy panarteritis with plasma cells, histiocytes and multinucleated giant cells.

Takayasu's arteritis is more common in Asia. The female to male ratio is 8.5:1, and 80% of patients are between 11 and 30 years of age. Initial or acute clinical features of temporal arteritis include fever, malaise, weight loss, arthralgias, and night sweats lasting for 4–6 works. Chronic disease is the result of ischemia of affected organs.

Pulmonary artery involvement is present in up to 50% of all patients with Takayasu's arteritis. Pathological lesions are generally localized to medium and large pulmonary arteries. Panarteritis with plasma cells, histiocytes and multinucleated giant cells lead to pulmonary arterial occlusion and stenoses A retrospective study of perfusion lung scans, revealed abnormalities in 76% of 120 patients with Takayasu's arteritis. Initially, the changes appeared in the upper lobes, and then progressed to involve arteries of the middle and lower lobes. In another study of 42 patients, in whom a respiratory problem was not clinically suspected, intravenous digital subtraction angiography in 42 patients with temporal arteritis showed involvement of pulmonary artery in 14.3% of patients even though chest radiographs were abnormal in only two patients. A comparison study of 59 patients with temporal arteritis showed that, although chest radiograms were abnormal in 68%, pulmonary angiography revealed arterial occlusions in 86%. A poor correlation has been noted between angiographic changes, and the results of spirometry and arterial blood gas analysis. Other thoracic complications described include aneurysms of pulmonary arteries. Takayasu arteritis presenting as idiopathic adult respiratory distress syndrome with a pathological diagnosis of acute interstitial pneumonia has been described.

Corticosteroids therapy results in symptomatic remission in within days to weeks, but approximately 50% of patients will require an additional agent because of relapsing disease. There are small open-label studies supporting the use of methotrexate and azathioprine. Patients with significant pulmonary artery occlusions may require surgical bypass. Death is usually the result of vascular complications such as rupture of aneurysm, myocardial infarction, congestive cardiac failure, or cerebrovascular accident. Pulmonary involvement signifies a poor prognosis.

Variable vessel vasculitis

Behçet's disease

Behçet's disease is a chronic recurring vasculitic syndrome, most prevalent in Turkey, followed by other countries along the ancient silk route from Asia to the Mediterranean. It is characterized by aphthous stomatitis together with two or more of the following: aphthous genital ulcerations, uveitis, cutaneous nodules, or pustules, synovitis, or meningoencephalitis. The histological features of mucocutaneous lesions are non-specific, and exhibit with various degrees of lymphocytic and plasma cell infiltration, and deposition of IgM and C_3 in the dermal vessels. Both arteries and veins, of variable sizes are involved by the vasculitis. Fever, elevated erythrocyte sedimentation rate, and anaemia are common. Obstruction of major vessels and aneurysms occurs in 10–37% of patients. Thrombosis of superficial and deep veins of both upper and lower extremities, and superior and inferior vena cava develop in 7–37% of patients.

Massive haemoptysis is the most serious respiratory complication in Becet's disease. Life-threatening haemoptysisis is common and is the cause of death in more than 1/3 of patients with pulmonary disease. Serious haemoptysis, initially sensitive to corticosteroid therapy, demonstrates a propensity to reoccur. A review of 28 patients with Behçet's disease with respiratory complications noted haemoptysis, fever, chest pain, and dyspnoea in all 28 patients, and the lung involvement was associated with extrapulmonary disease. Another report on 49 patients with lung involvement observed that recurrent dyspnoea, cough, chest pain, and haemoptysis were the primary clinical signs, particularly in young men, and appeared 3.6 years after the onset of Behçet's disease. Chest radiographs may show pulmonary infiltrates, pleural effusions, and prominent pulmonary arteries. The reasons for haemoptysis include aneurysms of the pulmonary artery, pulmonary artery-bronchus fistula, and mucosal ulcerations. Pulmonary angiography may reveal amputation of the branches of the pulmonary artery and aneurismal dilatations. Immunopathological studies have indicated that pulmonary vasculitis is a result of circulating immune complexes.

Pulmonary embolism occurs with greater frequency because of the high incidence of deep vein thrombosis of the extremities and the vena cavas. Other complications include formation of the fistulas between the coronary and pulmonary arteries, and between the bronchial and pulmonary arteries, pulmonary hypertension, pulmonary haemorrhage, thromboembolism of the superior vena cava and/or other mediastinal or hilar lymphadenopathy, and interstitial pulmonary fibrosis.

Corticosteroids suppresses, but seldom controls all manifestations of the disease. Sudden deaths in corticosteroid-treated patients have indicated that corticosteroid alone may be inadequate. Other drugs namely colchicine, chlorambucil, methotrexate, azathioprine, and cyclosporin have been utilized, but there is very little supporting data for any particular agent. Anticoagulant

therapy is contraindicated. Patients with significant haemoptysis or diffuse pulmonary infiltrates carry a poor prognosis; a mortality of 80% within 2 years after the onset of lung disease has been noted.

CHAPTER 278

Rheumatoid arthritis in the critically ill

Rodrigo Cartin-Ceba and Udaya B. S. Prakash

Key points

- Rheumatoid arthritis is a progressive chronic inflammatory disease of autoimmune aetiology that predominantly affects the joints.
- Rheumatoid arthritis frequently affects non-articular systems, most commonly the cardiopulmonary, gastrointestinal, and haematological systems.
- Treatment of rheumatoid arthritis includes corticosteroids and disease-modifying anti-rheumatic drugs, such as methotrexate, that reduce the inflammatory activity as well as inhibit joint destruction.
- Over the last years, the use of biologicals, such as infliximab, etanercept, adalimumab, anakinra, rituximab, and abatacept has dramatically enhanced the success of rheumatoid arthritis management.
- The main reasons for intensive care unit admission for patients with rheumatic autoimmune diseases include infections, life-threatening manifestations of the underlying disease, adverse effects of the treatment, and unrelated acute medical or surgical illness that are aggravated by the autoimmune disease.

Introduction

Rheumatoid arthritis (RhA) is a progressive chronic inflammatory disease characterized by joint swelling, joint tenderness, and destruction of synovial joints, leading to severe disability and premature mortality. RhA predominantly affects the sinovium of diarthrodial joints, with frequent involvement of tendons, ligaments, fascia, muscle, and bone [1]. Many extraskeletal systems are frequently affected and, indeed, may be the presenting manifestations of RhA. The prevalence of RhA has been estimated at 0.5–1% of the adult population and is the most common form of inflammatory joint disease. It affects women about three times as frequently as men. RhA can occur at any age, although its peak incidence is during the fourth and the sixth decade of life. Given the presence of autoantibodies, such as rheumatoid factor and anti-cyclic citrullinated peptide, which can precede the clinical manifestation of RhA by many years, RhA is considered an autoimmune disease [1]. Over the last years, the optimal use of disease-modifying anti-rheumatic drugs (DMARD), in particular methotrexate, and the availability of several new biological agents, have dramatically enhanced the success of RhA management.

A quarter of patients with autoimmune diseases are admitted to the hospital after presenting to the emergency department and a third of those individuals will require management in the intensive care unit (ICU), of whom a significant percentage are patients with RhA (between 25 and 36% of all autoimmune disease patients managed in the ICU). The main reasons for ICU admission for patients with rheumatic autoimmune diseases are infections resulting from the immunosuppressive therapy, flare or a new life-threatening manifestation of the underlying autoimmune disease, adverse effects of the treatment, and usual unrelated acute medical or surgical illness that are usually aggravated by the autoimmune disease [2,3].

Systemic manifestations of rheumatoid arthritis

RhA is a systemic disease that frequently affects many non-articular systems as outlined in Table 278.1.

Respiratory system

The respiratory system is the most commonly non-skeletal system affected by the disease itself or by severe infections. The pulmonary complications are more common in males with RhA. Pleuropulmonary complications may precede the onset of arthritic symptoms. Many of the intrathoracic manifestations have the potential to cause critical illness and respiratory distress. Acute respiratory failure can occur in RhA patients from a wide variety of causes, but most commonly is related to infections [4–6].

Pleural involvement

Pleural involvement is the commonest intrathoracic manifestation of rheumatoid arthritis [4–6]. Chest X-ray evidence of pleural involvement has been noted in 24% of males and 16% of females. Post-mortem analyses have observed pleural involvement in nearly 50% of individuals. Clinically, massive pleural effusion with the potential to cause respiratory distress is uncommon. Indeed, one-third of patients with rheumatoid pleural involvement are relatively asymptomatic. The pleural effusion is generally unilateral, small, persistent, or recurrent. Occasionally, effusions become chronic and persist for months to years. Pleural involvement is more common in those with active and seropositive rheumatoid

Table 278.1 Systemic complications in rheumatoid arthritis

System	Complication
Pulmonary	◆ Pleurisy and pleural effusion ◆ Pneumothorax ◆ Interstitial pneumonitis and fibrosis ◆ Obliterative and follicular bronchiolitis ◆ Obstructive airway disease ◆ Necrobiotic (rheumatoid) nodules ◆ Caplan's syndrome ◆ Pulmonary arterial hypertension ◆ Pulmonary vasculitis with diffuse alveolar haemorrhage ◆ Bronchiectasis ◆ Apical fibrobullous disease ◆ Pulmonary amyloidosis ◆ Drug-related pulmonary toxicity
Upper airway	◆ Cricoarytenoid joint inflammation ◆ Laryngeal nodules ◆ Upper airway obstruction
Cardiovascular	◆ Pericarditis and pericardial effusion ◆ Constrictive pericarditis ◆ Myocarditis ◆ Valvular disease ◆ Aortitis and aortic dissection
Central nervous system	◆ Rheumatoid pachymeningitis ◆ Cord compression from atlanto-axial dislocation
Haematological	◆ Anaemia of chronic disease ◆ Leukopenia (Felty's syndrome)
Gastrointestinal	Gastrointestinal bleeding (drug-associated: NSAIDS and corticosteroids)

arthritis than those with inactive disease. It is, however, important to recognize that rheumatoid effusions may become complicated by empyema. One complication that may lead to respiratory distress is the sudden occurrence of pneumothorax following transthoracic needle aspiration of rheumatoid lung nodules.

Analysis of pleural fluid typically shows exudative level of total protein (>3.0 g/dL). The fluid is usually pale yellow but occasionally bloody although it may assume opalescent green colour due to the high cholesterol content ('pseudochylothorax'). Typically, the glucose level in pleural fluid is very low (<30 mg/dL) in over 80% of patients and could be confused with an empyema. This is the result of selective blockage of glucose transport into the pleural space as well as the increased glucose utilization by the inflamed and metabolically active pleural mesothelial cells. Analysis of the fluid for its pH may reveal an acidotic fluid (pH <7.30) in acute rheumatoid effusions. The low pH is the result of localized acidosis caused by blockage to the efflux of the end products (lactate and CO_2) of glucose metabolism in the pleural space.

Interstitial lung disease

The term, 'rheumatoid lung' is used to describe the diffuse interstitial pneumonitis and fibrosis that occurs as a complication of RhA [4–6]. The rheumatoid lung disease is among the most serious complications. The estimated prevalence of this condition using high resolution computed tomography (HRCT) is 20–44%. A restrictive pattern of pulmonary dysfunction can be documented by pulmonary function testing in over one-third of patients. The clinical, physiological, and histopathological features of rheumatoid lung disease are analogous to those in idiopathic interstitial pneumonia and include usual interstitial pneumonia (the commonest pattern in RhA), non-specific interstitial pneumonia, organizing pneumonia, lymphocytic interstitial pneumonia, and desquamative interstitial pneumonia. Cough and dyspnoea on exertion are common symptoms [7]. Physical examination reveals fine late inspiratory crackles, more pronounced in the lung bases, and clubbing occurs in over two-thirds of the patients. The chest X-ray usually exhibits a bibasilar interstitial process or micronodules, with progression to other regions as the disease progresses. Late stage disease may show generalized honeycombing. HRCT of the chest in early stages of the disease may show 'ground-glass' infiltrates and as the disease progresses, interstitial process, and honeycombing appear.

Pulmonary function testing in patients with rheumatoid lung disease typically demonstrate restrictive lung dysfunction manifested by decreased lung volumes, relatively normal airflow, and diminished diffusing capacity of the lungs for carbon monoxide diffusing capacity of the lungs for carbon monoxide (DLCO); the latter being the earliest physiological abnormality. Exercise-induced hypoxia is common in patients with advanced disease.

Invasive diagnostic procedures are rarely indicated in patients with rheumatoid lung. Diagnostic bronchoalveolar lavage has demonstrated abnormalities identical to those in idiopathic pulmonary fibrosis, namely increased neutrophils at times lymphocytes, although diagnostic bronchoalveolar lavage and lung biopsy may be indicated in complicated situations, particularly in patients with immunocompromised status as a result of therapy of rheumatoid arthritis. A lung biopsy is rarely required to document rheumatoid lung disease. Moreover, the morphological features are non-specific without clinical correlates because the observed abnormalities are dependent on the stage of the disease.

The occurrence of rapidly progressive lung disease, respiratory failure, and cor pulmonale as the result of rheumatoid lung is rare. Occasionally, a rapid progression of the lung disease occurs when the arthritic features flare. Clinically, the respiratory disease in such patients demonstrates the course exhibited by patients with rapidly progressive idiopathic pulmonary fibrosis. The mortality from pulmonary disease in RhA patients is twice that of the general population.

Obstructive lung disease

Obstructive airway disease is a well-recognized complication of RhA [4–6]. More than 20% of patients with active rheumatoid lung disease develop obstructive airway disease secondary to obliterative bronchiolitis, follicular bronchiolitis, bronchiectasis, and bronchitis. Pulmonary function testing in patients (non-smokers) with rheumatoid arthritis has demonstrated obstructive lung dysfunction in nearly one-third of patients. A much higher prevalence of obstructive lung disease has been noted in patients with rheumatoid arthritis who smoke. The combination of rheumatoid arthritis and smoking is associated with a higher prevalence of airway disease than either of the factors alone.

Bronchiectasis has been described as a complication of rheumatoid arthritis. Bronchiolitis may predispose to this complication. Bronchiectasis is uncommon in earlier stages of the disease. In many reported cases, the occurrence of bronchiectasis has been in patients with advanced and severe rheumatoid arthritis. Progressive rheumatoid airway disease with rapid progression may lead to respiratory failure.

Laryngeal involvement

Cricoarytenoid involvement is an important complication of rheumatoid arthritis because it may present with inspiratory and expiratory difficulty caused by fixed obstruction at the level of larynx. Inflammation of the cricoarytenoid joint is a common finding [8,9]. Cricoarytenoid arthritis is recognized clinically in one-third of cases, even though its presence has been noted in most of the necropsy studies in patients with RhA. Clinical manifestations are episodic and include laryngeal pain, dysphonia, and occasionally pain on swallowing, all of which may be accentuated in the morning. Chronic persistent sore throat and hoarseness may be seen in some patients. Laryngoscopy may show erythema and oedema of the vocal apparatus, abnormal motion of vocal cords, and dysfunction of the arytenoids. Laryngeal obstruction rarely occurs, but may be seen in the few hours following extubation for endotracheal ventilation. Occurrence of rheumatoid nodule in the larynx may present with hoarseness, cough, and dyspnoea. It is of importance for specialists in critical care and anaesthesia to recognize that laryngeal nodules may remain asymptomatic and pose problems at the time of tracheal intubation.

Other complications

Pulmonary hypertension has been described in several patients with rheumatoid arthritis, although it rarely causes significant complications. Another uncommon complication of rheumatoid arthritis is pulmonary vasculitis. Anecdotal cases with description of vasculitic lesions within the pulmonary capillaries may explain the alveolar haemorrhage encountered in some of these patients.

Pericarditis secondary to rheumatoid arthritis has been identified in nearly 50% of autopsied patients. Symptomatic pericarditis and haemodynamic alterations caused by it are rare. Acute flares of rheumatoid pericarditis coincide with the activity of rheumatoid arthritis. Constrictive pericarditis, myocardial involvement, valvular dysfunction, conduction defects, and cardiomyopathy are also rare. A serious complication is unusual the occurrence of rheumatoid aortitis associated with aortic insufficiency and aortic rupture.

Cervical spinal involvement with resultant instability of the affected spinal column is an important complication to be reckoned by specialists in critical care and anaesthesia. Subluxation and instability of the atlanto-axial joint may preclude extension of the neck for purposes of laryngoscopic tracheal intubation. The temporomandibular joints can also be affected limiting the oral opening during intubation. The tracheal intubation in such patients should be accomplished with a flexible bronchoscope.

Treatment and prognosis

The general concept in the management of these patients in the ICU is to recognize the presence of a complicating infection, other side effects of the medications use for its treatment (particularly lung toxicity) or to recognize a flare of the disease. Most of the patients with RhA use non-steroidal anti-inflammatory drugs (NSAIDs) in the initial stages of their disease. NSAIDS are pivotal in the treatment of symptomatic pericarditis. Unfortunately, NSAIDs use is a common cause of upper gastrointestinal bleeding. Systemic corticosteroid therapy is generally used in the presence of systemic disease. In the earlier stages of rheumatoid interstitial lung disease, the use of corticosteroids may reverse the acute inflammatory process, and slow or stop progression to irreversible fibrotic lung disease. As the lung disease becomes chronic, the ability to reverse it with corticosteroid and other therapies diminishes. Poor prognosis is associated when the interstitial process is advanced. Such patients have shown a median survival of 3.5 years and a 5-year survival of 39%. Poor prognosis is also associated with rheumatoid bronchiolitis. Immunotherapy consisting of corticosteroid and cytotoxic agents has been reported, but the response has been unsatisfactory in chronic or advanced cases. It is important to recognize that certain cytotoxic agents used in the treatment of rheumatoid arthritis can produce pulmonary toxicity. The agents with known pulmonary toxicity include gold, methotrexate, and cyclophosphamide [4,5]. Prospective studies have shown that methotrexate has no major effect on pulmonary function in the majority of patients with rheumatoid arthritis and that there is no evidence that patients with pre-existing pulmonary disease are at increased risk for further deterioration of lung function.

Recently, the use of biological agents has changed significantly the management of RhA. Multiple studies have demonstrated the efficacy of anti-TNF therapy (infliximab, etanercept, adalimumab, anakinra), as well as other targeting agents such as rituximab and abatacept in reducing inflammatory activity, as well as inhibiting joint destruction in patients with active RhA. Today, these drugs play an important role in the treatment of RhA, particularly in patients whose disease is not responding to treatment with conventional DMARDs. Patients treated with biological agents have a higher risk of infection, particularly opportunistic infections. Severe deterioration of pulmonary function may occur with the use of anti-TNF therapy in RhA patients with underlying interstitial lung disease.

The studies evaluating the outcome of RhA patients admitted to the ICU have included other rheumatological conditions. However, they all have identified a high mortality ranging from 17 to 55%. In addition, the overall observed ICU mortality in these studies have found a considerably higher than predicted mortality when using the APACHE II and SAPS II score systems [10–12]. The main variables associated with mortality include a higher critical illness score, such as APACHE (II and III), SOFA, and SAPS; comorbidities, use of steroids, infection as the cause of admission, and older age [13,14].

PART 12.2

Wound and pressure sore management

CHAPTER 279

Principles and prevention of pressure sores in the ICU

Laura Crawford and Ruth Kleinpell

Key points

- A number of factors contribute to pressure ulcer development including the intensity and duration of pressure, tissue tolerance, shear, and friction.
- The elderly are at greater risk because of physiological changes that occur to the skin and tissue with age, such as dermal thinning and the inability of tissue to distribute the mechanical load.
- The most common anatomical sites for pressure ulcers to occur are the sacrum and heels.
- Hospitalized patients, especially the critically ill, should be evaluated for the risk of pressure ulcer development upon admission.
- A risk assessment should be performed to identify the vulnerability of pressure ulcer development and to provide guidance for the implementation of preventative interventions.

Principles and prevention of pressure ulcer

Pressure ulcers are a troubling complication of a hospital stay, especially for acute and critically-ill patients. Pressure ulcers can increase the length of hospitalization, recovery time and the risk of infection, increases the costs of care, and can cause pain and suffering for patients. Of significance for clinicians is that pressure ulcers are thought to be preventable in most cases and are seen as a reflection of the quality of care provided.

A pressure ulcer is defined by the National Pressure Advisory Panel and European Pressure Ulcer Advisory Panel (NPUAP and EPUAP) [1] as localized injury to the skin and/or underlying tissue usually over a bony prominence, as the result of pressure, or pressure in combination with shear. When a person is immobile the soft tissue is compressed between the skin and bone. This leads to ischaemia and later tissue death. Typically, a pressure ulcer occurs over a bony prominence, but can occur anywhere soft tissue is compressed. Pressure ulcers are characteristically rounded with regular edges.

Pressure ulcer prevalence rates range from 88 to 53.2%, and incidence rates vary from 7 to 71.6%, depending on associated risk factors. The most common anatomical sites for pressure ulcers to occur are the sacrum and heels [2]. The NPUAP and EPUAP [1] define pressure ulcers in six stages according to the degree of tissue damage present in the wound. There are a number of factors that contribute to pressure ulcer development. The intensity and duration of pressure, as well as tissue tolerance play a role. If the intensity of the pressure exerted exceeds the pressure that it takes to hold open a capillary to allow blood flow, tissue ischaemia, and subsequent necrosis will result. The duration of the pressure is also an important component [3]. High pressure over a short period of time is as damaging as low pressure over a long period of time. The last factor that influences the effect of pressure is tissue tolerance. This is the ability of the skin and underlying structures to undergo pressure without experiencing adverse effects. This tolerance is lower in some patients such as the elderly and those with spinal cord injuries [4].

There are a number of extrinsic or external factors that affect the tissue tolerance. Shear force is concept that plays a part in pressure ulcer development [3]. Shear occurs when parallel forces are exerted on the skin, for example, if a patient's head of bed is elevated greater than 30°, gravity pulls the skeleton downward, but the skin is held in place by friction. This force impairs blood at the fascial level causing ischaemia and necrosis. The 'knee gatch' position, (elevating the knees in bed), helps reduce sliding, and should be practiced in cases where the head of bed must be at 30° or higher, i.e. ventilated patients. Friction works synergistically with gravity and this results in shear. Friction is a significant factor in pressure ulcer development. It often occurs when patients are pulled up in bed or slid across a gurney or procedure table. It is best to use a lift device or transfers sheet to reduce the risk of dermal abrasion from the surface of the sheet rubbing on the skin. If patients have good upper body strength a trapeze also reduces their risk of friction injury and encourages independence. Moisturizing or applying a dressing can help to protect the skin on the elbows, heels, and sacrum. Friction can occur without pressure, and therefore, if it is the exclusive aetiology of injury it should not be labelled as a pressure ulcer, but as a partial thickness wound. Excessive moisture is an additional element that predisposes a patient to pressure ulcer development. When skin is persistently wet, through urine and/or faecal incontinence or wound drainage, the dermal integrity is at greater risk of injury. The combine assault of urine and faecal incontinence is very caustic to the skin; it raises the pH of the skin producing an alkaline environment that leads to further breakdown and dermatitis. Skin breakdown related to moisture should be classified according the underlying aetiology, i.e. incontinence-associated dermatitis should not be confused with a pressure

Table 279.1 Pressure ulcer classification: a brief guide

Category/Stage I pressure ulcer	Non-blanchable erythema. Intact skin
Category/Stage II pressure ulcer	Partial thickness tissue loss. Wound bed is pink/red
Category/Stage III pressure ulcer	Full thickness tissue loss extending into the subcutaneous tissue, slough/eschar may be present in the wound bed, but does not obscure depth of the wound
Category/Stage IV pressure ulcer	Full thickness tissue loss, the muscle, bone, or tendon may be present in the wound bed. Slough/eschar may be present in the wound bed, but does not obscure depth of the wound
Unstageable: Unknown depth	Full thickness tissue loss. Unable to visualize base of the wound due to slough or eschar
Deep tissue injury	Purple or maroon coloured. Intact skin

Data from National Pressure Ulcer Advisory Panel, European Pressure Ulcer Advisory Panel and Pan Pacific Pressure Injury Alliance. Prevention and Treatment of Pressure Ulcers: Clinical Practice Guideline. Emily Haesler (Ed.). Cambridge Media: Osborne Park, Western Australia; 2014.

ulcer. There is the chance of having the presence of both aetiologies. When moisture cannot be controlled it is important to protect the skin by using a barrier or skin protectant ointment. Underpads that draw away moisture should be used. The absorbent material in the pad helps reduce the risk of trapping the moisture against the skin and prevents maceration. For large volumes of faecal incontinence consider the use of a faecal containment device of a faecal management system. Immediately after each episode of incontinence clean skin gently and apply a skin barrier [4].

There are a number of intrinsic or internal factors related to the risk of pressure ulcer development. Poor nutrition and dehydration contribute to pressure ulcer development because these conditions make tissue more vulnerable to damage [3]. The elderly are at greater risk because of physiological changes that occur to the skin and tissue with age, such as dermal thinning and the inability of tissue to distribute the mechanical load. Low blood pressure is thought to divert blood away from the skin to more essential organs during critical times. Additionally stress, smoking, surgery, elevated body temperature are other conditions are understood to contribute to pressure ulcer development [4].

According to the NPUAP [5] the six stages of pressures are classified as the following (Table 279.1 gives a brief summary of this guideline).

Pressure ulcer stages

Suspected deep tissue injury

Purple or maroon localized area of discoloured intact skin or blood-filled blister due to damage of underlying soft tissue from pressure and/or shear. The area may be preceded by tissue that is painful, firm, mushy, boggy, warmer, or cooler compared with adjacent tissue. Deep tissue injury may be difficult to detect in individuals with dark skin tones. Evolution may include a thin blister over a dark wound bed. The wound may further evolve and become covered by thin eschar. Evolution may be rapid exposure of additional layers of tissue even with optimal treatment.

Stage I

Intact skin with non-blanchable redness of a localized area, usually over a bony prominence. Darkly pigmented skin may not have visible blanching; its color may differ from the surrounding area. The area may be painful, firm, soft, warmer, or cooler, compared with adjacent tissue. Stage I may be difficult to detect in individuals with dark skin tones. May indicate 'at risk' persons (a heralding sign of risk).

Stage II

Partial thickness loss of dermis presenting as a shallow open ulcer with a red pink wound bed, without slough. May also present as an intact or open/ruptured serum-filled blister. Presents as a shiny or dry shallow ulcer without slough or bruising. This stage should not be used to describe skin tears, tape burns, perineal dermatitis, maceration, or excoriation. Bruising indicates suspected deep tissue injury

Stage III

Full thickness tissue loss. Subcutaneous fat may be visible, but bone, tendon, or muscle are not exposed. Slough may be present, but does not obscure the depth of tissue loss. May include undermining and tunnelling. The depth of a stage III pressure ulcer varies by anatomical location. The bridge of the nose, ear, occiput, and malleolus do not have subcutaneous tissue, and stage III ulcers can be shallow. In contrast, areas of significant adiposity can develop extremely deep stage III pressure ulcers. Bone/tendon is not visible or directly palpable.

Stage IV

Full thickness tissue loss with exposed bone, tendon, or muscle. Slough or eschar may be present on some parts of the wound. Often include undermining and tunnelling. The depth of a stage IV pressure ulcer varies by anatomical location. The bridge of the nose, ear, occiput, and malleolus do not have subcutaneous tissue and these ulcers can be shallow. Stage IV ulcers can extend into muscle and/or supporting structures (e.g. fascia, tendon, or joint capsule) making osteomyelitis possible. Exposed bone/tendon is visible or directly palpable.

Unstageable

Full thickness tissue loss in which the base of the ulcer is covered by slough (yellow, tan, grey, green, or brown) and/or eschar (tan, brown, or black) in the wound bed. Until enough slough and/or eschar is removed to expose the base of the wound, the true depth, and therefore stage, cannot be determined. Stable (dry, adherent, intact without erythema, or fluctuance) eschar on the heels serves as 'the body's natural (biological) cover' and should not be removed [1].

Pressure ulcers should not be staged when located on a mucous membrane. The pressure ulcer staging system classifies ulcers according to the tissue type, i.e. partial or full thickness. The histology of the tissue on a mucous membrane is different than the histology of the skin and, therefore, cannot be used to classify this type of ulcer. It should be classified as a 'mucosal pressure ulcer'.

Pressure ulcers should never be 'reversed or back' staged. The classification system is used to describe the deepest layer of tissue injury [4].

To prevent pressure ulcers the confounding factors need to be eliminated. In the acute care setting patients usually develop pressure

ulcers within the first 2 weeks of admission and within 72 hours in the ICU setting [6]. Skin assessment, risk assessment, repositioning, nutritional status, and support surfaces are all key pressure ulcer prevention strategies. These concepts need to be considered when implementing an individualized prevention strategy [4].

Skin assessment

In an effort to establish a baseline assessment of the patient's skin, a full skin assessment should be completed upon admission to the unit and daily. A patient's skin should be inspected from head to toe and should focus on the most high-risk areas including over bony prominences, skin-folds (intertriginous areas), between the toes, and all areas of skin in contact with medical devices. All garments and stockings should be removed to visualize the skin [4].

Risk assessment

A patient's risk for pressure ulcer development should be evaluated to allow for implementations of interventions to mitigate their risk of development [7]. A risk assessment should be performed to identify the vulnerability of pressure ulcer development and to provide guidance for the implementation of preventative interventions. A patient's risk should be assessed at regular intervals. In the acute care setting the initial assessment in made on admission to the unit, then subsequently when the patient's condition changes or worsens and every 24–48 hours. The two most widely studied and validated risk assessment scales are the Braden and Norton Scales. The Braden scale consists of six subcategories. Each category is scored 1 for the (most at risk) to 4 (least at risk) with the exception of the friction and shear subcategory which is score 1–3. The numbers are added providing a total score that ranges from 4 to 23. If a score falls below 18 the patient is considered at risk for pressure ulcer development. The Norton score includes five parameters: physical condition, mental condition, activity, mobility, and incontinence. The rating for each category is 1–4 with a score potential of 5–20. For both the Braden and Norton scales the lower the score identifies a greater risk of developing a pressure ulcer [6]. Studies focusing on risk factors for critically-ill patients have identified several demographic and clinical factors. A retrospective, correlational study of 347 patients admitted to a medical-surgical intensive care unit found that age, length of stay, mobility, friction/shear, norepinephrine infusion, and cardiovascular disease explained a major part of the variance in pressure ulcers [8]. Another study focusing on the incidence of pressure ulcer development in intensive care unit (ICU) patients found that increased severity of illness as measured with the Acute Physiology and Chronic Health Evaluation (APACHE II) was associated with higher incidence of pressure ulcer development [9].

Nutrition assessment

Although the underlying relationship is uncertain, low body weight, poor food intake, and poor nutritional status are all risk factors for the development of pressure ulcers. Patients must have sufficient calories, fluid and proteins to reduce the risk of development. Patients must also maintain adequate hydration. All patients at nutritional risk should have an evaluation by a registered dietitian [4].

Repositioning

Repositioning should be scheduled for bed and chair bound patients who are at risk of pressure ulcer development. The patient's overall condition needs to be considered when repositioning. If the patient cannot be turned due to a medical condition then an advanced support surface should be used and attempts made for slight adjustments in position. Patients at risk should not sit for periods of time greater than 1 hour and they should use pressure relief chair cushions. If the patient is independent they should reposition themselves every 15 minutes when in the chair. Heels should be suspended off the surface of the bed to prevent pressure on that area. The use of a pillow or a heel elevation device is recommended [6]. Donut devices are no longer used for pressure relief; they have been found to cause ischaemia over the pressure area [1]. A turning schedule for bed bound patients is one of the most important concepts of pressure ulcer prevention. When turned to the side patients should be rotated to a 30° lateral position to prevent pressure on the trochanter. Pillows or blankets may be used to pad areas that may touch such as between the knees. Alterations to the position should be made regularly and frequently, rotate positioning on the right side, back, left side, back [6].

Support surfaces

Support surfaces should be use for those individuals at risk for pressure ulcer development. They are used as adjunct therapy, and are not to replace turning and repositioning. The support surface functions better with minimal linen and pads, between the patient and the surface. Continence pads that are compatible with the support surface should be used. There are many terms associated with support surfaces technology. Immersion refers to how deep the body penetrates into the surface to allow for the pressure to distribute over a large area and not directly over the bony prominence. Envelopment is the surfaces ability to conform to the body. Microclimate is the temperature of the skin, and the moisture or humidity of the interface between the surface of the skin and the support surface. The components of the support surface vary from solid, fluid, to air. They can be used alone or in combination. The exterior is often made of a material that reduces shear and friction. Alternating pressure or active surfaces have the ability to distribute the load over the area in contact with the patient's body. They require a motor to inflate and deflate the surface, which distributes the load.

A reactive surface is one that may or may not require a motor. This surface changes based on the load of the weight placed on the surface. There are a number of different types of reactive surfaces—continuous lateral rotation, low air loss, and air fluidized beds are examples. Low air loss is a feature that provides flow of air continuously across the surface of the skin to manage moisture. The bed is calibrated for pressure redistribution based on the patient's height and weight. Air fluidized therapy beds are used in cases where the patient has no turning surface, has had a muscle flap or skin graft or has suffered extensive burns. Two-thirds of patient immerses into the surface of the bed and the patient essentially 'floats' on the surface. Mattress overlays are surfaces that are placed on top of the mattress. There are indications and contraindications for the use of the different support surfaces. When selecting a support surface the patient's individual needs must be considered [4].

For the critically-ill patient, several specific measures are advocated for preventing pressure ulcers including frequent repositioning, continuous lateral rotation, progressive mobility, and frequent skin assessments, in addition to managing moisture and maximizing nutritional support [10–13].

Conclusion

Hospitalized patients, especially the critically ill, should be evaluated for the risk of pressure ulcer development upon admission. An individualized care plan should be implemented to focus on the specific factors placing the patient at risk including, but not limited to the use of skin care products and the use of a support surface if it is deemed necessary. Knowledge of pressure prevention strategies and the various products is important for critical care clinicians. A pressure ulcer prevention strategy should also include education for the patient and their caregivers.

CHAPTER 280

Dressing techniques for wounds in the critically ill

Ruth Kleinpell and Laura Crawford

Key points

- The appropriate selection of dressings for wounds and pressure ulcers can facilitate healing, although there is insufficient evidence to indicate which specific dressings are the most effective.
- A number of factors determine the selection of a dressing in the management of pressure ulcers, including the wound size, location, amount of drainage or exudates, condition of periwound, caregiver needs, ease of use, and costs, among other factors.
- The size and extent of tissue invasion can also determine the dressing size and material. As general concepts, larger wounds often need packing and wounds with exposed tendons or ligaments require moisture and occlusive dressings.
- While gauze dressings are absorptive and permeable to water, water vapour and oxygen, practice varies widely in the use of gauze dressings. Often, advanced wound dressings are used over gauze dressings for pressure ulcers.
- For the purposes of pressure ulcer prevention, several types of dressings are used to promote skin protection including semi-permeable film dressings, which are most often a thin polyurethane membrane coated with a layer of an acrylic adhesive; hydrocolloid dressings, which contain a dispersion of gelatin, pectin, and carboxymethylcellulose together with other polymers and adhesives; or foam dressings, such as an open cell, hydrophobic, polyurethane foam sheet. Additionally, topical agents can be used in isolation or in combination with dressings.

Introduction

For the purposes of pressure ulcer prevention, several types of dressings are used to promote skin protection including semi-permeable film dressings which are most often a thin polyurethane membrane coated with a layer of an acrylic adhesive; hydrocolloid dressings, which contain a dispersion of gelatin, pectin, and carboxy methylcellulose together with other polymers and adhesives; or foam dressings such as an open cell, hydrophobic, polyurethane foam sheet [1]. Additionally, topical agents can be used in isolation or in combination with dressings.

The appropriate selection of dressings for pressure ulcers can facilitate healing, although there is insufficient evidence to indicate which specific dressings are the most effective [2]. The primary function of a dressing for e.g. exudates management, may assist the health care clinician to choose one type of dressing over another based on the characteristics of the wound [3]. A number of factors determine the selection of a dressing including the wound size, location, amount of drainage or exudates, condition of periwound, caregiver needs, ease of use, and costs (Box 280.1) [4].

The aetiology or cause of the wound will directly affect the choice of dressing as factors such as whether a pressure ulcer has undermining and requires packing to fill dead space need to be considered. Other considerations related to aetiology include whether exudates management and compression are required as is the case with venous insufficiency, or whether moisture is preferred, as is often the case with arterial ulcers [2]. Factors related to the history of the wound including the duration and course of wound healing, and prior dressings or treatment strategies that have been used need to also be considered [2].

Box 280.1 Factors influencing the choice of dressing for pressure ulcers and wounds

- Location.
- Drainage/exudate.
- Wound factors (e.g. infection, necrosis).
- Size, depth, and presence of undermining or tunnelling.
- Wound history.
- Comorbid conditions.
- Goals for healing.
- Condition of periwound.
- Individual/caregiver needs (e.g. pain reduction, odour control).
- Availability.
- Ease of use.
- Cost/reimbursement of the dressing.

Data from Wound, Ostomy and Continence Nurses Society (WOCN) *Guideline for Prevention and Management of Pressure Ulcers*, WOCN Clinical Practice Guideline Series, (2010).

Comorbid conditions such as diabetes mellitus, which can impair wound healing, the presence of obesity, which can increase the risk of dehiscence, or the presence of arterial and venous disease, in which compression may be contraindicated, may need to also be considered. The size and extent of tissue invasion can also determine the dressing size and material. As general concepts, larger wounds often need packing and wounds with exposed tendons or ligaments require moisture and occlusive dressings. The amount and type of exudates is another factor that will impact the selection of dressings. Containment of exudates is important to managing the increased bioburden, protecting the periwound skin, controlling odour, and avoiding overuse of wound care products [5].

Dressing options

A large number of products and dressing options are available for wound and pressure ulcer management. Occlusive or semi occlusive dressing help to maintain wound bed moisture, which promotes re-epithelialization and wound closure [6]. The main occlusive or semi-occlusive dressings include hydrocolloid dressings, alginates, hydrogels, foam dressings, hydrofibre dressings, and paraffin gauze and non-adherent dressings. Gauze rolls and dressings can be used to additionally secure or anchor the tissue interface dressings. Other products used for wound care include hyaluronic acid cream or dressings, dressings supplemented with cadexomer iodine or silver, and dressings containing medical-grade honey [6]. Maintaining a moist ulcer bed is recommended for wound care, when the ulcer bed is clean and granulating, to promote healing or closure [6].

Often, institutions will outline the choice of products to be used for various types of wounds. Table 280.1 outlines one institutional resource for clinicians that outline different products, options for use, and instructions for application. Often, dressing options are outlined as part of an overall skin assessment and treatment plan of care (Fig. 280.1), or part of reference guides for clinical care (Table 280.2).

Table 280.1 Wound care products. This guide should be used in conjunction with a wound care algorithm (see Fig. 280.1)

Products	Options	Instructions for application	Tips
(1) Wound cleanser	Normal saline	◆ Cleanse wound prior to each dressing change for each of the following products (2–9). ◆ Be sure peri-wound skin is free of any residue before applying any products below.	Normal saline: expires 24 hour after opening.
	SAF-Clens®AF Dermal* Wound Cleanser (Cleanser Wound Saf Clen 12 oz)*		SAF-Clens®: no expiration. If patient complains of burning, stop use.
(2) Transparent dressing	Tegaderm™ (Dressing Tegaderm 4x10)* (Dressing Tegaderm 4x2)*	◆ Smooth dressing from centre out to edges. ◆ **Removal**: pull horizontal to skin in direction of hair growth. ◆ Used as a secondary dressing, not intended to be changed daily.	Not to be used on fragile skin or infected wounds. **Do not** use on blisters/skin tears.
(3) Hydrogel	DuoDERM® Hydroactive® *GEL (Dressing Duoderm gel 30 gm)*	◆ Apply onto or into wound bed or impregnated into gauze. Fill wound 2/3 full. ◆ Fill space with fluffed gauze. ◆ Apply cover dressing (gauze or ABD). ◆ Change Daily or prn. ◆ **Removal**: Rinse off remaining gel before new dressing is applied.	Expires 7 days after opening. Monitor for tissue maceration.
(4) Hydrocolloid	DuoDERM® CGF® Extra Thin Dressings* (Dressing Duoderm CGFx-Thin 6 × 6)*	◆ Apply, mould into place with warm hands (1 minute). ◆ Allow a minimum of 3 cm beyond wound edges to determine dressing size. ◆ May remain up to 3 days-may change sooner if discomfort, leaking, signs of infection is present or edges begin to roll. ◆ May use waterproof tape (Tape Hy-tape) to secure edges. ◆ May be used as a cover dressings with hydrofibre (6). ◆ **Removal**: Pull on opposite corners and stretch out.	Not to be used on fragile skin or if signs of infection present. Adheres better if warmed when placed. DuoDERM® Signal: used for heavier drainage. Change dressing when drainage extends to green line or edges begin to roll. **Do not** cut prior to application.
	DuoDERM® Signal* (Dressing Duoderm Sacral)* (Dressing Duoderm 5.3 × 5.3)*		
(5) Foam dressing	PolyMem® Foam* (Dressing Polymem Quadrofoam 4 ×4 pad)* (Dressing Polymem Quadrofoam 6.5 × 7.5 pad)*	◆ Apply over wound after cleansing wound. ◆ Allow a minimum of 1 cm beyond wound edges. ◆ Assess dressing daily and change if saturated. ◆ Handles more copious drainage than hydrocolloids. ◆ Maximum wear-time is 7 days. ◆ **Removal**: remove dressing and cleanse wound bed or drainage and residue with wound cleanser.	Use for skin tears, blisters. May use around tubes and/or tracheostomy sites.

(*continued*)

Table 280.1 Continued

Products	Options	Instructions for application	Tips
(6) Hydrofibres	Aquacel®* (Dressing Aquacel T-rope) (Dressing Aquacel 2 × 2) (Dressing Aquacel 6 × 6) Aquacel® Ag Hydrofiber® * (Dressing Aquacel Ag rope) (Dressing Ag 4x4) Dressing Aquacel Ag 8 x 12)	◆ Select an appropriate dressing size: • *Shallow*: cover wound bed. • *Deeper wounds*: apply Aquacel® to wound bed and fill extra space with loosely packed fluffed gauze. ◆ Place in wound bed, may extend ½- inch over wound edges. ◆ May use fluffed gauze over of Aquacel® as a wound filler. ◆ Cover with dry gauze or ABD; can cover with hydrocolloid or composite dressing; Change every 3 days or prn. ◆ Assess daily; changing is drainage dependent. ◆ **Removal**: remove cover dressing then lift Aquacel® from wound bed; cleanse wound to flush out any residue. If dressing adheres to wound, moisten with normal saline or sterile water prior to removal. Consider alternative wound therapies for less absorption.	AQUACEL® Ag Hydrofiber®: antimicrobial ◆ Not for minimally drainage wounds. ◆ Use only on recommendation of wound care nurse. **Avoid using AQUACEL® Ag with any enzymatic debridement ointment (collagenase (Santyl® ointment). Silver may deactivate the effects of enzymatic debridement.
(7) Negative pressure wound therapy	Wound VAC® (wound VAC ATS machine)* FOAM (silver, black, white) (Wound VAC silver dressing Lrg L)* (Wound VAC, dressing large)* (Wound VAC, dressing med)* (Wound VAC, dressing small)* (Connector Y Wound VAC)*	◆ May be used on wounds with less than 20% slough or eschar. If greater than 20%, debridement options need to be implemented first. ◆ Dressing changes Monday –Wednesday–Friday or as ordered by MD or NP. ◆ Refer to Policy on KCI vacuum-assisted closure therapy and Wound VAC®. **Therapy Clinical Guidelines** ◆ Obtain MD or NP order for settings. ◆ Obtain machine, dressing/foam, and canister via EPIC. ◆ Insert canister into machine and plug machine in. May turn on to set settings. ◆ Remove soiled dressing, cleanse wound, pat dry. ◆ Cut Wound VAC® foam to fill wound cavity. May use additional pieces for undermining or tunnelling. Do not over pack the wound bed. Place foam into wound cavity. Cover with drape, removing sheets in numerical order. ◆ Cut 2-cm hole in drape over foam. Apply the trac pad (piece with tubing) directly over hole in drape. ◆ Attach the tubing from the trac pad to the canister tubing. Ensure clamps are open. ◆ Turn the machine on, ensure Wound VAC® therapy settings are correct per MD/NP order. ◆ Be sure foam compresses when therapy is turned on. Assess dressing for air leaks. If air leaks noted, patch with extra drape. ◆ Mark the # of pieces of foam used on dressing ◆ Properly chart dressing change and wound condition. *Normal Pressure Settings*: 125 mmHg. May be continuous or intermittent therapy.	Refer to P&P and Wound VAC® **Therapy Clinical Guidelines**. *Contraindications*: • Malignancy in wound. • Untreated osteomyelitis (may use Wound VAC® therapy for a few days until osteomyelitis is confirmed and then may continue therapy if antibiotics are started). • Non-enteric and unexplored fistula. • Necrotic tissue with eschar present (must be debrided first). • **Do not** place over exposed blood vessels, organs, or tendons. *White Foam*: Non-adherent, use for tunnelling and undermining. *Silver Foam*: Silver-impregnated. Anti-microbial. Order set for Wound VAC® orders must include: equipment, dressing change schedule, and pressure.
(8) Debridement options	Autolytic body mediates debridement in the presence of a moist environment	See above notes on hydrogel, hydrocolloid, and composite dressings.	**Autolytic aids**: transparent dressing, hydrogel, and hydrocolloid.
	Enzymatic collagenase Santyl® ointment (requires MD order to pharmacy)	Debrides soft-tissue ulcers and burns, liquefies non-viable tissue, maintenance debridement by selectively targeting collagen. ◆ After cleaning wound, pat the wound dry. ◆ Apply Santyl® ointment to cover the entire wound bed using a Q-tip or wick.	**Do not** change from one product to another without reconsulting the wound care nurse. Contraindicated in patients who have shown local or systemic hypersensitivity to collagenase.

(*continued*)

Table 280.1 Continued

Products	Options	Instructions for application	Tips
	Sharp	◆ Apply slightly moistened gauze with normal saline (just to wound base). ◆ Cover with dry dressing and secure. ◆ Change daily or PRN if moist. ◆ **Removal**: remove dressing and cleanse wound bed or drainage and residue with wound cleanser. ◆ To be performed by physician or NP only.	Need surgical consult; be sure ABIs, laboratory, consent has been done.
(9) Xenaderm™	Xenaderm™ (Requires MD order to Pharmacy)	◆ Cleanse area with appropriate wound cleanser or soap (Aloe Vesta® cleansing foam). ◆ Apply a thin film bid and prn. ◆ May be left open to air or cover with a dry dressing.	When applied to sensitive areas, a temporary stinging sensation may occur. **Not** intended for use as a barrier cream.

*indicates product can be found in EPIC.

Transparent film dressings consist of polyurethane or synthetic polymer sheets and their use is often indicated for absent or minimal exudates, for use as a secondary dressing, or to promote autolysis. Film dressings are recommended to protect body areas at risk for friction injury [6].

Cover dressings are indicated when exudates are present, when skin is fragile, or if there is risk of frequent soiling due to incontinence. Cover dressings can range from gauze with tape for pressure ulcers with none to moderate exudates, foam dressings with tape or composite for moderate to heavy exudates, hydrocolloid, film or composite cover dressings when frequent soiling due to incontinence is a factor, to the use of stretch gauze or net when a critically-ill patient has fragile skin [6].

Gauze dressings are used to adhere to wound tissue and are available in rolls, strips, or squares, which may include cotton, rayon, or polyester. While gauze dressings are absorptive and permeable to water, water vapour, and oxygen, practice varies widely in the use of gauze dressings. Often, advanced wound dressings are used over gauze dressings for pressure ulcers [6].

Hydrocolloids consist of carboxymethylcellulose combined with pectin, which is absorbent and maintains a moist wound surface. Hydrocolloid dressings are recommended for clean Stage II pressure ulcers in body areas where they will not roll or melt, or for shallow Stage II pressure ulcers [6]. Due to their occlusive properties, hydrocolloids are not recommended for ischaemic wounds [6].

Hydrofibre consists of highly absorbent carboxymethylcellulose, which acts to bind exudates in the centre. The use of hydrofibre requires a secondary dressing.

Hydrogels consists of a three-dimensional cross-linked structure made up of hydrophilic polymers. They are available as amorphous gel or as sheets and are used to increase moisture content. Hydrogel dressings are indicated for shallow, minimally-exudating pressure ulcers or for pressure ulcers without depth and contours [6].

NaCl impregnated dressings can be used for wounds with moderate to large amount of exudates. The hypertonic medium discourages bacterial proliferation and promotes mechanical and autolytic debridement [6]. Petrolatum impregnated dressings are often used for wounds with minimal exudates. They are non-adherent and are used to protect the wound base and perimeter, while also providing a moist environment to promote epithelialization [6].

There are several forms of silver-impregnated dressings available for wound care. Silver ions are biocidal at very low concentrations due to the ability of microbial cells to absorb and concentrate silver from very dilute solutions [6]. Silver-impregnated dressings should be considered for ulcers at high risk of infection or for pressure ulcers that are infected or heavily colonized [6]. A *Cochrane Database Systematic Review* reported that silver dressings did not lead to pressure ulcer healing, but did results in reduction of the ulcer area [7].

Topical antimicrobials can be used as wound applications for their antibacteriocidal, as well as for their absorbency properties.

Alginate dressings are derived from seaweed and are highly absorbent and biodegradable. They have haemostatic properties and help to maintain a moist environment [6]. Collagen has mild absorptive capacity, and is used to stimulate wound repair and epithelial activity. Alginate dressings should be considered for the treatment of moderately and heavily draining exudating ulcers [6].

Foam dressings are made from hydrophilic polyurethane and are highly absorbent. Foams are beneficial as they decrease maceration of the periwound tissue. Foam dressings should be considered for use on exudative Stage II and shallow Stage III pressure ulcers [6].

Negative pressure wound therapy involves the use of subatmospheric pressure to promote contraction, remove excess exudates, reduce oedema, and increase blood flow. This therapy is often indicated for deep chronic open wounds, dehisced surgical sites, pressure ulcers, mesh grafts, and tissue flaps. Negative pressure wound therapy requires specific training and can be a costly option for wound management. An example of a negative pressure wound therapy is the VAC system [6].

Clean versus sterile dressing techniques

The Wound, Ostomy and Continence Nurses Society (WOCN) Wound Committee and the Association for Professionals in Infection Control and Epidemiology in the United States formulated

Table 280.2 Skin and wound care quick reference guide

For wounds that need a topical dressing	Intact skin Stage I Reddened area	Partial Thickness			Full thickness		Unstageable Slough/Eschar	Infected wounds
		Skin tear *With or without flap*	**Blister**	**Stage II**	**Stage III**	**Stage IV**		
This reference is not inclusive to all wounds								
Always clean wound with SAF-Clean™ AF (no expiration date) or saline (expire 24 hr) prior to each dressing change. Protect the periwound skin by applying **AloeVesta®#3 Protective Ointment** for draining wounds. Protect Periwound skin using No-Sting Barrier Film under tape. Avoid tape on fragile skin. Consider Xspan, Montgomery Straps (Senn Straps) or Kerlix to secure dressing Avoid diapers while in bed.	Do not massage area, turn Q2 hrs to relieve pressure **Preventing/ Friction** Apply **AloeVest #3 Ointment**, maintain layer on skin; Apply multiple time daily Hydrocolloid (DuoDERM® Extra Thin) every 3–5 days **Incontinence** Urinary: Cleanse area using **Aloe Vesta® 3-n-1 Cleansing Foamn.** *For Non-reddened, intact skin: Apply **Aloe Vesta® #3 Portective Ointment** daily and PRN. ***For Fecal**: Apply **Sensi-Care® #3 Protective Barrier** daily and PRN. Do Not Scrub off.	**Non Draining and Draining Wounds,** Aply foam (PolyMem®) over wound and extending about Icm beyound wound edges, and wrap with Kerlix. **Difficult Locations** *(Non-Draining / Minimal Drainage)* Apply **Xenaderm™** BID and PRN over open area.	Intact Blister Apply foam (PolyMem®) over blister to protect and extending about 1cm beyond blister edges, and wrap with Kerlix. Open Blister Apply foam (PolyMem®) over wound and extending about 1 cm beyond wound edges, and wrap with Kerlix	**Dry** **Hydrogel** (DuoDERM® Hydroactive® GEL) daily and PRN. May cover with gauze, ABD pad or DuoDERM® Signal) **Minimal Drainage** **Hydrocolloid** DuoDERM® Signal (every 3-5 days and PRN) **Foam** Polymem secure with tape every 3–5 days or when 75% saturated. **Moderate Drainage** Hydrofiber® (AQUACEL®) May cover with gauze or ABD pad daily *OR* may cover with hydrocolloid (DuoDERM® Signal every 3–5 days and PRN.)	**Minimal Drainage** **Hydrogel** (DuoDERM® Hydroactive® GEL) cover wound bed and edges, Cover with dry gauze, ABD pad daily or DuoDERM® Signal every 3-5 days. **OR** Saline moistened Hydrofiber® (AQUACEL®). May cover with gauze or ABD pad daily *OR* Signal every 3-5 days and PRN. **OR** Hydrogel (Duo DERM® Hydroactive® GEL) impregnate gauze, pack into wound and cover with dry dressing. Change BID. **Moderate to Heavy Drainage** Hydrofiber® (AQUACEL® loosely to pack wound bd and edges, May cover with gauze or ABD pad daily. Or may cover with hydrocolloid (DuoDERM®) every 3–5 days and PRN.	**Minimal Draingae** **Hydrogel** (DuoDERM® Hydroactive® GEL) daily and PRN to cover wound bed and edges. Cover with dry gauze or ABD pad or DuoDERM® Signal. **OR** Use **Negative Pressure Wound Therapy** (Wound V.A.C.®)*** Dressing change every Monday, Wednesday and Friday. **Moderate to Heavy Drainage** Hydrofiber® (AQUACEL®) loosely to pack wound bed and edges and cover with hydrocolloid (**DuoDERM®) every 3–5 days and PRN** **OR** User Negative Pressure Wound Therapy (**Wound V.A.C®)*** Dressing change every Monday. Wednesday. and Friday.	**Surgical debridement** may be necessary. **Fibrin/Slough** **Collaganase** (Santyl® Ointment) daily and PRN to cover wound bed and edges. Cover with slightly moist gauze or petroleum gauze directly over wound then with dry gaze or ABD pad. **Dry Eschar on Heels** Leave open to air and elevate. **Draining** Cover with gauze and wrap with Kerlix Assess for signs of infection Consult Wound Care RN. Suspend heels at all times using pillows or heel lift boots.	Notify MD of signs and symptoms of infection. Recommend wound culture and/or tissue biopsy to guide therapy. **Wound Culture Procedure** Always clean wound with sterile saline before obtaining wound culture. Gently rotate swab over wound in "Z" pattern using enough pressure to elicit exudate. **Surgical Debridement** may be necessary. **Managing Drainage** Apply **Hydrofiber® with silver** (AQUACEL® Ag) daily and PRN. May cover with ABD pad or Pack Heavy Drainage (12x10) **OR**

(*continued*)

Table 280.2 Continued

For wounds that need a topical dressing	Intact skin Stage I Reddened area	Partial Thickness			Full thickness		Unstageable Slough/Eschar	Infected wounds
		Skin tear *With or without flap*	**Blister**	**Stage II**	**Stage III**	**Stage IV**		
Assess wound on admission and with each dressing change. Measure wound weekly *Mondays* Reevaluate Effectiveness of treatment plan weekly. Call wound Care Nurses for further management.	*For mascerated, Severe incontinent-breakdown/ refractory incontinence-breakdown: Apply **ILEX** over area, covered with **Sensi Care® #3 Protective Barrier** daily and PRN.			**Heavy Drainage** **Hydrofiber® (AQUACEL®) May cover with gauze or ABD pad daily, Or may cover with hydrocolloid (DuoDERM® Signal) every 3–5 days and PRN.**	**OR** Use Negative Pressure Wound Therapy (**Wound V.A.C.®**)* Dressing change every Monday. Wednesday, and Friday.			Use **Negative Pressure Therapy** (Wound V.A.C.®) ***Use V.A.C.® GranuFoam™ with silver dressing. Dressing change every Monday, Wednesday, and Friday if antibiotics being used concomitantly. *Wound V.A.C.® is contraindicated for presence of untreated osteomyelitis, slough/ necrotic tissue more than 20%, malignancy in the wound, and placement over exposed blood vessels or organs. Application of Wound V.A.C® may be painful, give pain medication 30 minutes prior to initiation or dressing change.
	Avoid Adhesive Dressing on Fragile Skin (i.e. transparent, hydrocolloid)		If wound has more than 20% slough/necrotic tissue, see treatment plan for unstageable ulcer.				Suspected Deep Tissue Injury Implement measures to relieve pressure If draining- cover with gauze- Avoid adhesive dressings Consult WOCN

guidelines for the use of clean versus sterile dressings for the management of chronic wounds.

Sterile technique is generally defined as meaning free from microorganisms [8]. The use of sterile technique is aimed at reducing exposure to micro-organisms and maintaining objects and areas as free from micro-organisms as possible [4]. In comparison, clean technique means free of dirt, marks, or stains [8]. The use of clean technique is focused on reducing the overall number of micro-organisms or to prevent or reduce the risk of transmission of microorganisms from one person to another or from one place to another [4]. The use of clean technique is also referred to as non-sterile. Clean technique is considered most appropriate for routine dressings for chronic wounds, such as venous ulcers, or wounds healing by secondary intention with granulation tissue [4].

The Centers for Disease Control and Prevention recommend the use of sterile technique for post-operative management of wounds for 24–48 hours [4]. Clinical practice guidelines for pressure ulcer treatment, published by the Agency for Health Care Policy and Research, recommend the use of clean technique for pressure ulcers dressings [9]. The National Pressure Ulcer Advisory Panel-European Pressure Ulcer Advisory Panel guidelines for pressure ulcers do not address the use of clean or sterile technique other than to outline that tap water or potable water can be used to clean pressure ulcers and that sterile instruments are needed for sharp debridement [10,11]. An integrative literature review of seven published studies of clean and sterile technique for dressings confirmed a lack of consensus about the benefit of clean versus sterile technique to improve healing or infection rates, but identified that clean technique results in lower costs [12].

Support services

A number of pressure-relieving support surfaces are available for use with dressings to promote healing of pressure ulcers, including mattress overlays, foam mattresses, alternating pressure mattresses, air filled devices, and dry floatation cushions. A recent *Cochrane Collaborative Synthesis Review* identified that there is no conclusive evidence about the superiority of any support surface for the treatment of existing pressure ulcers [13].

Additional considerations

The National Pressure Ulcer Advisory Panel clinical practice guidelines [6] outline a number of general recommendations for the use of dressings for pressure ulcers and wounds. These include following manufacturer recommendations for use of a dressing or dressing product, particularly related to the frequency of dressing changes. A dressing should be selected that remains in contact with the wound bed or skin barrier product to keep the periwound dry and prevent maceration [14–16]. Careful removal of dressings is recommended on fragile skin to reduce tissue trauma. As a part of dressing care, assessment and management of pressure ulcer pain should be conducted as a routine part of patient care and with dressing changes. Additionally, ongoing patient and family education with dressing care is an indicated part of wound care management.

Conclusion

A number of factors affect the choice of dressing for pressure ulcer and wound care management. The type of dressing indicated may change over time as the ulcer heals or changes. Knowledge of the indications for use of currently available wound care products and dressings is important for critical care clinicians and often, consultation with a wound care specialist is recommended for optimal management of pressure ulcers and wounds in the critically-ill patient. This chapter has provided an overview of dressing choices and indications for use and examples have been provided from institutional protocols. As wound care guidelines may vary based on institutional protocols, clinicians are advised to consult their specific wound care policies and guidelines.

SECTION 13

Infection

PART 13.1

Diagnosis and surveillance

CHAPTER 281

Microbiological surveillance in the critically ill

A. P. R. Wilson

Key points

- The ICU is a focus for the emergence of bacterial resistance.
- Overuse of antibiotics is the main driver.
- Catheter-associated bacteraemia rates are the most frequently used performance indicator.
- Methicillin-resistant *Staphylococcus aureus* (MRSA) screening and topical suppression is effective in preventing spread.
- Screening for multiresistant Gram-negative bacteria needs to be considered according to local prevalence.

Introduction

Of all hospital wards, the intensive care unit (ICU) is the one with the highest risks of acquisition and transmission of hospital-acquired infection. Most patients are given antibiotics, there are numerous invasive procedures, and a large number of staff frequently come into contact with the patient. Infections acquired in the ICU have significant consequences for the rest of the hospital when the patient is discharged to a general ward. Furthermore, colonization or infections with multiresistant organisms can significantly delay discharge of a patient from ICU at considerable cost to the hospital. Surveillance is important to identify emerging outbreaks of multiresistant infections and the overuse of antibiotics that can give rise to them. Continuous collection of data using widely recognized definitions can allow comparisons between units and be used to reduce rates in outliers. Definitions and methods should be based on recognized international systems such as those of Centers for Disease Control (CDC) or European Centre for Disease Control (ECDC). National networks such as The Intensive Care National Audit & Research Centre (ICNARC) should form the basis for extracting denominator numbers and exchange of information between units.

Surveillance definitions

Identifying rates of infection and feeding back the results to the clinical teams is effective in reducing rates. Local and timely investigation of the causes of an infection is the best method of preventing further cases. Root cause analysis is a formal tool that has been used widely to identify specific failings and strategies to avoid them in future. In the USA nosocomial infection is no longer reimbursed by insurance companies and in other countries there is increasing scrutiny of these infections and in some cases financial penalties are applied. As a result there is now much interest in surveillance as a means of improving patient outcome.

The ECDC has used a range of definitions in multinational ICU surveillance in Europe [1]. ICU-acquired infection is defined as occurring later than 48 hours after admission. Device associated health care-associated infection (HAI) is an infection in a patient with a device used within 48 hours before onset of infection. Devices are intubation, central vascular catheter (CVC), and urinary catheter. Elsewhere CDC definitions are widely used, but not specific to ICU [2].

Antimicrobial resistance

Antibiotic consumption and resistance levels vary widely between units. Defined daily doses per 1000 occupied bed days is a common comparative measure, but the definition of length of stay must be agreed and antibiotics delivered to ICU may not necessarily be used. Dosage increased due to severity of illness or reduced due to renal failure are sources of error. One study found no relationship between prevalence of multiresistant pathogens and consumption of carbapenems, quinolones, or cephalosporins [3]. Poor hand hygiene or lack of antibiotic control may be an explanation. High rates of resistance in pseudomonas are related to high usage of carbapenems and quinolones.

Catheter-related or associated bacteraemia

Central line-associated bloodstream infections increase the length of stay in ICU and increase the risk of mortality. With appropriate catheter management these infections are avoidable and so catheter-associated bacteraemia is likely to emerge as a standard performance measure Box 281.1. Surveillance can cease 48 hours after the patient leaves the unit [1]. Bloodstream infections are central-line associated when a central line or umbilical catheter was in place (or within 48 hours) and not secondary to an infection at another site. If a line was inserted in the Emergency Department and is diagnosed within 24 hours of arrival in ICU it is still considered ICU associated. If it occurs within 48 hours of transfer out of an ICU it is attributed to that ICU. Pacemaker wires, femoral arterial catheters, intra-aortic balloon pump devices, or devices without lumens are not counted as central lines. The catheter-associated bloodstream infection rate is expressed per 1000 central line days. Surveillance at least at a regional level should be continuous.

Box 281.1 Surveillance definition CDC Device Associated Module January 2012

Infections associated with complications of infections already present on admission are not considered healthcare associated.

Primary blood stream infections (BSI)

Laboratory confirmed and not secondary to community-acquired infection or hospital-acquired infection meeting CDC criteria at another body site. The central line or umbilical catheter must be in place at the time or within 48 hours before onset of the event.

Laboratory-confirmed BSI

Must meet one of:

- Recognized pathogen cultured from one or more blood cultures and organism cultured from blood is not related to an infection at another site.
- Patient has at least one of following signs or symptoms: fever (>38ºC), chills or hypotension, and signs and symptoms and positive laboratory results are not related to an infection at another site and common commensal is cultured from two or more blood cultures drawn on separate occasions.
- Patient <=1 year of age and at least one of fever (>38ºC core), hypothermia (<36ºC) apnoea, or bradycardia and signs and symptoms and positive laboratory results are not related to an infection at another site and common skin commensal is cultured from two or more blood cultures drawn on separate occasions

Reproduced from CDC Device Associated Module January 2012: Central Line-Associated Bloodstream Infection Event (CLABSI).

One of the most significant examples of the efficacy of surveillance was the successful Michigan program to reduce CVC infections [4]. This project used peer pressure to encourage ICUs to join the program, created strong networking in the group, portraying catheter-related bacteraemia as a social problem, used a bundle of measures to reduce infections and data generated as a disciplinary measure. Four recommendations were applied related to insertion of the catheter: hand washing, using full barrier precautions, cleaning the skin with chlorhexidine, and avoiding the femoral site when possible. The fifth recommendation was to remove unnecessary catheters. In 90 ICUs, the number of catheter-related bloodstream infections was collected over 3 years. The mean and median rates of catheter related bloodstream infection per 1000 catheter days decreased from 7.7 and 2.7 at baseline to 1.3 and 0 at 16–18 months to 1.1 and 0 at 36 months. The project demonstrated that through a bundle of measures and a quality improvement ethos, improvements could be achieved and sustained.

As a result other countries have considered using catheter-associated or catheter-related blood stream infection as a measure of ICU performance in preventing nosocomial infection. 'Matching Michigan' was run by the National Patient Safety Agency in the UK. Definitions were based on CDC and ECDC and gained wide participation despite being voluntary and time limited. Results were sufficiently encouraging to consider a national voluntary quality improvement scheme [5]. Other studies have demonstrated that audit and feedback of these infections gradually reduces the number of cases.

In many countries, computerized data collection of morbidity and mortality is becoming more extensive, but infection surveillance is not usually the primary focus. While catheter-related bacteraemia requires additional laboratory resources for diagnosis (semiquantitative analysis of blood samples or roll cultures of catheter tips), catheter-associated bacteraemia is less stringent and more easily applicable. Collection of data on catheter-associated bacteraemia may not require significant extra resource as long as duplicate data entry is avoided. Voluntary surveillance may be under-reported if results are used for performance management or reimbursement or if there are major resource implications. On the other hand mandatory surveillance can be costly and less useful in small units. The main parameter for surveillance should be CVC associated infection expressed as a proportion of CVC patient-days using the ECDC definition. CVC patient-days (number of patients with at least one CVC in situ every 24 hours summed over one month) are needed to calculate device-associated rates. In the longer term, it would be desirable for microbiology departments to develop capacity for routine semi-quantitative cultures to allow use of catheter-related bloodstream infection as the eventual ideal marker.

Ventilator-associated pneumonia

Ventilator-associated pneumonia shortens patient survival and can arise from cross infection. However definitions are problematic and the use of bronchoscopy for diagnostic purposes varies widely between countries. Rates identified by the treating surgical intensivist and the infection control service in the same hospital can differ widely [6]. Therefore, it cannot be recommended as a subject for long-term surveillance.

Pathogen surveillance

Pseudomonas

Pseudomonas aeruginosa, including multiresistant strains, contaminating taps and other water sources in ICUs has been associated with the development of bacteraemia in patients, particularly neonates [7]. The hands of staff are the likely means of transmission and bathing infants in tap water a probable source. The hand wash station should only be used for hand washing and not for disposal of body fluids. Outbreaks have been reported with detergent diluted with contaminated tap water. Some neonatal units check rectal swabs every week to establish the prevalence of pseudomonal carriage, which can be helpful in monitoring the effect of interventions.

Studies confirm the effectiveness of point of use water filtration in reducing infection in critical care units. In one study, pseudomonas infections fell by 56% and water isolates fell from 97% to 0% when filters were introduced [8]. However filters have to be replaced monthly and are expensive. Sensor taps have been implicated in some outbreaks of Pseudomonas bacteraemia, probably because of biofilm accumulation in the end of the tap due to poor water flow and the thermoregulatory valve providing a carbon source. Surveillance of water samples in augmented care units for *Pseudomonas aeruginosa* has been advised.

Methicillin-resistant *Staphylococcus aureus*

In hospitals where methicillin-resistant *Staphylococcus aureus* (MRSA) is prevalent, the likelihood of carriage and acquisition is often highest in the ICU. Identification of carriage followed by topical suppression has been successful in reducing the risk of transmission. MRSA screening in many countries is performed on admission to hospital and/or the critical care unit. If a rapid PCR based method is used, the result is available the same day allowing immediate source isolation and more appropriate use of glycopeptides. If not, a patient with unknown carriage status may need to be source isolated or treated with topical suppression pending a result. All carriers are treated with topical chlorhexidine and mupirocin to reduce shedding into the environment and cross infection. Identified carriers should be source isolated in a single room. Units with universal screening report higher rates of MRSA as the result of better ascertainment, but only 20% of cases are likely to have been acquired during ICU stay [9].

Although topical suppression of all patients was cost effective in the short term, it carries a risk of selection of resistance. Rapid PCR based screening of all patients on admission and weekly thereafter is most cost effective [10]. Isolation or cohorting without topical suppression is effective, but increases costs unless prevalence is high (10%). The use of topical chlorhexidine and mupirocin may have been responsible for the dramatic reduction in MRSA prevalence in some countries, but probably is not cost effective when prevalence is already low.

Extended spectrum β-lactamase-producing Gram-negative bacteria

Extended spectrum β-lactamase producing Gram negative bacteria (ESBL) are rapidly increasing as a cause of invasive infection in ICU. Overuse of antibiotics is a major driver. Screening may be justified in units where there have been previous outbreaks or control of antibiotic use is poor. Surveillance over 11 years in Dutch ICUs showed changes in antimicrobial resistance in *Klebsiella pneumoniae*. Resistance to ceftazidime rose from 4.2% to 10.8%, ciprofloxacin from 5.8 to 18.5% and cefuroxime from 2.8 to 7.9% [11]. The prevalence of ESBL increased from 2% to 8%. Resistance was significantly greater in ICU than surgical wards.

Acinetobacter

Outbreaks of multiresistant Acinetobacter are very disruptive to the functioning of critical care units and cause bacteraemia and serious respiratory infection. Control of spread can be very difficult even with full infection control measures. Few ICUs screen routinely for the organism except during an outbreak. However, active surveillance (testing and either isolating or decolonizing) is cost saving when the colonization prevalence is greater than 1%. [12]. Even slight increases in length of stay in ICU can give rise considerable additional costs. Swabbing pharynx, wounds, axilla, and groin has a low sensitivity 13–78% compared with a sponge wiped on the upper arm and thigh (89%).

Future prospects

As health systems become more focussed on preventable infections, mandatory surveillance (or least peer pressure) will become more common. Financial incentives or penalties may be applied on the basis of reported numbers of hospital-acquired infections. While considerable reductions in infection rates can be achieved, use of national surveillance networks, standard definitions and methodologies are essential to ensure valid comparisons between units and appropriate actions for outlying performances.

CHAPTER 282

Novel biomarkers of infection in the critically ill

David T. Huang and Ayan Sen

Key points

- There is insufficient evidence for the routine use of novel biomarkers in infection and sepsis.
- A large number of biomarkers have been studied to date, but most studies only demonstrate correlation with outcome, rather than improvement in outcome.
- Several biomarkers are of prognostic value with strong associations with poor outcomes and mortality.
- Procalcitonin guidance to reduce antibiotic usage is promising, but most supporting data come from emergency department studies in a single European country.
- The future may involve development of high sensitivity assays, molecular strategies and a 'panel approach', all of which need to be investigated in well-designed studies.

Background

Over 25% of all annual deaths in the world are due to infection. Sepsis is defined as infection (probable or documented) with systemic manifestations such as systemic inflammatory response syndrome (SIRS) [1]. Severe sepsis is defined as sepsis with sepsis-induced organ dysfunction or tissue hypoperfusion. Severe sepsis is common, consumes considerable health care resources, and is associated with high mortality [2]. Surveillance and early response to infection and sepsis depend on rapid clinical diagnosis. The septic response is a complex chain of events involving inflammatory, humoral, cellular, and circulatory abnormalities. Early diagnosis and risk stratification facilitate timely and specific treatment, but are complicated by the highly variable and non-specific nature of the signs and symptoms of sepsis.

Biomarkers can be of value if they can improve medical decision-making by indicating the presence, absence, or severity of infection and sepsis determining aetiology (e.g. bacterial versus viral infection), and distinguishing systemic sepsis from local infection. Other potential uses include prognostication, guiding antibiotic therapy, and evaluating response to therapy. Large numbers of biomarkers have been studied in infection and sepsis. However, in many cases, reliability, validity, and clinical utility have not been fully evaluated, in part due to limitations of experimental models for human sepsis, and lack of a 'gold standard' for the diagnosis of infection or sepsis, prognosis of severe infections and sepsis [3].

White blood cells

The white blood cell (WBC) count is the most commonly used infectious biomarker. An elevated WBC is suggestive of an infection, but cannot be used in isolation and can indicate inflammation without infection ('false positive') or be absent despite infection in the elderly and immunocompromised ('false negative'). SIRS criteria include a WBC >14,000 or <4000 cells/mm^3, or a bandemia >10% [2].

C-reactive protein

C-reactive protein (CRP) is an acute-phase protein released by the liver after the onset of inflammation or tissue damage. It has been studied and used extensively in clinical practice as a biomarker of infection, inflammation, and sepsis. Its production is controlled by interleukin-6, an inflammatory cytokine. The median concentration of CRP in young adult blood donors is 0.8 mg/L, the 90th percentile is 3.0 mg/L, and the 99th percentile is 10 mg/L. A high-sensitivity CRP (hs-CRP) test measures low levels of CRP using laser nephelometry. The test gives results in 25 minutes with a sensitivity of 0.04 mg/L. Exact sensitivities and specificities of CRP for the diagnosis of bacterial infections vary in different studies and therefore its role should be interpreted based on context [4]. CRP level is also elevated during inflammatory states of non-infectious aetiologies, e.g. autoimmune disorders, myocardial infarction. As a result, its role in diagnosis of infection and sepsis is modest at best. Studies of critically-ill patients showed that elevated plasma concentrations of CRP correlate with an increased risk of organ failure and/or death. However, in studies of post-operative sepsis, procalcitonin and IL-6 levels significantly decreased in survivors from days 1 to 14, whereas CRP levels did not. Therefore, its role in prognostication in patients with sepsis is questionable. Elevated hsCRP at a stable phase of health was associated with increased risk of future sepsis events over 4.6 years of follow-up [5].

Procalcitonin

In normal physiological conditions, pro-calcitonin (PCT) is synthesized by thyroid C cells and serum levels are low (0.1 ng/mL) [4]. In bacterial infection, PCT is ubiquitously synthesized in multiple extrathyroidal tissues. PCT levels increase within 4–12 hours upon stimulation, and circulating PCT levels halve daily when the infection is controlled by the host immune system and antibiotic

therapy. A sample can be collected and sent to the laboratory with an average turnaround time of less than 3 hours. PCT can, however, increase after trauma or surgery, particularly major abdominal surgery, and in pancreatitis. Some authors report that PCT levels only transiently increase for 12–24 hours after surgery and in the absence of infection, fall back to normal levels. This is in contrast to both CRP and WCC, which can stay elevated for a number of days after surgery without underlying infection. PCT has a half-life of less than 24 hours.

Bacteraemic infections cause the highest rises in PCT with lower or negligible rises in localized, viral, and intracellular bacterial (e.g. Mycoplasma pneumonia) infections. In patients with community-acquired pneumonia (CAP) and urinary tract infections, PCT at a cut-off of 0.1 μg/L had a very high sensitivity to exclude bacteraemia [6,7]. PCT may not only differentiate between viral and bacterial infections, but also indicate the presence of bacterial super-infection in patients with viral diseases. Gram-negative bacteraemia may cause higher PCT rises than Gram-positive bacteraemia.

Six meta-analyses have been performed on the diagnostic accuracy of PCT to detect infection in different patient populations. Some of these meta-analyses identified PCT as being helpful for the diagnosis of clinically or microbiologically documented infection [8,9] whereas others have found moderate or moving towards null effect in the detection of bacteraemia [10]. However past studies did not use the high sensitivity PCT (Kryptor); this may have contributed to some to the discrepant conclusions. Recent guidelines issued by the Infectious Diseases Society of America suggest that use of PCT as an adjunctive diagnostic marker to differentiate sepsis from SIRS of a non-infectious origin may be considered [11]. However, the 2012 Surviving Sepsis Campaign Guidelines state 'the utility of procalcitonin levels or other biomarkers (such as C-reactive protein) to discriminate the acute inflammatory pattern of sepsis from other causes of generalized inflammation (e.g., post-operative, other forms of shock) has not been demonstrated. No recommendation can be given for the use of these markers to distinguish between severe infection and other acute inflammatory states' [2].

PCT may have a role in antibiotic stewardship and de-escalation. Thirteen randomized controlled studies, in which 4,395 patients were enrolled, showed a reduction in the prescription of antibiotics of between 74% and 11% and a reduction of days on antibiotics by 13% to 55% [12]. Most of those studies were performed with patients with clinically diagnosed respiratory tract infections in Swiss emergency departments, and less data exist for ICU patients. PCT levels in response to sepsis do not appear to be significantly affected by the use of steroids. PCT can be elevated in renal impairment, severe trauma and surgery or in patients after cardiac shock, acute graft-versus-host disease, immunotherapy, autoimmune diseases, and paraneoplastic syndromes. The role of PCT in systemic fungal infections is unclear. *Candida*-related severe sepsis or septic shock does not necessarily elicit a substantial increase in serum levels.

sTREM-1

Soluble triggering receptor expressed on myeloid cells 1 (TREM-1), a recently discovered member of the immunoglobulin superfamily, is greatly upregulated in infections, but not in non-infectious inflammatory conditions. It has been suggested that plasma sTREM-1 levels as an indicator of sepsis were superior to those of CRP and PCT. A meta-analysis found that the sensitivity of sTREM-1 for the diagnosis of bacterial infection, was 0.82 and that the specificity was 0.86 [13]. Other studies have reported that it is inferior to CRP and PCT.

Coagulation biomarkers

Protein C serum concentrations in neutropenic patients have been described to be significantly decreased, before clinical signs of severe sepsis and septic shock are apparent. Biphasic waveform (BPW) analysis, a new biological test derived from the activated partial thromboplastin time, has been proposed for the diagnosis of sepsis. The major limitation of coagulation parameters is that coagulation pathway abnormalities may be triggered by other disease states, such as trauma, obstetrical disorders, or cancer.

Other biomarkers

The quest for the magic biomarker, the 'troponin of sepsis' continues with several other acute phase reactants having failed to show clinical utility beyond a strong correlation with adverse outcomes. These include resistin, 'long' pentraxin 3, alpha-1 acid glycoprotein, and hepcidin, pro-inflammatory cytokines like IL-6 and IL-8, TNF-alpha, HMB1, proadrenomedullin, Macrophage migrating inhibitory factor (MgIF) and anti-inflammatory, endothelial, and apoptotic aspects of systemic inflammation, such as interleukin-1 receptor antagonist (IL-1ra) and IL-10. These biomarkers are of limited value because they can be induced by numerous non-infectious diseases like major surgery and major trauma, autoimmune disorders, viral infections, and transplant rejection. In a large US cohort study of subjects hospitalized with community acquired pneumonia, the circulating cytokine response to pneumonia was noted to be heterogeneous with considerable overlap between those who do and do not develop severe sepsis [14].

Panels of biomarkers

Combinations of biomarkers reflecting various aspects of the host response have been proposed to overcome limitations of single biomolecules. A panel consisting of sTREM-1, PCT, and CD64 index called the 'bioscore' was higher in patients with sepsis. In the emergency department (ED), the usefulness of a combination of suPAR, sTREM-1, and MgIF with CRP, PCT, and neutrophils was evaluated in patients with SIRS and found to have better sensitivity and specificity than any single marker [15]. Similarly, a biomarker panel of NGAL, IL-1ra, and protein C was predictive of severe sepsis, septic shock, and death in ED patients with suspected sepsis [16].

Molecular diagnostics

Blood culture reflects the current gold standard for the detection of bloodstream infection, since viable micro-organisms isolated from the blood can be analysed to identify species and susceptibility to antimicrobial therapy. However, culture data is impaired by the delay in the time to results and the fact that positive blood cultures can be found for only approximately 30% of severe sepsis patients. A number of molecular approaches to improve conventional culture-based identification, including PCR, have been suggested, such as

matrix-assisted laser desorption ionization–time of flight (MALDI-TOF) mass spectrometry, which may decrease the time to result to 4 hours. Another alternative strategy is the extraction and amplification of microbial nucleic acids from a positive blood culture and subsequent hybridization on a microarray platform to detect specific bacterial genes [17], which has recently been evaluated in an observational multi-centre design with conventional blood culture as the comparator. The assay had an overall sensitivity of 94.7% and a specificity of 98.8%, and 100% for meticillin-resistant *Staphylococcus aureus* (MRSA) bacteraemia, and resulted 18 hours faster than conventional blood culture [18]. However, shortcomings include an incomplete coverage of pathogens, the inability of the test to be applied directly to a biological sample, and restricted information regarding antimicrobial susceptibility.

PCR-based approaches, which amplify microbial nucleic acids directly from the bloodstream, carry the potential to improve the detection of infection with typical sepsis-associated bacteria, such as, streptococci and staphylococci, and also polymicrobial infections, including fastidious, multi-resistant, and fastidious species such as fungi. Comparable data are currently available only from studies which used the SeptiFast multiplex PCR. Concordance of PCR and blood culture results with respect to the recovery of blood culture-positive results by PCR was moderate to good in most, but not all studies. PCR-based approaches have potential as a supplement to blood cultures to reduce the time to results to readjust and narrow the spectrum of antimicrobial therapy, specifically for infections such as those by *Candida* or MRSA.

Conclusion

At present, there is insufficient evidence for the routine use of novel biomarkers in infection and sepsis. A large number of biomarkers have been studied to date, but have been constrained by lack of a 'gold standard', varying sensitivities and specificities, and inability to distinguish between infectious or inflammatory causes of a SIRS response. Most importantly, few have gone beyond correlation with outcome, to what really matters—improvement in outcome. The future is promising with development of high sensitivity assays, molecular strategies, and a 'panel approach', all of which need to be investigated in well-designed future studies, including randomized trials that can determine the true clinical utility of novel biomarkers of infection.

PART 13.2

Nosocomial infection

CHAPTER 283

Definition, epidemiology, and general management of nosocomial infection

Caroline Landelle and Didier Pittet

Key points

- A nosocomial infection or health care-associated infection (HAI) is defined by the World Health Organization (WHO) as an infection occurring in a patient during the process of care in a hospital or other health care facility, which was not present or incubating at the time of admission. This includes infections acquired in the health care facility, but appearing after discharge, and also occupational infections among health care workers (HCWs) of the facility.
- The prevalence of nosocomial infections generally exceeds 25% in intensive care units (ICUs) worldwide. Although ICU beds account for only 5% of all hospital beds and care for less than 10% of patients admitted, ICU-acquired HAIs account for more than 20% of all nosocomial infections.
- Nosocomial infection rates tend to be higher in surgical than in medical ICUs, and higher in adult than in paediatric ICUs (except neonatal ICUs).
- In the adult ICU, the most common site of infection is the lower respiratory tract, whereas bloodstream infections are more prominent in the paediatric ICU.
- Despite accumulated evidence and expert opinion for the effectiveness of hand hygiene in preventing pathogen cross-transmission, HCWs compliance with recommendations remains unacceptably low worldwide, usually 30% to 50%. Successful multimodal interventions have been associated with decreasing HAI rates.

Introduction

Nosocomial or 'hospital' infection were formerly so named to mark their hospital origin. The term 'health care-associated infection' (HAI) is now used to take into account more appropriately the patient care process in today's complex health care systems, often involving long-term, rehabilitation, ambulatory, and home care. HAI is one of the most common medical complications affecting patients in intensive care units (ICUs). In general, HAI prevalence exceeds 25% in ICUs worldwide. Although ICU beds account for only 5% of all hospital beds and care for less than 10% of patients admitted, ICU-acquired HAIs account for more than 20% of all HAI overall. Associated costs are equally tremendous. An assessment of mortality attributable to HAI in the ICU setting is difficult as it shares common risk factors with both the underlying disease and acuity of illness. Crude mortality rates are estimated to vary between 10% and 80% and attributable morbidity and mortality due to ICU-acquired HAI may be in excess of corresponding rates for the infections that initially led to the patient's hospitalization.

Definition

HAI is defined by the World Health Organization (WHO) as an infection occurring in a patient during the process of care in a hospital or other health care facility, which was not present or incubating at the time of admission. This includes infections acquired in the health care facility, but appearing after discharge, and also occupational infections among health care workers (HCWs) of the facility. The diagnosis of infection at specific body sites, e.g. urinary tract, surgical site, respiratory tract, and blood, should rely on standardized criteria based on clinical, laboratory, microbiological, and imaging parameters. The most commonly used definitions are those of the United States Centers for Disease Control and Prevention [1], although several European countries use also the definitions of the 'Hospital Infection Link for Infection Control through Surveillance' (HELICS) network for ICUs [2]. In particular, work is being conducted on the definition of ventilator-associated pneumonia (VAP) to decrease the complexity and subjectivity of the definition and to allow a more reliable assessment and comparison of quality of care for ventilated patients [3].

Host colonization is a prerequisite for the development of infection, particularly in critical care. Although factors favouring the progression from colonization to infection are not completely understood, it is estimated that almost 50% of ICU-acquired HAI are preceded by colonization with the same microorganism. Factors associated with colonization are similar to infection (duration of hospitalization, high exposure to invasive devices, prolonged antibiotic therapy). Several studies have shown that severity of illness and ICU admission contributed to rapid colonization with gram-negative bacteria. Often these are endemic in the ICU and imply that the physiological flora of a patient can be substituted by the local endemic flora after some days in this setting.

Epidemiology

In 1992, the European Prevalence of Infection in Intensive Care (EPIC) study [4] included data from 1417 ICUs in 17 West European countries and provided valuable information on the prevalence and epidemiology of infection in critically-ill European patients. Fifteen years later, the Extended Prevalence of Infection in Intensive Care (EPIC II) study was conducted to provide a picture of the extent and patterns of infection in ICUs worldwide [5]. In 2007, 14,414 patients in 1265 ICUs from 75 countries participated in a one-day point prevalence survey. Of 13,796 patients aged >18 years, 7087 (51%) were considered to be infected. Patients who had longer ICU stays prior to the study day had higher infection rates. Infection prevalence varied markedly by geographical region, ranging from 46% to 60%. There was a significant relationship between the percentage of infected patients and the hospital mortality rate. This likely reflects differences in critical care practices between countries and underlines the importance of controlling for case mix when interpreting and comparing HAI rates between hospitals or countries.

The frequency of the occurrence of infection may also differ among different sites in the ICU and within a hospital as well illustrated by the annual United States National Healthcare Safety Network (NHSN) report [6]. Urinary tract infections predominate in general wards, whereas the most common ICU-acquired HAIs are lower respiratory tract infections. The type of ICU also plays a role. Infection rates tend to be higher in surgical than in medical ICUs, and higher in adult ICUs than in paediatric units, with the exception of neonatal ICUs. In adult ICUs, the lower respiratory tract is the most common site of infection, whereas bloodstream infections are more prominent in paediatric and neonatal ICUs. High rates of pulmonary infections are unique to adult ICUs where patients are frequently admitted because of respiratory distress and require mechanical ventilation. Although primary bacteraemia and infections due to vascular devices are less common than lower respiratory tract infections, morbidity, and mortality associated with these infections are particularly high.

When HAI rates have been compared over shorter increments of time, i.e. monthly, wide variations can be noted. Observations in different ICUs suggested that the level of skilled nursing care may be an important determinant of this variation. Several studies show that overcrowding, understaffing, or an imbalance between workload and resources are important determinants of HAI and microorganism cross-transmission in ICUs. The higher the workload, the lower the compliance with preventive measures, and the higher the rate of HAI. Importantly, not only the number of staff, but also the level of training affects outcomes. The causal pathway between understaffing and infection is complex and several factors may contribute, including primarily lack of time to comply with infection control recommendations.

Additional reasons for high rates include selection pressure for resistant organisms induced by high antimicrobial use and extensive exposure to medical devices. The patient's underlying conditions play also an important role. Several studies demonstrate a correlation between the number of active comorbidities, the HAI rate, and other medical complications. In addition, almost all ICU patients are equipped with at least one vascular access or device breaking the normal skin barrier, thus enabling a direct connection to the external environment.

HAI do not only occur individually, they can develop also as outbreaks. Epidemics are associated with specific organisms sometimes introduced from outside and remaining within the ICU because of the continuous selection pressure of antibiotics. These do not necessarily need to be virulent—it is sufficient to be resistant enough in order to persist. Leading pathogens are methicillin-resistant *Staphylococcus aureus* (MRSA), multiresistant non-fermentative Gram-negative rods, such as *Pseudomonas* sp., *Enterobacter* sp., *Serratia* sp., *Stenotrophomonas maltophilia,* and *Acinetobacter* sp., all of which can become long-lasting problems. Pathogens producing extended-spectrum beta-lactamases (ESBL), such as *Klebsiella* sp. or *Escherichia coli,* are equally a major concern in many countries worldwide. In some parts of the world, vancomycin-resistant enterococci (VRE) and carbapenem-resistant *Enterobacteriae* have completed recently this list of worrisome pathogens. Last, but not least, non-bacterial pathogens can become a problem, e.g. the steady increase of HAI caused by non-albicans *Candida* sp.

Surveillance

Although resource-demanding, correctly performed surveillance is a condition *sine qua non* for effective infection control. Surveillance may help to define and detect common or unusual sources of cross-infection or failures in care management. It summarizes rates and reports feedback for corrective actions and is best performed by dedicated, specifically-trained, infection control staff in close collaboration with the ICU team. Controversy exists if surveillance should be continued post-discharge. It is wise to prolong it for a brief period after the patient has left the ICU because ICU-acquired HAIs may become evident only in the following days while the patient is in the general ward. Of note, this approach is labour-intensive and may not always be justified as only few HAIs may be detected after discharge. Target-oriented, post-discharge surveillance could be a rational alternative.

Surveillance has a major impact on the incidence of infections. However, to understand the meaning of infection rates always implies comparison. On a micro-epidemiological level, this implies comparison of endemic rates over time within the same population, before and after an intervention or system change, or outbreak detection. Inter-institutional comparison, termed 'benchmarking', is increasingly common with the aim of improving the effectiveness of health care and promoting patient safety. Similar comparisons might soon be made between different health care settings. Benchmarking among health care structures requires meticulous adjustment for case-mix and failure to adjust adequately for infection-associated factors will erroneously punish commitment to more challenging medical tasks and hinder quality improvement [7]. This is a field of intense research and expanding knowledge. Standardization of the surveillance method is a second challenge that has to be addressed to make comparison possible [8]. This obviously clashes with the will to improve and adapt definitions to medical progress and local specificities. Adjustment should be implemented according to variations in the use of microbiological investigation within the different health care settings and type of diagnostic techniques applied. Diagnostic power and accuracy largely impact on infection rates. Voluntary participation in a surveillance network, confidentiality, and adequate feedback of results are the prerequisites for health care settings' adherence to the method and dedication to data quality.

Indicators

Prevention must be guided by the measurement of indicators that identify gaps and point to the most appropriate solutions. These indicators are composed of HAI rates, structure indicators (e.g. alcohol-based hand rub available at the point of care), process indicators (e.g. hand hygiene compliance), and audits using checklists to assess if correct procedures and equipment are in place. This is known as the 'recognize-explain-intervene' concept, which was validated for the first time on a large scale by the Study on the Efficacy of Nosocomial Infection Control (SENIC) project carried out in United States hospitals in the 1980s [9]. While demonstrating that 35–50% of HAI are preventable by a few fundamental practices (e.g. correct use of urinary catheters and vascular access lines, therapy and support of pulmonary functions, surveillance of surgical procedures, timely hand hygiene, and application of isolation precautions), the SENIC project identified key elements for the success of an infection control programme: one infection control nurse per 200–250 beds; one epidemiologist per hospital (1000 beds); organized surveillance for HAI; and systematic feedback of HAI rates to administrators and HCW. Facing today's challenge in health care in general and in ICUs in particular, the respective needs are one infection control nurse per 100–150 acute care hospital beds and one per ~25–35 ICU beds.

Standard precautions

Standard precautions refer to the comprehensive set of recommendations that must be followed in each care process and across all health care settings, regardless of the presence of an infectious pathogen. These precautions represent the primary strategy to prevent pathogen transmission among patients and HCW. They include the performance of hand hygiene according to pre-specified guidelines, use of personal protective equipment, respiratory hygiene/cough etiquette, safe injection practices, use of masks for catheter insertion, and lumbar puncture procedures, safe handling of contaminated equipment, textiles and laundry, routine cleaning and disinfection of environmental surfaces, and protective measures related to building construction and renovation.

Hand hygiene: a transversal measure

HCWs' hands are the principal instruments in the course of complete nursing and highly invasive care in the ICU. Although hand hygiene is the single most important measure to prevent cross-transmission and to reduce the rate of nosocomial colonization and infection, compliance among HCWs is unacceptably low worldwide. Explanations for such a low compliance include insufficient time due to high workload, inconvenient access to hand cleansing facilities, inferior priority compared with other patient needs, lack of institutional priority for hand hygiene, lack of institutional safety climate, lack of leadership of senior medical and nursing staff, allergy or intolerance to hand hygiene solutions, and lack of awareness of recommendations or scepticism regarding their effect on HAI. Not surprisingly, high workload is correlated with an increasing number of hand hygiene opportunities per hour of patient care. To overcome the time constraint factor, hand hygiene indications have been condensed into five moments when action is required during health care [10,11] (Fig. 283.1).

During the past decade the strength of evidence in favour of alcohol-based hand antisepsis, unless hands are visibly soiled, has

Fig. 283.1 The 'My 5 moments for hand hygiene' concept.

Reprinted from *Journal of Hospital Infection*, **67**(1), Sax H et al., 'My five moments of hand hygiene: a user-centred design approach to understand, train, monitor and report hand hygiene', pp. 9–21, copyright 2007, with permission from Elsevier and Healthcare Infection Society.

become simply overwhelming. If actively promoted, alcohol-based hand rub can improve compliance with hand hygiene recommendations and can reduce HAI and transmission rates [12]. In high-demand settings such as ICUs, an alcohol-based hand rub appears to be the only method that might allow reasonable compliance. In addition, alcohol-based hand rubs with gels, rinses, or foams containing emollients are less harmful to the skin than regular hand washing with soap and water.

Multimodal strategies, including 'bundle' approach

As defined by the US Institute for Healthcare Improvement (www.ihi.org), 'care bundles, in general, are groupings of best practices with respect to a disease process that individually improve care, but when applied together result in substantially greater improvement. The science supporting the bundle components is sufficiently established to be considered standard of care'.

The proportion of HAI potentially preventable under routine working conditions remains unclear. Several reports suggest a great potential, ranging from a decrease of 10% to a maximum of 70%, depending on the setting, study design, baseline infection rates, and type of infection. The most important potential was identified for catheter-related bacteraemia. Although the optimal approach to reducing ICU-acquired HAI is unclear, studies and large quality improvement initiatives have shown that multimodal strategies can decrease HAI rates [13,14]. Problems of multiresistant organisms and isolation strategies, antibiotic control, selective oral or digestive decontamination, and prevention of some key ICU-specific infections are addressed in other chapters.

CHAPTER 284

Healthcare worker screening for nosocomial pathogens

Paul Van Buynder and Elizabeth Brodkin

Key points

- Healthcare workers (HCW) are both at risk of becoming infected in the health care setting as well as being a known source of nosocomial infection.
- Employers and HCW have an ethical responsibility to prevent occupationally acquired infections and avoid causing harm to patients by transmitting disease.
- After any recognized blood borne pathogen (BBP) exposure incident, timely post-exposure risk assessment, along with a schedule of follow-up BBP screening should be undertaken.
- Screening for and management of potential transmission sources can reduce risks.
- HCW vaccination strategies can further reduce risks.

Screening and management of specific pathogens

Blood-borne pathogens

Health care worker (HCW) screening for blood-borne pathogens (BBP) focuses on the three viruses which are responsible for most health care-associated blood-borne infections, Human immunodeficiency virus (HIV), hepatitis B virus (HBV), and hepatitis C virus (HCV). Infection control guidelines for BBP screening of HCWs reflect an increasing focus on the potential risk of nosocomial BBP transmission from an infected HCW-to-patient, in addition to early identification of patient-to-HCW BBP transmission [1,2].

Guidelines for HCW screening and subsequent management of infected HCW vary across jurisdictions internationally, with differing thresholds for the scope of practice of infected HCW. Some jurisdictions, such as United States of America (USA), Canada, and Australia allow for case-by-case review of infected HCWs by an expert review committee to assess the scope of practice restriction [3,4].

Voluntary screening for HBV, HCV and HIV infection is a professional and ethical responsibility of each HCW who has potential exposure to BBPs. HCW regulatory authorities in many jurisdictions, such as the USA, Canada, Australia, and a number of European countries promote, but do not mandate BBP screening by HCW. In the United Kingdom (UK), such screening is explicitly mandated for new (but not currently practising) HCW who will perform 'exposure prone procedures' (EPP), which are procedures that are assessed to pose a higher risk of HCW-to-patient BBP transmission [5]. Most guidelines either make no recommendation for repeat BBP screening (e.g. U.K.) or do not recommend a specific frequency of BBP screening in HCWs not previously known to be infected (e.g. U.S.A, Canada, Germany). Recent Australian guidelines propose a minimum one-year periodicity for HCW performing EPP. Some regulatory agencies advise a re-screening frequency based on personal assessment of risk of acquisition of BBP infection.

In general, where guidelines recommend practice restrictions for infected HCW, exclusions are limited to performance of EPP only. Notably, UK guidelines indicate that the intensive care setting does not 'generally' involve EPPs by medical or nursing staff; however, these guidelines indicate certain procedures involving accident or emergency care as EPP, which could possibly be performed in critical care settings. Further complicating the assessed potential for performing EPP in critical care settings is a lack of international consensus in defining or categorizing specific procedures as EPP.

After any recognized BBP exposure incident, timely post-exposure risk assessment, along with a schedule of follow-up BBP screening should be undertaken. Where indicated, HIV post-exposure prophylaxis should ideally be initiated within two hours of exposure, while HBV prophylaxis, including hepatitis B immune globulin, and/or hepatitis B vaccine, is preferably begun within 48–72 hours of exposure.

Hepatitis B pre-exposure immunization and screening of post-vaccination anti-HBs level one to three months after the final vaccine dose are highly recommended for all HCW. Hepatitis B vaccine non-responders, in addition to HCW performing EPP, should have further Hepatitis B surface Antigen (HBsAg) testing and HBV-infected HCW should undergo HBeAg and/or HBV-DNA screening to assess their degree of infectivity. Although HBeAg-positive status generally requires exclusion from performing EPPs, guidelines for similarly restricting HBV-infected, HBeAg-negative HCWs differ according to varying HBV-DNA levels, ranging from: any level of detectable HBV-DNA (Australia); 103 GE/mL (UK); 104 GE/mL (U.S.A. and European Consensus Group); or 105 GE/mL (Netherlands). Jurisdictions that permit HCWs with detectable HBV-DNA to continue performing EPPs, require varying frequency of ongoing nucleic acid testing to monitor viral levels, ranging from every 3 months in Australia, to twice per year in the USA, and annually in the UK [6].

Variance across jurisdictions also exists for managing HCV-infected HCW. In general anti-HCV-positive,

HCV-RNA-positive HCW are restricted from performing EPP. Some guidelines (USA) permit HCV-infected HCW with HCV-RNA levels up to 104 GE/mL who have not been implicated in cases of HCW-to-patient HCV transmission, to continue performing EPP although affected HCW are required to 'double-glove' and undertake semi-annual HCV nucleic acid testing. Australian guidelines make provision for HCW who achieve a sustained viral response following HCV treatment (i.e. undetectable HCV-RNA 6 months after completion of treatment) to resume performing EPP, with annual HCV-RNA rescreening.

Most jurisdictions exclude HIV-infected HCW from performing EPPs, regardless of HIV-RNA level (even if 'undetectable' by sensitive nucleic acid testing). Some USA guidelines are more permissive (i.e. Society for Healthcare Epidemiology of America, or SHEA), allowing HIV-infected HCW with HIV-RNA levels less than 500 GE/mL to continue performing EPP, with similar ongoing practice and follow-up test requirements as for HCV [3].

As available data increases, HCW screening and management guidelines will require ongoing review to optimally manage BBP-infected HCWs who achieve long term sustained, viral response using increasingly effective therapies.

Tuberculosis

All health care settings require a tuberculosis (TB) infection control program, a key component of which is screening HCW who are at risk for disease or who might be exposed to infected persons or clinical specimens [7].

Baseline screening of HCW allows for detection and treatment of latent and active TB disease before employment begins, and provides a basis for comparison should the worker be exposed to *Mycobacterium* TB. New HCW (or staff with no evidence of prior screening) who will be exposed to patients or clinical specimens, should only begin work after they have undergone a health check and TB screen, or can produce evidence of having been screened in the previous 12 months. The health check should include:

- Personal or family history of TB.
- Any signs and symptoms of TB disease.
- Evidence of Tuberculin skin testing (TST) or Interferon Gamma release Assay (IGRA) testing and Bacille Calmette–Guérin, (BCG) scar check by an occupational health professional.
- Previous TST results in the last five years if available.

HCWs should not begin work if they have signs and symptoms of active TB disease.

New HCWs who are not entrants from high incidence countries and have not previously had BCG vaccination should be offered TST testing. If the TST is positive IGRA testing should be performed. If both the TST and IGRA are positive the worker should have a chest X-ray and a medical assessment for latent or active disease.

IGRA testing should be offered to new HCW who have recently arrived from high incidence countries or who have worked in settings where TB is prevalent. If the IGRA is positive the HCW should be referred for medical assessment [8].

The frequency of ongoing screening for established HCW should be determined by the risk of exposure in their particular setting. Risk varies by patient population, prevalence of TB in the community, occupational group, and effectiveness of TB infection control measures. Settings in which infected persons or clinical specimens are unlikely to be present are considered low risk. Medium risk refers to settings in which HCW will or are likely to be exposed to infected persons or specimens. Potential ongoing transmission should be applied to any setting where there is evidence of person-to-person transmission during the previous year.

After baseline screening for TB, additional screening of HCW in low risk settings is not needed unless an exposure to M. TB occurs. HCW in medium risk settings should be screened annually by health check, and by TST/IGRA testing for those with negative baseline testing. In settings with potential ongoing transmission workers may need to be screened every eight to 10 weeks until the problem has been corrected and transmission has ceased. HCW who transfer from one setting to another may be at higher risk in the new setting and the frequency of screening should be adjusted accordingly.

Methicillin-resistant *Staphylococcus aureus*

HCW can become colonized with MRSA. One retrospective review of published data found HCW to have an average colonization rate of 5% and transmission to be documented from both transiently and persistently colonized HCW. No trials have been published on the benefit of routine HCW screening for MRSA colonization although this practice occurs in the Netherlands, Scandinavia, and Western Australia. This practice is not routinely recommended unless staff were epidemiologically linked to new MRSA cases or a cluster of infections, or if an outbreak persists despite appropriate control measures. Molecular testing has been helpful in these situations. Surveillance for skin and soft tissue infections in staff is also warranted in an outbreak. Eradication therapy should be provided for positive staff in these settings.

Screening of patients in critical care areas has been deemed cost effective by a Health Protection Authority modelling study and screening of all hospital admissions is required in the United Kingdom, but remains contentious with studies examining the link between colonization and infective complications showing conflicting results [9,10].

Other antibiotic resistant organisms

Routine screening of healthcare workers for vancomycin resistant enterococci (VRE), carbapenem-resistant Enterobacteriaceae (CRE) and Extended Spectrum Beta Lactamase (ESBL) producing organisms is not recommended as there is no evidence that rectal colonization of staff contributes to transmission.

Vaccination of health care workers

Recommendations for vaccination of HCW are largely based on either risk to the HCW for acquiring disease or the risk of HCWs transmitting disease to patients. A review of HCW vaccination status should occur at the time of hire and then annually with influenza vaccination. Robust HCW vaccination policies should be accompanied by secure record systems so that susceptible individuals can be identified during times of outbreaks [11].

Hepatitis B vaccine should be made available at no cost to all HCW who are exposed occupationally to infectious materials, preferentially during training prior to exposure. The three dose regime at zero, one, and six months produces a protective antibody response in over 90% of healthy young adults and lasts for over 20 years in vaccine responders. Post vaccination serologic testing should be undertaken after the third dose to confirm the presence

of hepatitis B surface antibody (anti-HBs >10mIU/mL). For those with an inadequate immune response after a complete vaccine series, (i.e. less than 10 IU/L), a second complete series of hepatitis B vaccine is recommended in many jurisdictions. UK guidelines also recommend offering an additional single vaccine dose to those with an intermediate response (i.e. 10-100 IU/L).

Non-responders who are not infected with Hepatitis B are susceptible and should be educated about preventing infection and post-exposure prophylaxis. Non-responders who are HBsAg positive should be counselled about preventing transmission to others and have their practice reviewed. Post exposure prophylaxis after significant exposure to blood or body fluids should be based on the HBsAg status of the source and the immune status of the exposed HCW. HCW engaging in high- risk personal practices associated with an increased risk of non-occupational acquisition of blood borne viruses have a responsibility to regularly check their status.

Many HCW are infected with influenza each year. Vaccinating HCW decreases morbidity in health care settings particularly in long term care and vaccination helps maintain a workforce in winter by reducing absenteeism. Professional bodies have recommended HCW vaccination as an ethical imperative for many years, but uptake has been almost universally disappointing and often less than 50%. In view of the failure of education, many organizations and some United States jurisdictions have now mandated HCW influenza vaccination [12].

Measles remains common in some parts of the world leading to travel related importations and risks of transmission even in areas where measles has been declared eliminated. Persons infected with measles are likely to seek medical care and measles transmission has been shown to occur in medical settings during outbreaks. HCW are at higher risk of acquiring measles. Exposure response in medical settings is expensive and entails reviewing measles immunity, and excluding and vaccinating the non-immune. All HCW born after 1956 should be vaccinated with two doses of Measles Mumps Rubella (MMR) vaccine and a record should exist in all facilities documenting these doses or documenting laboratory evidence of immunity or disease. Serological confirmation after vaccination is not required.

Mumps transmission in medical settings is also well recognized and the management of cases associated with similar economic costs as measles. Immunity to mumps vaccine wanes over time and correlates of protection are not known. All HCW should provide presumptive evidence of immunity to mumps. Despite waning immunity, two doses of MMR vaccine is considered sufficient protection.

Evidence of transmission of rubella in medical settings is scant in areas where rubella elimination has been achieved although it was common prior to that. All HCW should have documented evidence of immunity. History of disease is not considered adequate.

Pertussis is a highly contagious disease with a high risk of hospitalization and significant mortality in the very young. Since the widespread use of acellular pertussis vaccines in the last decade, with a duration of protection of only between 5 and 10 years, outbreaks are occurring on a regular basis. Documented transmission within medical settings has occurred and outbreak management is costly. All HCW in contact with young children should receive decennial booster vaccines and consideration should be given to boosting after 5 years in an outbreak setting. Modelling post outbreak has shown that HCW vaccination for pertussis is cost saving.

Vaccination against other preventable diseases such as varicella may be indicated depending on local epidemiology and local vaccination coverage data.

CHAPTER 285

Environmental decontamination and isolation strategies in the ICU

Leigh Ann Slater and Pamela A. Lipsett

Key points

- The care environment is an important factor in the transmission of health care-associated infections, but its role is incompletely understood.
- Potential avenues for infection transmission include hospital construction, unit and room layout, design materials, disinfection materials and methods, isolation equipment, and staff ratios and training.
- Limited evidence supports many currently employed cleaning and isolation techniques. Many are simply intuitive or based on non-controlled observations.
- Compliance is currently poor with both cleaning and isolation policies.
- Reduced colonization does not always translate to reduced infection rates.

Introduction

There are over 1.7 million health care associated infections annually in the US and 99,000 deaths [1]. With the clinical and financial burden of antibiotic resistance increasing exponentially, agencies such as the Joint Commission have clearly articulated regulations. The environment of care is a potentially important contributor to preventable health care associated infections. Potential avenues for infection transmission range from the initial hospital construction itself to unit and room layout, design materials, disinfection materials and methods, isolation equipment, and staff ratios and training. Better understanding of these avenues for transmission will suggest potential means to decrease the burden of environmental contamination. Several studies have demonstrated a two to three-fold increased risk of acquiring VRE (vancomycin resistant *Enterococcus*), MRSA (meticillin resistant *Staphylococcus aureus*), *Clostridium difficile* or ACB (*Acinetobacter baumanii*) when occupying a room previously used by a patient with one of these organisms [2]. Meanwhile, enhanced surveillance strategies demonstrate suboptimal routine disinfection with the potential to decrease transmission of VRE, MRSA, and ACB by 40% simply by improving compliance with existing cleaning protocols [3]. However, whether improvements in cleaning can lead to a clear decrease in acquired infections remains controversial. This chapter will provide a brief overview of the current understanding of the environment of care and its impact on infection control practices.

Construction

Construction-related risks include the release of airborne fungal diseases, most notably *Aspergillus* spp. The number of health care associated *Aspergillus* infections directly attributable to construction is unknown, but *Aspergillus* has a large cost burden, estimated at over $600 million in 1996 alone [4]. Treatment of *Aspergillus* infection adds 17 days to length of stay, or over $62,000 in costs per patient. Case fatality rate is over 50% overall and over 80% for bone marrow transplant recipients despite treatment, thus the urgency to prevent transmission. Thus during construction periods, high risk individuals such as transplant patients should avoid exposure to these areas.

Waterborne diseases are also a significant risk to the immunocompromised via the potable water supply. These include *Aspergillus* spp. and *Fusarium* spp., which can be transmitted via disruption of the biofilm after a water service interruption. *Pseudomonas* spp. and *Stenotrophomonas* spp. are opportunistic free-floating bacteria and can contaminate surfaces that come in contact with the water. Risk of transmission is heightened if contaminated water is used to wash equipment in direct contact with patients, or if water is allowed to stagnate and microbial count increases above 10,000 cfu/mL. *Legionella* spp. are found widely in soil and water and is easily introduced to the potable water supply, where it can spread through hospital water heaters and distribution systems to individual room faucets. *Legionella* spp. are commonly transmitted via inhalation of the aerosol at waterheads and there is no commonly utilized monitoring or eradication method. It is addressed by surveillance of patients for symptoms, prompt identification and treatment.

Unit design

Historically intensive care unit design emphasized arrangement of patient beds around a centralized nursing station to maximize visibility and communication and to more readily enable rapid response in the event of patient clinical decompensation. With more concern over the potential for cross contamination as well as more attention to the need for privacy and increased family presence, the emphasis has shifted to single occupancy rooms. Single rooms have demonstrated reduction in transmission of MRSA, *Pseudomonas* spp., and *Candida* spp. when compared with multi-bed wards [4].

Important aspects of unit design include optimizing availability of hand hygiene equipment near point of care. Water and alcohol based modalities are equally efficacious for most hand

hygiene. However, soap and water should be used for *Clostridium difficile*, since alcohol based cleansers have no effect against the spores. Alcohol based hand rub stations should therefore not be used in place of appropriate water based hand hygiene for this pathogen. Attention should be paid to sink size and depth to prevent splashing, avoidance of contamination of the faucet aerators, hands-free activation of the stream, direction of stream away from the drain, water pressure and temperature, proper drainage, and separate sinks for the toilet area versus for the remainder of the patient room. No storage should be allowed underneath the sinks. Travel distance for waste disposal should be minimized.

Water access for acute dialysis is another important consideration and care should be taken to avoid plugged lines and hoses with resultant mould growth. Waterproofing can be accomplished by gypsum board installed 10 mm (3/8″) above the floor board to prevent fluid wicking from floods [4].

Room design

The current trend is toward single occupancy rooms. Attention should be paid to ergonomic locations and heights of hand hygiene stations as well as to minimizing travel distance for waste disposal and separating it from the remainder of the room. The ideal arrangement may be a toilet room between every two patient rooms, to avoid transporting waste to a distant central area. In addition, patient rooms should have flexibility to increase acuity so that patient room transfers can be minimized, as increased transfers are linked to increased infection transmission. Specific isolation room design concepts will be discussed in a later section.

Surfaces and materials

Contaminated surfaces play an important role in the spread of MRSA, VRE, norovirus, *Clostridium difficile*, hepatitis B virus, and *Candida* spp., as well as *Acinetobacter* spp., *Pseudomonas* spp. and other multi-drug resistant Gram-negative bacilli. All of these organisms are able to colonize patients' and health care workers' (HCW) hands and can survive and remain virulent for prolonged periods on environmental surfaces. Surfaces in general need to be easy to clean with topical disinfectants at the appropriate concentration, duration, and frequency. There is little evidence identifying clearly superior surface materials that contribute to the reduction of health care associated infection. Desirable surfaces will be nonporous, non-cloth, smooth, water resistant, sealed, flat or with rounded corners, free of crevices, and durable against corrosion with the required frequent cleaning. Furniture should have 150–300 mm (6–12″) clearance above the floor to permit thorough cleaning. Soft or upholstered furniture or carpet must be discarded if soiled, as must be any furniture with soiled exposed particleboard. Intact hardwood laminate can be cleaned with dilute bleach. Some manufacturers use fungicides, antimicrobials, or insecticides in their floor treatments or upholstery. Copper has intrinsic antimicrobial properties and is gaining acceptance over the more common stainless steel, but has not been shown to decrease cross-contamination [4]. Drapes, curtains, and other porous materials must be discarded after each patient if they cannot be sterilized for reuse. Particular care must be taken with the sterilization of ventilator equipment between patients.

Disinfection materials and methods

Commonly used surface disinfectants include sodium hypochlorite, sodium hydroxide, alcohols at 70 or 90% (ethanol, 1-propanol, 2-propanol), phenols, and quaternary ammonium compounds. Care must be taken to use these per the package instructions to ensure they are applied at adequate concentration, duration, and frequency. In addition, knowledge of specific pathogens is necessary as they may be selectively resistant to certain agents.

Norovirus, *Clostridium difficile*, and *Acinetobacter* spp. can all survive on environmental surfaces for weeks and are resistant to commonly used disinfectants. Norovirus can be transmitted by faecal-oral route either directly person-to-person, via surfaces or contaminated food or even by inhalation of aerosolized vomitus. It has high infectivity with a low inoculating dose and a long shedding time. As it cannot be cultured, surrogate data from caliciviruses suggests that alcohol, phenols, and quaternary ammonium compounds are less likely to be effective cleaning agents, with the effect highly dependent on the precise formulation. Sodium hypochlorite solution is effective when used at 1000–3000 ppm. Hand hygiene with soap and water for at least one minute completely removes norovirus as demonstrated by reverse transcription polymerase chain reaction (RT-PCR) [1].

Clostridium difficile can be transmitted by faecal-oral route directly, via fomites or the hands of HCW. The vegetative form survives 15 minutes on a dry surface, but up to 6 hours on a moist surface, and spores can persist up to 5 months. 70% isopropanol, phenols, and quaternary ammonium compounds are not sporicidal [1]. Use of 1:10 diluted (5000 ppm) sodium hypochlorite is effective at reducing *Clostridium difficile* infections in the setting of an epidemic or high endemic caseload; this is advocated as effective against spores, but still leaves 10% *Clostridium difficile* positive toilets in rooms with *Clostridium difficile* positive patients [5]. Spores are thus a frustrating problem and the key to reducing transmission with this pathogen. Accelerated 0.5% H_2O_2 was found to be effective at spore removal in non-epidemic conditions [5]. Proper hand hygiene with soap and water is most effective at removing spores.

Acinetobacter spp. can survive for weeks on many different dry surfaces as well as in water; humidity prolongs its survival. It is often present in reservoirs such as respiratory equipment. It is susceptible to phenols, quaternary ammonium compounds, accelerated 0.5% H_2O_2, and UV light. 70% ethanol and 10% povidone-iodine are most effective at cleaning heavily contaminated hands [1].

For terminal cleaning of rooms or eradication of units such as during an epidemic, various no touch disinfection methods may be utilized after the initial room cleaning. An automated ultraviolet-C device for hospital room disinfection has been demonstrated to reduce frequency of positive MRSA and VRE cultures by 93% and *Clostridium difficile* cultures by 80%, with 45 minutes of treatment required to reduce spores > 2–3 $\log_{10}$ cfu/cm^2; MRSA and VRE killing were equivalent with 20 minutes versus 45 minutes of treatment [6]. However, such devices only function optimally after proper surface decontamination and only when used with the proper duration and treatment radius and intensity. Inferior cleaning rates (< 30%) have been demonstrated with commonly contaminated fixtures including doorknobs and light switches.

Alternative no touch disinfection methods include the use of gaseous agents such as H_2O_2, chlorine dioxide, and ozone, which are all powerful oxidizing agents [7]. All require the room to be

precleaned and pose some small hazard to staff. The vapourized H_2O_2 system manufactured by Bioquell reduced *Clostridium difficile* infection 53% during an epidemic, but no controls were utilized in the study [8]. The system requires removal of the patient from the room so it can be sealed completely with tape, including heating, ventilation, and air conditioning ducts. Treatment with vaporized H_2O_2 requires up to 5 hours compared with 1 hour for bleach cleaning, an important factor in patient throughut and bed availability. The newer system manufactured by Bioquell has considerably reduced the required disinfection time, minimizing this concern. Chlorine dioxide is sporicidal, but can penetrate plastics commonly found in the clinical setting, as well as being explosive at concentrations above 10% and yielding toxic chlorine gas. Ozone's corrosiveness and toxicity likewise limits its application in the clinical setting, as 15 minutes at 0.2 ppm is enough to induce respiratory symptoms while providing insufficient antimicrobial effect [7].

Isolation

Basic isolation concepts begin with the use of standard precautions for all patients, including hand hygiene before and after each contact and use of gloves for contact with any body fluid other than sweat. Transmission of blood-borne pathogens such as HIV, and hepatitis B and C can be minimized by adherence to standard precautions. For patients with certain specific infections, more stringent isolation protocols are required. The presence of such pathogens should be identified early and communicated broadly with appropriate signage and order sets to alert all HCW to the need to observe heightened precautions and cleaning protocols. The universal use of mandatory isolation remains controversial [9].

Certain infections require designated isolation rooms within an ICU. With the airborne infection isolation room (AIIR), air flow is directed into the room, i.e. these are negative pressure rooms suitable for airborne precautions. A minimum of 12 air changes per hour are required, as are gloves, gown, and N95 type particle respirator masks [4]. AIIR protect against airborne droplets, which are 5 μm or smaller and can remain suspended in the air for a long time and disperse widely. Such infections include tuberculosis, measles, varicella, herpes zoster, and the viral haemorrhagic fevers such as Lassa, Ebola, and Marburg viruses [10].

Standard droplets do not require a negative pressure room, but simply a single room along with gloves, gown, and mask. These droplets are larger than 5 μm and do not remain suspended in air as long or disperse as widely as the airborne droplets. Dispersal is typically limited to one meter. These infections include influenza, rubella, mumps, and meningitis (*Haemophilus influenzae* and *Neisseria meningitidis*) [10].

Contact precautions include single room and use of gown and gloves for each contact. In some settings and countries they are required for MRSA/glycopeptide intermediate *Staph. aureus*, VRE, *Clostridium difficile*, varicella, herpes zoster, and the viral haemorrhagic fevers (Lassa, Ebola, Marburg) [10]. Local epidemiology authorities may identify other pathogens, such as *Acinetobacter* spp., *Pseudomonas* spp., or other multi-drug resistant or Gram-negative bacilli that should have strict isolation precautions. These measures are reinforced by appropriate universal surveillance for pathogens, such as MRSA nasal swab, and VRE rectal swab, as well as by prompt recognition of diarrhoea or ileus prompting *Clostridium difficile* stool antigen and culture [11]. The routine use of isolation procedures (gown, gloves +/- masks) for all ICU patients has been favoured by some authors as a means to improve hand hygiene and more generally to decrease transmission of infections. While in some cases these more global isolation measures have been effective, the widespread use of mandatory isolation for all patients cannot be endorsed.

For immunosuppressed patients, a protective environment room is required, with the airflow directed out of the room and use of gloves, gown, and mask. Key opportunistic pathogens targeted include *Aspergillus* spp. and other airborne fungi, *Pneumocystis* spp., *Toxoplasma* spp., CMV, John Cunningham virus, tuberculosis, and *Mycobacterium avium* complex.

Staffing issues

Caregiver:patient ratio is a major contributor to staff stress level and understaffing clearly can lead to staff being overwhelmed and overburdened with increased chance of cross-contamination while moving between patient rooms. There may be more frequent trips required and less time to perform adequate hand hygiene. Hand hygiene campaigns and other educational interventions are useful reminders, but of limited impact in the face of inadequate staffing for the level of acuity and nursing activities. Other staffing approaches can include cohorting infected or colonized patients or cohorting staff caring for such patients to limit cross-contamination opportunities.

Patient specific interventions

Patient specific interventions for the prevention of transmission of pathogens include global measures such as providing daily chlorhexidine baths and frequent changes and skin care, use of linens made of cotton or other material designed to wick away moisture, maintenance of normothermia and glycaemic control, and proper antibiotic husbandry to cover likely pathogens while avoiding selection of resistant microbes.

Surveillance/quality control

Feedback about the efficacy of environmental cleaning and isolation strategies is paramount to achieving significant reduction in health care associated infection. Of particular importance, many currently employed cleaning and isolation strategies have a very limited evidence base. Many are simply intuitive or based on non-controlled observations. The cost of performing rigorous studies may be prohibitive. In addition, reduced colonization does not always translate to reduced infection rates. As one example, a crossover study of enhanced cleaning accomplished a significant reduction in MRSA hand carriage rate of HCW, but no change in the infection rate of patients. The authors calculated that data from at least 40,000 patients would be required to demonstrate a difference in MRSA infection rate with 80% power [12,13].

Quality control can be understood in terms of both process measures and outcome measures. Process measures could include education, checklists, or covert practice observation to assure that disinfectants are being diluted and applied properly, according to manufacturer recommendations for concentration, duration, and frequency [2,14]. Outcome measures include various forms of surveillance for post-clean contamination, such as swab or agar slide cultures, fluorescent gel, and adenosine

triphosphate (ATP) bioluminescence technologies [2,15,16]. They may also involve some assessment of the cost-effectiveness of different disinfection products and strategies. A key concept is that of measuring cleaning process (observation and fluorescent gel) versus cleanliness (swab and slide cultures, ATP bioluminescence) [2,16]. It is estimated that only 34% of surfaces currently are cleaned in accordance with institutional policy, providing a significant opportunity for improvement [2]. Data gleaned from such investigations should be utilized in recurrent educational programs to improve compliance with the best evidence based guidelines, promulgated by national authorities. Feedback rendered in a blame-free context with clear specific recommendations for improvement will yield the best result.

Conclusion

The care environment is an important factor in the transmission of health care-associated infections, but its role is incompletely understood. In particular, there is a limited evidence base for many currently employed cleaning and isolation techniques. There is, however, ample evidence of poor compliance with established cleaning and isolation protocols. Given the severe health and cost burden of health care-associated infections, increasing attention is being devoted to the impact of the environment of care. Work is ongoing to establish optimal regimens from an efficacy and cost perspective.

CHAPTER 286

Antimicrobial selection policies in the ICU

David L. Paterson and Yoshiro Hayashi

Key points

- Consider the potential source of infection when making empiric antibiotic choices.
- Local epidemiology in your intensive care unit (ICU) may differ from that published elsewhere.
- De-escalate antibiotics to the narrowest possible spectrum, when susceptibilities allow.
- Super bugs are now widespread in many ICUs—colistin is the last-line antibiotic and should be used prudently.
- Antibiotic stewardship is important in ICUs and pertains not just to initiation of antibiotics, but also to limiting duration of antibiotic courses.

Introduction

The selection of an antibiotic for an individual critically-ill patient depends on a number of factors. These include the patient's allergies and renal function, the likely bacterial and fungal pathogens typically found at the potential site of infection, prior isolation of antibiotic resistant pathogens, prior antibiotic use, the local epidemiology of antibiotic resistance, costs of comparator drugs, and the potential ecological effect of prescribed antibiotics. Five key policy issues determine antibiotic selection:

- The microbiological differential diagnosis.
- Use of epidemiology data.
- Adjusting antibiotic therapy with the aid of microbiology results.
- Special considerations for resistant organisms.
- Antimicrobial stewardship.

Microbiological differential diagnosis based on suspected source of infection and empiric regimens

Initial empiric antimicrobial therapy can be defined as the use of an antimicrobial for a patient with symptoms and signs of a serious infection prior to identification of the bacteria and the availability of susceptibilities. When making an initial antibiotic choice, definition of the likely location of infection based on clinical symptoms and signs and basic diagnostic testing is important because the microbiological differential diagnosis differs depending on the infection site (Table 286.1). For example, all of *Staphylococcus aureus, Enterococcus faecalis* and *Candida* spp. are frequent pathogens in intensive care units (ICU), but *S. aureus* is an extremely infrequent pathogen for urinary tract infection and neither *E. faecalis* nor *Candida* spp. typically cause pneumonia.

It is important to decide whether *Pseudomonas aeruginosa,* carbapenem resistant *Enterobacteriaceae/Acinetobacter* spp., MRSA, and/or *Candida* spp. need to be covered. As a general rule, most ICU-acquired infections such as late-onset ventilator-associated pneumonia (VAP) require both anti-pseudomonal and anti-MRSA cover, while most community-acquired infections do not except for special situations (e.g. MRSA cover for severe community acquired pneumonia where community-associated MRSA is endemic, especially following influenza infection). Fever in neutropenic patients requires anti-pseudomonal cover and most cases of undifferentiated ICU-acquired infections need both anti-pseudomonal and anti-MRSA cover in the initial therapy. The addition of antibiotics active against carbapenem-resistant Enterobacteriaceae or *Acinetobacter* spp. will depend on local epidemiology.

Before the initiation of any antibiotic treatment, obtaining appropriate specimens for culture, especially blood cultures, is crucial to facilitate subsequent important decisions such as antibiotic discontinuation, antibiotic rationalization, and duration of antibiotics (e.g. *Staphylococcus aureus* blood stream infection may require longer duration of antibiotic therapy).

Clinicians should be aware that some patients with symptoms and signs of a serious infection do not, in fact, have an infection at all. Systemic inflammatory response syndrome (SIRS) may have non-infectious aetiologies (e.g. burns, trauma, post-surgery, acute pancreatitis). Many non-infective pulmonary complications in mechanically ventilated patients (e.g. fluid overload, acute respiratory distress syndrome (ARDS)) mimic ventilator-associated pneumonia [1]. In these situations, antibiotic therapy is not only unnecessary, but creates an increased risk of disturbance of endogenous flora, potentially leading to *Clostridium difficile* infection or colonization with antibiotic-resistant bacteria [2,3]. Unfortunately even in the state-of-the-art practice, differentiation of these conditions is often difficult. Thus, daily review of antibiotic therapy by an experienced clinician is important.

Use of epidemiological data to guide antibiotic choice

Epidemiological data on antibiotic susceptibilities is a useful tool in the selection of empiric antibiotic therapy, because the expected reliability of each agent is significantly variable depending on the

Table 286.1 Microbiological differential diagnosis based on source of infection and suggested empiric antimicrobial regimen

Source of infection	Microbiological differential diagnosis	Possible empiric antimicrobial regimen
Community-acquired pneumonia	**No risk of multidrug resistant organisms:** *S. pneumoniae, H. influenzae, Legionella* spp., *Mycoplasma pneumoniae* **Risk of multidrug resistant organisms:** nosocomial GNB, such as *P. aeruginosa* in addition to the above **If CA-MRSA is of concern**	◆ Ceftriaxone + azithromycin ◆ Penicillin + doxycycline ◆ Piperacillin/tazobactam + azithromycin ◆ Cefepime + azithromycin ◆ Add vancomycin, clindamycin or linezolid to the above
Ventilator-associated pneumonia, hospital-acquired pneumonia, health care-associated pneumonia	**No risk of multidrug resistant organisms:** *S. pneumoniae, H. Influenzae, MSSA, sensitive E. coli and K. pneumoniae* **Risk of multidrug resistant organisms:** nosocomial organisms such as *P. aeruginosa*, ESBL-producing *E. coli* and *K. pneumoniae, Enterobacter* spp., *Serratia* spp., and MRSA in addition to the above	◆ Ceftriaxone (applicable to some northern European countries only) ◆ Piperacillin/tazobactam ± vancomycin ± amikacin ◆ Cefepime ± vancomycin ± amikacin ◆ Meropenem ± vancomycin ± amikacin
Community-acquired urinary tract infection	Mostly *E. coli*	◆ Ampicillin + gentamicin ◆ Ceftriaxone ◆ Ertapenem
Complicated urinary tract infection	*E. coli* including ESBL producer *P. aeruginosa*	◆ Piperacillin/tazobactam ±gentamicin ◆ Ertapenem ◆ Meropenem
Catheter-associated blood stream infection	*S. epidermidis* *S. aureus*, including MRSA *Enterococcus* spp. Nosocomial GNB including: *P. aeruginosa, Candida* spp.	Vancomycin + piperacillin/tazobactam ± fluconazole or echinocandin
Community-acquired intra-abdominal infection	Anaerobes, such as *Bacteroides* spp. GNB such as *E. coli*	◆ Ceftriaxone + metronidazole ◆ Ertapenem
Hospital-acquired intra-abdominal infection	Nosocomial organisms such as *P. aeruginosa*, ESBL-producing *E. coli* and *K. pneumoniae, Enterobacter* spp., *Serratia* spp., MRSA, *Enterococcus* spp., including VRE and *Candida* spp. in addition to the above	◆ Cefepime + metronidazole ± vancomycin ± fluconazole or echinocandin ◆ Piperacillin/tazobactam ± vancomycin ± fluconazole or echinocandin ◆ Meropenem ± vancomycin ± fluconazole or echinocandin
Complicated skin and soft tissue infection	**Community-acquired:** *S. pyogenes, S. aureus* (CA-MRSA where endemic), *Clostridium perfringens* **History of exposure to seawater/freshwater:** *Aeromonas hydrophila, Vibrio vulnificus* **Diabetic foot infection:** nosocomial organisms including MRSA and *P. aeruginosa*	◆ Penicillin G + clindamycin ◆ Meropenem + ciprofloxacin ◆ Piperacillin/tazobactam ± linezolid ◆ Meropenem ± linezolid
Community-acquired meningitis	*S. pneumoniae, Neisseria meningitidis* **If immunocompromised or age > 50:** *Listeria monocytogenes*	◆ High dose ceftriaxone + high dose vancomycin + aciclovir (until HSV negative) ◆ Add high dose ampicillin
Post-neurosurgical meningitis	*S. aureus* including MRSA, *S. epidermidis*, nosocomial GNB, including *P. aeruginosa*	◆ High dose vancomycin + high dose meropenem ◆ High dose vancomycin + high dose cefepime
Neutropenic fever	Nosocomial GNB including *P. aeruginosa, S. aureus*, including MRSA	◆ Cefepime + vancomycin ◆ Piperacillin/tazobactam + vancomycin ◆ Meropenem + vancomycin
Community-acquired undifferentiated sepsis	*S. pneumoniae, N. meningitidis*, sensitive GNB such as *E. coli*	**If meningitis is possible:** high dose ceftriaxone + high dose vancomycin + aciclovir ± gentamicin **If meningitis is unlikely:** piperacillin/tazobactam
Hospital-acquired undifferentiated sepsis	Nosocomial GNB, including *P. aeruginosa, S. aureus*, including MRSA, *Candida* spp. if risk factors present	◆ Piperacillin/tazobactam + vancomycin ± amikacin ± fluconazole or echinocandin ◆ Cefepime + vancomycin ± amikacin ± fluconazole or echinocandin ◆ Meropenem + vancomycin ± amikacin ± fluconazole or echinocandin

location (e.g. country, city, specific ICU). The following three methods can be used to increase the chance of adequate therapy.

Use of data from surveillance studies

Antibiotic resistance surveillance programs assist clinicians to ensure a substantial probability of effectiveness of empiric therapy [4]. For example, a Spanish nationwide surveillance of Enterobacteriaceae causing community-acquired urinary tract infection showed 56.7%, 30.3%, and 22.9% of *E. coli* isolates were non-susceptible to ampicillin, sulfamethoxazole-trimethoprim and ciprofloxacin, respectively [5]. Therefore, those agents would be a poor empiric choice for patients with suspected urosepsis in that country. National and international trends in antibiotic resistance, derived from sequential examination of surveillance data can also alert clinicians to a need to re-examine their empiric antibiotic choices. For example, the emergence of substantial degrees of fluoroquinolone resistance in *P. aeruginosa* described in national surveillance studies in the United States [6] necessitated discontinuation of use of fluoroquinolones as sole agents to cover Gram-negative bacilli (GNB) in empiric therapy for most of ICU-acquired infections.

Use of 'unit-based antibiograms' and 'combination antibiograms'

Unit-based antibiograms are cumulative antibiotic susceptibility reports from patients in a particular ward of the hospital (e.g. a specific ICU) in a specified time period. They are potentially more useful than international, national, or hospital-specific antibiograms for a prescriber making decisions about antibiotic therapy in a specific ICU. Unit-based antibiograms have been shown to have substantially different antibiotic susceptibility results compared to hospital-wide antibiograms [7,8].

Traditional antibiograms provide susceptibility data for organisms to a range of antibiotics, but do not answer the question of what antibiotic combinations may be optimal for providing coverage for any given organism. Combination antibiotic therapy is necessary as initial empiric antibiotic therapy for infections where *P. aeruginosa* is prominent, for example, because in most ICUs <90% *P. aeruginosa* strains are susceptible to any particular antipseudomonal beta-lactam [9]. Thus, for example, a traditional antibiogram does not give data as to what aminoglycoside or fluoroquinolone should be used in combination with a core antipseudomonal beta-lactam to ensure that initial empiric cover is optimized. A combination antibiogram provides information on the percentage of isolates susceptible to a particular antibiotic if the isolate is resistant to a core antipseudomonal antibiotic. For example, Bhat et al. [10] showed that, of the *P. aeruginosa* isolates resistant to cefepime in their institution, 19.5% were resistant to amikacin, 82.9% to ciprofloxacin, 43.9% to gentamicin, 87.8% to levofloxacin, and 39.0% to tobramycin. Therefore, in this case, combinations of cefepime plus amikacin would be much more likely to improve adequacy of initial empiric therapy than a combination of cefepime plus a fluoroquinolone. Unit-based, combination antibiograms can be constructed to complement individualized antibiotic choices.

Review of prior antibiotic use and previously isolated organisms with resistance profiles

Attention needs to be given to prior antibiotic use and previously isolated organisms with their resistance profiles because such knowledge could be useful to improve the adequacy of initial empiric therapy. For example, in one study [10], 37% of patients who received piperacillin/tazobactam in the month prior to the current infection were newly infected with a piperacillin/tazobactam-resistant strain and 64% of patients who had isolation of piperacillin/tazobactam-resistant GNB in the month prior to the current infection were now infected with piperacillin/tazobactam-resistant *P. aeruginosa*. Therefore, piperacillin/tazobactam was only considered appropriate initial empiric therapy if the patient had neither received the antibiotic nor had isolation of a piperacillin/tazobactam-resistant organism in the past month. Comparable findings were made with respect to cefepime. The policy to avoid antibiotics which were used in the last one month and antibiotics which have not demonstrated *in vitro* activity against bacteria from the patient in the last month may be useful not only to increase the chance of appropriate empiric treatment, but also to maintain antibiotic heterogeneity in the ICU.

Adjusting antibiotic therapy with the aid of microbiology results

Antibiotic rationalization should be considered at the following three stages: when formal identification is not completed, but the provisional identification is available, when the identification of organism is complete, but susceptibilities are awaited (which is now frequent with the advent of matrix-assisted laser desorption/ionization-time of flight (MALDI-TOF) mass spectrometry identification systems in many clinical laboratories), and when both identification and susceptibilities are complete. Even in empiric therapy with the best prediction strategy, antibiotic rationalization is often required in order to provide more reliable treatment than the initial therapy, to reduce the risk of antibiotic collateral damage, and to secure treatment for organisms which were initially not considered for the treatment, but revealed to have been the potential causative organism.

Optimizing choice for therapy when the organism is known, but susceptibilities are awaited

The new MALDI-TOF technology provides far more rapid organism identification than semi-automated technology used in laboratories over the last two decades. Close liaison with clinical microbiologists may allow clinical use of identification data to amend the initial regimen, even when susceptibility results are not available. For example, anti-pseudomonal therapy must be ensured if *P. aeruginosa* is identified. An important role of the microbiology laboratory is in alerting prescribers to the possibility of an organism not routinely covered by standard anti-pseudomonal therapy. For example, the identification of *Stenotrophomonas maltophilia* from respiratory specimens should allow treatment for this organism with co-trimoxazole, if there is a high clinical likelihood of VAP.

While MALDI-TOF systems in their current state do not provide rapid susceptibility results, they can be used to identify epidemic clones of multiply resistant organisms.

Earlier appropriate antibiotic therapy may be initiated for multi-resistant epidemic organisms, such as vancomycin-resistant enterococci (VRE), carbapenem-resistant *A. baumannii* or KPC- or extended-spectrum beta-lactamase (ESBL)-producing *K. pneumoniae* or *E. coli*, if the characteristic phenotype of these organisms is observed on incubation of specimens on solid media [11].

Direct susceptibility tests, although clearly not standardized, may also provide similar benefit. Bouza et al. demonstrated in

Table 286.2 Suggested antibiotics for definitive therapy

Causative organism	Antibiotics for definitive therapy	Alternative choice
Gram-positive cocci		
Enterococcus spp.	Ampicillin	Vancomycin (if ampicillin-resistant)
Staphylococcus aureus (MSSA)	Flucloxacillin, nafcillin, oxacillin	Cefazolin
Staphylococcus epidermidis	Vancomycin	
Streptococcus pneumoniae (penicillin sensitive)	Penicillin	Ampicillin, ceftriaxone
Group A, B, C, F, G streptococci	Penicillin	Ampicillin, ceftriaxone
Viridans streptococci	Penicillin	Ampicillin, ceftriaxone, vancomycin
Gram-positive bacilli		
Bacillus anthracis	Penicillin	Ampicillin, ciprofloxacin
Corynebacterium jeikeium	Vancomycin	Linezolid
Listeria monocytogenes	Ampicillin	
Nocardia spp.	Co-trimoxazole	
Gram-negative cocci		
Neisseria meningitidis	Penicillin G	Ampicillin, ceftriaxone
Gram-negative bacilli		
Aeromonas hydrophila	Ciprofloxacin	Co-trimoxazole
Achromobacter xylosoxidans	Meropenem	Co-trimoxazole
Acinetobacter baumannii	Colistin	Meropenem if susceptible
Burkholderia cepacia	Co-trimoxazole	
Campylobacter jejuni	Ciprofloxacin	
Citrobacter spp.	Cefepime	Ciprofloxacin, meropenem
Escherichia coli	Ceftriaxone	Meropenem (if ESBL producer)
Enterobacter spp.	Cefepime	Ciprofloxacin, meropenem
Haemophilus influenzae	Ampicillin	Ceftriaxone (if ampicillin-resistant)
Klebsiella spp.	Ceftriaxone	Meropenem (if ESBL producer); colistin (if carbapenem resistant)
Legionella pneumophila	Azithromycin	Ciprofloxacin
Proteus mirabilis	Ceftriaxone	Ciprofloxacin
Proteus vulgaris	Ceftriaxone	Ciprofloxacin
Pseudomonas aeruginosa	Piperacillin/tazobactam, ceftazidime, cefepime, meropenem, ciprofloxacin	Colistin
Salmonella spp.	Ceftriaxone	Ciprofloxacin
Serratia marcescens	Cefepime	Ciprofloxacin, meropenem
Shigella spp.	Ciprofloxacin	Co-trimoxazole, azithromycin
Stenotrophomonas maltophilia	Co-trimoxazole	Ciprofloxacin
Vibrio cholera	Ciprofloxacin	Co-trimoxazole
Vibrio vulnificus	Doxycycline + ·ceftazidime	
Clostridium difficile	Oral or intravenous metronidazole	Oral vancomycin
Non-difficile *Clostridium* spp.	Penicillin	Clindamycin
Mycoplasma		
Mycoplasma pneumoniae	Azithromycin	Levofloxacin, doxycycline

(*continued*)

Table 286.2 Continued

***Candida* spp.**		
Candida albicans	Fluconazole	Echinocandin
Candida tropicalis	Fluconazole	Echinocandin
Candida parapsilosis	Fluconazole	Echinocandin
Candida glabrata	Echinocandin	
Candida krusei	Echinocandin	
Candida lusitaniae	Echinocandin	

randomized controlled trials (RCT) with VAP patients that the rapid reporting of susceptibility testing of respiratory specimens led to decreased antibiotic consumption, decreased rates of *C. difficile* infection, and fewer days of receiving mechanical ventilation than the standard procedure group [12].

Despite not being final susceptibilities, early amendment of the initial empiric antibiotics with the these interventions may provide some clinical benefit.

'Fine-tuning' therapy when identification and susceptibilities are complete

When identification and susceptibility testing results are available for the clinician, antibiotic regimens can be 'fine-tuned.' Although it is sometimes not feasible in the treatment of serious infections, de-escalation is a reasonable and favourable strategy if the causative organism is found to be treatable with narrower spectrum antibiotics than used empirically. This may not only minimize antibiotic collateral damage, but also provide more reliable therapy. For example, anti-staphylococcal penicillins such as flucloxacillin or nafcillin have a superior track record in the treatment of serious infections due to meticillin sensitive *S. aureus* (MSSA) than vancomycin or carbapenems, although these agents may be active against MSSA. Continuous use of broad spectrum antibiotics is more likely to lead to risks of antibiotic collateral damage such as *C. difficile* associated disease and emergence of carbapenem-resistant GNB than use of an antibiotic only active against MSSA. Antibiotics for the definitive therapy of common organisms in ICU are shown in Table 286.2.

Table 286.3 Antibiotic therapy for drug-resistant organisms

Causative organism	Antibiotics for definitive therapy	Alternative choice
Hospital-associated MRSA	Vancomycin	Linezolid for pneumonia, and skin and soft tissue infection daptomycin for blood stream infection, but not for pneumonia
Community-associated MRSA	Linezolid	Vancomycin + clindamycin
Vancomycin non-susceptible *S. aureus*	Linezolid for pneumonia and skin and soft tissue infection daptomycin for blood stream infection, but not for pneumonia	
Vancomycin -resistant *E. faecalis*	High dose ampicillin (if sensitive) linezolid	Daptomycin
Vancomycin-resistant *E. faecium*	Linezolid	Daptomycin
Penicillin-resistant *S. pneumoniae* (non-meningitis)	High dose ampicillin	High dose ceftriaxone vancomycin
Penicillin-intermediate *S. pneumoniae* (meningitis)	High dose ceftriaxone	Vancomycin
Penicillin-resistant *S. pneumoniae* (meningitis)	High dose vancomycin + high dose ceftriaxone + rifampicin	
ESBL-producing Enterobacteriaceae	Meropenem	Ciprofloxacin (if sensitive) Amikacin (if sensitive)
Carbapenem-resistant Enterobacteriaceae	High dose meropenem extended infusion + colistin + tigecycline	Amikacin (if sensitive)
Pan-beta-lactam and quinolone resistant *P. aeruginosa*	Colistin	Amikacin (if sensitive)
Carbapenem-resistant *A. baumannii*	Colistin	High dose ampicillin/sulbactam (if sensitive)

Special considerations for drug-resistant organisms

Issues of antibiotic resistance in ICU have become increasingly serious across the globe. This pertains not only to relatively resistant bacteria in nature such as *P. aeruginosa* and *A. baumannii*, but also those which used to be susceptible to a wide variety of antibiotics, such as *S. aureus, E. coli*, and *K. pneumonia.* MRSA and multiply resistant *K. pneumoniae* and *E. coli* have already become common issues in many ICUs. At an extreme end of the spectrum are ICUs in some parts of the world where 90% of *A. baumannii* isolates, > 50% of *P. aeruginosa* isolates and >75% of *K. pneumoniae* isolates are resistant to carbapenems. Treatment for resistant organisms may require specialist input from Infectious Diseases Physicians or Clinical Microbiologists. Table 286.3 summarizes antibiotic choice for representative resistant organisms in ICU.

Working in an institutional framework: antimicrobial stewardship programs

Antimicrobial stewardship programs have become an integral component of most large hospitals. As stated in the Infectious Diseases Society of America and Society of Health Care Epidemiologists of America guidelines on antimicrobial stewardship programs, the primary goal of such programs is to optimize clinical outcomes while minimizing unintended consequences of antimicrobial use such as toxicity, the selection of pathogenic organisms (for example, *Clostridium difficile*) and the emergence of resistance. This goal should be compatible with care of patients with suspected infections in the ICU.

However, the execution of antimicrobial stewardship programs in the ICU environment may be quite different from that of a ward environment. 'Front-end' approvals, whereby a prescriber seeks approval from a physician or pharmacist from the Antimicrobial Stewardship Program, are rarely employed in ICUs. The major reason for this is the need for no delays in administration of antibiotics to septic patients. However, there is a role for discussion of choice of antibiotic with an Infectious Diseases Physician or Clinical Microbiologist, particularly when the patient is likely to be infected with a multidrug resistant pathogen. Other major contributions of antimicrobial stewardship programs in the ICU are: (1) to help create antibiotic guidelines for empiric choice of antibiotics, and (2) to help limit duration of antibiotic choices.

Conclusion

In summary, clinicians should apply logic in their selection and use of antimicrobials in the severely ill patient, rather than to use a 'tradition-based' method of selecting treatment. Tradition is hard to break, but results in patients receiving inappropriate antibiotics as well as contributing to the development of resistance in bacteria through increased selection pressure. Information is available with which to make a more logical choice of antibiotic, and closer liaison with microbiologists, antimicrobial pharmacists and infectious diseases physicians will greatly facilitate the decision-making process.

CHAPTER 287

Oral, nasopharyngeal, and gut decontamination in the ICU

Evelien Oostdijk and Marc Bonten

Key points

- Selective decontamination of digestive tract (SDD) aims to eradicate micro-organisms from the intestine, the stomach, and the oropharynx by non-absorbable antibiotics, which are combined with systemic antibiotic prophylaxis during the first days of ICU admission.
- An alternative to SDD is selective oropharyngeal decontamination (SOpD) alone.
- Both SDD and SOpD pursue decontamination of the oropharynx to prevent ventilator associated pneumonia.
- Dutch studies show SDD and SOpD are associated with reduced ICU-mortality, ICU-acquired bacteraemia with Gram-negative bacteria, and systemic antibiotic use.
- It is currently unknown to what extent these effects can be achieved in settings with different bacterial ecology.

The concept

In 1971 the concept of colonization resistance was proposed by van der Waaij et al. [1], who suggested a beneficial effect of the anaerobic flora in resisting colonization by aerobic Gram-negative bacilli in the digestive tract in ICU patients. Many infections are caused by enteric bacilli, presumably from endogenous origin. Selective decontamination of the digestive tract (SDD) was developed to selectively eliminate the aerobic Gram-negative bacilli from the digestive tract, leaving the anaerobic flora unaffected. The first clinical studies with SDD were performed in granulocytopenic patients yielding favourable results [2]. In the early 1980s, Stoutenbeek and co-workers [3] adapted the principle for ICU patients. The full concept of SDD aims to eradicate micro-organisms from the intestine, the stomach, and the oropharynx by non-absorbable antibiotics, which are combined with systemic antibiotic prophylaxis during the first days of ICU admission. In the SDD regimen the combination of colistin and an aminoglycoside are generally used, both are effective against Gram-negative bacilli and *Staphylococcus aureus*, non-absorbable and do not affect the anaerobic intestinal flora. Amphotericin was added to prevent overgrowth with yeasts and systemic prophylaxis to prevent early infections. Since the introduction of this preventive strategy, more than 45 randomized studies and multiple observational studies in a variety of ICU populations have been performed [4]. However, there are large differences in the regimens of SDD that were studied, the endpoints used, and the designs applied.

Several meta-analyses of SDD studies have been published, with more or less comparable results. They generally conclude that SDD decreases the incidence of ventilator-associated pneumonia (VAP) caused by aerobic Gram-negative bacteria with relative risk reduction (RRRs) ranging from 0.40 to 0.78, although reported outcomes regarding prevention of VAP were related to the methodological quality of the individual studies [5].

As an alternative to SDD, investigators have evaluated the effects of oropharyngeal decontamination alone [6,7]. In a prospective randomized placebo-controlled double-blind study, 87 patients received topical antimicrobial prophylaxis in the oropharynx and 139 patients received placebo. The aim of the study was to prevent VAP by modulation of oropharyngeal colonization, without influencing gastric and intestinal colonization and without systemic prophylaxis. Oropharyngeal colonization present on admission was eradicated in 75% of the patients (4% among control patients) and only 10% of study patients acquired oropharyngeal colonization, as compared to 61% of control patients. There were no significant differences in gastric and intestinal colonization. This regimen resulted in a RRR for VAP of 0.62 (95% CI 0.26–0.98) [6].

Experience with SDD/SOpD in the Netherlands

Most detailed data on the effects of SDD and SOpD in ICU-patients come from two studies performed in Dutch ICUs [7,8] The ecological setting of these ICUs is characterized by low levels of antibiotic resistance: For instance, prevalence of meticillin-resistance among *Staphylococcus aureus* isolates was <1%, of vancomycin-resistance among enterococci was <1%, and of extended-spectrum betalactame production among Enterobacteriaceae was <5%.

In the first study two ICU-wards, within a single university hospital, were compared. In one unit all eligible patients (n = 466) received during a two-year period SDD and in the other unit none of the 468 admitted patients received SDD [8]. Eligibility was defined as an expected duration of intubation of at least 48 hours or an expected stay in ICU of at least 72 hours if not intubated. The second study was a multicentre cluster-randomized cross-over study in 13 ICUs in the Netherlands [7]. During study-periods of six months all eligible patients (same criteria as in [8]) in a single unit received SDD, SOpD or standard care (no SDD and no SOpD), and all three regimens were applied in random order in all participating ICUs. The SDD-regimen was identical in both studies and in both studies interventions were applied for all patients eligible. As

SDD and SOpD pursue a change in the bacterial ecology within the unit, a study design in which all patients are exposed to the same procedures in time is the best to quantify effectiveness. If patients are individually randomized decontaminated patients may offer some protection against acquired colonization and subsequent infection in those receiving standard care, and vice versa, and this will underestimate true effectiveness.

Effects on patient outcome

In both studies the 'classical' SDD regimen (tobramycine, colistine and amphotericin B) was, compared to a control population (no SDD/SOpD), and SDD and SOpD were associated with reduced mortality. In the cluster-randomized study both SOpD and SDD were associated with a lower day-28 mortality. Compared to the control population, the RRR for day-28 mortality was 11% and 13% for SDD and SOpD, corresponding to an absolute mortality reduction on day-28 of 2.9% and 3.5% for SDD and SOpD [7]. In the single-centre study the RRR for ICU- and hospital-mortality was 35% and 22%, respectively [9].

The design of both studies had, undoubtedly, many advantages as compared to a study with randomization of individual patients, but had, inevitably, also some disadvantages. In a cluster-randomized design individual patients are not randomized, which may facilitate inclusion bias. In the cluster-randomized study patients included in the control population had—at the time of ICU-admission—on average a lower APACHE-II score, were less frequently mechanically ventilated and were more frequently admitted for surgical reasons. All these determinants are associated with a better prognosis. A random-effects logistic-regression model was used to adjust for these baseline differences, which may not adjust for all confounders. In the single-centre study SDD was applied in one ICU-ward only and the availability of beds determined in which ICU a new patient was admitted. Although baseline characteristics were comparable for both groups, residual confounding cannot be ruled out. Nevertheless, both studies provide convincing evidence that SDD and SOpD reduce ICU-mortality under the circumstances tested.

Effects on ventilator-associated pneumonia

Both SDD and SOpD pursue decontamination of the oropharynx to prevent VAP. In many studies the incidence of VAP, therefore, was the primary study endpoint, though this comes with major methodological problems. The most widely used combination of clinical, radiographic, and microbiological criteria are partly subjective and have suboptimal specificity, as other conditions, such as acute respiratory distress syndrome (ARDS), may have a similar clinical presentation. Bronchoalveolar lavage with quantitative microbiological cultures of obtained samples has a higher specificity, but this invasive approach is used infrequently for routine diagnostic purposes. The use of subjective criteria for endpoint determination in the absence of blinding may introduce considerable bias. Only few studies quantified the effects of decontamination on VAP incidence using both a double-blind placebo-controlled design and invasive diagnostics with quantitative culturing in all patients with a clinical suspicion of VAP. In one such study, in the Netherlands, the RRR of VAP was 55% when applying SOpD ($p < 0.05$) [6]. There are several meta-analyses in which SDD and SOpD are associated with statistically significant reductions in the incidence of VAP, but the before-mentioned methodological drawbacks apply to almost all individual studies included in these analyses.

Effects on ICU-acquired bacteraemia, antibiotic use and costs

In the Dutch multicentre study the RRR of ICU-acquired bacteraemia caused by enteric Gram-negative bacteria was, compared to standard care, 81% and 30% for SDD and SOpD, respectively [7]. The incidence difference between SDD and SOpD also reached statistical significance, and results from a post-hoc analysis suggest that this difference in effectiveness resulted from successful intestinal decontamination, that is pursued during SDD, but not during SOpD.

In the Dutch multicentre study SDD and SOpD were associated with a 10% reduction in systemic antibiotic use, which included the routine use of cefotaxim during the first four days as part of SDD. As part of SDD it is recommended not to prescribe antibiotics with anti-anaerobic activity, which resulted in a decline in the intravenous use of clindamycin, piperacillin-tazobactam, and carbapenem antibiotics and in a relative increase of 85% in the use of cephalosporins [7].

The results of this multicentre study were used to determine the cost-effectiveness of SDD and SOpD, in which costs for microbiology, antibiotics, and length of stay were compared to the benefits of life years gained, based on hospital mortality data. Both SOpD and SDD were associated with lower cost and were more effective than standard care. Even if the daily costs of the topical medication would increase tenfold (from €4 to €40 for SOpD and from €40 to €400 for SDD) SOpD would remain cost-saving. In such a scenario the costs of SDD would be €21,590 per life year gained.

Effects on antibiotic resistance

The benefits of SDD and SOpD should be carefully balanced against the potential disadvantages in the short-term, but also in the long-term. These include resistance against any of the antibiotics used and increased transmission of antibiotic-resistant bacteria in general because of the higher antibiotic pressure induced. In a systematic review and meta-analysis of 64 studies there was no evidence of a higher incidence of acquisition of resistance during SDD, as compared to control populations [4]. In the two Dutch studies SDD and SOpD were strongly associated with reduced incidences of infection and carriage with antibiotic-resistant bacteria (Table 287.1) [7,9]. As compared to SOpD, SDD offered better protection against ICU-acquired bacteraemia with antibiotic-resistant bacteria and against acquired carriage of the respiratory tract with Gram-negative bacteria intrinsically resistant to colistin and with acquired resistance for third-generation cephalosporins. The latter is quite remarkable, as the use of these antibiotics had increased with 85% during SDD.

The ecological effects of SDD and SOpD were determined through monthly one-day point prevalence surveillance of all patients present in any of the 16 participating ICUs [8]. The implementation of SDD/SOpD was immediately followed by a decline in the prevalence of antibiotic-resistant Gram-negative bacteria in the respiratory tract, but during the months that the interventions were used the prevalence of ceftazidim resistance increased (β 0.09 ($p < 0.05$). After discontinuation of SDD/SOpD the prevalence returned to pre-intervention levels. Similar observations were made for intestinal carriage: a rapid decline in prevalence after implementation of SDD, and a rapid return to pre-intervention prevalence levels after discontinuation. Only for ceftazidim resistance prevalence levels

Table 287.1 Overview of various endpoints obtained from Dutch randomized studies comparing SDD and/or SOpD to control

Endpoint		SDD versus control	SOpD versus control	SDD versus SOpD
Mortality	Day 28	RRR 13% [7]* ($p < 0.05$)	RRR 11% [7]* ($p < 0.05$)

PC, personal communication; Effects of Decontamination of the Digestive and Oropharynx in ICU Patients on one-year survival, Oostdijk E.A.N. De S with A.M.G.A., Bonten M.J.M., On behalf of the Dutch SOD-SDD trialists group, accepted for publication.

Data from: Oostdijk EA et al., 'Effects of Decontamination of the Digestive and Oropharynx in ICU Patients on one-year survival', *Journal of the American Medical Association*, 2014, **312**(14), pp. 1429–37; and various sources, see references.

remained elevated after SDD, as compared with pre-intervention. Stable and low prevalence levels of resistance during SDD were observed in longitudinal studies from Germany and Spain [10,11]. However, there are also reports of higher prevalence of carriage with Gram-positive bacteria during SDD, including MRSA, and of outbreaks with ESBL-producing Gram-negative bacteria.

Colistin is an old antibiotic, increasingly used worldwide as a last resort agent to treat infections with multiple antibiotic-resistant Gram-negative bacteria. Little is known about the mechanisms of resistance to colistin, but long-term intravenous treatment is considered an important risk factor. In Dutch ICUs daily use of topical colistin, as in SDD and SOpD, was not associated with acquired

carriage of colistin-resistant Enterobacteriaceae in the respiratory tract [12]. Observed rates of acquired carriage were 1.1, 0.7 and 0.8 per 1000 patient days at risk during SOpD, SDD and control, respectively. For rectal carriage (only measured during SDD) comparable rates were observed, but the risk increased (to 15.5 per 1000 patient days at risk) in patients colonized with tobramycin-resistant Enterobacteriaceae.

Eradication or suppression of carriage reduces colonization pressure, and as such SDD has been applied successfully as a control measure (together with other interventions) during outbreaks, for instance in France and the UK [13,14]. In the Dutch setting, eradication of intestinal carriage with Enterobacteriaceae during SDD was equally successful for strains that were susceptible or resistant to third-generation cephalosporins. Eradication, was less effective, if these bacteria were also resistant to tobramycin [15]. In Israel SDD (with gentamycin and polymyxin E) was tested in a double-blind placebo-controlled trial for its effectiveness in eradicating carriage with carbapenem-resistant Gram-negatives [16]. Among those that received SDD 61% had a negative rectal culture after 2 weeks, as compared to 16% in the placebo group (OR 0.13 (0.02-0.74)). All throat cultures were negative after one week in SDD patients, as compared to 14.2% in the placebo group. Nevertheless, after discontinuation of SDD, carriage rates rapidly increased again.

Adverse events

The oral paste used in SDD and SOpD may cause oesophageal obstruction if not dispelled carefully before application of the next dosage. Furthermore, sustained use of SDD may lead to some absorption of tobramycin from the intestinal tract. For instance, 83 of 100 patients had detectable tobramycin levels in blood (>0.050mg/L) [17], and 12 out of 19 patients that received both continuous venovenous haemofiltration and SDD had detectable tobramycin levels, in one patient being toxic (>3.0mg/L) [18].

The recent large studies performed in Dutch ICUs have provided strong evidence that, in that particular ecological setting, SDD and SOpD reduce ICU-mortality, ICU-acquired bacteraemia with Gram-negative bacteria, and systemic antibiotic use in a cost-effective manner. During a period of ten years there was no evidence that SDD or SOpD were associated with increased resistance in these ICUs. If any, both measures were associated with reductions in systemic antibiotic resistance. These counterintuitive observations might result from the overall lower usage of systemic antibiotics or from the fact that the topical antibiotics are still active against many resistant bacteria. Yet, all studies have used conventional culture techniques that may suffer from antibiotic carryover effects, and it is currently unknown to what the non-culturable flora is affected by SDD and SOpD. In Dutch ICUs SDD and SOpD appear equally effective on relevant clinical outcomes, such as survival and length of stay. SDD seems more protective against ICU-acquired bacteraemia and respiratory tract carriage with resistant Gram-negative bacteria, and SOpD seems to have a more attractive cost-effectiveness profile.

It is currently unknown to what extent these effects can be achieved in settings with different bacterial ecology. Although successful application has been reported from several, solitary, ICUs across Europe, more studies are needed. The potential threat of enhanced selection of pre-existing multiresistant pathogens is becoming more important, with the current emergence of carbapenem-resistant pathogens. Nevertheless, if similar effects would be achieved as in Dutch ICUs, these interventions could save 7,000 deaths per year in British ICUs, only. The use of SDD (or SOpD) as a measure to control outbreaks with multidrug resistant bacteria, that could not be controlled with classical infection control measures, should strongly be discouraged, until more data on its ecological safety and effectiveness have been obtained.

CHAPTER 288

Diagnosis, prevention, and treatment of device-related infection in the ICU

Walter Zingg and Stephan Harbarth

Key points

- Many patients in the intensive care unit (ICU) suffer from one or several device-related health care-associated infections (HAI).
- Intrinsic factors such as age, immunosuppression, neutropenia, or multi-organ failure are preconditions for HAI, but the main risk comes from breaches in aseptic technique of using medical devices.
- Emerging resistance due to the use of broad-spectrum antibiotics and poor infection control is a major challenge in the treatment of device-related HAI.
- Device-related HAI are preventable, but implementation of best practice in infection control is not easy.
- Successful prevention programmes offer a comprehensive protocol; follow a multidisciplinary approach in preparation, and a multimodal training and education programme in implementation.

Introduction

Many patients in the intensive care unit (ICU) suffer from one or several device-related health care associated infections (HAI) during their stay, including central line-associated bloodstream infections (CLABSI), ventilator-associated pneumonia (VAP), and catheter-associated urinary tract infection (CAUTI). Such infections are related to the use of medical devices, such as central lines, intratracheal tubes, and urinary catheters. Utilization ratios expressed as device-days per hospital-days can be up to 70, 50, and 80% for central lines, ventilators, and urinary catheters, respectively. Although factors on the patient side, such as immunosuppression, neutropenia, age, or multi-organ failure are important preconditions, device-related factors such as dwell-time or breaches in aseptic technique are the predominant risk factors for HAIs in the ICU. Shortcomings in structure and organization, such as low nurse-to-patient ratio, high bed-occupancy, or high ratios of float and pool nurses interfere with the use of medical devices and, thus, are equally important [1–3].

Catheter-associated bloodstream infections

Epidemiology

Almost half of all positive blood cultures obtained in a hospital are due to nosocomial BSI. Of these, most are primary and associated with central catheters. CLABSI represent 10–15% of all HAIs in intensive care [4] and the incidence density is two to seven episodes per 1000 catheter-days, depending on ward type, institution, and geographical region. CLABSIs are associated with increased length of stay (7–20 days), additional costs (US$ 3,000–40,000), and an attributable mortality of 2–12% [5].

Microbiology

In most institutions, a shift in predominant organisms from Gram-negative bacilli to Gram-positive cocci has been observed over the past two decades. However, in countries with limited resources, Gram-negative pathogens and, among these, non-fermentative organisms such as *Pseudomonas* species and *Acinetobacter* species are predominant. The shift towards Gram-positive cocci observed in high-resource countries is largely due to the use of intravascular devices and the fact that the proportion of patients with risk factors, such as neutropenia, solid organ and bone marrow transplantation, or the use of immunosuppressive agents has increased. Coagulase-negative Staphylococci (CoNS) are the most common pathogens isolated from blood cultures. Often considered as contaminants, their detection may not always be harmless and an associated mortality up to 18% has been reported. However, mortality from CoNS is usually much lower, while mortality from *Staphylococcus aureus* can be as high as 25%. Detection of *S. aureus* on a catheter tip is a predictor for subsequent bacteraemia, even in the absence of clinical signs and negative blood cultures at the time of catheter removal. The proportion of *Candida* species has considerably increased in many institutions, mainly due to prolonged treatments with multiple and broad-spectrum antibiotics and the use of total parenteral nutrition. CLABSI due to *Candida* species has a poor prognosis with an attributable mortality between 15 and 55%, especially when antifungal treatment is delayed by 3 or more days. An important shift in the epidemiology has occurred over the past decades with decreasing infections due to *C. albicans,* but increasing

infections due to non-albicans isolates, particularly *C. glabrata*. The latter represents an important problem as this species is often resistant to azoles.

Diagnosis

CLABSI is diagnosed by combining clinical signs, such as fever or systemic inflammatory response syndrome (SIRS), with microbiological cultures. If the central line is the most probable source of infection, it should be removed and the tip cultured. Detection of identical species with the same susceptibility testing confirms the catheter as a source. Alternatively, blood can be obtained from the catheter and from a peripheral vein. If the growth time of the blood sampling from the catheter is shorter than the growth time of the blood sampling from the peripheral vein by two hours or more, the central line is the most likely source for the bloodstream infection [6]. This test is called differential time to positivity and has the advantage that the catheter can be left in place.

Treatment

The management of suspected CLABSI in the ICU combines early antimicrobial treatment and the active search for sources other than the catheter. The choice of antibiotics must include at least a substance active against Gram-positive and non-fermentative micro-organisms, taking into account the local susceptibility pattern of bacteria and whether the patient was transferred from a country with a high prevalence of resistance. Immunocompromised or neutropenic patients should receive also an antifungal agent active against *Candida* species. Immediate effective treatment is important as either delayed or inappropriate antibiotic treatment is associated with increased morbidity and mortality. A multidisciplinary approach with close collaboration between the physician in charge of the patient, the infectious disease specialist, and the microbiology laboratory, improves the accuracy of the empiric therapy. Once susceptibility testing from micro-organisms identified from blood cultures is available, antibiotic treatment should be adjusted accordingly. Procalcitonin-based de-escalation of antibiotic therapy can be helpful to reduce antibiotic use. If CLABSI is confirmed, the central line should be removed and a new catheter inserted at a different site. Guide-wire exchange is a risk for recurrent BSI and should be avoided. Recent data suggest that an antibiotic lock in addition to a systemic antibiotic therapy can be used as a salvage strategy in long-term catheters if signs of exit site or tunnel infection are absent and blood cultures reveal the presence of CoNS or enterococci. Removal is mandatory in severe or complicated infections, in the presence of shock, recurrent BSI, and when *S. aureus*, Gram-negative bacilli, or *Candida* species are isolated. Relapse, continuous fever, or bacteraemia despite catheter removal requires active search for complications, such as endocarditis, metastatic abscess, or septic thrombophlebitis.

Prevention

CLABSI prevention programmes must focus on best practice with evidence-based guidelines on catheter insertion and catheter care. The strategy should be multidisciplinary and multimodal to encourage adoption and implementation [7-9]. Further, reduction can be achieved by using chlorhexidine-impregnated dressings, catheters coated with chlorhexidine/silver sulfadiazine or antibiotics, or by daily bathing the patients with chlorhexidine [10]. Lock-solutions with taurolidine, citrate, ethylenediaminetetraacetic acid (EDTA), or ethanol reduce catheter colonization, but still have to prove their efficacy in CLABSI reduction under routine working conditions.

Ventilator-associated pneumonia

Epidemiology

VAP is the most frequent nosocomial infection in critical care, contributing between 30 and 50% to the total number of HAIs. Published VAP rates range widely from 2.5 to 35.7 episodes per 1000 ventilator-days due to case-mix variations, inconsistent use of diagnostic tools, varying definitions, and different reporting modalities. VAP is associated with attributable costs of US$10,000–25,000, which is mainly due to an excess length of stay by 5 to 7 days. Attributable mortality is estimated at about 10–30% [11]. It is particularly high in VAP due to *S. aureus* and is associated with severe sepsis.

Microbiology

The most common pathogen is *S. aureus*, followed by *P. aeruginosa, Haemophilus influenzae, Klebsiella* species, *Streptococcus pneumoniae*, and *Escherichia coli*. Early onset VAP is due more often to *S. pneumoniae* and *H. influenzae*, while late onset VAP is due mainly to *S. aureus* (including meticillin-resistant *S. aureus* (MRSA)) and non-fermentative bacteria, such as *P. aeruginosa*.

Diagnosis

The diagnosis of VAP relies on clinical signs, such as fever, onset of purulent secretions, or worsening gas exchange in combination with radiological findings, such as infiltrates, consolidates, or cavitations. Positive blood cultures, if not related to another infection, contribute to the diagnosis. The addition of quantitative culture samples obtained by bronchoscopic techniques improves diagnostic accuracy by reducing the number of VAP diagnoses by 30% to 50%.

Treatment

Given the high risk of mortality, early and appropriate, broad-spectrum antibiotic therapy should be prescribed with adequate doses to optimize antimicrobial efficacy. An empiric therapy regimen should be installed, including agents from different antibiotic classes than the patient has recently received. VAP due to *P. aeruginosa* should be treated with a beta-lactam antibiotic in combination with an aminoglycoside. Linezolid is an alternative to vancomycin in the treatment of VAP due to MRSA. Infections due to carbapenem-resistant Gram-negative micro-organisms should be treated with a regimen including colistin. De-escalation of antibiotics should be considered once susceptibility data are available. If lower respiratory tract cultures are negative and the patient has improved clinically after 72 hours, antibiotics may be stopped at that time. A treatment duration of 8 days is recommended for patients with uncomplicated VAP who have received an appropriate therapy initially with a good clinical response and with no evidence of infection due to non-fermenting Gram-negative bacilli [12].

Prevention

Similar to CLABSI prevention, a multimodal strategy with strong emphasis on process control should be established. The

components of such a comprehensive intervention programme include:

- Hand hygiene, preferably using alcohol-based hand rub.
- Glove and gown use for endotracheal tube manipulation.
- Backrest elevation to 30–45°.
- Maintenance of tracheal cuff pressure of 20 cmH_2O.
- Use of orogastric tubes.
- Gastric overdistension avoidance.
- Good oral care with chlorhexidine.
- Elimination of non-essential tracheal suctioning.

Good compliance with such techniques has been shown to reduce VAP-rates by 50% [13]. There is evidence that subglottic secretion drainage is effective in VAP prevention.

Catheter-associated urinary tract infection

Epidemiology

The prevalence of CAUTI in the ICU is 12–20% [4] with an incidence density of 1 to 5 episodes per 1000 catheter-days [14].

Microbiology

Similar to non-ICU settings, Enterobacteriaceae (*E. coli, Klebsiella* species, *Proteus* species, *Enterobacter* species, *Citrobacter* species, *Providencia* species, *Serratia* species, *Morganella* species) are the predominant pathogens in CAUTI. However, non-fermentative micro-organisms, such as *Pseudomonas* species, *Acinetobacter baumannii*, and *Stenotrophomonas* species are also isolated. Gram-positive bacteria, such as *Enterococcus* species and *S. aureus* are less frequently identified.

Diagnosis

The definition of CAUTI in the ICU is controversial and challenging as clinical signs such as urgency, frequency, dysuria, or suprapubic tenderness cannot be assessed in sedated patients. The only clinically useful sign is fever. In practice, CAUTI diagnosis is likely if the patient has a fever without apparent source and confirmed by a positive urine culture ($\geq 10^5$ micro-organisms per cm^3 of urine with no more than two species of micro-organisms).

Treatment

CAUTI treatment must take into account antibiotic susceptibility testing from identified micro-organisms. Pre-emptive therapy of ICU-acquired CAUTI must include an antibiotic with activity against Enterobacteriaceae and non-fermentative micro-organisms. Emerging resistance in Gram-negative bacteria is a real concern. Enterobacteriaceae, in most countries harbour extended-spectrum beta-lactamases, in particular *Klebsiella* species and *E. coli*, and carbapenem resistance is emerging worldwide.

Prevention

Most guidelines recommend limiting catheter use by evaluating the necessity of catheterization and reviewing the ongoing need for urinary catheters. Catheter insertion should use an aseptic technique with sterile equipment. Whether silver alloy or antibiotic-impregnated catheters reduce the risk of infection remains a controversial issue. However, there is consensus to use the smallest bore catheter. For catheter maintenance, a closed drainage system should be used, routine irrigation should be avoided, and the drainage bag must be placed below the level of the bladder. Routine urine cultures must be avoided as asymptomatic bacteriuria should not be treated. Systemic antibiotic prophylaxis is not recommended outside urinary tract malformations in small children [15].

Implementation of best practice

The successful implementation of best infection control practices is not an easy task. It depends on individuals, the hospital setting, the local and national context, the design of the prevention programme and how it is structured and conducted [16]. Successful prevention programmes offer a comprehensive protocol; follow a multidisciplinary approach in the preparation phase, and a multimodal training and education strategy in the implementation phase [17]. Education and training sessions should be as practical as possible and actively involve frontline workers, e.g. in workshops, simulator training, and focus groups [17]. Distributing guidelines or merely promoting bundles is insufficient to motivate health care workers to change practice [17]. Messages must be embedded in a multimodal training strategy and actively supported by the top leaders [18]. Champions who actively lead efforts to implement best practices in their teams and a positive organisational culture by fostering working relationships and communication across units and staff groups help in the implementation process. Surveillance of process indicators or outcomes, such as CLABSI, VAP, or CAUTI, preferably in a surveillance network similar to US National Healthcare Safety Network, the German nosocomial infection surveillance system (KISS), or the International Nosocomial Infection Control Consortium (INICC), and in combination with timely performance feedback to health care workers at the frontline help to maintain best practice.

CHAPTER 289

Antibiotic resistance in the ICU

Jonathan Edgeworth

Key points

- Most countries are documenting a steady increase in antimicrobial resistance amongst common bacterial pathogens found on the ICU.
- The increase in antimicrobial resistance, particularly amongst Gram-negative bacteria compromises empiric therapy choices and can lead to selection of strains that are resistant to essentially all available antibiotics.
- Infection prevention, control, and antimicrobial stewardship programmes aim to limit the selection and transmission of resistance on the ICU.
- The ability of successful antibiotic-resistant clones to become pandemic necessitates a co-ordinated global response beyond local measures introduced on individual ICUs and health care institutions.
- Advances in rapid diagnostics holds promise of providing identification and information on antimicrobial resistance of bacterial pathogens at the time of initial decision making in the treatment of septic patients on ICU.

Principles of pathogenesis and treatment of ICU-acquired infections

Infections dealt with on a general intensive care unit (ICU) can be defined as either community-associated or health care associated. Community-associated infections usually involve organisms with defined virulence factors conferring the ability to colonize surface epithelia, invade the host and then evade the immune system. In the pre-antibiotic era many were known to have a high mortality. Health care and more specifically ICU-associated infections usually involve organisms capable of colonization, but they require assistance with invasion through epithelial surfaces from a catheter, drain or knife, or the bypassing of other innate defences through insertion of endotracheal and urinary catheters. It is uncertain whether they use mechanisms to evade the immune system and the attributable mortality of ICU-acquired infections is hard to define because of the high background mortality associated with an ICU stay. Nevertheless ICU-patients frequently develop systemic inflammation that in the setting of a community-associated infection would indicate involvement of a virulent pathogen. Microbiological data does not become available for 2–3 days, and although biomarkers of systemic inflammation such as the white-blood cell count, C-reactive protein and procalcitonin are available within a few hours they have high sensitivity, but low specificity for predicting microbiologically confirmed infection. A decision to start antimicrobial therapy is therefore made empirically. Unfortunately, although bacteria commonly associated with ICU-acquired infections are remarkably similar worldwide (Table 289.1), they have higher intrinsic antimicrobial resistance than community bacteria and a frightening ability to acquire further resistance. Consequently, the selection of appropriate antibiotics for acutely unwell patient is challenging. There is usually a need to cover Gram-positive and Gram-negative bacteria (GNB) and sometimes fungi, particularly *Candida* spp. All three groups present problems, but it is particularly acute with GNB because there are such a large number of species and resistance elements. For this reason the main focus of this chapter will be on GNB. Many guidelines recommend two antibiotics active against GNB for treatment of ICU-acquired infections with de-escalation to a single antibiotic around day 3 when culture results become available. There is little evidence to guide length of therapy with practice ranging from 5 to 14 days [1]. Overall about half of ICU patients are judged to be infected at any one time and about 70% are receiving systemic antibiotics [2].

Main resistant organisms and resistance mechanisms

A comprehensive description of antimicrobial resistance genes and mechanisms has been recently reviewed elsewhere [3]. Many common ICU bacteria such as *P. aeruginosa, Enterobacter* spp., MRSA and *Enterococcus faecium* have intrinsic, but predictable resistance to antibiotics commonly used for community infections. Thus empiric therapy for ICU-acquired infections usually comprises one or more antibiotics from 6 main classes, comprising aminoglocosides, fluoroquinolones, third generation cephalosporins, aminopenicillins, carbapenems, and polymixins that have activity against Gram-negative bacteria, with the addition of a glycopeptide or oxazolidinone if MRSA is considered a likely cause. The choice of antibiotic(s) with activity against GNB is usually based on local levels of resistance to each agent and is made challenging by a number of emerging trends including:

- Intercontinental spread of plasmids with extended spectrum β-lactamases (ESBL) particularly CTX-M, active against cephalosporins and aminopenicillins, and often linked fluoroquinolone and aminoglycoside resistance elements that are found in *Klebsiella* spp., *E. coli,* and other Enterobacteriaciae.
- Development of resistance in *P. aeruginosa* to many antibiotic classes under selective pressure of antibiotic use on ICU.
- Endemic colonization of ICUs with organisms such as *A. baumanii* that can be resistant to all commonly used antibiotics.

Table 289.1 A comparison between predominant bacteria causing community and hospital associated intensive care unit infections

Community-associated bacteria	Hospital/ICU associated bacteria
Gram positive	
Staphylococcus aureus (MRSA*) **(IR)**	*Staphylococcus aureus* (MRSA) **(IR, O)**
Streptococcus pneumoniae	Coagulase negative Staphylococci
Group A Haemolytic Streptococcus	*Enterococcus* species (VRE) (**O, IR**)
Group B Haemolytic Streptococcus	
Group C/G Haemolytic Streptococcus	
Gram negative	
Escherichia coli	*Pseudomonas aeruginosa* **(O, AR)**
Klebsiella spp.	*Enterobacter* spp. **(O, AR)**
N. meningitidis	*Escherichia coli* **(AR)**
Haemophilus spp.	*Klebsiella* spp. **(O, AR)**
Moraxella spp.	*Morganella* spp.
Legionella spp.	*Serratia* spp.
	Proteus spp.
	Acinetobacter baumanii **(O, IR)**
	Citrobacter spp.
	Stenotrophomonas spp. **(IR)**
	Hafnia spp.
	Other GNB†

*Community MRSA has become more frequent in some parts of the world.

†There is a large number of different usually environmental GNB found sporadically and occasionally as small outbreaks in ICU that separately can be considered rare but collectively can be identified on about 5–10% of ICU patients (e.g. Chryseomonas, Commomonas. Ochrobacter, Elizabethkingae).

O, frequently reported to cause outbreaks; IR, high level of intrinsic antibiotic resistance; AR, frequent additional clinically relevant acquired resistance.

- Increasing carbapenem resistance due to a variety of mechanisms commonly manifesting as either:
  - *P. aeruginosa* outbreaks.
  - Emergence of intrinsically resistant bacteria, such as *S. maltophilia.*
  - Most importantly, selection of numerous transferable plasmids encoding carbapenemases (eg KPC, IMP, OXA 48 and NDM) within enterobacteriaceae particularly *E. coli* and *Klebsiella* that have the potential for pandemic spread [4].

Together this creates a high degree of uncertainty selecting empiric GNB therapy in ICU patients. There has been an increasing reliance on carbapenems in many ICUs over the past 5–10 years even as first line, but the emergence of resistance compromises this choice and is leading to use of older agents such as colistin that have more side-effects [5].

Main factors increasing the burden of antimicrobial resistance on ICU

Antimicrobial resistance increases on ICU through importation, patient-to-patient transmission, selection in an individual, horizontal gene transfer within and between bacterial species and induction of new resistance (Fig. 289.1) [6]. The relative importance of each pathway varies between species and antibiotic resistance mechanism. Two main factors influence these pathways: antimicrobial use and health care practices.

Importation of resistance on patients (and to a lesser extent staff) reflects antimicrobial use in the community and the result of previous health care contacts. In addition, patients transferred out of ICU often have a prolonged stay on general wards where they may transmit resistance to other patients who then get admitted to ICU. Some patients have multiple admissions to hospital or the ICU providing many opportunities for increasing imported resistance.

Transfer of resistant organisms from patient to patient predominantly occurs via contaminated health care workers hands either directly from patient-to-patient or via inanimate objects. Antibiotic use may also influence transmission although this is likely to be complex given the potentially opposing effects of the many prescribed antibiotics [7].

Induction of resistance due to selection of new mutations during antimicrobial therapy may be a particular problem in units with high antimicrobial consumption. Fluoroquinolones are reported to be associated with induction of resistance in enterobacteriaciae and *P. aeruginosa* during therapy. There is emerging evidence for outbreaks of resistance with transfer of mobile resistance elements both within and between species [8], although the frequency, risk factors, and mechanisms of limiting such resistance are unclear.

Outbreaks of resistance

An outbreak can be defined as a period of increased incidence above an expected background The literature is dominated by reports of species outbreaks with resistant organisms such MRSA, *Acinetobacter* and MDR-*Klebsiella* that presumably drew significant clinical attention at that time. It is not clear what the total burden of outbreaks is on ICU and thereby derive general conclusions about risk factors and dissemination routes [9]. Outbreaks are often identified by a member of the health care team, although there are resistance outbreak detection tools that provide a more objective surveillance method [10,11]. It will be interesting to explore what might underlie the difference between large 'outbreaks' that reach clinical attention, and small clusters of largely sub-clinical and presumably self-terminating transmission clusters. Large outbreaks are often attributed to lapses in infection control practice, a patient or staff 'superspreader' or an environmental reservoir although some bacteria may be more adapted to spread better on the ICU [12].

Preventing the emergence and transmission of resistance on the intensive care unit

There are two main intervention programmes targeting a reduction in antimicrobial resistance: infection prevention and control (IPc), and antimicrobial stewardship.

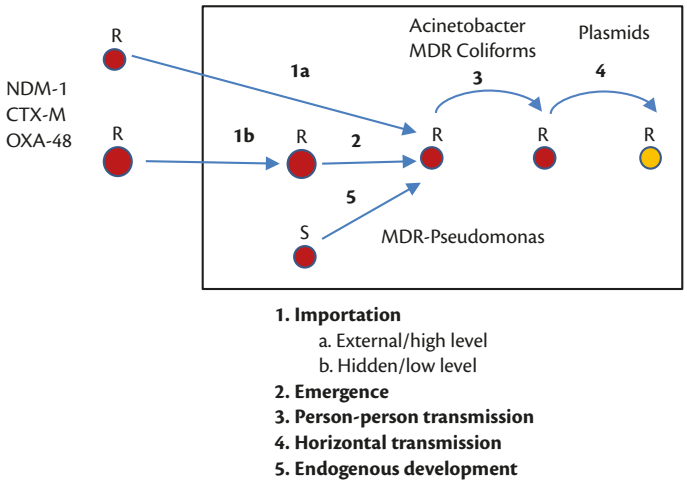

Fig. 289.1 Control of Gram-negative resistance is much more complicated: multiple species, resistance mechanisms and potential routes of transmission. R, resistant; S, sensitive.

An ICU infection prevention and control programme

An effective ICU IPc programme includes universal and targeted measures [13]. Universal measures that can be implemented in all ICUs include universal hand hygiene, environmental cleaning, and a training programme for staff that includes aseptic techniques required for good nursing and medical care. Success of these behavioural and operational practices benefits from a combination of education, training, and audit with clear accountability from 'board to ward' with consequences for poor performance. IPC has been transformed in many countries over the past few years by political, media, and public campaigns, demanding reductions in health care-associated infections to improve patient safety in hospitals.

Targeted components of an IPc programme comprise isolation and decolonization of patients carrying specific resistant organisms. Isolation can be used broadly to define any physical or distance barrier placed around a colonized patient and ranges from gloves and aprons for staff (contact precautions), patient cohorting or side-room isolation with or without staff cohorting, and use of an isolation ward. An additional component of a targeted IPc programme is collection of active surveillance cultures (ASC) to rapidly identify colonized patients and implement infection control interventions. Organisms most frequently screened are MRSA, VRE, and certain MDR-GNBs. A key attribute of a screening programme is the speed of returning results for action. Conventional culture often takes 3–4 days, which could be close to the median length of stay, such that results are delivered as the patient leaves. More rapid laboratory culture and molecular techniques can bring the turnaround time to same day or next day, and some point of care tests are being evaluated for organisms such as MRSA and *C. difficile* that provide results within a few hours. The effectiveness and cost-effectiveness of ASC programmes remains unclear.

Decolonization of patients with known resistant species is the other common targeted intervention, introduced to reduce both infections in the individual patient and transmission to others. With MRSA, decolonization involves use of surface antiseptics such as chlorhexidine and nasal mupirocin. In healthy patients, this has a reasonable chance of effecting MRSA eradication; however, in the ICU setting where patients have multiple skin breaches eradication is not considered achievable and the IPc goal is suppression at surfaces to reduce the bacterial load available to contaminate health care worker hands. The use of systemic antibiotics to further suppress the bacterial load of MRSA is not generally recommended on ICU. There is evidence that surface agents such as chlorhexidine may also suppress VRE at skin sites leading to a reduction in transmission. Skin antiseptics probably have little effect on MDR-GNB transmission, given that they predominantly colonize the gut and respiratory tract. There is evidence that enteral components of the selective digestive decontamination protocol, which includes neomycin and polymixin, suppress GNBs including MDR-GNB carriage in the gut, colonization of the respiratory tract and potentially transmission [14], although it's use has not become widespread in part due to concerns about emergence of resistance.

Although targeted decolonization is an accepted intervention for known MRSA carriers, there is a growing practice of using surface antiseptics such as chlorhexidine for all patients on ICU from admission [15]. Thus, although a distinction is generally made between universal and targeted components of an infection control programme, given that all ICU patients are at high risk of acquiring or carrying resistant organisms universal contact precautions and surface antiseptic decolonization is currently implemented in some ICUs. Although, this may be feasible in some settings, the lack of evidence to support effectiveness and cost-effectiveness of universal measures leads to a wide variation in practice [16].

Antimicrobial stewardship programme

A second approach to controlling antimicrobial resistance on ICU is the reduction of inappropriate antimicrobial prescribing through implementation of a stewardship programme [17]. The principle is that although international and local guidelines are usually in place recommending choice and duration of antibiotic therapy for ICU-acquired sepsis, there is huge scope for variation in practice within and between units. This variation is perhaps compounded by recognition that the grade of evidence supporting treatment guidelines is mostly poor. Stewardship therefore aims to support decision-making and adherence to generally acceptable guidelines endorsed by local stakeholders. Measures include introducing restriction or pre-approval for certain antimicrobials; regular advice provided by a visiting infection specialist to the attending team, on the need, choice, and duration of antibiotics in individual patients; formal review of therapy around day three to implement de-escalation, particularly if combination empiric GNB-therapy is used; and introduction of computer assisted decision making or automatic stop dates. Finally, studies have investigated whether some guidelines are more associated with resistance than others, comparing heavy reliance on a limited range of antibiotics, regular cycling from one class to another or continuous mixing [18,19].

New interventions to help control antimicrobial resistance

A number of new technologies are on the horizon with the potential to provide more and faster clinically-useful microbiological and epidemiological information, which should improve both treatment of sepsis and infection control practice leading to a control of antimicrobial resistance on ICU [20]. Multiplex PCR technologies are in development that can identify organisms in clinical samples within a few hours. Such information could be

used to deliver more appropriate empiric therapy for those with positive samples and in theory the withholding of antibiotics in those with negative samples. High throughput and rapid (same day) whole pathogen genome sequencing (WPGS) technologies are also being developed that may provide genotypic prediction of antimicrobial resistance phenotype and help with early detection of outbreaks. It is still unclear how long these disruptive technologies will take to enter routine practice, whether they will be used to guide both infection control and early therapy decisions, and whether they will save lives and resources and reduce resistance. There also remains an underlying need for better evidence on when to start antibiotics in ICU patients and how long to treat for. It is generally accepted that antibiotics are overused in ICU, but hard to strike a balance at the bedside between the needs of the individual patient for appropriate empiric therapy and the needs of society to prevent emergence of resistance. Hopefully a combination of new evidence from multi-centre randomized studies, including those that evaluating rapid diagnostics will meet this important challenge.

PART 13.3

Infection in the immunocompromised

CHAPTER 290

Drug-induced depression of immunity in the critically ill

Russell J. McCulloh and Steven M. Opal

Key points

- Glucocorticoids are the most commonly-used immunosuppressive drugs today and affect gene transcription, leukocyte distribution, and clearance of microbial pathogens.
- Calcineurin and MTOR inhibitors are commonly used in autoimmune diseases and organ transplantation, but require close monitoring for drug-related toxicities and interaction with other medications metabolized by the liver.
- Cytotoxic and antimetabolite medications used in the treatment of various cancers can be associated with bone marrow suppression and pancytopenia.
- Newer biological agents such as monoclonal antibodies target specific immunomodulatory chemokines or chemokine receptors which can result in profound immunosuppression, particularly of cell-mediated immunity.
- Clinicians should use data on infectious complications commonly associated with specific immunosuppressive drugs to help guide their evaluation of immunosuppressed patients suspected to have an opportunistic infection.

Introduction

The use of immunosuppressive drugs is now commonplace in multiple disciplines of medicine and surgery from organ transplantation, neurosurgery, neoplastic diseases, autoimmune diseases and an array of inflammatory diseases affecting many organ systems. These agents have greatly benefitted patients, but come at the price of induction of specific and at times generalized immunosuppression with all the associated risk of infections and even some neoplasms with long-term use of these agents [1]. This chapter will summarize the major categories of immunosuppressive agents now in common use to which critical care specialists need to maintain a working familiarity with their indications, major risks, and side effects. The list of biological agents and monoclonal antibody therapies entering clinical usage is rapidly expanding to fulfil the need for new therapeutic indications and safer immunomodulation than existing agents. We will discuss corticosteroids, transplant regimens and common agents used for neoplastic diseases and inflammatory disorders, and provide a summary of the newer biological agents entering clinical practice.

Glucocorticoids remain the mainstay for anti-inflammatory therapy needs and have proven their worth over the past 75 years of clinical use. The mechanisms of action that account for their anti-inflammatory effects are complex, but increasingly well understood as summarized in Fig. 290.1 [2]. Glucocorticoids are lipid soluble and freely diffuse across cell membranes where they bind to their specific receptors. Glucocorticoid receptors disassociate from Heat Shock Protein 90 when glucocorticoids enter the cell; they dimerize and translocate to the nucleus and markedly alter cellular and transcriptional activity of the cell. Anti-inflammatory genes are upregulated as they have GRE (Glucocorticoid response element) sequences near promoter sites. A prominent effect of steroids is upregulation of IκB-α, a potent inhibitor of the capacity of NFκB to translocate across the nuclear membrane and activate pro-inflammatory genes. Another major impact of glucocorticoids is their capacity to block transcription of inflammatory gene programs at the level of the essential co-activator complex of the transcriptional machinery of the cell. Steroids also block the actions of other transcriptional activators including a number of mitogen activated protein kinases and activator protein 1. Stability of mRNA is impaired by glucocorticoids limiting the translation of mRNA into protein products such as pro-inflammatory cytokines, chemokines, and enzymes that generate prostaglandins and other inflammatory mediators.

Clinical experience has clearly delineated the importance of escalating doses of glucocorticoids and most importantly the duration of steroid use as major determinants of the risk of infectious and metabolic complications of glucocorticoids. High doses of these immunosuppressive agents are remarkably well tolerated for the first 14–21 days of therapy before major complications associated with their use become clinically manifest [3]. Similarly, the administration of low doses of glucocorticoids (<10 mg prednisone or equivalent agents) are tolerated with minimal to no excess infection risk for years of therapy. Numerous functional consequences affecting the cellular constituents of both the innate and adaptive immune systems occur and account for the increase risk of infection from steroids. Neutrophilia with initial use is commonplace as a consequence of decreased egress out of the circulation and increased release from bone marrow stores. Conversely T lymphocytes, NK cells, and eosinophils redistribute to extravascular sites with glucocorticoid use. Of greater functional consequence is steroid-induced reduction in surface expression of Fc receptors, complement receptors (CR3 receptor) and reduced expression of class II molecules and co-stimulatory signals by macrophages, eosinophils, and monocytes. Chemotaxis of monocytes and intracellular killing and cytokine and chemokine signalling are all reduced by

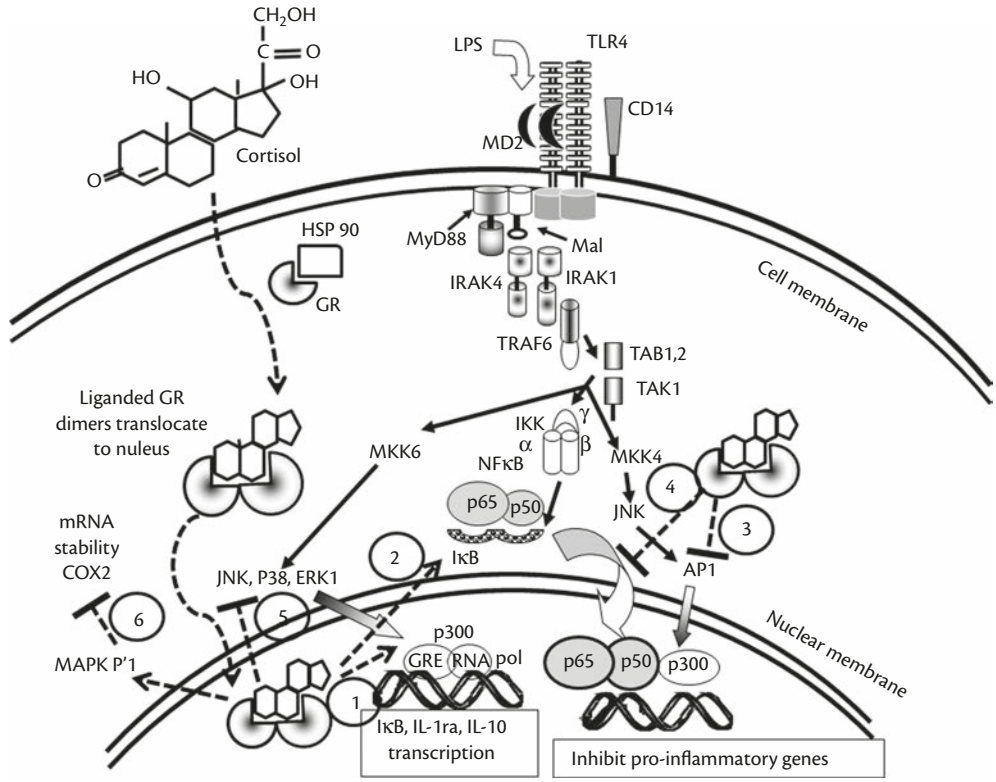

Fig. 290.1 Molecular mechanisms of glucocorticoid anti-inflammatory actions. Glucocorticoids have multiple ant-inflammatory actions including: (1) binding to glucocorticoid response elements at promoter sites for upregulation of anti-inflammatory gene transcription; (2) upregulation of I kappa B levels that block NFκB (nuclear factor from kappa B cell) nuclear translocation; (3) inhibition of AP-1 (activator protein 1) and 4) inhibition of NFκB activation of pro-inflammatory gene transcription by blocking coactivators of transcription; (5) inhibition of MAPK (mitogen activated protein kinase) activated transcriptional factors; (6) activation of MAPK phosphatase-1 that degrades MAPKs and induces mRNA instability with reduced translation of pro-inflammatory mediators and enzymes.

HSP, heat shock protein; GR, glucocorticoid receptor; COX2, cyclooxygenase 2; JNK, janus N terminal kinase; ERK, extracellular receptor activated kinase; GRE, glucocorticoid response element; RNA pol, RNA polymerase; MKK, MAPK kinases; IκK, inhibitor kappa B kinase; TAK, transforming factor beta associated kinase; TAB, TAK binding protein; TRAF6, TNF receptor associated factor 6; IRAK, interleukin-1 receptor associated kinase; MyD88, myeloid differentiation 88; Mal, Myd88 adaptor like; LPS, lipopolysaccharide; TLR4, Toll-like receptor.

corticosteroids resulting in poor microbial clearance and excess infection risk.

Lymphocyte populations, particularly T-cells (both CD4 and CD8 cells) are also affected with reduced proliferative capacity and cytokine generation after exposure to steroids with 2 weeks of starting these drugs. Reduced IL-2 generation associated with steroid use primarily accounts for impaired proliferative capacity of T-cells to respond to intracellular pathogens. B cell and plasma cell populations are only mildly affected by high dose steroids and antibody synthesis is well preserved to recall antigens. NK cell function is well preserved even after long term exposure to glucocorticoids. It should be remembered that therapeutic doses of steroids impair fever generation by the upregulation of lipocortins that block phospholipase A_2. Blockade of fever occurs from reduced arachidonic acid synthesis and thereby loss of prostaglandin E2 alpha levels in the hypothalamic thermoregulatory centre of the brain. Steroid-induced blockade of fever generation not only removes this cardinal sign of inflammation from the clinician's attention, it also likely impairs the capacity to clear pathogens.

An array of well-known opportunistic pathogens and a host of routine pathogens remain a constant concern with the long-term use of glucocorticoids [3–5]. Isoniazid preventive therapy is indicated in steroid-treated patients with evidence of latent tuberculosis. Special concern should be paid to opportunistic fungi and endemic mycoses in specific geographic regions where coccidioidomyocosis and histoplasmosis are prevalent in the environment. The hyperinfection syndrome with strongyloidasis is a real risk in steroid treated patients and should be screened for in endemic regions of the world.

Immunosuppressive agents used in oncology and transplant medication

Calcineurin inhibitors and MTOR inhibitors

Cyclosporin

Cyclosporine (cyclosporin A, CSA) is used for immunosuppression in a variety of circumstances, including human organ transplantation, treating graft-versus-host disease (GVHD) after haematopoietic stem cell transplantation (HSCT) [13], and in the treatment of autoimmune disorders including rheumatoid arthritis, psoriasis, and uveitis [16]. It is a peptide antibiotic that blocks activation of T-cells during antigen receptor-mediated induction of differentiation by binding to cyclophilin, an intracellular protein belonging

to the immunophilin protein class. Together with cyclophilin, cyclosporin forms a complex that inhibits calcineurin, a cytoplasmic phosphatase crucial to activating NF-AT. This transcription factor is necessary for synthesis of several interleukins, including IL-2, IL-3, and IFN-gamma, by activated T-cells. Of note, cyclosporin does not block the effects of these cytokines on primed T-cells or interaction with antigen. Cyclosporin is metabolized by the CYP450 3A enzyme, which means it has multiple drug-drug interactions and requires monitoring of drug levels. Toxicities can include nephrotoxicity, hypertension, hyperglycaemia, liver dysfunction, hyperkalaemia, mental status chances, and seizures.

Tacrolimus

Tacrolimus (FK 506) is a macrolide antibiotic produced by *Streptomyces tsukubaensis*. It suppresses T-cell transcription of NF-AT by binding to the immunophilin FK-binding protein (FKBP). Its immunosuppressive activity is similar to cyclosporin but 10-100 times greater on a per-weight basis. It has been used in a similar array of conditions, including solid-organ transplant, HSCT, and treatment or prevention of GVHD. It is used topically to treat various dermatological conditions including atopic dermatitis and psoriasis. Tacrolimus is metabolized via the CYP450 pathway with similar drug interaction concerns as cyclosporin. Trough levels should be monitored in patients. Toxicities are also similar to cyclosporin, including nephrotoxicity, neurotoxicity, hyperglycaemia, hypertension, and hyperkalaemia, although gastrointestinal effects may be more common [16].

Sirolimus

Sirolimus (rapamycin) is the prototype immunosuppressive macrolide antibiotic that inhibits the kinase activity of mammalian target of rapamycin (mTOR). Other 'rapalogs' in this group include everolimus and temsirolimus. Inhibition of the mTOR pathway has pleiotropic effects on various cellular processes including angiogenesis, metabolism, and cellular proliferation such as interleukin-mediated T-cell activation and proliferation. Sirolimus and the other rapalogs have potential applications in both targeted oncologic therapies as well as immunosuppression. Currently sirolimus is used in preventing solid organ allograft rejection, prevention, and treatment of GVHD, as well as in topical preparations for dermatological disorders. Sirolimus is metabolized by CYP450 3A and P-glycoprotein, with similar concerns for drug-drug interactions as the calcineurin inhibitors. Its half-life is 60 hours, resulting in prolonged toxicity even after drug cessation. Unlike cyclosporin and tacrolimus, sirolimus has no significant nephrotoxicity. However, use of the mTOR inhibitors has been associated with myelosuppression, thrombocytopenia, hepatic dysfunction, diarrhoea, headache, elevated serum triglycerides, and pneumonitis. Additionally, when combined with tacolimus for treatment of HSCT-related GVHD, sirolimus has been associated with increased incidence of haemolytic-uremic syndrome.

Mycophenolate mofetil

Mycophenolate mofetil (MMF) inhibits several T- and B-lymphocyte actions, including mitogen and mixed lymphocyte responses, most likely via inhibition of purine synthesis. A semisynthetic derivative of mycophenolic acid, MMF can be given orally or intravenously. Unlike sirolimus and the calcineurin inhibitors, MMF is not metabolized via the CYP450 3A system. Mycophenolate mofetil is used in combination with prednisone as an alternative to cyclosporin or tacrolimus in patients intolerant to these medications. It also is used in refractory solid organ transplant rejection and GVHD [4]. Outside of transplant medicine, MMF is used to treat lupus nephritis, rheumatoid arthritis, inflammatory bowel disease, and severe atopic dermatitis. Common side effects include headache, hypertension, gastrointestinal disturbances, and reversible myelosuppression.

Thalidomide and derivatives

Thalidomide

Historically known as a sedative drug withdrawn from the market due to its severe teratogenic effects when used in pregnant women, thalidomide is being tested and/or used in a wide array of clinical applications due to its anti-inflammatory, immunomodulatory, and anti-angiogenic effects. It inhibits tumour necrosis factor alpha (TNF-α), decreases neutrophil phagocytic activity, increases IL-10 production, alters adhesion molecule function, and enhances cell-mediated immunity through interaction with T-cells. Current approved applications include treatment of multiple myeloma, erythema nodosum leprosum, and dermatological disease due to systemic lupus erythematosis (SLE). It is under study for use in various oncologic conditions, myelodysplastic syndrome, and GVHD. Besides its teratogenic effects, thalidomide can cause peripheral neuropathy, constipation, rash, fatigue, hypothyroidism, and increased risk for deep venous thrombosis. Currently thalidomide may only be prescribed under close supervision from the manufacturer. The severe side effect profile has prompted the development and study of alternative agents known as immunomodulatory derivatives of thalidomide or IMiDs.

Lenalidomide

The first IMiD approved for treating patients with myelodysplastic syndrome and multiple myeloma, lenalidomide has fewer side effects than thalidomide, although concomitant use of anticoagulant therapy, close monitoring of renal function, and monitoring for neutropenia and thrombocytopenia remain important [17].

Cytotoxic agents and antimetabolites

Azathioprine

Azathioprine is a prototypic immunosuppressive antimetabolite. It is a prodrug of mercaptopurine that is well-absorbed from the GI tract. Azathioprine is cleaved by xanthine oxidase to 6-thiouric acid, and care must be taken to reduce the dose to one-quarter to one-third the usual amount to avoid toxicity. Its mechanism of action is through interference with purine nucleic acid metabolism resulting in destruction of stimulated lymphoid cells, causing cell-mediated and humoral immune suppression. Azathioprine and mercaptopurine are used in renal allograft maintenance, lupus nephritis, Crohn's disease, rheumatoid arthritis, multiple sclerosis, and steroid-resistant idiopathic thrombocytopenic purpura and autoimmune haemolytic anaemias. Azathioprine's primary toxicity is bone marrow suppression, but can also include rash, nausea, vomiting, diarrhoea, and hepatic dysfunction, particularly at higher doses.

Cyclophosphamide

Cyclophosphamide is an alkylating agent that is highly toxic to proliferating lymphoid cells and has some effect against resting cells. High doses may induce tolerance to a new antigen if the drug is

Table 290.1 Other immunosuppresive drugs

	Primary mechanism of action	Major toxicities
Antimetabolites		
Fluorouracil (5-FU)	Blocks DNA methylation during DNA synthesis	Myelosuppression, CNS, heart failure
Cytarabine	Pyrimidine synthesis inhibitor	Myelosuppression, bleeding
Cytotoxic agents		
Dapsone	Inhibits neutrophil migration, adherence	Haemolysis, agranulocytosis
Vincristine	Inhibits mast cell degranulation	Marrow suppression
Bleomycin	Causes DNA strand breaks	Myelosuppression, fevers, skin changes
Pentostatin	Adenosine deaminase inhibitor	Leukopenia, thrombocytopenia
Fingolimod	Decreases lymphocyte recirculation	Lymphopenia, Flu-like syndrome

Table 290.2 Common biological agents and their principal immunological effects and infection risks

Biological agent or antibody	Molecular target	Indications	Infection risk
Polyclonal anti-thymocyte or anti-lymphocyte antibodies	T lymphocytes	Organ transplant rejection	Impaired cell-mediated immunity increases risk of numerous OI
Infliximab (Remicade)	Chimeric murine-human mAb blocks TNF and tmTNF	RA, psoriasis, AS, ulcerative colitis, Crohn's disease	TB, Herpes virus, histo, cocci, other opportunistic bacterial, viral infections
Entanercept (Enbrel)	Type 2 TNFr:Fc IgG blocks sTNF and lymphotoxin	RA, psoriasis, AS, JRA	Lower risk than Infliximab-TB, histo, cocci, other fungi, bacterial, viral infection, OIs
Adalimumab (Humira)	Humanized anti-TNF mAb targets sTNF, tmTNF	RA, psoriasis, AS Crohn's disease	TB, other fungal, viral and bacterial OIs
Golmumab (Simpori)	Human anti-TNF mAb targets sTNF and tmTNF	RA, psoriasis, AS	TB, other bacterial, viral OIs
Certolizumab pegol	Pegylated humanized anti-TNF Fab fragment	Crohn's disease, RA	Limited data, likely similar to other TNF inhibitors
Anakinra (Kineret)	IL-1 receptor antagonist targets IL-1 beta	RA	OI risk less than with TNF inhibitors; URI, pneumonia
Daclizumab (zenapax)	Humanized mAb blocks IL-2R (CD25) on T-cells	Transplant rejection	Low risk of CMV, other OIs
Basiliximab (Simulect)	mAb blocks IL-2R (CD25) on T-cells	Transplant rejection	Low risk of OI, CMV reactivation
Rituximab (Rituxan)	Blocks CD20 on B cells	RA, SLE, B cell neoplastic disease	Some Bacterial infections, CMV, VZV, HBV, PML
Alemtuzumab (Campath)	mAb blocks CD52 on T and B cells, NK cells, myeloid cells	Transplant rejection, CLL, neoplastic disease	Neutropenia; multiple OI with bacterial, viral, fungal pathogens, PJP, PTLD
Tocilizumab (Actemra)	mAb blocks IL-6R on T and B cells	Autoimmune disease, neoplastic disease	URI, might increase risk of other infections
Natalizumab (Tysabri)	Humanized mAb, blocks alpha-4 integrin and lymphocyte trafficking	MS, Crohn's disease	PML, especially if anti-JC virus + and prolonged immune suppression
Belatacept	mAb blocks co-receptor CD28 on T-cells	Kidney transplantation	EBV-associated PTLD, ?PML, UTI, CMV infection
Brodalumab (AMG 827)	mAb blocks IL-17AR	Psoriasis	Limited experience, increased pharyngitis, URI

OI, opportunistic infections; mAb, monoclonal; TNF, tumour necrosis factor; RA, rheumatoid arthritis; histo, histoplasmosis; cocci, coccidioidomycosis; AS, ankylosing spondylitis; JRA, juvenile rheumatoid arthritis; MS, multiple sclerosis; R, receptor; Fc, crystallizable component of immunoglobulin; IL, interleukin; CMV, cytomegalovirus; VZV, varicella zoster virus; HBV, hepatitis B virus; SLE, systemic lupus erythematosis; PML, progressive multifocal leukocencephalopathy; PJP, *Pneumocystis jirovecii* pneumonia; CLL, chronic lymphocytic leukaemia; EBV, Epstein–Barr virus; PTLD, post-transplant lymphoproliferative disorder; UTI, urinary tract infection, URI, upper respiratory infection.

administered with or immediately after the antigen, which can help improve rates of successful engraftment after HSCT. It is also used to prevent or treat GVHD. In addition to its use in oncology, it is used in modest doses for systemic lupus erythematosis, antibody-mediated factor XIII deficiency, pure red cell aplasia, and Wegener's granulomatosis. Side effects include haemorrhagic cystitis, pancytopenia, nausea, vomiting, cardiac toxicity, and electrolyte abnormalities.

Leflunomide

Leflunomide is an orally-active prodrug of a pyrimidine synthesis inhibitor. It has a half-life of several weeks, and is currently used for treatment of rheumatoid arthritis. Owing to its relative lack of cytochrome interactions and antiviral activity against cytomegalovirus, leflunomide is being studied in a wide array of transplant-associated and rheumatologic conditions [19]. Associated toxicities include hepatic dysfunction or damage, nephrotoxicity, and teratogenicity. Patients have also experienced angina and tachycardia while taking leflunomide.

Hydroxychloroquine

An antimalarial agent that also possesses immunosuppressive activity, hydroxychloroquine suppresses antigen processing and loading onto MHC class II molecules, leading to decreased T-cell activation. This is thought to occur through increasing the pH in lysosomes and endosomes. Hydroxychloroquine is used in rheumatoid arthritis and SLE as well as the management and prevention of GVHD. Longitudinal monitoring for retinopathy and permanent visual impairment is necessary in patients on long-term therapy.

Methotrexate

An inhibitor of dihydrofolate reductase, methotrexate is used both in chemotherapy and in the treatment of various malignancies as well as in rheumatoid arthritis and psoriasis [20]. It is a substrate of P-glycoprotein and has multiple drug-drug interactions. Additionally, methotrexate has multiple potential toxicities, including stomatitis, myelosuppression, skin rash, and short-term or long-term central nervous system effects (headache, vomiting, encephalopathy, among others).

Alkylating agents and platinum coordination complexes

These agents, which include nitrogen mustards, ethyleneimines, alkyl sulfonates, nitrosureas, triazenes, and DNA-methylating drugs, are primarily used in the treatment of neoplastic diseases. Their mechanisms of action all involve the alkylation of reactive amines, oxygens, or phosphates on DNA, resulting in cytotoxic effects. They are most effective in rapidly-proliferating tissues, which accounts in part for their immunosuppressive effects. This can result in suppression of all bone marrow-derived cell lines. For some agents, their effects can also be seen on resting-phase immune cells such as mature lymphocytes.

Other immunosuppressive drugs

Additional selected agents with immunosuppressive properties are listed in Table 290.1.

Immunosuppressive antibodies and other biological agents

First utilized as antisera derived from animals for treatment of infections in the pre-antibiotic era, antibody-mediated therapies for rheumatologic and oncologic disorders have experienced a rapid expansion in development and utilization in the past two decades [18]. Current therapies use hybrid antibodies composed of murine- or human-derived constant regions paired with specific active regions that target cell receptors and cytokines. Humanized murine monoclonal antibodies and now even fully human monoclonal antibodies are in clinical use. Table 290.2 lists the common biological agents currently in use for a variety of indications with immunosuppressive or immunomodulatory effects and major infection risks. Some of the agents are markedly immunosuppressive (e.g. rituximab, TNF inhibitors, alemtuzumab) and place the patient at major risk for opportunistic infections, while others are well tolerated or increase infection risk for a specific set of pathogens [6–15].

Worth noting is the remarkable association with the opportunistic JC virus-induced PML associated with natalizumab. This integrin inhibitor is highly effective for some forms of multiple sclerosis and is widely used despite the risk of PML. Patients should be screened for antibodies against JC virus and treated for as short a period as possible to avoid this complication. PML has also occurred during rituximab therapy and is a potential risk with the use of other broadly immunosuppressive agents in this class. As a testament to the degree of immune suppression induced by these biological agents, IRIS (immune reconstitution inflammatory syndrome) has occurred with withdrawal from natalizumab therapy and often necessitates the use of corticosteroids to control this reaction.

CHAPTER 291

HIV in the critically ill

Mark Hull and Steven C. Reynolds

Key points

- Human immunodeficiency virus (HIV) is increasingly a controllable disease in North America and life expectancy in patients adherent to combination antiretroviral therapy (cART) is similar to the general population.
- The majority of admissions of HIV positive patients to the ICU are for reasons unrelated to their HIV, although presentations due to opportunistic infections and malignancies must be considered in those with previously undiagnosed infection or in those patients non-adherent to cART.
- The CD4 count is critical in determining the degree of immune suppression in a patient and should be checked in all critically ill HIV-infected patients to determine appropriate work-up and management of HIV-related infections/complications.
- It is important to involve an infectious disease specialist familiar with HIV in the care of a critically ill HIV-infected patient, particularly if therapy requires alterations or cessation of cART or if the patient is found to be significantly immunocompromised.
- Antiretroviral agents have many potential drug interactions and rare toxicities which must be evaluated throughout the ICU stay as concomitant medications are introduced.

Introduction

It has been over 30 years since the identification of the first cases of unusual opportunistic infections and malignancies linked to infection with the human immunodeficiency virus (HIV). The use of combination antiretroviral therapy (cART) has been shown to halt progressive immunologic decline with concomitant improvement in morbidity and mortality due to HIV-related acquired immunodeficiency syndrome (AIDS). As a result, survival rates of HIV-infected individuals who are able to access cART approach those of the general population [1]. Management of patients presenting to the intensive care unit (ICU) must now encompass these expectations, and HIV infection alone should not affect decisions to pursue life-saving interventions. Reasons for admission to the ICU can include non-HIV-related conditions (including trauma or drug overdose), HIV-related infections, as well as infections similar to that of the general population. Physicians working in the ICU must have an awareness not only of the common opportunistic infections that remain a cause of hospitalization for HIV-infected individuals, but also be mindful of the possibility of causing inadvertent harm when altering or discontinuing antiretroviral therapies, their common toxicities and the importance of drug-drug interactions that can occur between antiretrovirals and other commonly used medications.

HIV epidemiology

There were an estimated 35 million individuals living with HIV/AIDS worldwide in 2013 [2]. The majority of individuals (24.7 million) reside in Sub-Saharan Africa, with an estimated 2–3 million individuals living in North America and Europe. Within the United States, by the end of 2011 there were an estimated 1.2 million individuals living with HIV—of whom 20% are thought to be undiagnosed [3]. Despite advances in therapy, individuals with undiagnosed HIV, and those with incomplete linkage to care may present with common opportunistic infections and morbidities related to untreated HIV.

The CD4 cell count is regarded as one of the key surrogate markers for prognostic staging and therapeutic monitoring of HIV-infected individuals (see Table 291.1). The CD4 count quantitates the magnitude of immune suppression and thus the array of opportunistic infections for which the patient might be at risk (Fig. 291.1). Plasma viral load has been shown to be an independent predictor of disease progression and death in untreated HIV-infected individuals [4].

Antiretroviral therapy in the ICU

Current recommendations for antiretroviral therapy

Therapeutic guidelines for the management of HIV-infected individuals are updated regularly by national and international organizations, and continue to evolve with time [5–7]. Individuals with symptomatic disease or AIDS-defining conditions require therapy regardless of CD4 cell count. At present, there is broad consensus that therapy should be initiated at a CD4 cell count threshold of 350 cells/mm^3 and is recommended at thresholds < 500 cells/mm^3 in most guidelines [5,7]. In addition, the presence of other co-infections (such as active hepatitis B) or comorbidities may be indicators for cART, regardless of CD4 cell count [5,6].

Antiretroviral drug classes

There are six major classes of antiretroviral therapy. Commonly available agents within each drug class are listed in Table 291.2.

Recommended regimens for first-line therapy include the combination of two nucleoside reverse transcriptase inhibitors (NRTIs) in combination with either a non-nucleoside reverse transcriptase inhibitor (NNRTI), or a protease inhibitor (PI), or an integrase inhibitor. PIs require pharmacokinetic boosting with ritonavir, a potent cytochrome P450 3A4 inhibitor.

Table 291.1 Common laboratory evaluation of the HIV-infected patient

Test	Comment
HIV-specific tests	
Plasma HIV RNA (viral load)	
CD4+ lymphocyte count (absolute and percentage)	
Baseline HIV resistance testing (HIV genotype)	
HLA-B5701 assay	Presence of this marker is associated with increased risk of abacavir hypersensitivity reaction
Co-infection/opportunistic diseases assessment	
CD4 > 350	
Serological testing for syphilis	T.pallidum EIA or rapid plasma reagin (RPR)
Serological testing for Hepatitis A, B, and C	
Tuberculosis screen	
CD4 < 200	
Consider PJP	Bronchoscopy is required to confirm the diagnosis
CD4 < 100	
Toxoplasma Serology	Disease seen in those with CD4 < 100
Serum Cryptococcal Antigen	Sensitive screen for cryptococcal meningitis
CD4 < 50	
AFB blood cultures	Disseminated *Mycobacterium avium* complex seen with CD4 < 50
CMV	Serology and ophthalmology screen with CD4 < 50

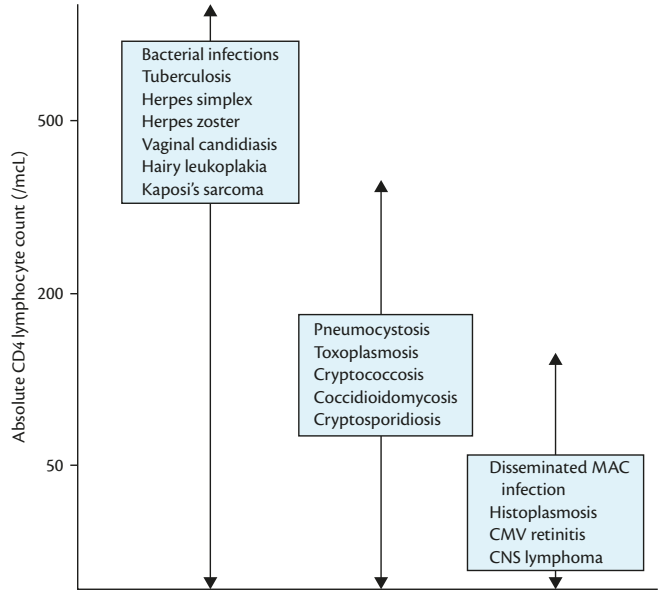

Fig. 291.1 Relationship of CD4 count and risk of opportunistic infections. CMV, cytomegalovirus; CNS, central nervous.

Potential issues relating to cART in the ICU

When to start therapy/discontinuation of therapy

Initiation of antiretroviral therapy is rarely required on an urgent basis within the ICU for individuals who are newly diagnosed, or who have not previously been receiving treatment. In most circumstances, baseline HIV-related laboratory work (Table 291.1) can be completed to determine an optimal regimen. Consultation with an HIV-experienced physician/service may aide in selecting appropriate therapy and with linkage to care for long-term management.

In circumstances where the individual has presented with an opportunistic infection, early initiation of cART is desirable to prevent further morbidity. Results of an open-label trial have demonstrated fewer AIDS progression events/deaths in those initiating therapy after completing 14 days of treatment for the underlying infection [8].

A potential risk of early therapy is the development of immune reconstitution inflammatory syndrome.

Commonly, patients with underlying HIV may already be receiving antiretroviral therapy when admitted to the ICU. This poses concerns in terms of potential drug-drug interactions, poor absorption of medications in critically ill patients, and the risk of resistance if medications are abruptly discontinued. Agents such as the NNRTI class are known to have longer pharmacological half-life, leading to functional monotherapy if the cART regimen is stopped abruptly. This period of monotherapy is associated with the development of drug resistance [9]; if a regimen is to be discontinued due to NNRTI toxicity, then the offending agent should be substituted for another agent such as a PI if at all possible [10]. If the entire NNRTI-containing regimen or integrase inhibitor is to be discontinued, a staggered stop in which the nucleoside backbone is continued for an additional 7–10 days can be considered [6,7].

Both the NNRTI and PI classes are active at the level of the cytochrome P450 iso-enzyme system, with the potential to act either as potent inducers or inhibitors of metabolism of other medications, or conversely to have their levels affected by the action of other medications with similar properties. As such, use of certain anti-arrythmics, antihistamines, and even some benzodiazepines may be contraindicated, either relatively or absolutely [11].

Immune reconstitution syndrome

Suppression of HIV replication through the use of cART, and the associated CD4 cell count rebound, has led occasionally to exaggerated inflammatory responses to newly recognized antigens. This phenomenon has been named immune reconstitution inflammatory syndrome (IRIS). Proposed criteria include documented viral load decreases in addition to new or worsening symptoms of an infectious or inflammatory condition after initiation of HAART [12]. Currently IRIS is thought to be due to the interactions between the degree of immune recovery, previously unrecognized (subclinical or residual) antigenic burden and possible host genetic factors. Clinical management usually includes therapy with nonsteroidal

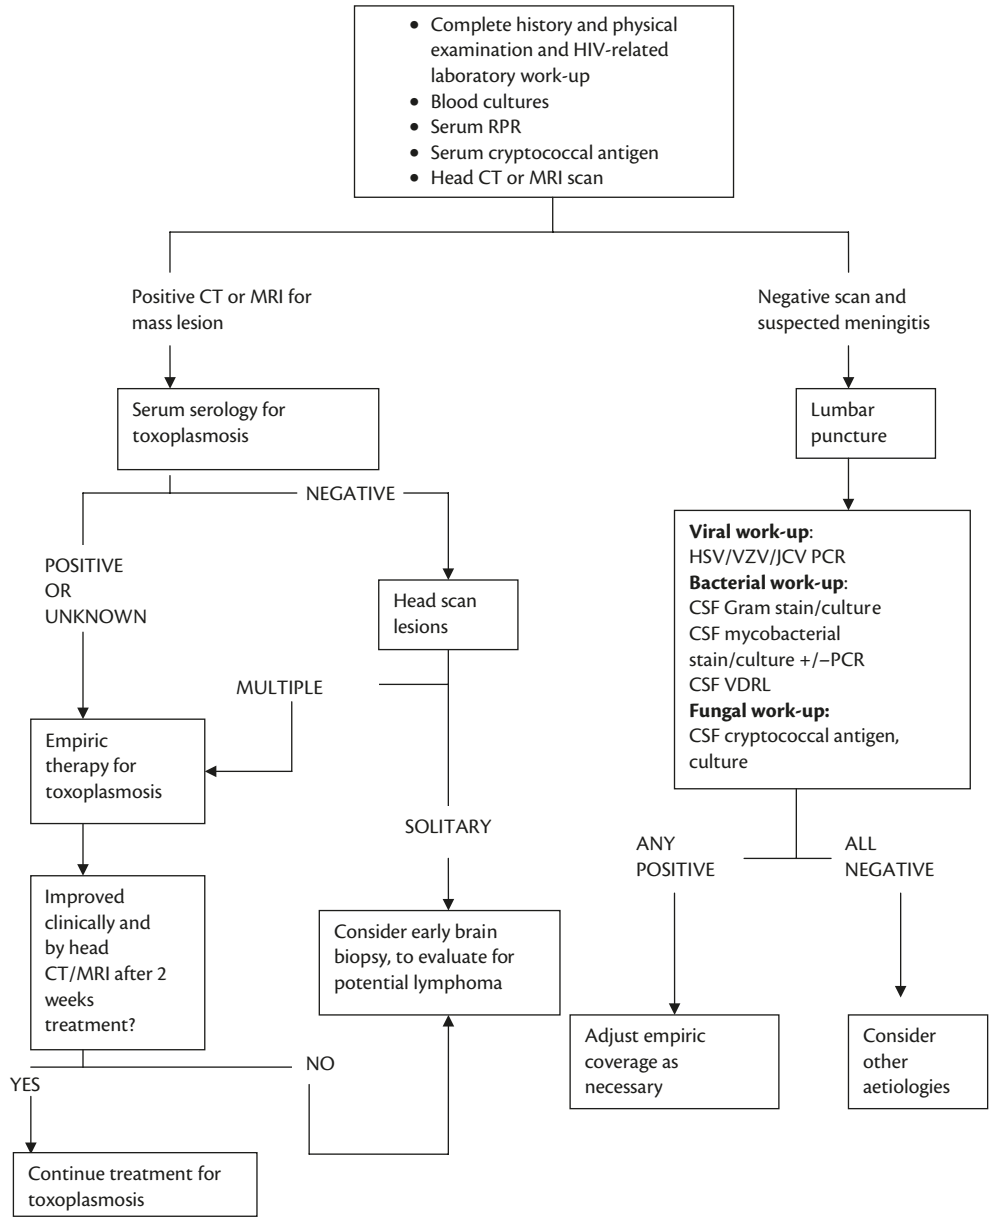

Fig. 291.2 Diagnostic algorithm for infectious aetiology of mental status changes in immunocompromised HIV-infected patients.

anti-inflammatories or corticosteroids, and antiretroviral therapy should be continued unless life-threatening features are present.

Approach to the HIV-infected patient in the ICU

The majority of presentations of HIV-infected patients to the intensive care unit are due to issues independent of their HIV such as trauma, neurological events, post-operative care, sepsis, and respiratory failure. One observational study from San Francisco found that only 21% of HIV positive patients admitted to the ICU over a 5-year period were admitted for HIV-related concerns. This was further reduced to 12% HIV associated admissions in those receiving cART [13].

Trauma-related outcomes amongst HIV-infected patients are similar to the general population, with the exception of increases in renal/respiratory and infectious complications [14,15]. In burn patients, HIV status does not affect outcome [16]. HIV-infected patients undergoing surgery (both general and orthopaedic) have been noted to have an increased risk for infection, and advanced disease with CD4 cell count <50 cells/mm^3 has been associated with an increased risk of complications [17].

Comorbidities related to the aging of the HIV-infected population including cardiovascular disease or end-stage liver disease related to hepatitis-C co-infection are also common reasons for ICU support.

It is important to identify HIV status early on in the history and locate the most recent CD4 count, CD4 percentage, and HIV viral

Table 291.2 Common antiretroviral agents by drug class

Class	Agent	Common side effects/comments
Nucleoside reverse transcriptase inhibitors (NRTIs)	Lamivudine (3TC)*	
	Emtricitabine (FTC)*	
	Tenofovir*	Renal impairment, classically Fanconi's syndrome with proximal tubular injury
	Abacavir*	Hypersensitivity reaction, requires prescreening with HLA B5701 assay
	Zidovudine (AZT)	Anaemia. An IV formulation is available
	Didanosine (DDI)	Pancreatitis, lactic acidosis
	Stavudine (D4T)	Pancreatitis, lactic acidosis
Non-nucleoside reverse transcriptase inhibitors (NNRTIs)	Efavirenz*	Potentially teratogenic, neuropsychiatric side effects common in first 4 weeks
	Nevirapine	Hypersensitivity reaction. Should not be used in men with CD4 > 400 and women with CD4 > 250 cells/mm^3
	Etravirine	
	Rilpivirine*	Should not be used if viral load > 100,000 copies/mL
Protease inhibitors These require boosting by ritonavir	Atazanavir*	Requires acid environment for absorption, concomitant proton pump inhibitor therapy should be avoided Causes indirect hyperbilirubinaemia
	Darunavir*	Potential cross-reactivity in severe sulpha allergy
	Lopinavir	Only agent co-formulated with ritonavir
	Saquinavir	
	Fosamprenavir	
Integrase inhibitors	Raltegravir*	Few side effects, but twice daily dosing recommended
	Elvitegravir*	Requires boosting with cobicistat
	Dolutegravir*	
Entry inhibitors	Enfuvirtide	Administered by subcutaneous injection twice daily
CCR5 antagonists	Maraviroc	Requires prescreening with viral tropism assay to evaluate if CCR5 coreceptor is utilized in binding process

*Common first-line agents.

load results. This essential information frames the subsequent clinical and investigational plan: a suppressed CD4 count may be indicative of opportunistic infections/malignancies which could account for the current presentation. The CD4 percentage is a useful adjunct as during acute illness the total lymphocyte population may be reduced, but the ratio will remain preserved and thus reflect more accurately the degree of immune suppression.

HIV associated reasons for ICU admission

Respiratory disease

Pulmonary manifestations of HIV infection are diverse, and include both infectious and non-infectious conditions (see Box 291.1) [18]. Opportunistic infections and malignancies should be considered when the CD4 cell count is below 200 cells/mm^3 although *Pneumocystis jirovecii* (formerly *carinii*) pneumonia (PJP) may occasionally present at higher CD4 thresholds.

Initial therapy should include broad-spectrum antimicrobial therapy, and empiric influenza coverage should also be considered during the winter seasons.

Empiric coverage for PJP is not unreasonable if the clinical or radiographic findings are suggestive of this diagnosis. PJP typically presents as a sub-acute condition, with a history of progressive exertional dyspnoea accompanied by fever, cough and, occasionally, spontaneous pneumothorax. Classically, radiographic imaging demonstrates bilateral interstitial infiltrates.

Laboratory abnormalities may include an elevated lactate dehydrogenase, although this is not diagnostic. Bronchoscopy with bronchial brushings and bronchoalveolar lavage (BAL) can be used to establish the diagnosis.

Intravenous trimethoprim-sulphamethoxazole is recommended for severely ill patients (e.g. PaO_2 <70 mmHg, A–a gradient >45 mmHg) for 21 days. Intravenous trimethoprim-sulphamethoxazole usually is associated with a daily volume of 1–2 litres of fluid as a diluent which can be problematic for the patient managed with a fluid restricted strategy which is standard of care in Acute Respiratory Distress Syndrome (ARDS) patients. Adjunctive corticosteroids are recommended in severe cases and have been shown to reduce mortality and morbidity [19].

Patients may worsen clinically during the initial 24–48 hrs of treatment, but usually show signs of improvement by about the 5th day. A meta-analysis of salvage therapy suggested that clindamycin in combination with primaquine was the most effective alternative

Box 291.1 Pulmonary conditions seen in HIV-infected patients

Viral infections

- Influenza.
- HSV.
- CMV.

Bacterial infections

- *Streptococcus pneumoniae.*
- *Haemophilus influenza.*
- *Pseudomonas aeruginosa.*
- *Legionella pneumonia.*
- *Rhodococcus equi.*

Mycobacterial infections

- *Mycobacterium tuberculosis.*
- *Mycobacterium avium complex.*

Fungal infections

- *Pneumocystis jiroveci.*
- *Cryptococcus neoformans.*
- *Histoplasma capsulatum.*
- *Coccidioides immitis.*
- *Aspergillus fumigatus.*

Malignancy

- Carcinoma of the lung.
- **Lymphoma**: Non-Hodgkin's lymphoma
- **Human Herpes 8 associated conditions:**
  - Kaposi's sarcoma.
  - Multicentric Castleman's disease.
  - Primary effusion lymphoma.

Other conditions

- Chronic obstructive pulmonary disease.
- Pulmonary hypertension.
- Bronchiectasis.

to the initially prescribed regimen [20], and older therapies such as pentamidine are not recommended unless allergy limits options.

Neurological manifestations

Causes of altered mental status in HIV infection in patients in the ICU may represent HIV-related opportunistic infection or associated systemic illness or may represent the many causes of altered mental status in the general ICU population. The prevalence of these opportunistic infections is dependent upon the level of immune suppression. In addition to standard viral and bacterial aetiologies of meningoencephalitis, opportunistic infections such as tuberculosis, *Cryptococcus neoformans* and Toxoplasma must be considered. With advanced disease (CD4 cell counts <50 cells/mm^3) progressive multifocal leukoencephalopathy (PML) associated with JC virus, and primary CNS lymphomas must be considered. An initial approach is suggested in Fig. 291.1.

Cryptococcal meningitis was seen in 5–10% of patients in the pre-cART era presenting as an acute or subacute onset meningitis with progressive symptoms of headache and often fever. Patients with cryptococcal meningitis may also have photophobia, drowsiness, reduced visual acuity, and papilloedema. Neuro-imaging may be normal or show parenchymal enhancement or cryptococcomas. A positive serum cryptococcal antigen has high sensitivity for diagnosis, however a lumbar puncture is mandatory to evaluate for an elevated opening pressure. Examination of the CSF may not reveal significant abnormalities other than elevated protein—in advanced HIV disease the CSF white blood count may be low, but may demonstrate lymphocytic predominance.

Therapy consists of amphotericin B (0.7 mg/kg/day) or liposomal preparations of amphotericin (4–6 mg/kg/day) in conjunction with flucytosine (100 mg/kg daily in four divided doses) for two weeks, followed by fluconazole once CSF sterilization is documented. If the opening pressure is elevated at presentation, daily lumbar punctures are recommended to decrease intracranial pressure. If this approach is unsuccessful, CSF shunt should be considered [19].

Conclusion

Antiretroviral therapy has provided major advances in the care of the HIV infected patients and increasingly transformed HIV into a chronic controllable disease in North America. HIV itself should not be considered a reason to limit provision of care as careful medical management of the acutely unwell HIV positive patients lead to outcomes that approach those of the general population.

PART 13.4

Tropical diseases

CHAPTER 292

Diagnosis and management of malaria in the ICU

Christopher J. M. Whitty

Key points

- Malaria is a very common cause of severe infection from Africa, Asia, and Latin America. All severely-ill patients from these areas should have a malaria blood film.
- There is good evidence that artesunate reduces mortality compared to quinine, but do not delay treatment with quinine if artesunate is not available.
- Cerebral malaria, renal failure, and acute respiratory distress syndrome (ARDS) are the major syndromes in adults. There is little evidence for specific adjunctive treatments for these.
- Severe malaria is a significant risk factor for bacterial sepsis in children, but probably not adults.
- The prognosis for adult malaria patients if they survive is good.

Introduction

Malaria is the commonest life-threatening tropical infection. Diagnosed and treated early it will seldom require critical care and the outlook is good. Once severe malaria is established, it is a serious multi-system disease, which can continue to evolve even once the malaria parasites have cleared from the blood. This chapter is written for critical care physicians caring for predominantly adult patients. There are important differences from the management of severe childhood malaria, and as much of the data comes from children these are highlighted.

Epidemiology and when to suspect malaria

Malaria occurs in most countries in Africa, Asia, and Latin America, but incidence varies widely. In many parts of sub-Saharan Africa people can have clinical attacks of malaria four or more times a year. Malaria is much less common from most of Asia and Latin America, with many areas malaria-free. This can mean the diagnosis is not suspected and therefore delayed. The great majority of malaria that leads to critical illness is falciparum malaria, which causes around 95% of malaria in Africa. Vivax malaria is the most common form in much of Asia and Latin America, and relatively rarely causes critical illness, although severe cases have been more frequently recognized recently and a benign course cannot be assumed. In returning travellers presenting in non-endemic countries over 90% of cases of falciparum malaria will present within 3 months of return and most within a month, although delayed presentation of up to a year after return does occasionally occur. Very occasionally unexpected malaria is caused by blood transfusion, or sharing needles with intravenous drug use.

Diagnosis of malaria

Malaria can present in multiple ways; no clinical symptom or sign either proves or excludes the diagnosis. In a critically unwell patient with an exposure history fever, unconsciousness, or fitting, jaundice or splenomegaly are suggestive. Whilst a history of fever is usual, around half of patients with malaria are afebrile at the time of presentation. A malaria blood test is therefore essential.

For management of the critically-ill patient blood film microscopy for parasites remains the best test. It identifies the species of malaria, and importantly, the percentage of red cells parasitized. Rapid diagnostic tests for malaria are mostly as sensitive as microscopy, and may speed the diagnosis, but they are not a substitute for microscopy in severely ill patients as they give an all-or-nothing response. In critically-ill patients prior to treatment a sufficient number of parasites for diagnosis will almost always be present so microscopy is sensitive and specific.

Initial assessment of severity

Severe malaria can present with a number of syndromes. These may occur in isolation, or in any combination.

The most well-known is cerebral malaria. Strictly unrousable coma in the presence of asexual malaria parasites, any reduction of consciousness, neurological signs or fitting should be treated as cerebral malaria. It generally presents before starting antimalarial treatment, but especially in patients who present with very high parasite counts cerebral malaria may occur in the first 48 hours after starting treatment as parasites mature and begin to stick down (sequester) in the blood vessels in the brain.

Renal failure may present as oliguria or anuria, or be diagnosed from raised creatinine or blood urea. Renal failure may be present at initial diagnosis or develop in the first few days after treatment has started, including when parasites have cleared from the blood. There are potentially two components to renal failure in malaria; pre-renal failure in febrile patient not drinking adequately, and the direct effects of malaria on the kidney (the exact pathological mechanism is currently unknown). If there is any doubt whether prerenal failure is a major component rapid fluid challenges will help identify it. Renal failure is common in critically-ill adults with malaria (but rare in children) [1].

Malaria-associated respiratory distress in adults is usually due to problems in the lungs, with two potential causes. Pulmonary oedema, often caused or exacerbated by enthusiastic rehydration in patients with renal failure, is reversible. Adult respiratory distress syndrome (ARDS)/acute lung injury (ALI) often presents late in the course of severe malaria, including days after malaria parasites have cleared from the blood. In children respiratory distress is also a sign of severe disease, but is generally caused by acidosis rather than poor oxygen transfer and lungs are normal. In both adults and children coexisting pneumonia should be excluded.

Of the uncommon manifestations of severe malaria the most important is disseminated intravascular coagulation (DIC), and occasionally cerebral or other serious bleeds where there is no DIC due to the very low platelets which are commonly found in severe malaria.

In contrast to most critically-ill patients with sepsis, shock is relatively rare except when there is coexisting bacterial sepsis. Bilirubin is often raised due to massive haemolysis, but liver function rarely significantly impaired.

Two warning signs in otherwise well patient with malaria make it likely the patient will deteriorate even after starting treatment. The first is finding a high parasite count in the peripheral blood. Patients with parasite counts of greater than 10%, even if appearing initially well, have a very high chance of deteriorating over the next 48 hours as parasites mature. In high resource settings where malaria is not endemic, it is prudent to treat any patient with parasite count greater than 2% with parenteral drugs even if they are otherwise well as their risk of severe disease is significantly raised [2]. The second is jaundice which in the presence of malaria generally indicates massive haemolysis.

Three groups are at particular risk of poor outcomes; elderly patients as mortality increases steadily with age [3], pregnant patients where the risk of complications in the pregnancy are significant, and patients with AIDS.

Treatment

Antimalarial treatment

All patients with severe malaria should be treated rapidly with high doses of effective parenteral antimalarials, and this is by far the most important step in managing critically-ill patients. In practice the choice is between quinine (or in the USA quinidine) and artesunate. Quinine has been the mainstay of managing severe malaria for over a century, and remains an effective drug. In the last few years however there has been clear evidence from large randomized trials in children and adults in Africa and Asia that artesunate has a significant mortality advantage [4,5]. When both drugs are available therefore artesunate is preferable. No head-to-head comparisons of quinidine with artesunate have been undertaken, but there is no reason to believe that it would perform better than quinine so artesunate remains the best drug available. At present however stocks of artesunate are limited in many countries and the priority should be to treat as fast as possible with a high dose of an intravenous effective drug; better to use quinine (or quinidine) immediately than artesunate after several hours delay. In most non-endemic countries specialist centres hold critical stocks of artesunate.

A number of factors make artesunate particularly appropriate. Where patients have hyperparasitaemia (>10%) artesunate brings down parasite counts much faster than quinine, kills all ages of parasites, and it is in this group that the biggest survival advantage was found in trials in adults [4]. In patients who are at risk of arrhythmia quinine and quinidine are arrhythmogenic. Quinine has a number of unpleasant, but generally non-severe side-effects, but an important one is that it is hypoglycaemic, and in patients on quinine blood glucose must be monitored closely. The side effects of quinidine are very similar to those of quinine, but there is a roughly 2 times higher risk of arrhythmias with quinidine for the same malaria killing dose.

Quinine should have a loading dose of 20 mg/kg as a slow infusion, followed by 10 mg/kg 8–12-hourly. Artesunate is given at a dose of 2.4 mg/kg as a bolus, repeated at 12 and 24 hours, then daily. Both should be continued until either parasites have cleared from the blood, or the patient is able to take oral treatment and has no remaining signs of severe disease (again until parasites are clear). For oral follow-up a combination of two drugs should be used with either quinine or an artemisinin drug; most countries have local guidelines for oral treatment.

Treatment of complications

Other than rapidly treating malaria, the majority of the treatment of the critically-ill malaria patient is supportive, and does not differ significantly from the management of other critically-ill patients with multisystem disease. Many adjunctive therapies such as steroids have been tried, generally based on contemporary (often erroneous) beliefs about malaria pathophysiology, but almost all have fallen into disuse when proper clinical assessment demonstrated either they do not work or that they do harm. The evidence base for managing severe malaria in children is generally better than that in adults. Unfortunately, as the pathophysiology of the disease differs between adults and children, it is unwise to extrapolate between them.

Cerebral malaria

The most important thing in cases of reduced consciousness and malaria is to ensure that they do not have hypoglycaemia, which can be caused by the parasite and in patients on quinine the treatment.

In children in particular there is also risk of subclinical fitting for which the treatment is of complex partial status with antiepileptic drugs. This can manifest by subtle twitchings or, where available, EEG monitoring. Based on the finding that they reduce the risk of fitting, for a time prophylactic anticonvulsants were recommended for adults and children, but a trial in Kenyan children which demonstrated reduced fitting, but increased mortality means they are now generally only recommended in established fitting [6].

Because of evidence of some degree of brain oedema in cerebral malaria, steroids and mannitol have both been tried and seem to increase risks if anything.

In adults who recover even from prolonged (i.e. many weeks) unconsciousness in malaria, neurological deficits are surprisingly rare compared to other neurological infections. The great majority of patients with cerebral malaria will recover with no noticeable deficits. The rate of neurological sequelae is higher in children.

Renal failure

As with all acute renal failure the key is to minimize electrolyte disturbance, particularly high potassium and this may well require haemodialysis or haemofiltration. There is very weak evidence that early haemofiltration speeds recovery. Although renal support may be needed for some weeks following recovery from malaria, kidneys almost invariably recover back to their normal function with only a few case reports of persisting renal failure.

A very rare complication, although it used to be common when quinine was given in repeated low doses as prophylaxis, is blackwater fever (almost black urine). Almost all cases now are associated with G6PD deficiency, and are probably caused by quinine related drugs causing haemolysis. It is not a reason to stop therapy provided the haemoglobin is monitored and maintained when necessary.

Adult respiratory distress syndrome, disseminated intravascular coagulation

These are treated as with any other patients with these syndromes with no malaria-specific therapy proven to help other than treating the underlying condition.

Hyperparasitaemia and exchange transfusion

There is a logic that in patients treated with quinine who have very high parasite counts (>20% red cells) physically removing parasites will prevent them from developing into mature forms that sequester in vital organs. Quinine exerts the majority of its effect on mature parasites so many of these immature forms will progress if not removed even when on quinine treatment. In some centres it is therefore the practice with these very high parasite counts either to undertake an exchange transfusion where six units of blood are removed and six replaced simultaneously, or mechanical red-cell exchange. There is relatively little evidence either that this does any good, or any harm, beyond the usual risks of transfusion and substantial fluid shifts [7]. In patients treated with artesunate parasite counts drop rapidly, and the drug kills young parasite forms, so the logic of exchange transfusion largely disappears. Exchange transfusion is therefore now rarely recommended.

Fluid management

In adults, how best to manage fluids in malaria patients is hotly debated, largely because little convincing evidence exists. There is weak evidence that over hydration of patients leading to pulmonary oedema may increase the risk of ARDS. Malaria physicians are therefore usually cautious about minimizing the risk overhydration. In children a recent major trial showed convincingly that bolus fluids lead to increased mortality; it is not clear whether this is relevant to adults [8].

Shock, and coexisting bacterial sepsis

Shock is relatively rare in malaria except when patients are significantly dehydrated, there is coexisting bacterial sepsis (particularly Gram-negative sepsis) and in rare cases of occult gastrointestinal bleeds with DIC. Patients who become shocked with malaria therefore should be treated with broad spectrum antibiotics with Gram-negative cover in addition to supportive treatment. In children, severe malaria seems to increase substantially the risk of sepsis, but this association is less clear in adults [9]. It is therefore prudent to treat children prophylactically with antibiotics if they have severe malaria even without shock.

Anaemia and thrombocytopenia

Life-threatening anaemia is a common manifestation of malaria in children in low resource settings, but in non-pregnant adults it is rare, although some degree of anaemia is likely in all malaria cases because malaria destroys red cells. Transfusion is only likely to be useful in cases where haemoglobin has fallen substantially, or there is cardiovascular compromise. There is no consensus over what level of haemoglobin is appropriate treat in the absence of cardiovascular compromise, although in high resource settings Hb below 7 g/dL is a reasonable threshold. Thrombocytopenia is invariable in severe malaria. Except when coexisting with DIC it rarely causes significant clinical problems, and there is little association between scale of thrombocytopenia and severity of malaria. Platelet transfusions are probably only useful in the context of active bleeding where platelets fall below 30/L as hypersplenism means transfused platelets will be rapidly consumed.

Long-term prognosis

Depending on syndrome, mortality from severe malaria by the WHO criteria in adults is likely to be 5–15%. In a high resource settings childhood deaths from malaria are extremely rare [3] although in Africa childhood deaths are the great majority. In patients with isolated cerebral malaria and no other organ involvement, if the patient survives the first 48 hours the outlook is usually good. Deaths from isolated renal failure should not occur where haemodialysis and haemofiltration are available. The mortality from ARDS, the rarest of the major syndromes, is the highest with over 50% reported in some series.

The majority of those who die from malaria in well-resourced critical care settings do so from the complications associated with long intensive care unit stays, in particularly nosocomial infection once parasites have cleared. The great majority of patients with severe malaria will survive, even if unconscious for a long time, and their outlook for making a full recovery is good, with very rare cases of significant neurological impairment or other disability, although these do occur.

CHAPTER 293

Diagnosis and management of viral haemorrhagic fevers in the ICU

Emersom C. Mesquita and Fernando A. Bozza

Key points

- Always suspect viral haemorrhagic fevers (VHFs) in a sick traveller from an endemic area in whom an alternative diagnosis cannot be established.
- Always perform a malaria test (thick blood films) in a VHF suspected case and, if not quickly available and/or reliable, start empirical antimalarial treatment.
- Immediately place the patient in a negative pressure room and alert local infection control unit, state, and national authorities.
- Health care professionals should always use appropriate barrier and aerosol precautions. Access to patient's room should be limited to only staff personnel.
- Supportive therapy is the main stay of treatment, but specific antiviral agent (ribavirin), preferably by intravenous (iv) route, should be started early in the diagnosing setting. Apply easily done diagnostic test (RT-PCR) and discontinue antiviral therapy if the diagnosis of filoviral or flaviviral infection is made.

Introduction

Viral haemorrhagic fevers (VHFs) represent a group of clinically indistinguishable diseases caused by four different families of small, enveloped, RNA virus: *Arenaviridae, Filoviridae, Bunyaviridae*, and *Flaviviridae*.

VHFs poses great medical challenge because:

- Diseases are associated with a high mortality rate.
- Many VHFs have the potential for person-to-person transmission (Filoviruses, Arenaviruses, and Bunyaviruses).
- Widespread international travel made possible for viral agents to migrate from endemic areas to non-endemic areas.
- Early diagnosis and treatment are paramount for improving clinical outcome and for minimizing health care associated transmission.

Main clinical and laboratory findings, major viral agents, as well as epidemiological characteristics of VHFs are depicted in Table 293.1.

VHFs are characterized by acute fever, coagulation disorders and organ specific syndromes such as encephalitis, pneumonitis, nephritis, and arthritis. The severity and clinical presentation of VHFs may vary from an unspecific febrile disease to severe forms with severe bleeding, intravascular coagulation, multiple organ dysfunctions and death. Often, the mechanisms of severe disease include a combination of endothelial dysfunction, causing capillary leak syndrome and bleeding disorders, associated with thrombocytopenia and disseminated intravascular coagulation. Different organ specific syndromes can be more associated to a specific virus family [1–6].

In the last years, a substantial progress in the understanding of pathogenesis and dissemination of VHFs has been made. However, to date, lack of available vaccines for most VHFs, absence of potent specific antiviral therapies and the potential for bioterrorism usage of these agents makes VHFs a major global public health concern [7].

Dengue is the most frequent haemorrhagic viral disease and re-emergent infection in the world. Currently, 25–30% of the world's population lives in areas at risk of dengue infection. It is estimated that there are 50 to 100 million cases of dengue infection per year, and the global incidence of dengue continues to increase. In the last decades a progressive global expansion of the disease including a higher frequency of severe forms (DHF/DSS) was observed. This expansion included tropical and subtropical areas in Americas, Europe, Asia, and Africa. Recently, the burden of dengue was reviewed as more than three times the previously estimated by World Health Organization (WHO). Due to its public health relevance, severe dengue will receive special attention in this chapter.

Pathogenesis

Information regarding the pathogenesis of VHF in humans is limited and, in general, comes from clinical observations and experimental infections in non-human primates (NHP). Careful interpretation of experimental studies is necessary due to virus type, viral load, administration route, host previous immunity, and animal species utilized in these studies.

Endothelial infection is a common finding among the diseases, but can be limited or widespread depending on the agent. In the case of Ebola haemorrhagic fever (EHF) and in severe forms of Rift Valley fever (RVF), the virus has a highly destructive interaction

Table 293.1 Main viral haemorrhagic fevers

Disease	Ebola HF	Marburg HF	Lassa HF	HFRS	CCHF	RVF	Severe dengue	Yellow fever
Causative virus (Family name)	Ebola (Filoviridae)	Marburg (Filoviridae)	Lassa (Arenadiridae)	Hantan (Bunyaviridae)	CCHV (Bunyaviridae)	RV (Bunyaviridae)	Dengue (Flaviviridae)	Yellow fever (Flaviviridae)
Distribution	Africa	Africa	West Africa†	Eastern Russia, Korea, China, and Balkans	Africa, Middle east, central Asia, Europe	Africa, Saudi Arabia and, subsequently, Yemen	Endemic in Asia, the Pacific, the Americas, Africa, and the Caribbean	Africa and tropical Americas
Transmission	Bat	Bat	Rodent	Rodent	Tick	Mosquito	Mosquito	Mosquito

†Other pathogenic members of the *Arenadiridae* family can also be found in the Americas.

with the endothelium leading to vascular leakage, disseminated intravascular coagulation (DIC), shock, and death. Arenaviruses and dengue, in contrast, infect the endothelium, but these cells are not the primary cellular targets and cause little direct damage to the endothelium; they may induce abnormal cytokine production and disrupt endothelial function, but this is in the absence of obvious morphologic signs. Other viruses, such as Hantaviruses, are virtually non-cytopathic, can infect cells in vitro without inducing any permeability or other major change, and depend on the host immune response to induce changes in vascular permeability [8–10].

All VHF induces thrombocytopenia. Different degrees of platelet dysfunction, including platelet activation, apoptosis, elevated clearance, and abnormal thrombopoiesis, are well documented in severe dengue, Ebola, Lassa fever, and Arenavirus infection. Decreased levels of coagulation factors, frequently observed and derived from hepatic failure or DIC, can be observed in yellow fever (YF) and RVF.

High concentrations of pro-inflammatory cytokines (cytokines storm) clearly play an important role in the different VHF infections, but the mechanisms for cytokine induction and their exact role are different and poorly understood among the infections. The clotting defects are also quite variable in both their obvious manifestations and their pathogeneses.

Most of the VHF produce very severe symptoms in their infections; however, dengue virus infections produce distinct disease outcomes. The immunopathological mechanisms responsible for the increased disease severity associated with severe dengue are only partially understood. Several lines of evidence have indicated that non-neutralizing anti-DENV antibodies play a modulatory role that involves antibody-dependent enhancement (ADE) of infection, via Fc-gamma receptor (FcγR)-facilitated virus entry. However, other factors, including altered T-cell responses, virus strain virulence, and innate immunity have been implicated in modulating the clinical outcome of the infection. These data support four non-mutually exclusive theories to explain the immune mechanisms leading to DHF [2,4,11,12]. The main theories are:

- **ADE**: anti-DENV antibodies can form non-neutralizing immune complexes with the virus and facilitate the infection of cells expressing FcγR.
- **Original antigenic sin (OAS)**: memory T-cells are abnormally activated by altered peptide epitopes that are capable of production of high levels of cytokines, but are not effective in killing infected cells.
- **Dengue strain virulence (DSV)**: specific strains of the dengue virus, of any of the serotypes, are more able to replicate in the human host tissues.
- **Host innate responses (HIR)**: the specific human genetic background influenced by environmental factors can result in inadequate innate responses, notably, dendritic cells, type I and II interferon responses and responses of the complement system.

Clinical presentation and laboratory findings

Describing in details clinical and laboratory findings of each viral agent is beyond the scope of this chapter and has been recently

reviewed elsewhere (WHO 2009 and 2013). Major clinical and laboratory features, shared by the four viral families aforementioned (*Filoviridae, Arenadiridae, Bunyaviridae, Flaviviridae*), are depicted here.

Patients usually become abruptly ill after an incubation period of 3–21 days. At presentation, fever, chills, headache, joint and muscle aches, fatigue, diarrhoea, nausea, vomiting, sore throat, and conjunctivitis can be present. Routine laboratory panel performed at this point should display leukopenia with lymphopenia, thrombocytopenia, and a mild to moderate elevation in liver enzymes (AST and ALT). Leukocytosis can also be observed usually after the second week of symptoms on filoviral infections. Prominent liver involvement is a common feature of YF and, together with patient's travel history, could help in distinguishing between different VHFs syndromes. Prominent renal impairment is a typical feature of haemorrhagic fever with renal syndrome (HFRS) and, together with a longer incubation period (usually 2 weeks) and patient's travel history, should point towards this diagnosis. As disease progresses, coagulopathy, with prolonged prothrombin (PT) and partial thromboplastin times (PTT), altered mental status, renal and liver , and DIC becomes evident. Haemorrhagic manifestations can include petechial skin rash, epistaxis, haematemesis, melena, conjunctival and venipuncture site bleeding and, finally, death.

Severe dengue is characterized by clinical and laboratorial evidence of increased capillary permeability and plasma leakage. After the febrile phase, patients experience sudden defervescence, circulatory and perfusion changes (hypotension and hypovolemic shock), ascites and pleural effusion, and organ dysfunctions such as liver failure, encephalitis, myocarditis, and clotting disorders. Usually a sudden drop of leucocytes and platelets precedes plasma leakage, and a progressive haematocrit increase can be observed reflecting the magnitude of haemoconcentration. The critical phase, which is evident in 10–15% of dengue cases, discloses the progression to severe disease. The duration of this phase is 1–3 days.

Differentials

Most important differentials are depicted in Table 293.2.

Diagnosis

Diagnosis should be considered in a sick traveller from an endemic area in whom an alternative diagnosis cannot be made (see Table 293.2 for relevant differential diagnosis). Malaria test (thick blood films) should always be performed in a suspected VHF case and, if not quickly available and/or reliable, empirical antimalarial treatment should be initiated. Lack of clinical and laboratory response to antimalarials and/or to the treatment of most common bacterial infections should raise suspicion of VHF in a patient returning from an endemic area. It is likely that most VHF suspected cases will end up with a more common definitive diagnosis; nevertheless, early diagnosis is paramount for achieving a better clinical outcome.

Table 293.2 Relevant differentials for VHFs

Bacterial and rickettsial infections	Viral and parasitic infections	Non-infectious conditions
◆ Leptospirosis ◆ Meningococcaemia ◆ Gram-negative bacterial septicaemia ◆ Typhoid fever ◆ Rocky Mountain spotted fever	◆ Malaria ◆ African trypanosomiasis ◆ Viral hepatitis	◆ Thrombotic or idiopathic thrombocytopenic purpura ◆ Haemolytic uraemic syndrome

Specific diagnoses of VHFs agents are usually obtained on blood samples by detecting specific antibodies, viral antigens (ELISA), viral nucleic acid (reverse transcriptase polymerase chain reaction (RT-PCR)) and virus isolation.

Detection of specific IgM antibodies or a four-fold increase in IgG antibody titres can be achieved by collecting acute-phase blood samples within 7 days of illness and convalescent-phase blood samples 8–20 days later. Detection of antibodies can be difficult because they are not easily detected early in the course of the diseases and some patients, usually associated with fatal outcome, fails to produce robust immune response. RT-PCR is an important diagnostic tool and offers the advantage of rapid detection with high sensitivity and specificity even in the first days of illness, when antibody titres are still low. Viral nucleic acid detected by RT-PCR can be performed even a few days after the viraemic period. Virus isolation should only be performed in laboratories biosafety level 3 or above.

Dengue infection can be firmed by detecting viral antigen (Ns1Ag), virus isolation, or RNA virus detection (RT-PCR). Around the fifth day, viremia and antigenemia disappear, which coincides with the appearance of specific antibodies. From the sixth day, IgM ELISA is the method of choice for diagnosis of dengue. High levels of IgM and low levels of IgG characterize primary infections, while low levels of IgM with high levels of IgG suggest secondary infections. In dengue endemic countries, acute clinical cases with a positive IgM are classified as probable dengue cases. The study of paired sera (acute and convalescent serum samples with the second sample being collected 15–21 days after the first sample), allows for serological confirmation of dengue infection.

Treatment in the intensive care setting

VHFs greatly resembles sepsis pathogenesis and their approach in the intensive care setting is quite similar. Intravenous volume replenishment, management of pain, anxiety and electrolyte imbalance is essential. Aggressive treatment of multi organ dysfunctions and haemorrhagic events frequently requires vasoactive drugs, haemodialysis, mechanical ventilation, platelet transfusion, and red blood cells transfusion.

Adjunctive antimicrobial therapy is usually implemented to treat coexisting or secondary infections. Antimalarial treatment should also be initiated if a malaria test (thick blood films) is not quickly available and/or reliable, and patients travel history is compatible.

Empirical antiviral treatment with Ribavirin should be started as soon as a case of VHF is suspected. Ribavirin (1-beta-D-ribofuranosyl-1H-1,2,4-triazole-3-carboxamide) interfere with intracellular RNA and DNA synthesis and subsequently inhibits protein synthesis and viral replication of ribavirin-sensitive RNA or DNA viruses. Ribavirin should be preferably administered through iv route. Start with a loading dose of 30 mg/kg, followed by 16 mg/kg every 6 hours for 4 days, followed by 8 mg/kg every 8 hours for 5–10 days (Ribavirin treatment should be maintained if Arenavirus or Banyavirus infection). Ribavirin comes in vials of 1000 mg and

800 mg, to be diluted in 10 mL phosphate buffer solution. Infuse over 10–15 minutes. Major side effects and caution includes haemolytic anaemia, pancytopenia, pancreatitis, renal, and liver impairment.

The cornerstone for severe dengue therapy is a rapid recovery of the effective volaemia through an adequate fluid resuscitation (recently reviewed by WHO experts [6]). Briefly, a reference haematocrit (Ht) obtained before to start the fluid therapy, associated with the BP, will be major parameters to be used to evaluate the response to the therapy. To patients with shock, start iv fluid resuscitation with isotonic crystalloid solutions at 20 mL/kg as a bolus given over 15–30 minutes. If the patient's condition improves maintain the infusion at 10 mL/kg/hour for 1 hour more. Then gradually reduce to 5–7 mL/kg/hour for 1–2 hours, then to 3–5 mL/kg/h our for 2–4 hours, and finally to 2–3 mL/kg/hour (or less), which can be maintained for up to 24–48 hours.

When hypoperfusion signs persist after volume infusion in association with a drop in Ht it should be suspect bleeding complications. Red blood cell transfusion is indicted if there is severe overt bleeding, and transfusion of platelet concentrate is indicated for patients with lower than 50,000/mm^3 platelets with suspected severe bleeding.

If the Ht increases compared to the reference Ht or remains high continue fluid infusion at 10–20 mL/kg as a third bolus over 1 hour, colloid solution can be used. After this dose, reduce the rate to 7–10 mL/kg/hour for 1–2 hours, and then reduce the rate of infusion as mentioned previously when the patient's condition improves [15–18].

Biosafety measures

Installation of proper biosafety measures should not be delayed by any laboratory test. Notify local infection control unit and state and national authorities. All suspected cases of VHF should be immediately placed in a negative pressure room and access should be limited to necessary only staff personnel. Face shields, goggles, N-95 masks or powered air-purifying respirators, double gloves, impermeable gowns, leg, and shoe coverings should be worn while handling the patient. After handling the patient, it is mandatory to remove and discard gown, leg and shoe coverings, and gloves. Proper hand hygiene should be performed prior to the removal of facial protective equipment to minimize exposure of mucous membranes. Patient care equipment including thermometers, blood pressure cuffs and stethoscopes should be dedicated to the patient. If patient dies, handling of the body should be minimal.

Acknowledgements

The authors would like to acknowledge Ernesto Marques whose help in writing this chapter was greatly received.

CHAPTER 294

Other tropical diseases in the ICU

Arjen M. Dondorp

Key points

- A wide range of tropical infectious diseases can cause critical illness. Knowledge of the local epidemiology where the disease is likely acquired is essential.
- In addition, local resistance patterns of common bacterial pathogens can be very different in tropical countries, so that antibiotic regimens might need adaptation.
- The 'surviving sepsis' guidelines are not always appropriate for the treatment of tropical sepsis, including in dengue shock syndrome and severe malaria. Both diseases require a more restricted fluid management.
- Leptospirosis is another important (mainly) tropical disease that can cause sepsis with liver and renal failure or acute respiratory distress syndrome (ARDS) with pulmonary haemorrhages.
- Recent epidemics of respiratory viruses causing life-threatening pneumonia have had their origins in tropical countries, including Severe Acute Respiratory Syndrome (SARS), Influenza A subtype H5N1 ('avian influenza'), and recently Middle East respiratory syndrome coronavirus (MERS-CoV).

Introduction

In addition to severe malaria and viral haemorrhagic fevers (discussed in the previous chapters), there is a wide range of tropical diseases that might be encountered in the ICU setting. Knowledge about the local epidemiology of the area where the disease was most likely acquired is a prerequisite for the proper diagnostic work-up. For instance, a patient admitted with septicaemia acquired in north-eastern Thailand will have a high chance (20%) that this is caused by the soil-dwelling bacterium *Burkholderia pseudomallei*, whereas in Nepal *Salmonella typhi* or *paratyphi* will be the most common causes. These differences in a priori chances will have important consequences for the choice of initial empirical antibiotic therapy, e.g. *B. pseudomallei* should be covered by a carbamapenem or ceftazidim. HIV/AIDS is a very common disease in several tropical countries, especially in Sub-Saharan Africa, which will also affect the differential diagnosis in patients presenting with severe febrile illnesses.

It should also be realized that although a diagnosis of severe malaria often to be excluded first, the main causes for severe febrile illness acquired in tropical countries also include common bacterial pathogens like *Str. pneumoniae, Staph. aureus*, and Enterobacteriaceae. Resistance patterns of these bacteria acquired in tropical countries can, however, be very different, although good surveillance data from low-income countries are often lacking [1]. Methicillin resistant *Staph. aureus* infections in these tropical countries are often not only hospital associated, but now also widespread in community acquired infections (up to 20%) and reported from rural areas of both Asian and African countries [2]. Extended Spectrum β-lactamase (ESBL) producing Enterobacteriaceae (e.g. *E. coli*) have spread into the community in many low-income tropical countries, probably accelerated by increased consumption of 3rd generation cephalosporins. Fluoroquinolone resistance in typhoid in Asia has severely curtailed the usefulness of these drugs. More recently, and more worrying, carbapenemases producing Enterobacteriaceae (including NDM-1 producing *Klebsiella pneumonia*) have been identified in India and are increasingly reported in hospitals elsewhere [3].

Some other common tropical diseases that can present as severe sepsis include severe dengue (dengue haemorrhagic fever/dengue shock syndrome) and severe leptospirosis.

Dengue virus

Dengue virus (serotypes DENV 1,2,4, and 4) is transmitted through the bite of infected female *Aedes aegypti* mosquitoes and less common *Aedes albopticus*. The disease is widespread throughout the tropics and more than 1 billion people are at risk in over 100 countries. Although usually infections result after an incubation time of 4–7 days only in an uncomplicated undifferentiated fever, or a febrile illness with severe headache and generalized pains in muscles and bones ('breakbone fever'), a minority of patients develops severe disease typically starting at the time of defervescence. The hallmark of dengue haemorrhagic fever is an acute vascular permeability syndrome accompanied by abnormal haemostasis. Capillary leakage results in hypoproteinaemia, elevated haematocrit, pleural effusions, ascites, and a haemorrhagic diathesis aggravated by concomitant thrombocytopenia. In cases with more severe capillary leakage, haemodynamic shock can result called dengue shock syndrome (DSS). The relatively slow development of hypovolaemia and the prominent thrombocytopenia distinguishes DSS from other (bacterial) causes of septic shock. Treatment of DSS is supportive, with a particular focus on careful fluid management [4]. Because of the generalized capillary leakage, fluid volumes should be restricted, but sufficient to maintain cardiovascular stability and adequate renal function. Resuscitation with colloids rather than crystalloid solutions can be recommended for patients with hypotension [5]. The altered vascular permeability is short-lived and usually reversible after 48–72 hours [6]. As soon as re-absorption begins intravenous fluids should be stopped. Preventive transfusion of platelet concentrates in the absence of bleeding, even for profound thrombocytopenia, and the use of corticosteroids have not shown to improve outcome [7].

Leptospirosis

Leptospirosis is primarily a zoonosis affecting humans in both rural and urban settings in temperate and tropical climates. Human infection most often follows exposure to soil and water contaminated with excreta of animals infected with pathogenic species of *Leptospira*. Leptospirosis is an important cause of febrile illness in tourists returning from the tropics, and usually manifests as a mild febrile illness typically 7–12 days after exposure. However, a minority develops a severe systemic illness characterized by a systemic vasculitis resulting in a wide spectrum of clinical features. The major affected organs include the kidneys and liver ('Weil's disease') and the lungs, resulting in focal or massive intra-alveolar haemorrhage [8]. Haemodynamic shock is also common in severe leptospirosis and myocarditis, meningoencephalitis, and uveitis can also develop. Antibiotic treatment of severe disease is with penicillin G, cefotaxim, or ceftazidime [9]. Supportive treatment in the ICU will often have to include renal replacement therapy.

Therapy

Although many tropical infectious diseases in the ICU can present fulfilling the criteria for severe sepsis or septic shock, not all recommendations of the 'Surviving Sepsis Campaign' guidelines are always applicable. Fluid therapy in dengue shock syndrome should be much more careful then in septic shock from other causes, because of the generalized capillary damage and leakage. Fluids should also be restricted in patients with severe malaria, where hypotension is fortunately a rare event (10%) [10]. Permissive hypercapnia as a ventilation strategy in patients with cerebral malaria should be avoided because of the risk of herniation of the engorged brain. Corticosteroids are not recommended in patients with severe dengue or severe malaria.

Neurological syndromes

In addition to septic syndromes, severe neurological diseases might be encountered in the ICU in patients who resided in or visited the tropics. Again, in most cases, cerebral malaria will have to be excluded first. Meningitis caused by Neisseria meningitis is endemic in the so-called meningitis belt across central Africa, and it is important that travellers are asked whether they have received proper vaccinations before their trip to these areas.

Causes of meningitis and encephelitis

A large number of viruses with a prominent presence in tropical countries can cause meningitis, encephalitis, or meningo-encephelitis in humans [11]. Common examples include enteroviruses (including EV71 and polio, now close to eradication), Nippah virus, Herpes simplex virus, Rift Valley fever (caused by a phlebovirus (Bunyaviridae), and transmitted by mosquitoes), Japanese encephalitis (transmitted from cattle by culex mosquitoes and vaccine preventable), and West Nile virus infection (transmitted from birds by culex mosquitoes), some of the tick-borne encephalitides, and Venezuelan Equine Encephalitis (also mosquito borne). Except for the herpes viruses, no specific anti-viral treatment is available for these infections.

Rabies

Rabies causes between 40,000 and 70,000 deaths per year, mostly in Southeast Asia, Africa, and South America [12]. Although the majority (99%) is caused by dog bites, other terrestrial animals transmit the disease. Vampire bats can transmit the rabies related lyssaviruses. The incubation time is usually between 3 and 12 weeks, but can be as long as 19 years [13]. Disease can be prevented by post-exposure (bite) prophylaxis with vaccination and administration of human rabies immunoglobulin (HRIG). Once symptomatic disease develops, rabies is fatal. A rabies case related to bat transmitted lyssavirus has been reported who survived after treatment according to an experimental protocol ('Milwaukee protocol') including sedation with ketamine and midazolam and the antiviral drugs ribavirin and amantadine. This success has not been reproduced by other groups [14].

African trypanosomiasis

African trypanosomiasis (sleeping sickness) is endemic in most Sub-Saharan African countries (but not in South Africa, Namibia, and Botswana) and can occasionally affect travellers. The disease is a zoonosis transmitted to humans by the bite of the tsetse fly (*Glossina sp.*). The local skin lesion at the site of inoculation (chancre) is followed by the haemolymphatic stage of the disease (stage I) which may be followed by invasion of the central nervous system and cerebrospinal fluid, leading to a meningoencephalitis (stage II). *Trypanosoma b. gambiense* (Middle and West-Africa) causes a protracted illness over months, but *T.b. rhodesiense* (East-Africa) causes a severe acute febrile disease with rapid progression to meningoencephalitis. Treatment of stage II requires treatment of drugs that cross the blood-brain barrier, which include the toxic arsenic drug melarsoprol. Nifurtimox and eflornithine are less toxic, but only effective against *T. b. gambiense* [15].

Other causes

Other parasitic tropical diseases that can cause a meningoencephalitis include angiostrongyliasis, *Naegleria fowleri, Acanthamoeba castellani, Gnathostoma spinigerum, Trichinella spiralis*, and others.

Origins of epidemics

Many epidemics have their origins in tropical countries, and it is important for the treating physician to have up to date information, for instance through the Program for Monitoring Emerging Diseases—an Internet-based reporting system under the International Society of Infectious Diseases dedicated to rapid global dissemination of information on outbreaks of infectious diseases. Also many emerging or re-emerging infectious diseases have their origin in the tropics (see Fig. 294.1), and global spread is importantly facilitated by the nowadays intense global human movement through air traffic. Recent examples include Severe Acute Respiratory Syndrome (SARS), which originated in Hong Kong in 2002–2003, and quickly spread through the region and globally to a total of 37 countries. Acute respiratory distress syndrome (ARDS) caused by this SARS coronavirus, had a high case fatality rate and caused around 800 deaths globally [16]. Avian Influenza caused by *Influenza A* subtype H5N1 is an enzootic disease of many bird species including poultry, and can cause a rapidly progressive pneumonia in humans. It has caused over 100 outbreaks since 2003 with over 300 fatalities recorded [17]. Severe influenza with pneumonia caused by *Influenza A* subtype H1N1 caused a pandemic in 2009 which originated in Mexico [18]. Epidemics with other *Influenza A*

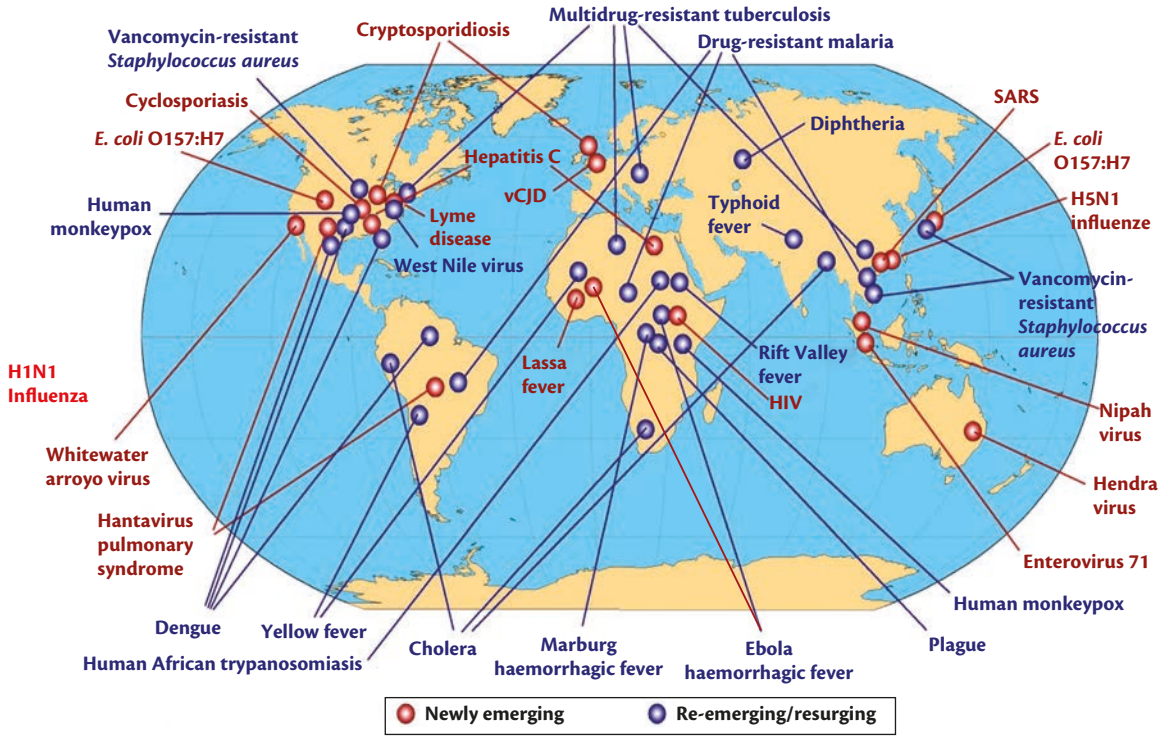

Fig. 294.1 Examples of emerging and re-emerging infectious diseases.

subtypes have been reported since then. In 2012 a novel virus causing severe pneumonia with high mortality was reported from several countries in the Middle East. This epidemic caused by Middle East respiratory syndrome coronavirus (MERS-CoV) which was worrying because its virulence and ability of person-to-person transmission [19].

PART 13.5

Sepsis

CHAPTER 295

Assessment of sepsis in the critically ill

Osamudiamen Idahosa and David T. Huang

Key points

- Sepsis is the presence of a known or suspected infection and a systemic inflammatory response.
- Severe sepsis is sepsis with acute organ dysfunction. Septic shock is a subset of severe sepsis characterized by systemic arterial hypotension or occult hypoperfusion.
- Severe sepsis is common, affecting more than 750 000 individuals in the United States each year with a hospital mortality of about 30%.
- Severe sepsis is a medical emergency that requires early identification, prompt evaluation, and treatment.
- The signs and symptoms of sepsis are influenced by the virulence of the pathogen, the portal of entry, the degree of organ dysfunction as well as the susceptibility and response of the host.

Definition

Sepsis is a clinical syndrome resulting from the presence of both an infection and a systemic inflammatory response. It can be complicated by organ dysfunction (severe sepsis) and shock (septic shock) [1,2]. Although the consensus definition for septic shock requires frank hypotension however, some have argued that evidence of hypoperfusion such as an elevated blood lactate ≥4 mmol/L should also be regarded as shock [3].

Epidemiology

In the United States, more than 750 000 individuals develop severe sepsis each year with a hospital mortality of about 30% [4]. Typically, about two cases per 100 hospital admissions develop severe sepsis, and about 10% of all ICU patients have severe sepsis on admission or during their ICU stay [5,6].

The Sepsis Occurrence in Acutely Ill Patients (SOAP) study across Europe reported that more than 35% of ICU patients had sepsis at some point during their ICU stay, with a mortality rate of 27% [7].

Nearly all microbes can cause sepsis. In immuno-competent hosts, typical causes are Gram-positive and Gram-negative bacteria, such as *Staphylococcus aureus, Streptococcus pyogenes, Streptococcus pneumonia*, Escherichia *coli* and *Pseudomonas* species [8]. In immunocompromised hosts, in addition to the usual pathogens, sepsis can also develop secondary to opportunistic organisms. The most frequent type of infection that leads to severe sepsis is pneumonia (44%), followed by primary bacteraemia (17%), genitourinary infection (9%), abdominal infection (9%), and, less commonly, wound and soft tissue infections (7%) [3]. Approximately one-third of septic patients are culture-negative [8]. Bacteria is the predominant cause of severe sepsis, with Gram-positive bacteria accounting for about 52% of cases, Gram-negative bacteria (38%), polymicrobial infections (5%), anaerobes (1%), and fungi (5%) [9].

When to suspect sepsis

Obvious sepsis cases with fever, leukocytosis, hypotension, and known infection require little skill to detect. The astute clinician recognizes that the initial presentation of sepsis can be subtle and non-specific, such as unexplained tachypnoea, altered mental status, hyperglycaemia, and diaphoresis. It is also important to recognize that elderly and immuno-suppressed patients with sepsis often do not have fever or leukocytosis. In such patients, hypothermia should specifically be sought for, and if found, treated seriously. Other physical and laboratory findings that prompt an experienced clinician to conclude that an infected patient 'looks septic' are outlined in Box 295.1. This list is by no means specific, but should help the clinician in identifying a septic patient and guide the early institution of adequate therapy including empiric antimicrobial therapy.

How to work up sepsis

History and physical

Determining the nature of the underlying infection and presence of organ dysfunction is critical. Presence of predisposing conditions such as advanced age, history of organ transplantation, immunosuppression, diabetes mellitus, trauma, and surgery should be quickly ascertained. Travel and pet exposure as well as history of intravenous drug and alcohol use should be obtained.

Vital signs need to be closely monitored. Although many patients with sepsis will be febrile, up to half of septic patients can be hypothermic or normothermic [10]. Tachycardia is a common sign as is tachypnoea and respiratory status needs to be closely monitored for evidence of respiratory failure. Blood pressure particularly diastolic pressure is usually lower than normal, with severe sepsis being the most common cause of vasodilatory shock [11].

A detailed examination could give you direct clues on the likely source of infection as well as the general clinical state of the patient.

Box 295.1 Diagnostic criteria for sepsis according to the sepsis definitions conference

Infection (documented or suspected) and some of the following:

General variables

- Fever (core temperature >38.3°C).
- Hypothermia (core temperature <36°C).
- Heart rate >90 min or >2 SD above normal value for age.
- Tachypnoea.
- Altered mental status.
- Significant oedema or positive fluid balance (>20 mL/kg over 24 hours).
- Hyperglycaemia (plasma glucose >120 mg/dL or 7.7 mmol/L) in the absence of diabetes.

Inflammatory variables

- Leukocytosis (WBC count >12,000 μL).
- Leukopenia (WBC count <4000 μL).
- Normal WBC count with >10% immature forms.
- Plasma C-reactive protein >2 SD above the normal value.
- Plasma procalcitonin >2 SD above the normal value.

Haemodynamic variables

- Arterial hypotension—SBP <90 mm Hg, MAP <70 or an SBP decrease >40 mmHg in adults or <2 SD below normal for age.
- SvO2 >70%.
- Cardiac index >3.5 L/min.

Organ dysfunction variables

- Arterial hypoxaemia (PaO_2/FIO_2 <300).
- Acute oliguria (urine output <0.5 mL/kg/hour or 45 mmol/L for at least 2 hours).
- Creatinine increase >0.5 mg/dL.
- Coagulation abnormalities (INR >1.5 or a PTT>60 seconds).
- Ileus (absent bowel sounds).
- Thrombocytopenia (platelet count <100,000 μL).
- Hyperbilirubinaemia (plasma total bilirubin >4 mg/dL or 70 mmol/L).

Tissue perfusion variables

- Hyperlactataemia >1 mmol/L.
- Decreased capillary refill or mottling.
- Definitions of abbreviations: CRP, C-reactive protein; WBC, white blood cell; SBP, systolic blood pressure; MAP, mean arterial pressure.

There may be evidence of depleted intravascular volume with dry mucous membranes and low jugular venous pressure as well as signs of impaired cutaneous perfusion with livedo reticularis and poor capillary refill. Altered mental status is often an important early indicator of sepsis with abnormalities in attention and cognition present especially in elderly patients. Careful attention should be paid to abnormalities in lung and abdominal examination such as asymmetric air entry and abdominal tenderness. Indwelling devices and surgical incisions should be closely examined for areas of tenderness, swelling, or erythema. Patients with diabetes mellitus are at risk for invasive polymicrobial infections such as necrotizing fasciitis and careful attention should be paid to the skin and soft tissues in such patients.

Laboratory

Patients with evidence of sepsis should have blood drawn for basic laboratory data including a complete blood count, complete metabolic panel as well as coagulation parameters. Leukocytosis, leucopenia, metabolic acidosis, renal or hepatic dysfunction should be sought. Abnormal liver function may also be a clue to the presence of acalculous cholecystitis, hepatic abscess, or biliary sepsis and further imaging may thus be useful. In addition, a blood lactate level should be obtained in the septic patient with an elevated level reflecting evidence of sepsis-related organ hypo perfusion. It is important to remember that except for immediate post-ictal patients and patients on an epinephrine infusion, an elevated lactate level, while not necessarily indicating sepsis, is always abnormal. Compensated cirrhotic have normal lactate levels. Only when they become ill do their lactate levels rise. Whenever possible, especially in the septic patient with tachypnoea or change in mental status, a blood gas should be obtained, as it provides a wealth of data in one simple test. If your facility's blood gas analyser allows it, always check a lactate level with the gas, as well as other useful basic laboratory indices such as haemoglobin, ionized calcium, and potassium. Early on in the septic process, an acute respiratory alkalosis will be apparent reflecting a state of increased minute ventilation. Metabolic acidosis occurs later in the septic process and thus if present, indicates greater severity. In patients who already have a central venous catheter, a venous blood gas sample is just as useful as an arterial gas, especially when combined with a working pulse oximetry value. Only if PaO2 is a specific concern is an arterial gas needed. The arterial pH as well as PCO2 can easily be inferred by adding ~0.05 to the venous pH and subtracting ~5 from the venous PCO2 levels [12]. In addition, a central venous blood gas can provide you central venous oxygen saturation, while an arterial gas cannot. Central venous lactate and arterial lactate are essentially equivalent.

Microbiology

In a patient with sepsis, all likely foci of infection should be cultured. Blood cultures should be routinely sent; however, 70% of patients with sepsis will not have organisms recovered from blood [8]. The Surviving Sepsis Campaign recommends obtaining appropriate cultures prior to antimicrobial therapy provided that such cultures do not cause a significant delay in antibiotic administration [13]. At least two sets of blood cultures should be obtained and if a vascular device is present, at least one is drawn percutaneously and one drawn through each vascular access device, unless the device was recently (<48 hrs) inserted. If the

same organism is recovered from both cultures, the likelihood that the organism is causing the severe sepsis is enhanced. In addition, if the culture drawn through the vascular access device is positive much earlier than the peripheral blood culture (i.e. >2 hrs earlier), the vascular access device is the likely source of infection [14]. If the likelihood that a vascular device is infected is felt to be high, it should be removed even before culture results are available. The search for the culprit pathogen should not be limited to blood alone, but depending on the clinical scenario could include examination and culture of materials from the lower respiratory tract, urine, cerebrospinal fluid, wounds, or other body fluids that may be the source of infection.

Imaging

Imaging studies should be geared towards localizing the source of infection and the pros and cons of various imaging modalities. Chest radiographs are routinely obtained, but are limited in critically ill patients with pneumonia. A portable supine chest film has a sensitivity of 0.60 and specificity of only 0.29 for the prediction of pneumonia in the critically ill patient with pneumonia [15]. Patients who are volume depleted or neutropenic may initially not have any detectable infiltrate on a chest radiograph. Generally, this becomes more obvious after hydration.

Ultrasounds are valuable particularly as they can be done at the bedside in unstable patients. It is commonly used to visualize the biliary tree and liver parenchyma in patients with unexplained abnormal liver function tests. It is also useful in viewing the renal parenchyma and the collecting system in the septic patient with suspected perinephric abscess and to exclude an obstructive uropathy. Importantly, bedside ultrasound may be of value for other diagnostic purposes such as estimating a patient's intravascular volume status. Both plain films and ultrasound have limited utility in establishing diagnosis of disease states like sinusitis, occult abscesses or fluid collections, ischaemic bowel or a perforated viscus. For such conditions, a computed tomographic (CT) scan is more useful.

Biomarkers

Many biomarkers have been evaluated for use in sepsis. Most have been evaluated as prognostic markers in sepsis; others for diagnosis. Thus far, none have been found to have sufficient specificity or sensitivity to be routinely employed. Procalcitonin has been the most widely studied, but has known false positives (e.g. massive trauma, burns, and severe shock) and false negatives (early infection, localized abscesses). As a prognostic marker, procalcitonin levels have been shown to correlate with mortality and some authors have proposed using procalcitonin levels to help decide on length of antibiotic treatment especially in culture negative sepsis [16]. The true clinical role of biomarkers remains to be determined.

Risk stratification

The extent of infection and the severity of organ failure have a significant impact on the prognosis of patients with sepsis. The site of infection also has a prognostic value. In the PROWESS (Protein C Worldwide Evaluation in Severe Sepsis) trial, patients with urinary tract infections as their source of severe sepsis had a 28 day mortality of 21% compared with patients with a pulmonary source who had a mortality rate of 34% ($p < 0.01$) [17]. Additionally, the response to infection varies among patients, reflecting the enormous heterogeneity in the patient population suffering from severe sepsis. While some patients have a marked systemic response, such as in patients with meningococcal sepsis, others often die of overwhelming infection with an inadequate host response for example neutropenic cancer patients with septic shock.

The PIRO model has recently been proposed as a way of stratifying septic patients according to their Predisposing condition, the severity of Infection, the host Response to infection, and the degree of Organ dysfunction [2]. PIRO is a staging score similar to the tumour nodes metastases (TNM) staging system in clinical oncology. The PIRO staging system could be used to assess risk and predict outcome in septic patients since the classification represents the different factors that contribute to the development of and outcome from sepsis. It could also help in early identification of those patients that need immediate ICU admission.

The degree of organ dysfunction can be assessed with various scoring systems, one of the most common being the Sequential Organ Failure Assessment (SOFA) score-a simple, but effective method to describe organ dysfunction or failure in critically ill patients [18]. Another prognostic scoring system, the Acute Physiology and Chronic Health Evaluation II (APACHE II), evaluates the risk of mortality, but however do not individualize the various degrees of organ dysfunction [19].

Conclusion

Severe sepsis is a medical emergency that is frequently fatal. It requires early identification, prompt evaluation, and treatment. The signs and symptoms of sepsis are influenced by the virulence of the pathogen, the portal of entry, as well as the susceptibility and response of the host. A quick and thorough history and examination with relevant ancillary studies are needed in evaluating a patient with sepsis. No biomarker has yet been found to have sufficient specificity or sensitivity to be routinely employed in the management of a septic patient.

CHAPTER 296

Management of sepsis in the critically ill

Jon Sevransky

Key points

- Early identification of the patient with sepsis facilitates the delivery of appropriate treatment.
- The use of screening tools and algorithms may help with identification of sepsis patients.
- Delivery of rapid empiric antibiotics directed at the most likely source and organisms in conjunction with infection source control improves patient outcomes.
- Early aggressive therapy directed at targeted measures of perfusion do not provide additional benefit if early antibiotics and fluids are successfully delivered.
- Clinicians must be aware of potential complications of therapy, and should take precautions to limit nosocomial complications.

Introduction

The inciting insult that leads to sepsis necessarily involves an infection. Thus, the initial strategy for treating a patient with sepsis involves identifying the source and site of the infection, sending off cultures and rapidly treating with antibiotics [1,2]. In many patients, source control of the infection, such as removing an infected catheter or draining an abscess, is also required. As the previous chapter has noted, the absence of a biomarker for sepsis requires that the treating clinician have a high index of suspicion for sepsis in critically ill patients.

Antibiotic therapy

Sepsis patients require prompt delivery of antibiotics directed at the most likely causative organisms. It is useful to have appropriate cultures drawn to assist with subsequent tailoring of antibiotics, but delivery of such antibiotics should not be excessively delayed in order to obtain these cultures. Since the results from cultures take hours to days, the selection of antibiotics should be driven by the site of infection, host susceptibility, and the likelihood of exposure to resistant organisms. In general, patients with recent exposure to the health care system including hospitalization, nursing home residence, or visits to dialysis or chemotherapy clinics will be at risk for resistant organisms. The prevalence of resistant organisms in the community also needs to be considered when selecting initial empiric therapy, in addition to local sensitivity patterns. The site of infection: lungs, abdomen, urine, bloodstream, or central nervous system will also assist with the initial antimicrobial choice [3].

In general, most patients with sepsis require broad coverage including both Gram-positive and Gram-negative organisms. Using two different antimicrobial agents to 'double cover' Gram-negative organisms remains controversial, and, in the absence of extreme local resistance patterns or diseases such as cystic fibrosis, is not generally recommended [4].

Delay in appropriate antibiotic infusion has been associated with increased patient mortality [5]. Current treatment goals for hypotensive sepsis patients include the administration of effective antibiotics within an hour of hypotension for hospitalized patients [5]. This need for rapid delivery requires that the physician pay attention to the mechanics of ensuring that any order for antibiotics is expeditiously communicated to the nurse and pharmacy so that the medication ordered is delivered promptly to the patient.

Duration of antibiotic therapy should be driven by the site of infection, likely causative organisms, and clinical response to therapy. Patients who are in shock will often require longer courses of therapy than those patients who are clinically improving. In the absence of clinical deterioration, a shorter course of antibiotics of 7–8 days appears to be as effective as a longer course of 15 days for patients with ventilator associated pneumonia without resistant Gram-negative organisms [6]. Biomarkers such as procalcitonin are a potential option to use as part of an antibiotic de-escalation strategy [7]. Other strategies to limit length of therapy include use of clinical scores for pneumonia. While these strategies to limit antibiotic use have been clearly shown to decrease risk of complications and decrease exposure to antibiotics, they have not shown to effect patient mortality [3,7]. At this time, we do not recommend the use of biomarkers as a trigger to withhold antibiotics for critically ill patients with presumed sepsis. Most clinicians will, for patients with severe sepsis start broad spectrum antibiotics and modify the type and duration of antibiotics based on results from cultures and the patient's clinical response.

Infection source control

In conjunction with effective antibiotics, infection source control is an essential part of sepsis therapy. Both surgical and interventional radiological procedures should be considered in a patient with a closed space infection such as an abscess or empyema;

those patients with an indwelling catheter that is suspected of being infected should have it removed as soon as alternate access is obtained. Treating through an infected catheter without its removal in patients with severe sepsis or septic shock is not recommended. Some sepsis patients have co-morbidities such as coagulopathy or shock that may complicate the ability to achieve source control, and the treating clinician may need to treat these co-morbidities in order to facilitate source control

Early aggressive therapy

Supportive therapy buys time for the patient's host defence system to work in conjunction with antibiotic therapy to treat severe infections. Since the host response to infection often leads to vascular leak and decreased filling pressures, patients with sepsis require infusion of IV fluids to increase cardiac output and restore systemic perfusion of vital organs as a first line supportive treatment. There are many choices for types of fluid therapy: crystalloid fluids are most commonly used, and usually require higher doses than colloids [8]. Initial therapy of a severe sepsis patient should include a rapid infusion of crystalloids of at least 15–30 cc/kg, with many patients requiring additional boluses [3]. The largest randomized trial comparing crystalloid to colloid therapy in critically ill patients did not show a benefit to use of colloid therapy compared with crystalloids [9]. While no type of fluid therapy has been proven to be superior in patients with sepsis, the use of hydroxyethyl starches such as pentastarch and hetastarch have been shown to be harmful and are not recommended [8,10]. Patients with more severe forms of sepsis such as septic shock will require large amounts of fluid resuscitation both initially and over the first 24 hours of therapy, in doses that may approach 8–9 litres of crystalloid in over a 24 hour period [11].

In addition to following the patients vital signs in response to therapy, many patients receive assessment of filling pressures such as central venous pressure, and targets of resuscitation such as venous oxygen saturation or lactate (See Box 296.1). Use of early aggressive strategies based on treatment goals including specific targets do not provide additional benefit if early antibiotics and fluids have been effectively delivered.. Failure to reach treatment goals should prompt both re-evaluation of initial diagnosis, as well as consideration of additional therapy to both improve cardiac output and peripheral perfusion as well as limitation of oxygen consumption (See Fig. 296.1) [12,13]. While complicated algorithms have been used for acute care of the sepsis patient, it is not known which patient's part of the algorithms are most helpful. We therefore suggest using some clinical target such as lactate clearance or central venous oxygen saturations in addition to usual measures of vital sign monitoring such as following blood pressure, pulse, and urine output.

Delayed aggressive care of the sepsis patient that waits until the patient is stabilized in the ICU does not improve patient outcomes [14]. For most patients the aggressive phase of therapy should be continued for at least 6 hours and perhaps up to 24 hours. It is reasonable, if a patient is responding to fluid loading or additional therapies to increase oxygen delivery or decrease oxygen consumption, to continue these therapies beyond this 24 hour time point. If the patient does not respond to therapies to increase oxygen delivery such as adding additional fluids, transfusing packed red cells or adding an inotrope, the clinician will need to balance the risk of adding new goal directed therapies against any potential risks in an individualized fashion.

Box 296.1 Recommended treatment paradigm for severe sepsis patients

Early (hours 1–6)

- Make sepsis diagnosis.
- Send cultures from likely sites.
- Deliver antibiotics within 1 hour.
- Measure lactate.
- Obtain adequate access, including CVC for most patients.
- Ensure patient has adequate monitoring and nursing staffing.
- Follow measures of perfusion (urine output, capillary refill, pulse).
- Volume resuscitate.

Mid (hours 7–72)

- Monitor for signs of organ failure.
- Additional volume resuscitation if needed.
- **Follow-up cultures**: adjust antibiotics as needed.
- **Minimize nosocomial complications**: limit sedation, use lung protective ventilation.
- Wean supportive therapies as feasible.

Late (hours > 73)

- Wean supportive therapies as feasible.
- Remove unnecessary devices.
- **Minimize nosocomial complications**: limit sedation, use lung protective ventilation.
- Set endpoints for antibiotic therapy.

Supportive therapy for sepsis patients

Patients with sepsis are at risk for developing complications such as respiratory failure, acute respiratory distress syndrome (ARDS), acute kidney injury, disseminated intravascular coagulation, and delirium. Each of these complications of sepsis may require specific supportive therapy. Patients with sepsis who require positive pressure ventilation should receive therapy designed to both rest respiratory muscles and limit work of breathing including mechanical ventilation, pain and symptom control, and in many patients endotracheal intubation. Since sepsis patients who develop respiratory failure are at increased risk of developing ARDS, the clinician should choose a ventilator strategy that limits volumes and plateau pressures to decrease the likelihood of developing ventilator induced lung injury and ARDS [15].

The use of manoeuvers such as the straight leg raise may allow determination of whether additional fluid boluses might be helpful [16]. Once adequate volume resuscitation has occurred, there is little value in infusing additional IV fluids [16].

Some patients will require use of renal replacement therapy after the development of sepsis induced acute kidney injury. While dialysis will assist with fluid balance and potassium and solute clearance, the use of early or more intensive dialysis does not provide

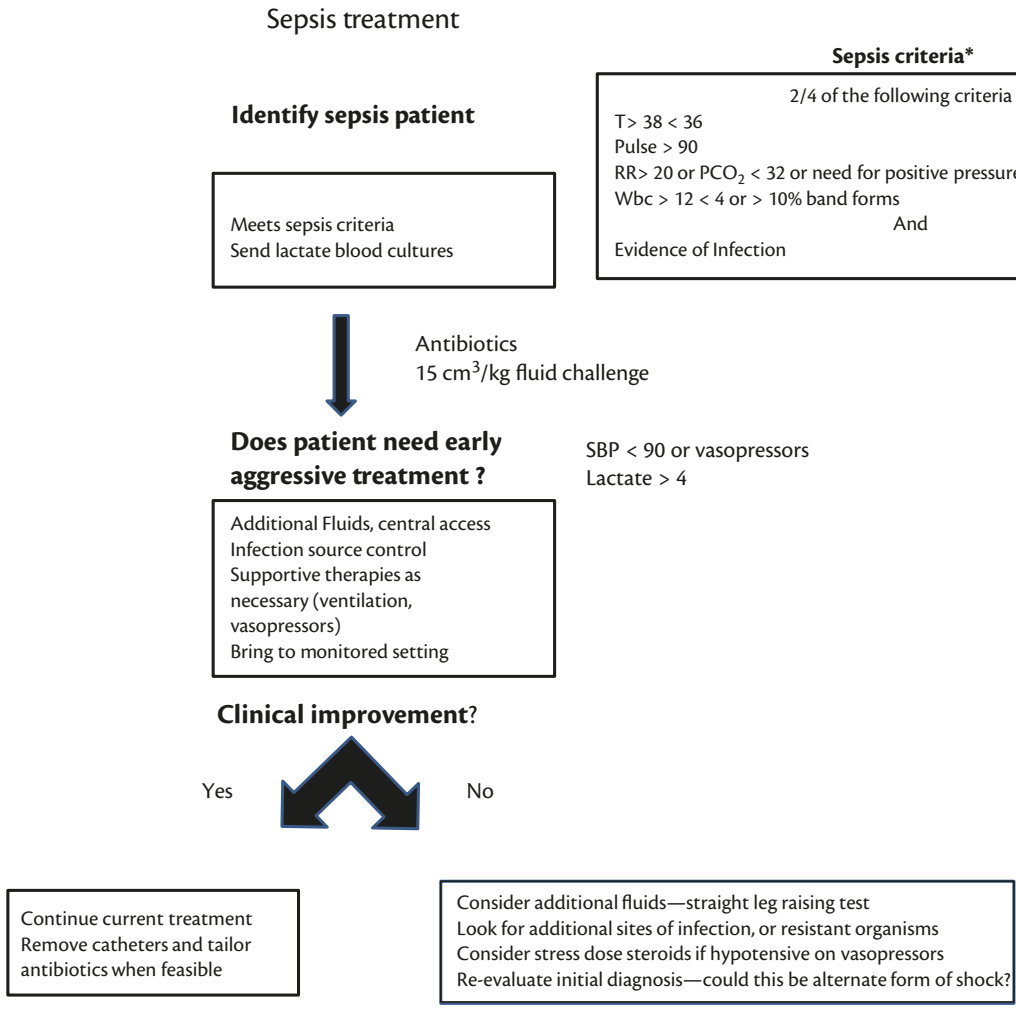

Fig. 296.1 Treatment pathway for sepsis.
*Will be updated in early 2016.

additional benefit over use for specific indications. There is no proven value in using dialysis therapies for clearance of specific inflammatory mediators. Additional support therapies such as nutritional are necessary in many patients, with the enteral route preferred for most.

Limitation of complications for sepsis patients

While early aggressive care of the sepsis patient in the emergency department and ICU may save lives, it is clear that these aggressive treatments are associated with risks including the development of nosocomial infections, delirium, critical illness weakness, stress ulceration, and ventilator induced lung injury [17]. It is important that the clinician carefully consider the risks of therapy when applying therapies. Strategies that may be useful in preventing ICU complications include limiting tidal volume in patients at risk for developing acute lung injury, limiting use of sedation and analgesics and mobilizing patients early in the course of sepsis. Avoidance of hyperglycaemia and hypoglycaemia are important ancillary goals, although the goal glucose level in a patient with sepsis remains controversial. Strategies to prevent nosocomial infections such as catheter checklists and ventilator bundles are also essential.

Response to treatment and continued care

Most patients with severe sepsis and septic shock will require treatment in an ICU where staffing ratios of nurses, physicians, and other caregivers will allow repeated and detailed observation of vital signs and organ perfusion. With early appropriate supportive care and antibiotics patients should demonstrate response to therapy including decreased fever, decreased pulse, and improved organ perfusion, and decreased need for supportive therapies such as mechanical ventilation and vasopressor support. If a patient does not show such clinical improvement, the clinician will need to reconsider whether there is an undrained infectious focus, whether the initial antimicrobial strategy was correct and whether there might be an alternate explanation for the patient's illness.

When available, culture results should allow tailoring antibiotics based on minimizing side effects, resistance, and costs. Use of clinical biomarkers such as procalcitonin may be helpful in limiting antibiotic length of therapy where available [7]. Since there is little guidance as to the length of therapy for most types of infections, it is reasonable to consider de-escalation of therapies when a patient is clinically improving

Once a sepsis patient with respiratory failure has been stabilized, the clinician needs to consider measures that will lead to

expeditious removal of endotracheal tubes and mechanical ventilation. Such measures would include a targeted sedation strategy, such as daily interruption of sedation, often in conjunction with early rehabilitation and mobility strategies, and fluid removal with diuretics in patients off vasopressor support for more than 12 hours [3,18]. Clinical improvement should also prompt consideration of whether other invasive devices such as arterial and venous catheters, as well as urinary catheters are still required. Use of cognitive aids such as checklists to remind clinicians about whether such devices are still required has been shown to be an effective technique.

Prevention of long-term complications of sepsis

While initial care of the sepsis patient requires aggressive and often invasive therapy, many sepsis patients will transition out of the ICU to regular wards. Many sepsis patients will develop ICU acquired weakness, delirium, and depression that will persist after ICU discharge [19]. While strategies designed to limit sedation and mobilize ICU patients may get them off the ventilator earlier, it is not yet known whether these strategies will limit the development of weakness or delirium [17].

CHAPTER 297

Pathophysiology of septic shock

John M. Litell and Nathan I. Shapiro

Key points

- Sepsis results from a dysregulated homeostatic response to infection.
- Immune activation and immunosuppression are both present in sepsis syndromes.
- The host's inflammatory and coagulation systems are closely interrelated, and disruptions in both are central to sepsis pathophysiology.
- Abnormalities in macrovascular, microvascular, endothelial, and mitochondrial function all contribute to the haemodynamic changes and organ failures seen in septic patients.
- Sepsis mortality increases with successive organ failures.

Introduction

Sepsis is the result of a complex and dysregulated homeostatic response to infection. Untreated, sepsis progresses to hypoperfusion, hypoxia, and dysfunction at the level of cells, tissues, and organ systems, leading to death in at least 30% of cases [1]. The clinical syndrome of sepsis is a manifestation of pro- and anti-inflammatory intermediates and is intimately linked to disruptions in coagulation, microcirculatory flow, and mitochondrial function, leading to common pathways of failure in multiple organ systems. The severity of the response depends on both host and pathogen characteristics and the relevant underlying pathophysiology arises principally from interactions between an infectious agent and the host's innate immune system.

Innate immunity is characterized by a rapid response capability to novel insults, which results from an interaction between conserved molecular signals on pathogens and corresponding pattern recognition receptors on host immune cells. All non-vertebrate organisms—pathogenic, non-pathogenic, or commensal—express microbial-associated molecular patterns (MAMPs) [2]. These bind to pattern recognition receptors (PRR) expressed by host immune cells. The best-known human PRR are the ubiquitous toll-like receptors (TLR), a highly diversified family of cell surface and cytoplasmic receptors for an extraordinary number of microbial invaders and endogenous danger signals.

TLR activation, via multiple secondary signalling pathways, leads to translocation of nuclear factor kappa B (NF-κB), a central regulatory factor for several inflammatory target genes, including pro-inflammatory cytokines such as tumour necrosis factor alpha (TNF-α) and interleukin 1 (IL-1). These trigger the cardinal pathophysiological manifestations of sepsis—leukocyte activation and transmigration, endothelial damage and dysfunction, and increased capillary permeability—resulting in hypovolaemia and exposure of tissue factor to circulating coagulation factors [3].

Circulating apoptotic or necrotic cell debris can initiate a similar response via damage-associated molecular pattern (DAMP) receptors. Since ischaemia and necrosis often accompany infection, these responses can coexist in positive feedback loops, wherein PRR are stimulated both by infectious agents and by damaged host cells resulting from the infection.

The pro-inflammatory cytokine high-mobility group box 1 protein (HMGB1) is also thought to play an important role late in the pathogenesis of sepsis. Several hours after exposure to infectious stimuli, macrophages, dendritic cells, and natural killer cells all release HMGB1, as do necrotic host cells. Apoptotic host cells may trigger release of HMGB1 from macrophages. The receptor for advanced glycation end-products (RAGE) may also contribute to pro-inflammatory signalling in sepsis. HMGB1 protein and several other endogenous ligands are recognized by RAGE, which may then activate NF-κB signalling pathways.

Historically, sepsis was thought to result from disproportionate release of pro-inflammatory mediators in response to infection. More recent work has identified features of both hyperinflammation and immunosuppression in sepsis [4]. That both are relevant is fairly clear, but the timing and relative contributions of their effects are uncertain.

Immune suppression in sepsis is partially due to elaboration of anti-inflammatory cytokines and likely also to lymphocyte apoptosis. TLR activation results in upregulation of signal transduction pathways, which lead to DNAse activation and apoptosis. Interestingly, although necropsy studies in septic patients reveal relatively little parenchymal cell death in failing organs, they do show profound apoptotic loss of components of cellular immunity. In addition to responding to anti-inflammatory cytokines, immune cells are also receptive to efferent vagal suppression via cholinergic receptors.

Inflammation and coagulation

There is substantial cross-talk between the inflammatory and coagulation systems, the full extent of which is still not elucidated. These systems are evolutionarily linked. Although they have diverged in humans and other vertebrates, in invertebrate species, inflammation and coagulation are performed by a single cell type, the haemocyte, reflecting an evolutionary precursor [5].

The coagulant response to an infectious insult is initiated by increased amounts of circulating tissue factor, which results from endothelial permeability as well as haematogenous spread of necrotic debris. This initiates a procoagulant response resulting in

thrombin generation and increased fibrin formation, balanced by early fibrinolysis via increased expression of plasminogen activator. Further counterbalance is provided by increased expression of plasminogen activator inhibitor.

These effects can proceed rapidly, and coagulation is an essential protective response to infection [6]. The formation of fibrin nets traps not only activated platelets, but also bacteria and leukocytes. By aggregating bacteria in a region of decreasing nutrient supply, bacterial trapping limits both haematogenous spread and local growth. The majority of known human bacterial pathogens employ fibrinolytic properties to evade these fibrin nets.

When overwhelmed, the pro- and anticoagulant responses to infection can accelerate to a consumptive coagulopathy and disseminated intravascular coagulation (DIC). Widespread microvascular thrombosis contributes to multi-organ failure, resulting in a progressive cycle of maladaptive immune response, dysregulated coagulation, and deepening critical illness.

Microcirculatory effects

Organ perfusion is impaired not only by abnormalities in macrovascular flow (oxygen circulation), but also by direct effects on the microcirculation (oxygen distribution) and the mitochondria (oxygen processing). A complex interplay between the endothelium, vascular smooth muscle, and the cellular components of blood is largely responsible for capillary blood flow, nutrient delivery, exchange of products of cellular respiration, and coagulation and immune function. The autoregulatory capability of the microcirculation, as well as arterial driving pressure and the physical characteristics of the blood, can all be adversely impacted in sepsis [7].

Toxic products of infection, pro-inflammatory mediators, reactive oxygen species (ROS), activated host leukocytes, and inducible nitric oxide synthase all exert direct effects on vascular tone, integrity, and endothelial cell signalling, leading to increased venous capacitance and massive capillary leak. Clinically, these contribute to impaired cardiac filling pressures that can be partially restored by volume resuscitation.

However, conventional measures of fluid balance and effective circulating volume do not fully reflect the substantial extravasation of fluids due to endothelial dysfunction, which can persist beyond initial resuscitation. Loss of normal autoregulatory function in end-organ tissue beds also contributes to maldistribution of blood flow, with hyperaemia at some sites and hypoperfusion at others.

Flow limitations are only part of the problem. Mitochondrial oxygen utilization is also disrupted, resulting in a cytopathic hypoxia even in regions with normal or supranormal blood flow [8]. Taken together, these changes result in a persistent anaerobic metabolism and lactic acidosis even after the restoration of adequate circulating volume. These microcirculatory and mitochondrial abnormalities are undetected by conventional haemodynamic measurements.

Organ system manifestations

Septic patients often manifest single or multiple organ failures, which share characteristic pathophysiological mechanisms. Mortality in these patients has been shown to roughly double for each additional organ system failure. Recovery of organ failures, where possible, is largely accomplished by reversal of the underlying insult and associated host inflammatory response.

Renal

Approximately one-third of critically ill patients experience AKI, with a mortality of 20–60% depending on the severity of the injury. Half of these cases are due to sepsis. For several reasons, the pathophysiology of septic AKI is incompletely understood. Ethical restrictions preclude widespread biopsy collection from critically ill patients, so histopathological data are limited. Most human data are flawed and over 30 years old [9]. Animal models created to fill this knowledge gap have largely relied upon mechanisms—such as ischaemia/reperfusion and drug toxicity—that are probably only indirectly relevant. More recent animal and human studies have called into question the theory that septic AKI involves renal hypoperfusion and tubular ischaemia.

Septic shock is typically a hyperdynamic hypotensive state. While septic AKI is typically attributed to renal hypoperfusion, this may not actually be the case. Animal data have revealed that hyperdynamic septic subjects often have increased renal blood flow, as the renal arterioles undergo the same dilation as the systemic vasculature. Septic AKI may therefore be misclassified, due instead to hyperaemic renal failure, with tubular cell injury and dysfunction due primarily to non-haemodynamic factors [10]. These may include the cytokines, coagulation factors, and other inflammatory and neuroendocrine mediators circulating in supranormal concentrations in septic patients.

Renal parenchymal cells express TLR, which may be directly activated by endotoxin. TNF, one of the principal inflammatory cytokines released after TLR activation, is also bound in increased quantities to renal parenchymal receptors in animals with experimentally induced septic AKI [10]. Thus, the dysfunction seen in septic AKI may result from both remote activation and local propagation.

Indirect evidence for this is seen in studies of remote effects of single organ injury, for example the development of AKI in rabbits with acute respiratory distress syndrome who are ventilated with injurious tidal volumes, or the initiation of in vitro apoptosis of renal tubular cells treated with plasma from burn patients [11]. This type of crosstalk between the kidneys and remotely failing organs suggests that our concept of AKI in sepsis as primarily a problem of renal perfusion is relatively rudimentary.

Renal tubular cell apoptosis is likely one of the non-haemodynamic mechanisms underlying septic AKI [12]. In contrast to ischaemic necrosis, apoptosis is triggered by intercellular signals and results in an organized sequence of steps that terminally extinguish cell function. Prevention of this sequence of events requires more than simply restoration of renal perfusion pressure. Identification of the signals responsible for the initiation of renal tubular cell death may allow the prevention of their release or blockade of their interaction with receptors in vulnerable renal tissues.

Pulmonary

Given its exposure to both the external environment and the systemic circulation, the lung can be both a primary site of infection or suffer collateral damage during sepsis. The extent and fragility of the pulmonary parenchyma renders it vulnerable to circulating mediators and chemical and mechanical disruption. Multiple direct and indirect inflammatory aetiologies can lead to acute pulmonary parenchymal injury, manifested by impaired alveolocapillary membrane integrity and non-cardiogenic pulmonary oedema.

In the case of acute lung injury as a secondary consequence of remote insults, systemically activated leukocytes traversing the pulmonary microcirculation migrate into the interstitium, where they perpetuate the inflammatory response locally via signalling intermediates. With local infections, TLR activation leads to microbial clearance or, if overwhelmed, necrosis and apoptosis of parenchymal cells. Since these processes result in DAMP release they are in themselves immunogenic [3]. This results in amplified local leukocyte activation, endothelial dysfunction, and interstitial oedema, as well as activation of platelets and coagulation factors. Progressive parenchymal dysfunction manifests as pulmonary shunt with refractory hypoxemia, contributing to multi-organ dysfunction.

Cardiac

Sepsis disrupts normal cardiovascular function through overlapping effects on myocardial function, vascular tone, and capillary integrity. Although commonly understood as a subtype of distributive shock, sepsis also involves features of hypovolemic and cardiogenic shock. Systemic presence of inflammatory cytokines contributes to peripheral arterial dilation, diffuse capillary leak, decreased contractility, and reflex tachycardia. Patients generally exhibit diastolic hypotension and decreased mean arterial pressure.

Myocardial dysfunction in sepsis manifests as biventricular dilation, decreased ejection fraction, diastolic dysfunction, and decreased cardiac output [13]. These reversible abnormalities are present even during the hyperdynamic phase of shock. Elevated concentrations of TNF-alpha, IL-2, and IL-6 may exert a direct myocardial depressant effect. Increased nitric oxide generation and dysregulation of intracellular calcium flux are theorized to contribute to cardiomyocyte dysfunction, via unclear mechanisms. Initial biventricular dilation is postulated as a compensatory Frank-Starling response to decreased vascular resistance. However, as with this and other changes in myocardial function during sepsis, it is not clear which are abnormal and which may be protective (e.g. energy-conserving).

Both left and right ventricular function can be impaired in sepsis, the latter being further compromised by increased pulmonary vascular resistance in the case of acute lung injury. To date, most studies of myocardial dysfunction in sepsis have evaluated systolic changes. Diastolic dysfunction also occurs, but it is technically more difficult to assess via echocardiography. As with other organ systems, myocardial dysfunction is likely not simply attributable to ischaemia, illustrated by thermodilution studies demonstrating normal or even supranormal coronary flow. Microcirculatory dysfunction is among the postulated mechanisms.

Structural myocardial structural changes also occur during sepsis, including leukocyte infiltration, interstitial oedema, collagen deposition, and mitochondrial damage, with unclear reversibility and functional consequences. As elsewhere, endothelial dysfunction and TLR activation on circulating leukocytes play central roles, as do locally generated ROS. The resultant interstitial oedema and inflammation are attributed to both leukocyte activation and the direct effects of toxic microbial products, though the degree to which each is responsible for myocardial dysfunction remains unclear. Furthermore, mitochondrial structural and functional abnormalities are seen in human autopsy specimens, though cardiomyocyte apoptosis has thus far primarily been seen in vitro.

Gastrointestinal

As little as one cell layer separates normally sterile tissues from a dense collection of faecal bacteria. Translocation of these microbes or their components is thought to play a role in the initiation or perpetuation of systemic inflammation in critically ill patients. Although the precise mechanisms remain unclear, hypomotility of the gut may contribute to this development [14].

Systemic effects of infection are known to affect gastrointestinal motility, likely due to a combination of effects on the enteric nervous system, sympathetic and vagal input, resident leukocytes, macrophages, and mast cells, and smooth muscle. It is not known whether these occur directly or are mediated by leukocyte signalling, and little is known about the specific associated TLR pathways. The presence of endotoxin and increased production of nitric oxide and prostaglandins are all implicated.

Sepsis-induced ileus likely contributes to a cycle of hypomotility, inflammatory cell recruitment and activation, and production of ROS and inflammatory cytokines. This may compromise the protective intestinal epithelial surface, with subsequent translocation of enteric flora or their PAMPs. The gut contains an unparalleled reservoir of potential pathogens. While some degree of translocation may serve an important immune function, in critically ill patients the homeostatic interplay among normal commensal enteric flora can become dysregulated, and the compromised gut wall may become a potent driver of systemic inflammation and multi-organ dysfunction. Translocation of gut flora and/or PAMPs may explain the delayed appearance of sepsis among some ICU patients, in whom progressive organ dysfunction includes deterioration of the gut mucosal protective barrier. Sepsis-induced ileus may also contribute to micro-aspiration and pulmonary infection, particularly in intubated patients.

Neurological

Among the neurological manifestations of sepsis, acquired delirium can complicate ICU outcomes and impact recovery. As many as 70% of patients with severe sepsis develop encephalopathy, which is associated with worsened outcomes [15]. Although initially attributed to toxic products of invading microorganisms, septic encephalopathy is now thought to result primarily from the systemic response to infection, including alterations in cerebral haemodynamics and the ratios of amino acid substrates for cerebral metabolism. Other potential causative factors include blood-brain barrier disruption, CNS inflammation, complement activation, increased production of nitric oxide and other vasoactive substances, neurotransmitter dysregulation, and leukocyte recruitment.

Endocrine

An association between sepsis and adrenal insufficiency has been recognized for over a century. As many as 60% of patients with sepsis and septic shock manifest a corticosteroid response that is apparently insufficient, given their severity of illness [16]. Critical illness-related corticosteroid insufficiency (CIRCI), results from decreased production of corticotropin-releasing hormone and its downstream products, as well as diminished sensitivity of peripheral tissues to activated glucocorticoid receptor [17]. The results include an impaired haemodynamic response to sepsis and insufficient downregulation of pro-inflammatory cytokines.

The diagnosis of CIRCI is complicated in part by the lack of an assay for corticosteroid activity at the level of the target tissue.

Clinicians must therefore rely on macroscopic features, as well as random measurements of absolute cortisol level and its response to stimulation by exogenous steroid, both of which are less accurate in the setting of sepsis.

The adverse effects of CIRCI seem to be due to its further perturbation of an imbalance between pro-inflammatory mediator overexpression and sepsis-related immune suppression. The optimal steroid replacement strategy must not further worsen this imbalance. Underdosing may allow the inflammatory vasoplegia and microvascular leak to persist, whereas overdosing may increase vulnerability to infectious insults, and can delay wound healing.

Glucose transporter (GLUT) dysfunction, insulin resistance, glucose intolerance, and hyperglycaemia commonly accompany critical illness. In sepsis, hyperglycaemia is likely due to pro-inflammatory cytokine-mediated GLUT dysfunction, sympathetic nervous system activation, and upregulation of counter regulatory hormones and insulin growth factor binding protein. Detrimental cytotoxic effects of hyperglycaemia appear to be mediated by cellular glucose overload and the accumulation of toxic products of glycolysis and oxidative phosphorylation. Multiple investigators have prospectively evaluated the association between glycaemic control and outcomes among critically ill patients, with largely mixed results [18]. For those limited populations in which tight glycaemic control has seemed beneficial, the purported benefits of insulin therapy may be directly due to glycaemic control or to salutary metabolic effects of insulin.

CHAPTER 298

Management of septic shock in the critically ill

Sandra L. Peake and Matthew J. Maiden

Key points

- The pathophysiology of septic shock involves variable degrees of macrovascular, microvascular, and cellular dysfunction.
- Early recognition, resuscitation, appropriate antimicrobials, and source control are essential.
- Intravenous fluids are the first therapeutic strategy, but the optimal type and volume of fluid and resuscitation targets remain uncertain.
- If hypotension persists despite fluid resuscitation, noradrenaline is the currently recommended first-line vasopressor. If cardiac contractility is impaired despite adequate fluid replacement, consider adding dobutamine or adrenaline.
- Lactate and/or $ScvO_2$ can be used as a guide to adequacy of resuscitation. However, high $ScvO_2$ is associated with high mortality.

Introduction

Over the last 20 years, numerous clinical trials of novel therapeutic agents for septic shock have been evaluated. Nonetheless, conclusive evidence of a mortality benefit has not been forthcoming. Accordingly, the fundamental management principles of septic shock, namely early recognition, source control, appropriate and timely antibiotics, and haemodynamic resuscitation, remain the most important and effective therapeutic strategies.

The 2012 Surviving Sepsis Campaign (SSC) guidelines [1] recommend early (within 6 hours), protocolized resuscitation for septic patients with evidence of tissue hypoperfusion (hypotension despite an initial fluid challenge or blood lactate ≥4 mmol/L). Key recommendations and the levels of supportive evidence are outlined in Table 298.1.

Of note, the haemodynamic goals and the time frame for resuscitation were particularly influenced by one small, single-centre, randomized, controlled trial of protocolized early goal-directed therapy (EGDT) in patients presenting to the emergency department (ED) with severe sepsis or septic shock [2]. This trial, published in 2001, reported that delivery of EGDT for 6 hours was associated with a 16% reduction in hospital mortality. Implementation of 'bundled' care, incorporating the EGDT resuscitation algorithm, has been reported to improve survival in subsequent non-randomized studies. More recently, three randomized trials of protocol-based resuscitation for patients presenting to the ED with early septic shock in the United States (Protocol-based Care for Early Septic Shock, ProCESS) [3], Australasia (Australasian Resuscitation In Sepsis Evaluation, ARISE) [4] and England (Protocolised Management In Sepsis, ProMISe) [5] have failed to demonstrate a survival benefit with EGDT compared with non-protocolized usual care.

The aim of this chapter is to review the current management of septic shock, with particular emphasis on the importance of *early* infection control and haemodynamic resuscitation.

Infectious source identification and control

Urgent identification of the infectious focus should occur for all septic patients. If the source is not apparent clinically, imaging studies are often required to assist in site determination.

To help identify the infecting organism(s) and direct antimicrobial management, ≥2 sets of blood cultures (and other sites as appropriate) should be taken prior to commencing antimicrobials. Prospective data from >15,000 patients in the SSC performance improvement initiative demonstrated that mortality was lower for patients in whom blood cultures were obtained before starting antimicrobials (odds ratio [OR] 0.86, 95% Confidence Interval [CI] 0.79–0.93) [6]. Nevertheless, obtaining cultures must not unduly delay antimicrobial administration.

Although there are no, and unlikely to ever be, any randomized trials studying the effect of source control, once the site of infection is identified attention must be directed towards definitive treatment (e.g. drainage of collections, removal of infected tissue or intra-vascular devices). Highly lethal diseases like necrotising soft tissue infections and intestinal ischaemia require immediate intervention. Timing for other infections depends upon the type of infection, severity of physiological disturbance and the likely risk of deterioration.

Antimicrobial therapy

Timely administration of empirical broad-spectrum agents to cover all likely pathogens and susceptibility patterns (with subsequent narrowing of therapy) is vitally important. The importance of providing appropriate initial antimicrobials has been highlighted in a number of retrospective and observational studies in which delayed or inappropriate antimicrobial administration is associated with increased mortality [7,8]. Survival benefit with timely antimicrobials has also been described for immunosuppressed patients

Table 298.1 Summary of the key 2012 Surviving Sepsis Campaign guidelines recommendations for early infection control and haemodynamic resuscitation in patients with severe sepsis or septic shock#

Early resuscitation strategies	Level of evidence	Strength of recommendation
Determining infection source and causative organisms		
◆ Appropriate cultures before starting antimicrobials, provided administration not delayed	1	C
◆ ≥2 blood culture sets (other sites e.g. vascular access devices as clinically indicated)	1	C
Appropriate, timely antimicrobial therapy and source control		
◆ Broad-spectrum iv antimicrobials *within 1hr* of recognizing septic shock	1	B
◆ Broad-spectrum iv antimicrobials *within 1hr* of recognizing severe sepsis without shock	1	C
◆ Source identification and control *within 12hr* of diagnosis if feasible, including removal of potentially infected intravascular devices	1	C
Haemodynamic resuscitation		
◆ Goal-directed resuscitation for *first 6hr* after hypoperfusion recognized	1	C
◆ iv fluid to achieve CVP 8–12 mmHg (12–15 mmHg if mechanically ventilated or decreased ventricular compliance)	1	C
◆ Initial fluid resuscitation with crystalloids	1	A
◆ Minimum initial fluid challenge 30 mL/kg of crystalloids	1	C
◆ Suggest adding albumin for initial fluid resuscitation	2	B
◆ Noradrenaline as first-line vasopressor	1	B
◆ Adrenaline added or substituted to maintain MAP	1	C
◆ MAP target ≥65 mmHg	1	C
◆ Dobutamine if evidence of myocardial dysfunction or hypoperfusion	1	C
◆ PRBC transfusion (if Hct < 30%) and/or dobutamine to attain $ScvO_2$ ≥ 70% or SvO_2 ≥ 65%	1	C

#Quality of evidence assessed using the Grading of Recommendations Assessment Development and Evaluation (GRADE) system. Evidence graded as high (A), moderate (B), low (C) and very low (D). Strength of recommendation graded as strong (1) or weak (2).

iv, intravenous; hr, hour; CVP, central venous pressure; MAP, mean arterial pressure; PRBC, packed red blood cells; Hct, haematocrit; $ScvO_2$, central venous oxygen saturation; SvO_2, mixed venous oxygen saturation (SvO_2) of ≥65%.

and for critically ill patients with specific infections such as candida, nosocomial infection, and ventilator-associated pneumonia.

Although delayed antimicrobial administration may be a critical determinant of outcome, the observed relationship does not necessarily imply causality. Early and appropriate antimicrobial therapy could simply be a surrogate marker for better overall processes-of-care and hence, better outcomes from septic shock. This provides impetus for processes-of-care that facilitate early recognition and definitive treatment of severe sepsis. A recent meta-analysis of providing 'bundled care' for sepsis, reported reduced time to antibiotic initiation (weighted mean difference –0.58 hrs [–0.85 to –0.33]) and increased likelihood of providing appropriate antimicrobials (OR 3.06, 95%CI 1.69–5.53) [9].

Haemodynamic resuscitation

Resuscitation of septic shock is a medical emergency. Early recognition is vital as survival is decreased if treatment is delayed. Resuscitation should occur in an environment with continuous physiological monitoring and close medical and nursing attention.

The fundamental disorder in septic shock is inadequate cellular oxygen delivery (DO_2) and/or impaired utilization. The circulatory disturbance involves decreased preload (secondary to increased capillary permeability, venodilatation, hypovolaemia), myocardial depression, arteriolar dilatation, and peripheral shunting. The causes of impaired cellular oxygen utilization remain unclear.

Whilst the resuscitation principles of optimizing preload, afterload, contractility, heart rate, haemoglobin concentration and oxygen saturation seem straightforward, a number of issues merit further consideration, including:

- The choice of resuscitation fluid.
- How much fluid to administer.
- Which vasoactive agent(s) to use.
- The best way to reliably guide resuscitation.

Resuscitation fluids

The predominant circulatory disturbance in septic shock is a maldistribution of circulating blood volume and inadequate preload. Myocardial dysfunction also occurs, but fluid resuscitation often increases stroke volume (SV), resulting in a hyperdynamic circulation. Hence, fluids are usually the first therapeutic strategy in the management of septic shock and an initial challenge with

≥500–1000 mL of either crystalloid or colloid should be immediately and rapidly infused.

However not all patients respond to fluid administration, particularly if the heart is fully loaded (Frank-Starling law). Of interest, results from the Fluid Expansion as Supportive Therapy (FEAST) trial even suggest that a fluid bolus (5% albumin or 0.9% saline) may be harmful; at least in children with severe infection in Africa [10]. A conservative approach to ongoing fluid management is also supported by a randomized trial of liberal versus restrictive fluid administration in mechanically ventilated patients with acute lung injury.

Unfortunately, there is little evidence to indicate how much fluid to give or what are the most appropriate end-point(s) to guide fluid resuscitation. For example, there are no large-scale randomized studies evaluating the recommended '≥30 mL/kg crystalloid as initial resuscitation'. In the absence of such a trial, we are left with clinical assessment of the heart rate and blood pressure (BP) response to fluid administration, indices of end-organ perfusion (e.g. urine output, capillary refill) and evidence of fluid overload (e.g. oedema).

Clinical assessment may be supplemented with invasive and/or non-invasive haemodynamic monitoring. Although the SSC guidelines recommend targeting a central venous pressure (CVP) of 8–12 mmHg (mechanically ventilated 12–15 mmHg), cardiac filling pressures often fail to discriminate when a patient will respond to a fluid challenge.

Repeated assessment of the ability to increase CO with fluid boluses or a passive leg-raise are more reliable than static measures such as CVP or pulmonary artery occlusion pressure (PAOP). Dynamic measures of systolic pressure variation, pulse pressure variation, and SV variation (using pulse contour analysis) are currently the most reliable techniques of assessing fluid responsiveness. However, these techniques have only been validated in patients in sinus rhythm and receiving positive-pressure ventilation. Other dynamic measurement techniques include ultrasound assessment of inferior vena cava diameter, left ventricle end-diastolic area (echocardiography), and global end-diastolic volume index (GEDVI) using transpulmonary thermodilution; albeit these techniques have proven too unreliable to adopt widely.

Which resuscitation fluid?

The choice of fluid has engendered considerable debate for many years and there is no evidence that one fluid is better than another for patients with septic shock. An international survey of resuscitation fluid use in 391 intensive care units (ICU) and 25 countries reported that whilst colloid is more commonly administered than crystalloid, considerable geographical variation is evident.

In principle, the choice of fluid should be determined by the type of fluid lost, adverse effects of the fluid administered, degree of peripheral/interstitial oedema, serum albumin, availability, and costs. Whilst crystalloids are cheap and readily available, the potential for interstitial oedema, electrolyte, and acid-base disturbances (e.g. hypernatraemia and hyperchloraemic acidosis with large volume 0.9% saline resuscitation) are considered problematic. Conversely, colloids restore circulating volume more quickly, but are more expensive than crystalloids, can accumulate in the interstitium contributing to persistent interstitial oedema and some solutions have specific side-effects.

In the Saline versus Albumin Fluid Evaluation (SAFE) study comparing 4% albumin and 0.9% saline for fluid resuscitation, albumin was associated with less fluid administration on days 1–4 (ratio 1:1.4). Over the same time-frame, no difference in mean arterial pressure (MAP) was observed, although CVP was statistically, but not clinically, significantly different (albumin ~1 mmHg higher). Twenty-eight-day mortality was also not different. Analysis of the pre-defined severe sepsis subgroup suggested that albumin improved survival (OR 0.71, 95% CI 0.52–0.97) [11]. A recent meta-analysis of albumin resuscitation in sepsis also supports a beneficial role (OR 0.82, 95% CI 0.67–1.0) [12].

Whilst hydroxyethyl starch (HES) is widely used in many countries, there is considerable concern regarding the safety profile, particularly with respect to renal function. The Intensive Insulin and Pentastarch Resuscitation in Severe Sepsis Randomized Trial reported a significant increase in renal dysfunction and a trend to increased 90-day mortality with 10% HES (200/0.5). The Scandinavian 6S Trial Group has also recently reported that resuscitation with 6% HES (130/0.42) is associated with both an increased mortality risk and requirement for renal-replacement therapy (RRT) compared with Ringer's acetate in a multi-centre, blinded trial of 798 severe sepsis patients [13]. However, a small, randomized trial of HES 130/0.4 versus 0.9% saline in severe sepsis (CRYSTMAS study) reported that HES was not associated with adverse outcomes. In contrast, the Crystalloid versus Hydroxyethyl Starch Trial (CHEST) trial involving 7000 ICU patients requiring fluid resuscitation reported that 6% HES was associated with increased requirement for RRT, although 90-day mortality was not different compared to patients receiving 0.9% saline for resuscitation [14].

Vasoactive agents

When fluid resuscitation alone fails to optimize end-organ perfusion, vasoactive agents should be commenced. As with the choice of resuscitation fluid, the optimal agent(s) is also controversial and the survival benefit of any particular agent has not been proven in large-scale trials.

The SSC guidelines advocate noradrenaline (predominantly α-agonist) as the initial vasopressor of choice to maintain a MAP ≥65 mmHg. Adrenaline has not been recommended as first-line therapy; in part because of concerns about tachycardia, hyperlactataemia and impaired organ perfusion. There is no evidence that adrenaline is associated with increased mortality and concerns are ameliorated by a recent blinded, randomized trial of adrenaline versus noradrenaline in patients with shock (57% septic shock), which reported that adrenaline-associated tachycardia and lactic acidosis were non-sustained and attainment of MAP goals was similar for both catecholamines. Mortality (secondary end-point) was also similar [15]. Haemodynamic end-points and survival were also similar in a randomized trial of septic shock patients comparing adrenaline with noradrenaline plus dobutamine.

Dopamine has often been considered an alternative first-line catecholamine for septic shock. A recent meta-analysis comparing dopamine and noradrenaline in septic shock suggested increased mortality and arrhythmias with dopamine. Accordingly, routine use of dopamine is not supported by the SSC guidelines.

Although the Vasopressin in Septic Shock Trial (VASST) failed to show a survival benefit for adding vasopressin (vs. noradrenaline) in septic shock patients, low-dose vasopressin administration may still be considered for catecholamine-resistant hypotension and tissue hypoperfusion [16]. Early, rather than late, administration may also be more beneficial.

Irrespective of the vasopressor choice, it is recommended that BP is continuously monitored using invasive measurement and that the MAP target is ≥65 mmHg. However, the appropriate BP target must be individualized to account for factors such as pre-morbid BP, vascular disease, and the clinical response to resuscitation. Although an increase in MAP from 65 to 85 mmHg with noradrenaline has been reported to improve the macrocirculation and microvascular blood flow, the ideal BP goal has never been formally evaluated in large-scale trials.

Finally, if MAP is restored, but signs of organ hypoperfusion remain, some authors advocate commencing an inotrope (generally dobutamine) to increase CO and improve DO_2. In particular, the Rivers' EGDT protocol calls for dobutamine commencement (≤20 μg/kg/min) if $ScvO_2$ is <70% and haematocrit is >30% despite intravenous (iv) fluid repletion and restoration of MAP [2]. Although the addition of dobutamine is recommended by the SSC guidelines, the level of evidence supporting its use is low.

Glyceryl trinitrate (GTN) has been reported to improve microvascular flow in a small observational study using sublingual orthogonal polarization spectral imaging in septic shock patients. A subsequent randomized, blinded trial of 70 severe sepsis patients demonstrated that whilst fluid resuscitation improved microvascular flow, GTN was not different to placebo and was associated with a trend to increased mortality.

Resuscitation targets

Tissue perfusion and O_2 utilization may remain inadequate despite seemingly normal global haemodynamic parameters. The ability to monitor adequacy of cellular resuscitation is becoming increasingly important. Given the complex and varied interplay of macro-vascular, micro-vascular, and cellular changes that occur in septic shock, it is unlikely that any one variable is reliable enough to guide resuscitation. Based on available evidence, a combination of clinical assessment, venous oxygen saturation monitoring, and/or lactate measurement provides the most useful guide to the adequacy of resuscitation.

Venous haemoglobin-O_2 saturation

Mixed venous oxygen saturation (SvO_2) monitoring provides information regarding the balance between DO_2 and global oxygen consumption. However, measurement requires pulmonary artery catheter placement. More recently, continuous central venous oxygen ($ScvO_2$) monitoring, with therapies titrated to achieve a $ScvO_2$ >70%, has been proposed as an alternative resuscitation target. Although $ScvO_2$ measurement does not include coronary venous blood, and in health is usually 5–20% higher than SvO_2, the two measures behave similarly in shock and $ScvO_2$ may be a useful surrogate marker.

Low $ScvO_2$ (<70%) suggests inadequate DO_2 and is associated with higher mortality rates. However high $ScvO_2$ (>85%) is also commonly encountered in septic shock and is associated with even higher mortality rates [17]. High $ScvO_2$ represents inadequate oxygen utilization or vascular shunting and how best to manage microvascular dysfunction and cellular dysoxia is an area of burgeoning research.

The utility of $ScvO_2$-guided resuscitation as described by Rivers' et al. has been investigated in three independent, multicentre, randomized trials of EGDT in the United States (ProCESS) [3], Australasia (ARISE) [4], and the United Kingdom (ProMISE) [5]. No evidence of a survival benefit has been demonstrated. Given concerns regarding the generalizability of Rivers' trial findings, the complexity and potential risks associated with elements of the resuscitation algorithm (e.g. blood, dobutamine), financial and infrastructure implications, and limited adoption despite incorporation into the SSC guidelines, widespread implementation of EGDT for the management of patients with septic shock cannot be recommended at this stage.

Lactate

Hyperlactataemia occurs in the setting of oxygen supply/demand imbalance and/or microcirculatory or cellular dysfunction. Serum lactate is a useful parameter to guide resuscitation as it is rapidly and easily measured at point-of-care and may be more readily available than continuous $ScvO_2$ monitoring. However, lactate is not specific for cellular hypoxia and can be elevated with β-agonists, some iv fluids and reduced hepatic clearance.

The utility of lactate as a marker of severity of sepsis has been reported by several investigators. In a retrospective study of 830 severe sepsis patients, adjusted mortality was increased with higher presenting lactate levels [18]. Normotensive septic patients with a lactate >4 mmol/L also have a similar mortality risk as hypotensive septic patients.

Lactate clearance may also provide a useful resuscitation guide in severe sepsis. Observational studies suggest that failure to achieve ≥10% lactate clearance during resuscitation is a better predictor of mortality than $ScvO_2$ or persistent hypotension. In controlled studies, lactate clearance was non-inferior to $ScvO_2$ as a resuscitation target and in a separate trial of ICU patients with lactate >3 mmol/L (39% sepsis), targeting therapy to achieve a ≥20% lactate clearance every 2 hours increased fluid administration and reduced mortality (hazard ratio 0.61, 95% CI 0.43–0.87) [19].

Other resuscitation tools

Monitoring venous–arterial CO_2 difference, tissue oxygenation, and sublingual micro-circulatory flow provide fascinating insights into the pathophysiology of septic shock. Currently, these techniques remain experimental.

SECTION 14

Inflammation

PART 14.1

Physiology

CHAPTER 299

Innate immunity and the inflammatory cascade

Marianna Parlato and Jean-Marc Cavaillon

Key points

- Inflammation and innate immunity are two overlapping physiological processes aimed at addressing host tissue insults and infection.
- Interleukin-1 and tumour necrosis factor are the two main cytokines that orchestrate the inflammatory response.
- A cascade of mediators acting in synergy characterizes inflammation.
- Cytokines, free radicals, lipid mediators, coagulation factors, proteases, and neuromediators all contribute to the inflammatory process.
- Anti-inflammatory cytokines, specific IL-1 and TNF inhibitors, acute phase proteins, leukocyte reprogramming, neuromediators, and lipid mediators contribute to the resolution of inflammation.

Innate immunity and the inflammatory response

Inflammation and innate immunity are two overlapping processes aimed at addressing sterile insults of host integrity, and acts of aggression by infectious agents. In the case of trauma, burns, haemorrhage, surgery or ischaemia, endogenous mediators known as alarmins, or 'damage-associated molecular patterns' (DAMPs) are released by injured tissues and necrotic cells. DAMPs recognized by specific receptors initiate the production of inflammatory cytokines that orchestrate the inflammatory response. Similarly, in the case of infection, 'pathogen-associated molecular patterns' (PAMPs) derived from micro-organisms are the initiators of the cascade of events aimed at eliminating the pathogens. DAMPs and PAMPs are sensed by 'pattern recognition receptors' (PRRs), either at the cell surface (Toll-like receptors, scavenger receptors, C-type lectins) or expressed intracellularly (Nod-like receptors, Rig-like receptors) [1]. These receptors initiate a cascade of intracellular signalling events that lead to the synthesis and release of cytokines. Cytokines favour an anti-infectious response by boosting phagocytosis, enhancing haematopoiesis, favouring cell recruitment, and inducing fever. Their key roles in fighting infection have been demonstrated in numerous animal models. Enhanced protection can be achieved by pretreatment with cytokines such as interleukin-1 (IL-1), IL-12, tumour necrosis factor-α (TNF-α), gamma-interferon (IFN-γ), and the haematopoietic factors IL-3, granulocyte/macrophage colony-stimulating factor (GM-CSF), M-CSF, and G-CSF. Studies using neutralizing antibodies targeting endogenous cytokines, or mice lacking the functional gene for a given cytokine or cytokine receptor, have unravelled the role of these mediators. For example, the use of anti-TNF-α antibodies in a caecal ligature and puncture (CLP) model employed to mimic polymicrobial sepsis revealed the key role of tumour necrosis factor (TNF)-α in fighting the microbial insult. Of note is that the great number of pathogens that have developed strategies to inhibit cytokines further illustrates the central role of cytokines in the host defence against infection.

Cytokine storm and synergy

The physiological response can be associated with pathogenicity when the host is chronically exposed to inflammatory stimuli, or when the innate immunity response is overwhelmed and leads to a 'cytokine storm' as seen in severe malaria or sepsis. In septic patients, cytokines are overproduced and therefore detectable in the blood. Circulating cytokines are only the tip of the iceberg [2]. High plasma levels generally correlate with severity and poor outcomes, and this is true for both pro- and anti-inflammatory cytokines. Some inflammatory cytokines display side effects. For example, IL-1β injected into animals results in hypotension, increased cardiac output, tachycardia, leucopenia, thrombocytopenia, haemorrhage, and pulmonary oedema. TNF-α toxicity includes haemodynamic instability, fever, diarrhoea, metabolic acidosis, capillary leak syndrome, activation of coagulation, late hypoglycaemia, induction of a catabolic state, neurotoxicity, cachexia, and renal and haematological disorders, all phenomena associated with sepsis. The dark side of cytokines has been illustrated in humans with the so-called 'cytokine release syndrome' observed in patients treated with anti-CD3, anti-CD20 or anti-CD28 antibodies. Administration of endotoxin (lipopolysaccharide, LPS) to human volunteers induces significant amounts of circulating TNF-α, IL-6, and IL-8.

The production of inflammatory cytokines results from the synergy between numerous activating signals, such as PAMPs, DAMPs, anaphylatoxins (from complement activation), cytokines, haemoglobin, lipid mediators, neuromediators, and coagulation factors. Similarly, the severity of the clinical features reflects the synergy between the action of the inflammatory mediators (complement system, cytokines, free radicals, eicosanoids, neuromediators) and physiological events (coagulation, hypoxia, apoptosis,

viral reactivation). For example, co-injection of a non-lethal dose of TNF-α with a non-lethal dose of LPS, or co-injection of a non-lethal dose of IL-1β and IFN-γ, induces 100% mortality in mice.

Inflammatory cascade and regulatory loops

Cytokines and chemokines

IL-1β and TNF-α play a synergistic role in orchestrating the inflammatory response (Fig. 299.1). Their production in response to PAMPs and DAMPs can be amplified by other cytokines, such as IL-3, GM-CSF, or IFN-γ. IFN-γ is produced by T-cells and NK cells in response to other cytokines such as IL-2, IL-12, IL-15, and IL-18. IFN-γ possesses both pro-inflammatory and anti-bacterial properties. In particular, IFN-γ enhances phagocytosis and free radical production, thus increasing the bactericidal activity of macrophages and neutrophils. However, inhibition of IFN-γ is associated with a better prognosis in animal models of sepsis with a decrease in bacterial load and systemic inflammation. Among the IFN-γ inducing cytokines, neutralization of IL-18 protected mice against lethal endotoxaemia, while IL-18-deficient mice showed decreased sensitivity towards LPS-induced shock.

Sepsis and systemic inflammatory response syndrome (SIRS) are often associated with the development of the multiple organ dysfunction syndrome (MODS), and reflects the inflammatory processes occurring within the tissues. A major feature of this phenomenon is the recruitment of inflammatory leukocytes, which implies the adherence of circulating cells to the endothelium and their response to the locally produced chemokines. Endothelial cells are highly responsive to IL-1 and TNF-α in terms of adhesion molecule expression, cytokine production, and alteration of tight junctions. Endothelial cell wall integrity perturbed by these cytokines is illustrated by the absence of endothelial damage in IL-1 receptor type I deficient mice. Once immobilized on endothelium, leukocytes migrate towards the tissues in response to IL-8 and other chemokines. These can be directly induced by microbial agonists, as well as IL-1β and TNF-α. They contribute to the inflammatory cell infiltrate which, in turn, induces loss of tissue integrity. In acute respiratory distress syndrome (ARDS) patients, elevated levels of IL-8 in bronchoalveolar lavage correlated with poor outcomes. In sepsis, all plasma chemokine levels are enhanced with the exception of RANTES (CXCL5), of which levels are diminished. The inhibition of binding of CXCL chemokines to their receptors improved survival following CLP. The relative contribution of chemokines to the pathophysiological events associated with sepsis is linked to their capacity to recruit inflammatory cells within tissues. In contrast, their presence within the bloodstream may limit the inflammatory process by unpriming circulating cells to further chemoattractant signals. Notably, blocking CXCL receptors or giving anti-IFN-γ antibodies reduced levels of high mobility group box-1 (HMGB-1), a DAMP that is a late mediator of inflammation. Indeed, anti-HMGB1 antibodies improved gut dysfunction and were beneficial in a murine peritonitis model.

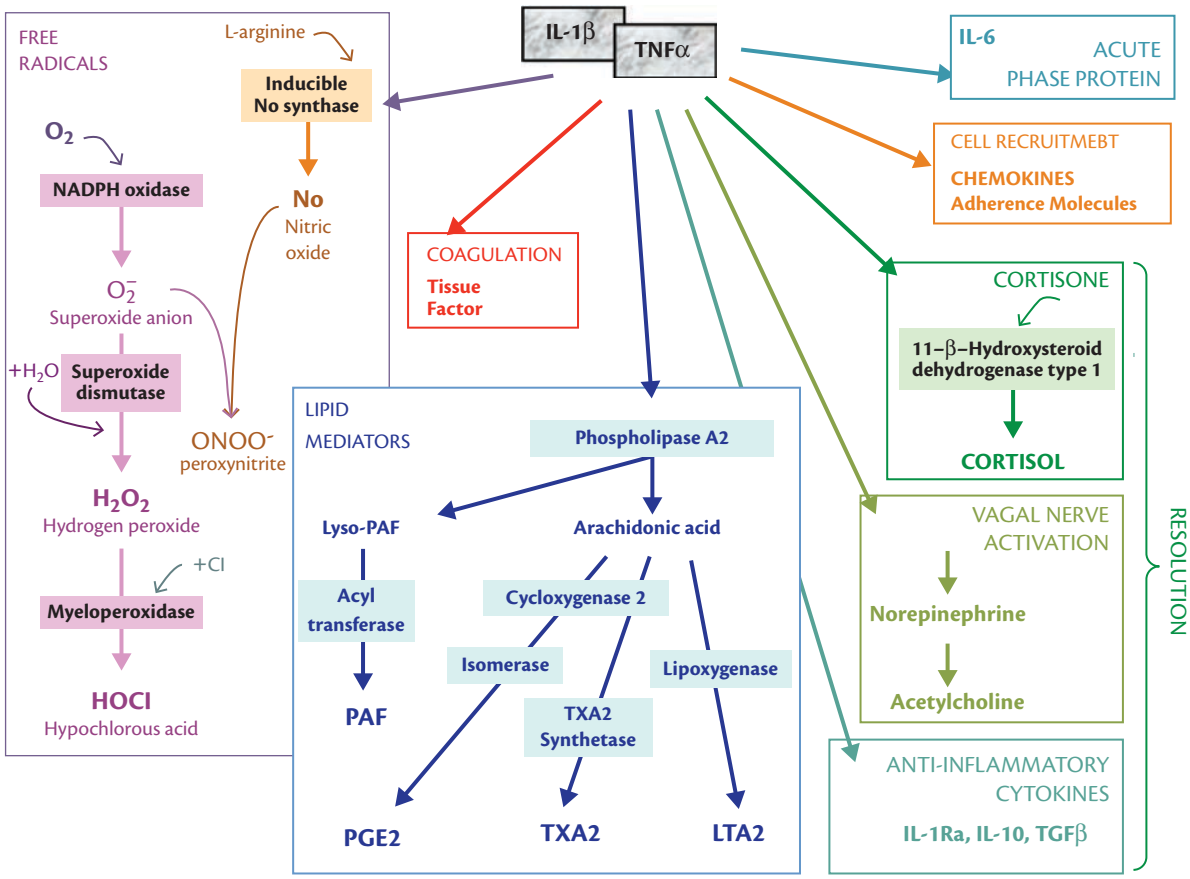

Fig. 299.1 Interleukin-1 (IL-1) and tumour necrosis factor (TNF) orchestrate a cascade of inflammatory events.

Macrophage migration inhibitory factor, produced in response to TNF-α, IFN-γ, IL-23 and IL-27, also contributed towards lethality in a CLP model. In contrast, conflicting reports have been published on the role of IL-17 and IL-33 during experimental sepsis. However, the role of IL-17 in the cross-talk between inflammatory tissues and in the perpetuation of the inflammatory process is now well established.

Among growth factors, vascular endothelial growth factor (VEGF) contributed to lethality in a CLP model by altering VE-cadherin expression and strength of tight junctions. Other mediators, e.g. the ligand of 'triggering receptor expressed on myeloid cells-1' (TREM-1), and the anaphylatoxin C5a act in synergy with TLR and NLR ligands favouring inflammatory cytokine production [3]. Finally, enhanced levels of programmed cell death 1 ligand (PD-1L) favour liver injury and lymphocyte apoptosis.

Free radicals

During inflammation, nitric oxide (NO) is produced in excess by inducible NO synthase (iNOS). Large amounts of NO are released after endotoxin exposure or cytokine-related stimulation of iNOS activity in inflamed tissues and vessels wall. NO production has been involved in many pathophysiological processes, including MODS. A major deleterious effect of NO is its ability to alter epithelial tight junctions, and this was shown to play an important role in the development of pulmonary, liver, and gut dysfunction in endotoxaemic mice. However, iNOS-deficient mice have a high mortality when exposed to polymicrobial sepsis, illustrating the fact that NO, as with many other mediators involved in both inflammation and innate immunity, has an ambiguous effect depending upon the experimental model or the timing of observation.

Upon activation by bacterial products or inflammatory cytokines, nicotinamide adenine dinucleotide phosphate (NADPH) oxidase catalyses the production of superoxide anions. These are transformed by superoxide dismutase into H_2O_2, which, in turn, is converted into HOCl by myeloperoxidase (Fig. 299.1). These molecules are potent anti-microbial agents and probably contribute to tissue damage. Indeed, NADPH oxidase is involved in the impairment of capillary blood flow, lung injury, and intestinal damage.

Lipid mediators

Pro-inflammatory cytokines induce the synthesis of phospholipase-A2 (PLA2), inducible cyclooxygenase (COX2), 5-lipooxygenase, and acetyltransferase, which contribute to eicosanoid synthesis (Fig. 299.1). These factors promote inflammation, alter vasomotor tone, and increase blood flow and vascular permeability. PLA2-deficient mice are endotoxin-resistant while *in vivo* inhibition of PLA2 decreases neutrophil infiltration into the lungs and deterioration of gas exchange following endotoxin or zymosan challenge. COX-2 deficient mice are also resistant to endotoxin-induced inflammation and death. Blocking the synthesis of leukotrienes or using 5'-lipoxygenase deficient mice demonstrated the deleterious effect of this eicosanoid in vivo. Platelet activating factor (PAF) is released by a large amount of cell types such as platelets, endothelial cells, macrophages, and neutrophils. Blood levels of PAF are elevated during septic shock. In different animal models inhibiting or antagonizing PAF led to improved blood pressure, prevention of microvascular alterations, protection from gastrointestinal lesions, reduction in TNF-α levels, and protection against the lethal effects of LPS. All these data confirm the involvement of PAF within the network of inflammatory mediators. However, no significant beneficial effects of PAF antagonism could be observed in human settings.

Coagulation and fibrinolysis

Disorders of coagulation are common in sepsis; 30–50% of patients with the most severe clinical form have disseminated intravascular coagulation. Numerous animal models with tools aimed at inhibiting coagulation or enhancing fibrinolysis have been successful in improving outcomes. Tissue factor (TF) is the link between inflammation and coagulation. It interacts with factor VII and increases the production of fibrin through activation of prothrombin and thrombin. In healthy volunteers challenged with LPS and in sepsis patients, TF expression is enhanced; increased membrane expression by monocytes prognosticates for a poor outcome. IL-1 and TNF-α, IFN-γ, CD40L, VEGF and MCP-1 induce TF expression on both monocytes and endothelial cells, while IL-6 favours thrombin expression. In parallel, both IL-1 and TNF-α induced production of plasminogen activator inhibitor-1 (PAI-1), thus favouring microvascular thrombosis following depression of fibrinolysis and enhanced coagulation. Coagulation factors such as factor Xa or thrombin also display pro-inflammatory activities.

Proteases

During sepsis, proteases are released by activated leukocytes and play an important role in the inflammatory host response. However, excess levels of elastase are associated with organ dysfunction. Matrix metalloproteinases (MMP) are involved in tissue remodelling (degradation and remodelling of all components of extracellular matrix), as well as in various inflammatory processes. Plasma levels of MMP-1 and MMP-9 are enhanced in human sepsis, and correlate with both severity and mortality. Whereas MMP-9 deficiency protected mice against mortality in an endotoxin model, such a deficiency was associated with enhanced bacterial growth and bacterial dissemination following CLP. Blockade of MMP-1 activity suppressed endothelial barrier disruption, disseminated intravascular coagulation, lung vascular permeability, and the cytokine storm, and improved survival.

Neuromediators

Some neuromediators displays pro-inflammatory properties. Substance P and neurokin A are encoded by the preprotachykinin-A gene. In preprotachykinin-A deficient mice, mortality following CLP decreases compared with wild type. Substance P antagonists reduce stress-induced cytokine up-regulation. Finally, norepinephrine increases TNF-α production via α_2-adrenergic receptors.

Resolving mediators

Anti-inflammatory cytokines

The pro-inflammatory response is balanced by the release of cytokine inhibitors, such as interleukin-1 receptor antagonist (IL-1Ra), IL-10, transforming growth factor-β (TGF-β), and soluble IL-1 and TNF receptors. The capacity of these natural inhibitors to downregulate or counteract cytokines produced by activated monocytes, eosinophils, and polymorphonuclear leukocytes, has been well-established. For example, following endotoxin or staphylococcal enterotoxin B injection, IL-10 treatment reduced TNF-α production, hypothermia, and death. In addition, IL-10 deficient mice develop chronic inflammatory bowel disease, which could be reduced by IL-10 treatment. IL-10 deficient mice are also highly

susceptible to colitis leading to aberrant inflammation to commensal bacteria; this colitis is more severe when combined with deficiency in TGF-β signalling. Similarly, IL-1Ra treatment reduced lethality of endotoxin-induced shock in rabbits and mice [4]. Of note, IL-1Ra deficient mice are prone to develop certain chronic inflammatory disorders. Other cytokines have also been reported to display anti-inflammatory properties (i.e. IL-4, IL-13, IL-25, IL-27, IL-35, and IFNα). Similarly, other cytokine antagonists have been described (e.g. IL-18 binding protein, IL-38, IL36Ra).

Glucocorticoids

Glucocorticoids (GCs), steroid hormones produced by adrenal glands, elicit potent anti-inflammatory effects signalling through a ligand dependent transcription factor, GR (glucocorticoid receptor). Following translocation to the nucleus, GR binds to palindromic glucocorticoid response elements (GREs) or interacts with other transcriptional regulators such as activating protein-1 (AP-1) and nuclear factor kappa B (NF-κB). GCs also exert non-genomic anti-inflammatory effects, such as promoting apoptotic cell clearance by phagocytes. In vivo, the endogenous GC cortisone is converted into its active counterpart cortisol, by 11β-hydroxysteroid dehydrogenase type-1 (11β-HSD1; Fig. 299.1). Indeed, 11β-HSD1 deficient mice are unable to reactivate cortisone to the bioactive cortisol. In sterile peritonitis model, 11β-HSD1 deficient mice show an exacerbated inflammatory response and delayed resolution mechanisms. Moreover, 11β-HSD1 deficient mice are more susceptible to endotoxaemia, with increased weight loss and overproduction of pro-inflammatory cytokines such as TNF-α and IL-6 following LPS injection. Altered GC metabolism has been reported in sepsis and trauma patients who may display adrenal insufficiencies.

Acute phase proteins

Many inflammatory cytokines (e.g. IL-6, IL-1, TNF, IL-11, IL-22, leukocyte inhibitory factor, TGFβ) can induce the release of acute phase proteins by hepatocytes such as C-reactive protein (CRP). Acute phase proteins favour the elimination of debris and neutralize inflammatory mediators. CRP has also been shown to alter O_2- release by neutrophils and to limit their chemotaxis, and to be protective in varied in vivo models (e.g. C5a instillation, LPS, or histone injection)

Lipid mediators

Lipoxins, maresin, and members of the resolvin and protectin families act as pro-resolution molecules, providing signals that selectively reduce neutrophil and eosinophil infiltration to inflamed tissues, promoting macrophage clearance of apoptotic cells, and micro-organisms, favouring the exit of phagocytes from the inflamed site through the lymphatics, and stimulating the expression of antimicrobial molecules. For example, treatment with resolvin D2-enhanced macrophage-dependent bacterial clearance, reduced plasma levels of the pro-inflammatory cytokines IL-6, IL-1β and TNF-α, and increased survival rates following CLP. In addition, lipoxin A4 treatment promoted survival and stimulated IL-10 production [5].

Neuromediators

Epinephrine, via β_2-adrenergic receptors, decreases TNF, IL-6 and NO production in response to LPS and potentiates IL-10 production. Adrenomedullin is a neuropeptide, structurally related to corticotropin-releasing factor (CRF), which inhibits TNF expression and stimulates IL-6 production by macrophages in response to LPS. A growing number of observations implicate the vagus nerve in events associated with the down-regulation of inflammation. Acetylcholine produce by the vagus nerve and by norepinephrine activated T-cells can dampen inflammation via the α7-nicotinic receptor [6].

PART 14.2

Organ-specific biomarkers

CHAPTER 300

Brain injury biomarkers in the critically ill

Patrick M. Kochanek and Rachel P. Berger

Key points

- The brain exhibits a secondary injury cascade that includes traditional, but also unique mechanisms, such as excitotoxicity, synaptic injury, axonal injury, and selective vulnerability. Quantification of brain injury biomarkers in serum and CSF has helped to define these biochemical, cellular, and molecular pathways.
- Three cellular targets, neurons, astrocytes, and axons have served as the principal cellular targets that have been used to develop brain injury biomarkers.
- Brain injury biomarkers have potential utility to aid in diagnosis and prognosis, guide therapy selection, and monitor therapeutic efficacy in acute brain injury in the intensive care unit (ICU).
- Protein biomarkers of brain injury such as NSE, S100B, GFAP, UCH-L1, and MBP, among others, have the potential for clinical use in the ICU, either alone or in combination. More novel brain injury biomarkers, such as oxidized cardiolipin and microRNAs deserve further exploration.
- Many factors can uniquely influence serum biomarker levels after brain injury, most notably the amount of disruption of the blood–brain barrier and the amount of cerebral blood flow in the injured tissue.

Introduction

Few areas in neurocritical care have attracted more attention recently than brain injury biomarkers. With the recent recognition of traumatic brain injury (TBI), particularly mild TBI, as a major public health problem, the search for reliable rapid diagnostic serum markers of brain injury has become a priority. Issues arising from sports concussion, blast TBI in combat casualty care, and abusive head trauma in infants and young children have driven this search. The development of one or more brain injury biomarkers would also have a broader impact, including utility in neurocritical care.

The roots of the potential use of serum or cerebrospinal fluid (CSF) biomarkers of brain injury in critical care medicine lie in seminal work of Vaagenes et al. in the early 1980s [1]. They examined the potential utility of CSF concentrations of the brain-specific isoform of creatine phosphokinase to identify morphological changes in the brain after experimental cardiac arrest. However, the use of brain injury biomarkers has a richer history than simply serving as a tool to identify brain injury. Serum and CSF biomarkers have been essential to understand the evolution of the unique secondary injury mechanisms occurring within the brain. Research linked to the search for brain injury biomarkers has yielded many dividends for the field of neurocritical care, notably in our understanding of the pathobiology of various acute insults [2].

Many things can serve as 'biomarkers'. A finding on cranial CT scan or brain MRI can serve as a biomarker of brain injury. Similarly, quantification of levels of various metabolites in brain tissue using magnetic resonance spectroscopy can aid in diagnosis or management in the ICU. This chapter focuses on brain injury biomarkers assessed in biological samples, such as serum or CSF, that are readily available in many intensive care unit (ICU) patients. This chapter will:

- Provide examples of how biomarkers of brain injury can be helpful in contemporary neurocritical care.
- Discuss the secondary injury mechanisms that represent the 'inflammatory response' to brain injury and the biological samples that are most often used to assess these biomarkers.
- Present key data on some of the biomarkers used to identify brain injury in research.
- Discuss novel brain injury biomarkers.
- Consider approaches that simultaneously evaluate multiple biomarkers.
- Briefly discuss innovative approaches to analysing biomarker profiles.
- Discuss factors that are relevant to neurocritical care that can influence the observed serum levels of brain injury biomarkers.

Table 300.1 identifies the biomarkers of acute brain injury discussed in this chapter.

The interface between critical care-relevant insults to the brain and brain injury biomarkers

The availability of reliable biomarkers could benefit ICU patients with a wide variety of acute brain injuries. For example, serum biomarkers could rapidly confirm the presence of acute brain injury in victims of polytrauma who are intoxicated and in whom a reliable

clinical exam is problematic. Similarly, biomarkers of brain injury could alert the physician to possible evolving brain injury in patients with status epilepticus, especially in cases where the admission CT scan is negative, but an acute injury is evolving. Serum or CSF biomarkers of brain injury could also aid in defining the severity of injury across various known neurocritical care disorders, such as TBI, cardiac arrest, stroke, meningitis, subarachnoid haemorrhage, and sepsis, and aid in prognostication. Serum levels of the brain injury biomarker, neuron specific enolase (NSE) have recently been incorporated into guidelines for prognostication in patients with hypoxic-ischaemic encephalopathy after cardiac arrest [3]. Finally, serum biomarkers might also be used in a theragnostic fashion, defining the response to treatments and/or guiding therapy selection. For example, recent studies suggest the possibility of using biomarkers to define the contribution of necrotic versus apoptotic neuronal death in patients with severe TBI or cardiac arrest. Two strategies in this regard are noteworthy. CSF levels of cytochrome C are strongly associated with neuronal death from apoptosis in children with severe TBI [4], while elevations in high mobility group box 1 (HMGB1) suggest alternative cell death pathways, such as necrosis, pyroptosis, or autophagy [5]. Assessing the breakdown products of the neuronal protein α-spectrin in CSF can similarly aid in this regard [6]. Caspase 3 cleaves α-spectrin to a 120 kDa fragment during apoptosis, while the enzyme calpain cleaves α-spectrin to 145 and 150 kDa fragments during necrosis. Examining the ratio of these two categories of products could thus help guide therapy.

The potential utility of serum biomarkers to evaluate the relative contributions of necrotic versus apopototic cell death as shown in a study assessing the neuronal injury biomarker NSE across three causes of brain injury in paediatric neurocritical care, namely, hypoxic-ischaemic encephalopathy from cardiopulmonary arrest, accidental TBI, and abusive head trauma [7]. In TBI, serum NSE levels were markedly increased, with peak levels seen on the initial day after TBI suggesting necrosis from the primary traumatic injury. In contrast, in both hypoxic-ischaemic encephalopathy and abusive head trauma, serum NSE generally peaked in infants and children in a delayed fashion, suggesting delayed neuronal death, probably from apoptosis. This illustrates the potential for serum biomarkers of brain injury both as a diagnostic tool and to potentially guide therapy. Similarly, in adults after cardiac arrest, serum NSE increased in a delayed fashion, suggesting delayed neuronal death from apoptosis. A marked attenuation of NSE levels was seen in patients treated with mild hypothermia, providing a biochemical correlate of beneficial effects of this therapy after cardiac arrest [8].

The use of biomarkers to assess mechanisms of secondary damage in brain in the ICU

The brain is complex and secondary damage after acute injury is multifaceted. The requisite mechanisms involved in injury cascades such as ischaemia/reperfusion, energy failure, and inflammation operate in the injured brain. However, after ischaemia, hypoxia, trauma, haemorrhage, or infection additional mechanisms are set into motion. Unique pathways linked to neurotransmission, connectivity (axonal and synaptic injury) and intracranial hypertension play significant roles (Fig. 300.1). Highlighting the complexity of the brain, after a hypoxic-ischaemic insult, such as cardiac arrest, delayed neuronal death occurs in selectively vulnerable regions, such as the CA1 region of the hippocampus, Purkinje cells in the cerebellum, and neurons in cortical layers. Yet neurons adjacent to these vulnerable cells and sharing the same blood supply are often not damaged. Similarly, highlighting the unique and complex injury cascades in brain, cognitive deficits can develop after mild TBI where no histopathological alterations are observed.

Several sources of biological samples are used to study secondary injury pathways in humans with severe brain injury. For example, the evolution of axonal injury after severe TBI can be monitored by assessing CSF levels of myelin basic protein (MBP) [9]. Similarly, assessment of the time course and magnitude of oxidative stress in brain can be accomplished by serially measuring CSF levels of markers such as ascorbate or F_2-isoprostane [10]. CSF is often available in patients with severe TBI, since ventricular catheters are placed to drain CSF in the treatment of raised intracranial pressure. Other methods, such as intracerebral microdialysis, which requires insertion of a probe directly into the brain, have allowed continuous sampling of brain interstitial fluid. Biomarkers of energy failure (lactate/pyruvate) or neurotransmitters (glutamate) have been assessed using this approach [11]. Microdialysis is a research tool, but has become standard care in several neurointensive care units.

Biomarkers to detect brain injury in the critically ill

Protein biomarkers: assessment of individual markers

A comprehensive review of protein biomarkers of brain injury is beyond the scope of this chapter, although several important markers will be discussed. In general, three categories of protein biomarkers—neuronal, astrocyte, and axonal—have been used. What is sought in a brain injury biomarker is a protein that is as unique as possible to brain as opposed to other tissues. However, few molecules are unique to brain. Individual brain injury biomarkers

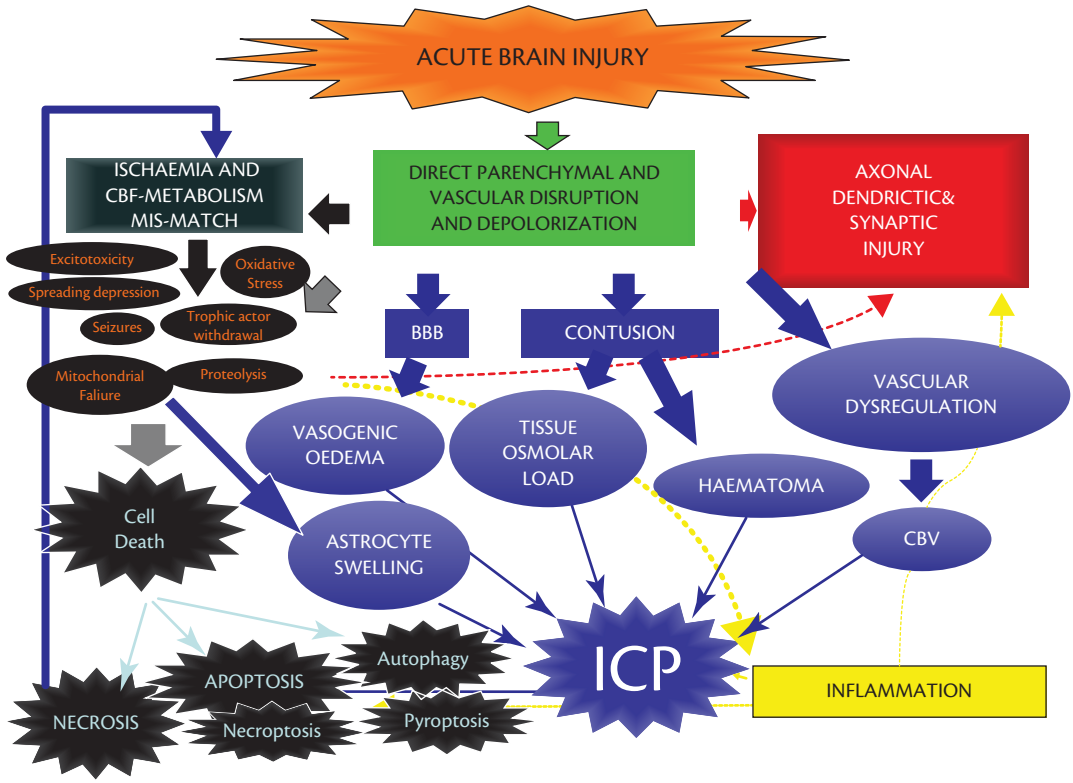

Fig. 300.1 Key mechanisms of secondary injury in the brain as defined by biomarker studies. In this example, traumatic brain injury is used as the example of acute brain injury. A vast array of biomarkers of acute brain injury in cerebrospinal fluid, serum, brain interstitial fluid, and brain tissue have been used to identify key mechanisms of secondary injury that evolve in the brain of critically-ill patients. Many of the biomarkers discussed in this chapter have contributed to current knowledge of these pathways. Secondary injury in the brain is notably more complex than in other organs related to several important factors including selective vulnerability of certain neurons to hypoxic-ischaemic insults, unique injury mechanisms, such as excitotoxicity, and unique and highly complex anatomical targets, such as synapses and axons. Please see text for details.

ICP, intracranial pressure; BBB, blood–brain barrier; CBV, cerebral blood volume.

as assessed in serum or CSF are generally quantified using ELISA or enzyme-linked immunofluorescence assays [2].

Neuronal injury markers

Several markers of neuronal injury have been studied extensively and have potential for clinical development. The most widely studied neuronal injury marker is NSE, a glycolytic enzyme localized predominantly in neuronal cytoplasm. It has a half-life of ~24 hours and has shown sensitivity and specificity in neurocritical care-relevant conditions, such as cardiac arrest and TBI [3]. A limitation of NSE is the occurrence of false positive values resulting from haemolysis due to the presence of enolase levels in erythrocytes and platelets. However, the level of NSE resulting from haemolysis in serum or CSF samples can be corrected. Two other neuronal injury markers have been the focus of investigation. Ubiquitin C-terminal hydrolase-1 (UCH-L1) is an abundant brain-specific protein involved in the addition or removal of ubiquitin from damaged proteins [12]. It has shown promise as both serum and CSF biomarker for mild and severe TBI, and may have broader utility in prediction of outcome after paediatric TBI [12]. As discussed previously, α-spectrin degradation products also show promise as serum and CSF biomarkers of brain injury. α-Spectrin is abundant in presynaptic terminals and, as previously discussed, the presence of its cleavage products in CSF or serum can suggest apoptotic versus necrotic injury pathways. Finally, other neuronal biomarkers have shown potential, including the protein 14-3-3-γ.

Astrocyte injury markers

Astrocytes are the most abundant cell type in brain and are a robust potential source for biomarkers. One promising biomarker is the astrocyte protein, glial fibrillary acidic protein (GFAP). It is almost exclusively found in brain and is released from the astrocyte cytoskeleton [13]. GFAP is showing promise as a brain injury biomarker in TBI, cardiac arrest, and stroke. Another marker studied extensively in brain injury is S100B, a calcium-binding protein found largely in astrocytes. This has shown effectiveness as a diagnostic marker in TBI, stroke, cardiac arrest, and subarachnoid haemorrhage [2]. Limitations of S100B include a short half-life, extracerebral sources, and high baseline levels in infants. Nevertheless, it has a substantial track record as a brain injury biomarker. Indeed, S100B is used as a standard of care in some European countries to exclude the need for a head CT scan in patients with mild TBI [14]. In a recent study comparing S100B, GFAP, NSE, and other biomarkers in adults after cardiac arrest, S100B exhibited the best sensitivity (87%) and specificity (100%) for predicting poor outcome [15].

Axonal injury markers

White matter is injured in various forms of acute brain injury. In diffuse axonal injury from certain forms of TBI, it can be selectively damaged. In contrast, in ischaemic brain injury from cardiac arrest, white matter is resistant to damage relative to gray matter. Thus, biomarkers of axonal injury can help differentiate brain injury mechanisms. MBP is an abundant protein in white matter that has been studied as a marker of axonal damage in acute brain injury. CSF levels of MBP increase >4000-fold in children after TBI [9].

Protein biomarkers: assessment of multiple markers

It is likely that multiple, rather than a single brain injury marker will be used in a panel to aid in diagnosis and patient management. The origins of this approach and indeed of much of the ultimate success in defining unique biomarkers came out of the use of 2D-gel and protein array approaches in TBI [16]. Multiplex bead technology was used to aid in the identification of silent brain injury with high sensitivity and specificity in infants and children who were victims of abusive head trauma [17].

Novel brain injury biomarkers

Although most clinical investigation has focused on the use of protein biomarkers of brain injury, two novel alternative acute brain injury biomarkers (oxidized cardiolipin and microRNA) are noteworthy. The mitochondria-specific lipid cardiolipin has special characteristics in brain that make it a potentially useful biomarker. Cardiolipin is a phospholipid with four fatty acid chains allowing for the existence of a diverse number of molecular species. In brain, there can be over 100 molecular species; markedly fewer species exist in other organs [18]. Many of these side chains contain unsaturated fatty acids and, given its mitochondrial location, aberrant oxidation can produce products that could serve as brain injury biomarkers. Similarly, recent work in TBI suggests there are unique microRNAs within brain that reflect injury; specifically, levels of the microRNA let-7i are elevated in serum and CSF [19]. These and other novel biomarkers merit additional investigation.

Novel analytical approaches to enhance the use of biomarkers in diagnostic, prognostic, and theragnostic applications

For diagnosis of brain injury, assessment of sensitivity and specificity, and identification of cut-off values for single point levels of biomarkers represent the standard approach to brain injury biomarker development and validation. For prognosis, what has served to be most useful is identification of cut-off values at a specific time point after a given insult. Other analytic approaches are also being used. Trajectory analysis incorporates all data collected over time by identifying subpopulations that follow specific paths of change in their biomarker levels. Once different subpopulations are identified, outcome of individual subjects can be successfully predicted based on subpopulation assignment [20].

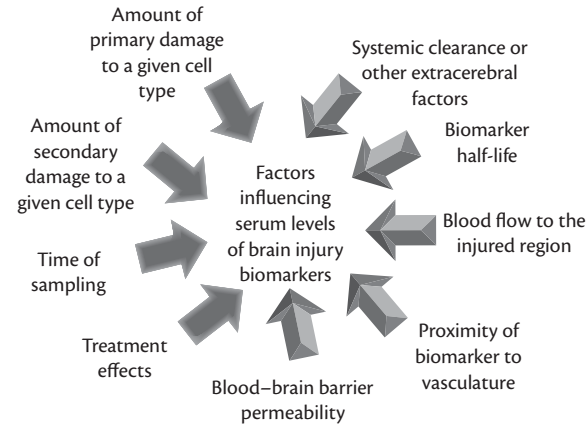

Fig. 300.2 Factors that affect serum levels of biomarkers of acute brain injury relevant to neurocritical care.

Factors that influence levels of brain injury biomarkers

Many factors influence the levels of brain injury biomarkers (Fig. 300.2). Factors such as the amount of primary and secondary damage, time of sampling, and treatment effects are important. The presence of the blood–brain barrier (BBB) and proximity of a given biomarker to the vasculature can also have special importance. For example, astrocyte foot processes represent a component of the BBB; thus, their proximity to the vasculature probably contributes to the value of astrocyte proteins as sensitive biomarkers. Blood flow to an injured brain region can also influence serum biomarker levels. In stroke, brain regions with extensive damage may have negligible perfusion and might be unable to transduce an increase in biomarker levels from tissue to blood. Finally, biomarker half-life and factors affecting clearance are important. In the setting of renal failure, sustained increases in serum levels of S100B could be observed after cardiac arrest despite its short half-life. Release of biomarkers from extracranial neuronal sites can also influence levels in diseases such as cardiac arrest and polytrauma.

Conclusion

The field of brain injury biomarkers is one of the most rapidly developing areas in contemporary neurocritical care. We expect that there will soon be one or more protein biomarkers of neuronal, astrocyte, and/or axonal injury available for routine diagnostic, prognostic, and/or theragnostic use in the ICU.

CHAPTER 301

Cardiac injury biomarkers in the critically ill

Anthony S. McLean and Stephen J. Huang

Key points

- Only a few cardiac biomarkers have relevancy in the intensive care setting.
- The most useful cardiac injury marker is cardiac troponin, with recent high-sensitive assays being a significant advance.
- The cardiac stress biomarker B-type natriuretic peptide is useful for screening and diagnosis in the intensive care patient, although lacks specificity.
- Inflammatory markers for cardiac diseases are too non-specific.
- Although cardiac biomarkers are very helpful in the critically-ill patient, the presence of concomitant confounding factors requires considered interpretation.

Introduction

Despite an intensive search over many decades for accurate circulating cardiac biomarkers, only a handful have clinical relevance in the acute setting. Even this small number has been evaluated primarily in the setting of single organ dysfunction, such as a person presenting to hospital with chest pain, or for prognosticating in patients with known heart failure, and are thus not easily applicable to the intensive care unit (ICU) patient with multi-organ failure. The clinician also needs to clarify the reason for seeking biomarker levels, whether for screening, diagnosis, monitoring, or prognosis.

The evolution of most cardiac diseases involves three stages, beginning with inflammation, followed by acute injury to the myocardial cells and, finally, cardiac stress where the myocardium is subjected to pressure and/or volume overload. Parallel to this process is the sequential release of biomarkers reflecting each stage. Some overlap is to be expected (Fig. 301.1).

Inflammatory markers

Inflammation plays a key role in coronary artery disease—all stages of plaque development and eventual rupture leading to an acute coronary syndrome can be considered to be an inflammatory response [1]. Inflammation also plays an important role in heart failure and myocarditis. While inflammatory marker levels are increased in heart diseases, their uses as diagnostic markers and prognosticators are limited in the ICU due to various confounding inflammatory conditions (e.g. infection, trauma) often found in this setting. A summary of common inflammatory markers is provided in Table 301.1.

Markers of cardiac injury

Evaluating cardiac injury, especially where coronary artery occlusion has caused myocardial necrosis, has been at the forefront of medicine for the past 50 years. Creatinine phosphokinase (CPK), troponin, myoglobin, and heart-type fatty acid binding protein (H-FABP) have progressed to becoming useful clinical tools.

Cardiac troponins

Cardiac troponin (cTn) is the standout serum biomarker, past or present, in the evaluation of cardiac disease. Refinement of laboratory testing, now detecting a few ng per litre of serum, has increased diagnostic accuracy for identifying very small amounts of ischaemic/infarcted myocardium, greatly enhancing the diagnosis of underlying coronary artery disease in patients presenting with chest pain and/or other clinical features suggestive of a cardiac origin. The high sensitivity cardiac troponins (hs-cTn) can correctly be seen as a significant clinical advance, but challenges the physician dealing with the critically ill. Even with previous generations of less sensitive assays, the diagnostic potential was lessened by confounding factors. To optimize the benefit of hs-cTn testing, the clinician needs to: understand the analytical parameters of the actual cTn test used in their institution, know the serum half-life of troponin, consider more than a single static blood level, and be aware of both non-ischaemic cardiac pathology influences and non-cardiac pathologies. Furthermore, the result should be interpreted according to whether the test was performed for diagnostic or prognostic reasons.

Cardiac troponin assays

The troponin complex regulates striated muscle contraction by controlling the calcium-mediated interaction of actin and myosin. It consists of three subunits—T (tropomyosin binding), C (calcium binding) and I (inhibitory) (Fig. 301.2). T and I subunits are unique to cardiac muscle whereas the C subunit is found in both cardiac and skeletal muscle. The majority of cTnT and cTnI are bound to the myofibril with approximately 7% of cTnT and 3–5% cTnI free in the cytoplasm [2]. The biphasic rise in blood troponin following myocyte damage reflects this, with initial release of cytoplasmic troponin followed by gradual disengagement of the

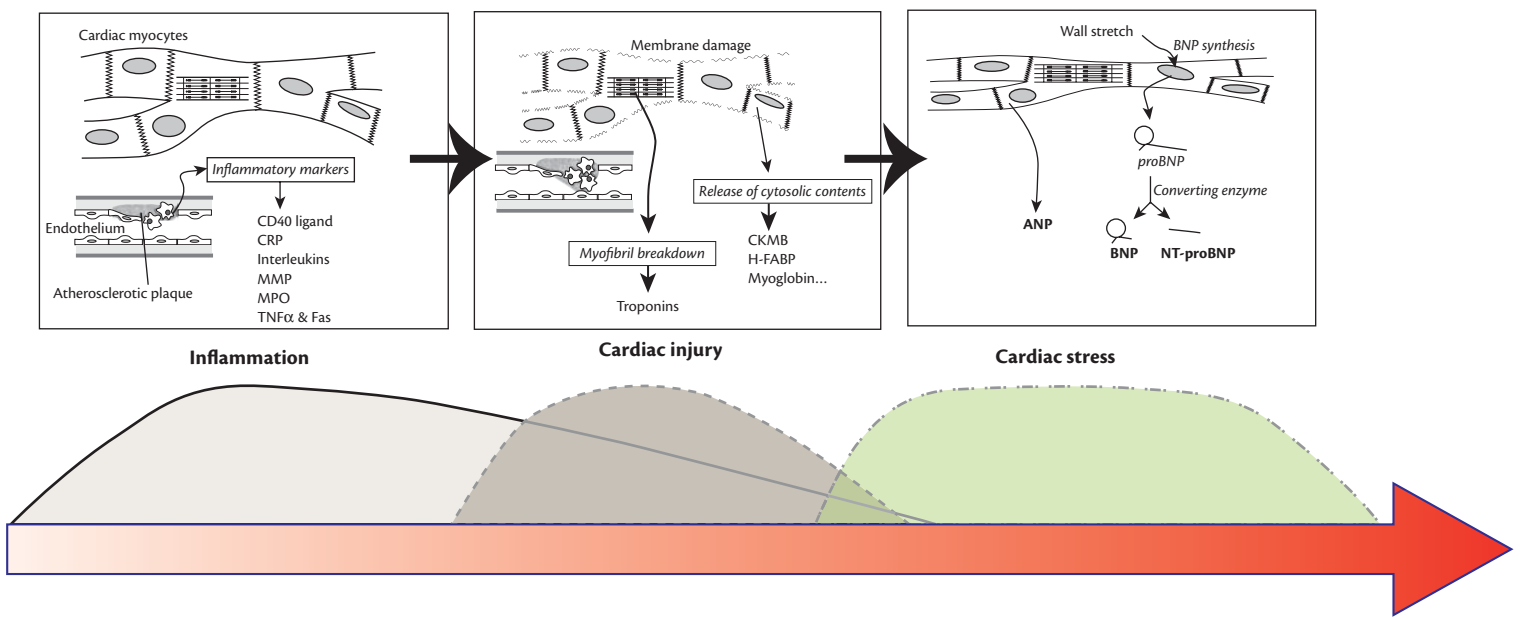

Fig. 301.1 Evolution of cardiac diseases. Most cardiac disease can be divided into three phases: inflammation, cardiac injury, and cardiac stress. There can be overlapping between the three phases.
ANP, atrial natriuretic peptide; BNP, B-type natriuretic peptide; CRP, C-reactive protein; H-FABP, heart-type fatty acid binding protein; MMP, matrix metalloproteinases; MPO, myeloperoxidases; TNF, tumour necrosis factor.

Table 301.1 Common inflammatory markers associated with coronary artery disease

Biomarker	Source(s)	Biological role or function	Uses
C-reactive protein (CRP)	Atherosclerotic plaque	◆ Pathophysiology of atherosclerosis ◆ Enhance macrophage uptake of lipids and formation of foam cell ◆ Causes plaque instability	◆ Elevated in patients with unstable angina, higher level is associated with worse outcome ◆ Also increased in patients with acute injury, infection and acute renal failure
Interleukins (IL) IL-6, IL-18	Atherosclerotic plaque and nucleated cells in the heart	◆ Pro-inflammatory cytokines ◆ Induce liver to produce all acute phase proteins, including CRP ◆ Destabilizes plaque	◆ Found in both stable and unstable atherosclerotic plaque ◆ Positively correlated with severity of decompensated heart failure ◆ Independent predictors of mortality
Tumour necrosis factor-α (TNFα) and FAS	TNFα: atherosclerotic plaque. Fas: cardiac myocytes and other cells	◆ TNFα induces left ventricular dilatation ◆ Fas mediates apoptosis and contributes to progression of heart failure	◆ TNFα is associated with higher incidence of heart failure ◆ Fas is positively associated with severity of heart failure
CD40 and soluble CD40 ligand (sCD40L)	Vascular cells, macrophages, platelets	Promotes degradation of fibrous cap	High sCD40L is associated with higher cardiovascular risk
Matrix metalloproteinases (MMPs)	Cardiac fibroblasts	◆ Pathophysiology of atherosclerosis and vascular disease ◆ May promote plaque rupture ◆ Take part in adverse remodelling in heart failure, hypertension, and MI	◆ MMP-9 is higher in CAD, and increases in acute MI ◆ MMP-9 is positively associated with risk of stroke or cardiovascular death
Myeloperoxidase (MPO)	Atherosclerotic plaque, activated neutrophils	◆ Pathophysiology of atherosclerosis ◆ Destabilizes plaque	◆ Predictor of MI ◆ Risk stratification for CAD ◆ Not specific for cardiac disease

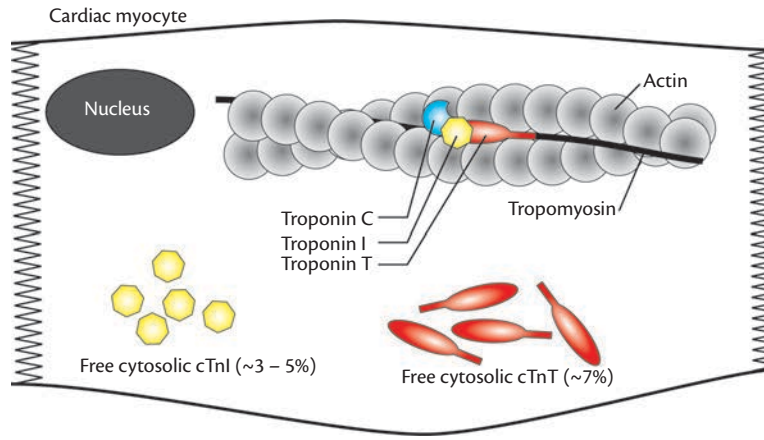

Fig. 301.2 The troponin complex and sources of troponin in cardiomyocytes.

myofibrillar-bound troponin. Elevation of serum cTn measured by conventional cTn assay can be detected 1–4 hours following myocardial damage, but with some uncertainty still surrounding the mechanisms by which it is cleared from the blood. Serum levels of cTnI remain elevated for 4–7 days following myocardial injury, whereas cTnT persists up to 10–14 days. cTn has a large molecular size and its clearance is believed to occur through the reticuloendothelial system.

Due to its release kinetics, the sensitivity of cTn as a diagnostic marker of myocardial infarction, increases with time; at the time of hospital admission conventional assays of cTnT and cTnI had sensitivities of 25–65% and 45%, respectively, but this increased to 100% by 6–12 hours later [3]. The introduction of hs-cTn assay, with detection limits as low as 3.0 ng/L for cTnT and 2.0 ng/L for cTnI, improved sensitivity and reduced the time to detection. In a study involving transcoronary ablation of septal hypertrophy, a

model of a diagnostic marker of myocardial infarction, hs-cTnT assay detected a significant cTnT rise (>50% above baseline) at 15 minutes after commencement and exceeded the 99th percentile after 30 minutes [4]. On the other hand, the first detectable significant change using cTnT was observed after 60 minutes, and this lagged behind myoglobin for which a rise was detected 30 minutes earlier. With increasingly sensitive assays, the number of healthy individuals with detectable troponin in the blood also increases, thereby changing the definition of abnormal serum levels. High sensitivity cTn assays are differentiated from contemporary ones in that detection of cTn is found in up to 90% of a reference population. This allows for a precise definition of abnormal by using a serum hs-cTn level above the 99th percentile of a normal reference population [5]. This renders hs-cTn as an ideal rule-out tool for a diagnostic marker of myocardial infarction within a shorter timeframe than standard assays. The clinician should be aware of the analytical quality and limitations of the particular assay used in their institution.

Applications of cTn assays

The diagnostic performance of hs-cTn outside the Emergency Department when assessing patients presenting with chest pain is uncertain. The debate about whether absolute or relative levels are better for rapid diagnosis of myocardial infarction is far from resolved [6].

In the ICU environment, where confounding factors are commonly found and adjuncts, such as complaints of chest pain or the typical electrocardiographic changes of acute coronary syndrome are often absent, moving from standard cTn to hs-cTn assays has compounded the interpretative challenges in an environment where multiple confounders are present. Interpretation is assisted by serial measurements and the use of relative rather than absolute levels (Fig. 301.3). Where very high serum cTn levels are identified, the diagnosis of coronary artery disease needs to be ruled out, usually by imaging of the coronary arteries. At the other end of the scale, a cTn level below the 99th percentile means myocardial necrosis is very unlikely, but a second sample 3–6 hours later may be of assistance. Intermediate values (e.g. 14–100 ng/L with cTnT) alerts to the evidence of myocardial damage or necrosis, but not the cause. If a rising or falling (>30% relative change) level is found over 3–6 hours then it is likely to be ischaemic necrosis; in the absence of classical electrocardiographic changes this may represent a Type II infarction where ischaemic damage is due to increased oxygen demand or decreased supply, and not necessarily a primary coronary artery event [7]. However, an elevated and rising serum cTn level informs the clinician that myocardial cell death has occurred,

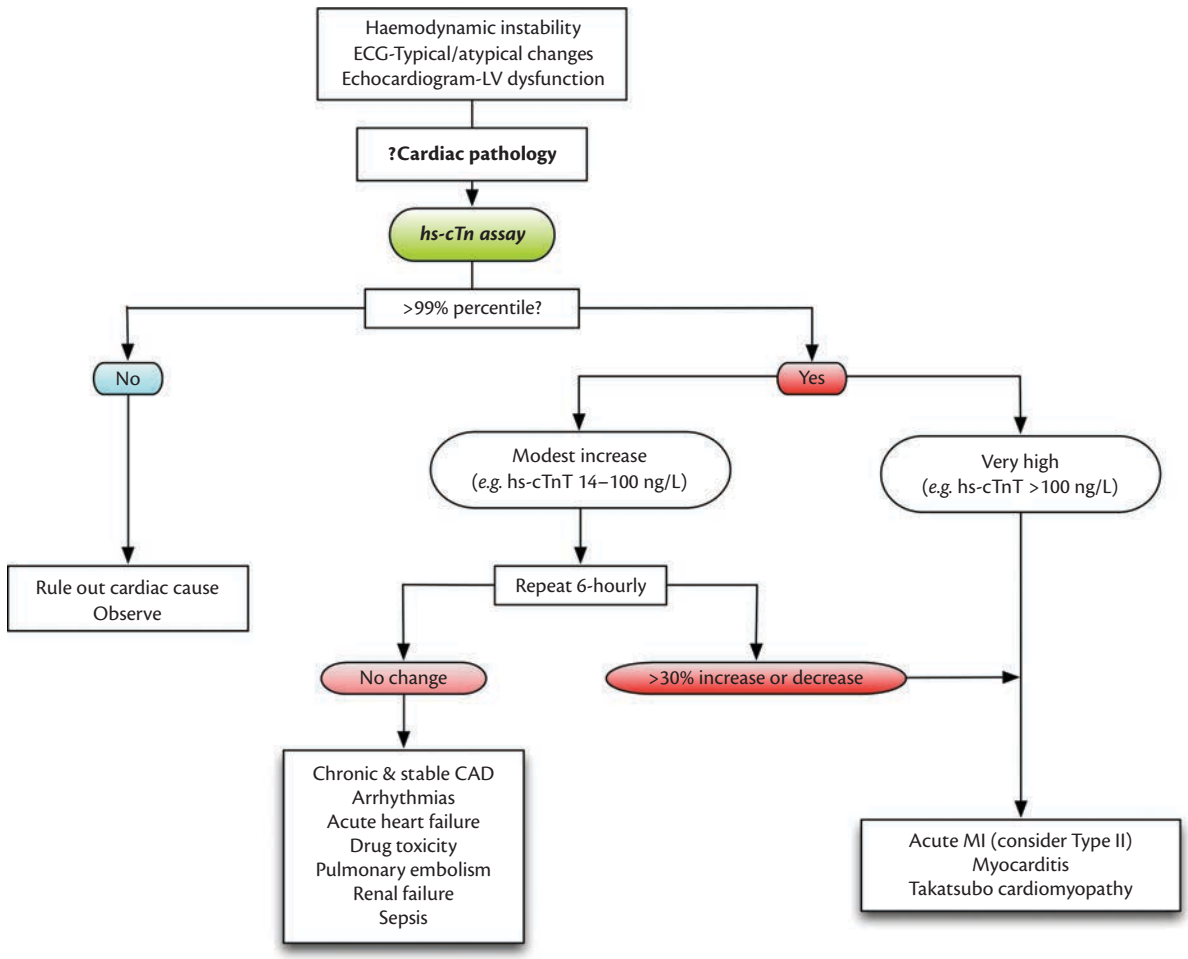

Fig. 301.3 Flow chart showing the possible use of hs-cTn in the ICU.

but not necessarily the cause of that necrosis. A slowly falling level over days raises the possibility of myocardial injury occurring some days previously. A steady level may implicate a non-ischaemic cause such as renal failure, pulmonary embolus, acute heart failure, or sepsis, for example.

Dismissing hs-cTn as having too low a specificity to be clinically useful, overlooks the gains in further understanding of the mechanisms and severity of cardiac damage in critically-ill patients that a simple blood test offers. In terms of prognosis, an elevated serum cTn levels is highly prognostic in the critically-ill population; future studies are likely to confirm these findings with hs-cTn. The translation of this information in improved patient care is implied, but not yet proven.

Box 301.1 Non-cardiac conditions known to alter BNP levels

- Sepsis.
- Inflammatory diseases.
- Pulmonary hypertension.
- Acute or chronic renal failure.
- Obesity.
- Embolic stroke.
- Liver cirrhosis.

Cardiac marker for cardiac stress: B-type natriuretic peptide

In contrast to cTn, which is a biomarker-related to myocardial cell injury, B-type natriuretic peptide (BNP) is best viewed as a biomarker of the physiological function of maintaining fluid homeostasis. In response to cardiac stress, such as volume and pressure overloading, *BNP* gene expression is induced in ventricular myocytes within an hour. The first product synthesized is a 132-amino acid preprohormone that is then processed into a 108-amino acid precursor protein (proBNP). ProBNP is cleaved into the biologically active 32-amino acid carboxyl-terminal peptide (BNP) and a 76-amino acid amino-terminal (N-terminal) fragment (NT-proBNP) by a converting enzyme. BNP contains a 17-amino acid ring structure common to the natriuretic peptide family.

Heart failure and other stimulants for BNP release

The low output state of heart failure leads to the adaptive activation of the renin-angiotensin-aldosterone system (RAAS) and the sympathetic nervous system (SNS). Although activation of both systems provides a short-term favourable haemodynamic response, if left unchecked their activation leads to worsening of heart failure. Tachycardia, increased peripheral resistance and volume overload are common amongst the heart failure population and are partly due to activation of RAAS and SNS. Other deleterious effects include rendering patients refractory to diuretics as a result of angiotensin II-induced increased Na^+ reabsorption, down-regulation of cardiac β_1-adrenoceptor leading to reduced contractility, tachycardia-induced cardiomyopathy, and myocardial remodelling. The end results of the maladaptive responses of the RAAS and SNS are deterioration of cardiac function and fluid retention (increase in preload and afterload).

The release of BNP is associated with an improvement in haemodynamics and reduction in cardiac stress. This is brought forth mainly by vasodilation (including both venous and arterial trees), and promoting natriuresis and diuresis. The vasodilatory effect not only reduces afterload but also improves the coronary circulation, and hence, oxygen supply to the myocardium. BNP, by inhibiting renin and aldosterone release, counteracts the deleterious effects of prolonged activation of the RAAS in decompensated heart failure [8]. This inhibitory effect on RAAS reduces both preload and afterload and lessens cardiac stress.

Cardiac stress is not the only stimulant for BNP release. Other factors, either directly or indirectly, also can cause an increase or decrease in BNP release (Box 301.1) [9]. For example, BNP concentrations are elevated in septic patients, even in those showing no symptoms or signs of myocardial dysfunction [10,11]. Inflammatory cytokines, lipopolysaccharide, mechanical ventilation, and catecholamines are known to interfere with BNP synthesis and release.

Clinical applications of BNP in critical care: screening and diagnosis

Approximately 30% of all patients admitted to a general ICU were identified by BNP to have some form of cardiac dysfunction, either overt or covert [12,13]. When BNP was used as a screening tool in the ICU, the concentration was significantly higher in patients with cardiac dysfunction. A cut-off value of 144 pg/mL offered 92% sensitivity and 86% specificity in predicting cardiac dysfunction. Most of these patients had subclinical signs of cardiac dysfunction, including left ventricular systolic and diastolic dysfunction, and right ventricular dysfunction. Early identification of these patients may prevent iatrogenic adverse events, such as pulmonary oedema as a result of fluid overload, and provide a better outcome [14].

The use of BNP for the diagnosis of heart failure is well established in the outpatient and emergency settings. In patients presenting to the Emergency Department with acute dyspnoea, a plasma BNP cut-off of 100 pg/mL had a sensitivity of 90% and a specificity of 76% in diagnosing heart failure [15]. NT-proBNP, at a cut-off of 300 pg/mL, is also useful in diagnosing acute heart failure in this setting [16]. To improve accuracy, age-related cut-offs for NT-proBNP are recommended: 450 pg/mL for people aged <50 years, 900 pg/mL for 50–75 years, and 1800 pg/mL for >75 years. Although diagnostic processes may be improved by measuring BNP and NT-proBNP levels, whether or not such tests confer significant clinical benefit remains questionable [17,18].

The future of cardiac biomarkers

The search for improved biomarkers continues unabated with ongoing publications on a myriad of potential candidates, very few of which appear to have clinical potential. One approach that offers potential is genetic markers. While the search for polymorphisms that may predispose an individual to certain cardiac diseases is yielding results, these are of little use to the practising intensivist. However, circulating microRNAs do have considerable potential. These are non-coding ribonucleic acids (RNA), 20–25 nucleotides long that bind to messenger RNA and play a role in gene silencing. The half-life of circulating miRNA is only a few hours and their disappearance from blood does not appear to be affected by the

presence of organ dysfunction, an advantage over cardiac troponins and natriuretic peptides. Some, like microRNA208a, are highly cardiac-specific and are associated with necrosis. In a study of 186 circulating microRNAs in patients with heart failure, elevated levels of microR-423–5p, microR320a, microR-22, microR-92b identified systolic heart failure patients and correlated with important clinical prognostic parameters [19].

CHAPTER 302

Renal injury biomarkers in the critically ill

John R. Prowle

Key points

- Acute kidney injury (AKI) is a complex clinical syndrome that is strongly associated with adverse outcomes in the critically ill.
- The traditional diagnosis of AKI, based on serum creatinine and urine output, is often delayed and imprecise, particularly in critical illness.
- Novel plasma and urinary biomarkers can diagnose AKI very early in its clinical course, and provide information on its nature and severity.
- Application of biomarker measurements may enable early identification of patients developing AKI for specific therapeutic interventions.
- Before widespread application, prospective interventional trials must demonstrate clinical benefits from biomarker-guided management.

Acute kidney injury: need for better diagnostics

Acute kidney injury (AKI) is independently associated with increased morbidity and mortality in hospitalized patients, and the critically ill in particular [1]. Its pathophysiology is complex—while 'pre-renal' acute haemodynamic changes can cause reversible falls in glomerular filtration rate (GFR), established AKI involves renal tubular injury leading to more sustained reductions in GFR. Inflammation plays a central role in the pathogenesis of tubular injury, which is often of multifactorial aetiology. Importantly, tubular injury can occur alongside or in the absence of prerenal changes in GFR, so renal injury may be well-established by the time it becomes clinically evident (Fig. 302.1) [1].

Conventional diagnosis of AKI is based upon an elevation of serum creatinine, reflecting reduced renal filtration of endogenously produced creatinine. Creatinine is thus a marker of GFR and does not directly distinguish tubular injury from rapidly reversible decreases in GFR, nor does it identify early stages of tubular injury when GFR may not have been affected. Importantly, when GFR decreases, time is required for creatinine to accumulate in the blood. This accumulation depends on the creatinine generation rate, which is depressed in acute and chronic, and may be masked by haemodilution during fluid resuscitation. Therefore, creatinine is a late and imprecise marker of AKI and performs less well in sicker patients [2].

Many specific interventions to avert or ameliorate AKI have proven ineffective in clinical practice. Therapeutic approaches thus remain essentially supportive. A delayed and imprecise diagnosis of AKI may preclude effective therapy to alter its natural history. This may explain our difficulty in applying specific interventions clinically. In addition, some treatments, such as vigorous fluid resuscitation or renal replacement therapy, may be beneficial or harmful depending on the point of intervention in the time-course of AKI. Finally, in the recovery period, recurrent tubular injury is difficult to detect, and therefore prevent, using conventional diagnostics. Consequently, there is a longstanding need for better diagnostic markers of AKI, particularly in the setting of critical illness.

Development and classification of novel biomarkers for AKI

Novel biological markers of AKI have been recently identified by proteomic analysis of urine or plasma [3], or by gene-expression analysis. These include urinary neutrophil gelatinase-associated lipocalin (NGAL) [4] and kidney injury molecule 1 (KIM-1) [5]. Other biomarkers have been identified by specifically examining mediators in the inflammatory pathogenesis of AKI, such as urinary IL-18, or more sensitive markers of changes in GFR, such as plasma cystatin-c (Cys-c). Most recently, two new AKI biomarkers, tissue inhibitor of metaloproteinase-7 (TIMP-7) and insulin-like growth factor binding protein-2 (IGFBP-2) have been identified from a pool of over 300 candidate molecules and validated as highly predictive of AKI in a separate validation study [6]. More data are likely to merge on these markers, which appear directly linked to the cellular response to tubular injury.

Novel biomarkers are in varying stages of development and validation (Table 302.1). Broadly, they can be classified into structural biomarkers that are specifically expressed or released from the kidney or other tissues in association with tubular injury, and functional biomarkers that accumulate in plasma or urine as a result of renal dysfunction. Structural biomarkers include substances directly released by injured tubular cells, but may also include markers of local or systemic inflammation that correlate with the occurrence of AKI. Functional biomarkers include measures of GFR, e.g. plasma creatinine and plasma Cys-c, as well as the appearance of filtered substances in the urine that would normally be removed by

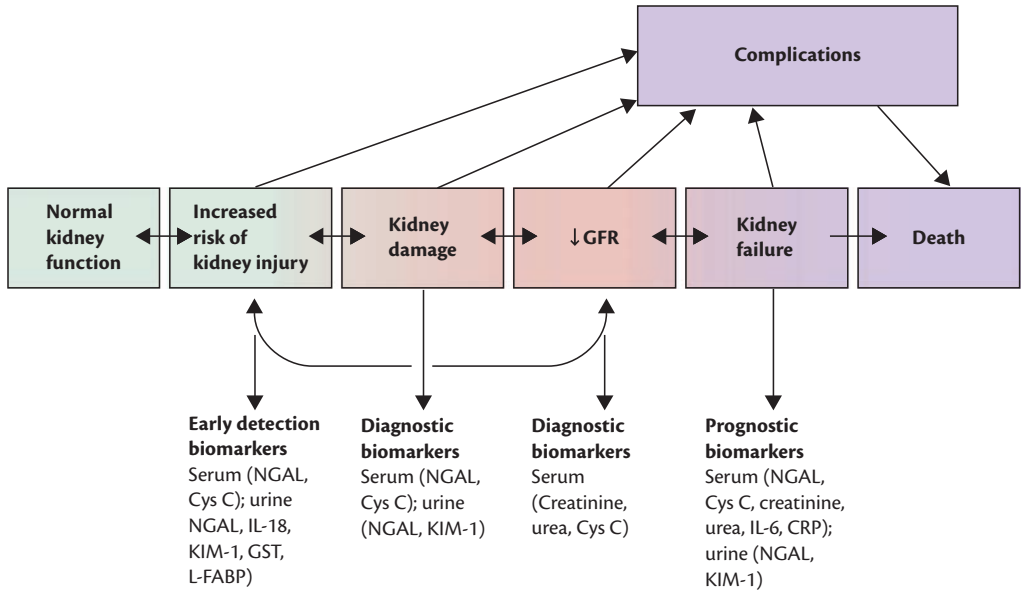

Fig. 302.1 Evolution of acute kidney injury. Injury begins before excretory function is lost (i.e. decreased GFR) and can, in some cases, be detected by measurement of biomarkers. Such biomarkers can also be used for diagnostic and prognostic assessment.

GFR, glomerular filtration rate; NGAL, neutrophil gelatinase-associated lipocalin; Cys C, cystatin C; KIM-1, kidney injury molecule 1; IL-18, interleukin-18; GST, glutathione-S-transferase; L-FABP, liver fatty-acid-binding protein; CRP, C-reactive protein; IL-6, interleukin-6.

Table 302.1 Some biomarkers of acute kidney injury currently under active clinical investigation

Biomarker	Structure	Source
NGAL: neutrophil gelatinase-associated lipocalin	25 kDa monomer with neutrophil gelatinase, an acute-phase, bacteriostatic protein that binds and sequesters iron-carrying siderophores	Produced in distal nephron, activated neutrophils, and other stimulated epithelia in response to inflammation, renal ischaemia, nephrotoxic or septic AKI
IGFBP-7 and TIMP-2: insulin-like growth factor binding protein-7 and tissue inhibitor of metalloproteinase-2	Involved in the process of G1 cell cycle arrest acting in an autocrine and paracrine mechanism via transmembrane receptors	Induced and released in response to tubular cellular injury
KIM-1: kidney injury molecule-1	Transmembrane phosphatidylserine receptor, which recognizes apoptotic cells	Specifically upregulated in de-differentiated proximal tubule cells after ischaemic or nephrotoxic AKI
IL-18: interleukin-18	Pro-inflammatory cytokine	Induced and cleaved in the proximal tubule and mediates ischaemic acute tubular injury in animal models. Systemic production in inflammatory diseases
L-FAB: liver-type fatty acid binding protein	One of a family of intracellular lipid chaperones	Cytoplasm of proximal tubular epithelial cells. Appears in the urine in association with AKI
GST: glutathione-S-transferases	Ubiquitous enzymes involved in the scavenging of free radicals	α and π forms are expressed in the renal tubules in a site-specific fashion. Appearance in urine may be related to different aetiologies of AKI
CysC: cystatin C	13-kDa endogenous cysteine proteinase inhibitor	Produced by all nucleated cells. Accumulates in the blood as GFR falls. Appears in the urine as a consequence of reduced proximal tubular catabolism of filtered CysC

functional proximal tubular cells, such as urinary Cys-c. Thus, different biomarkers may reflect different aspects of the pathogenesis of AKI, can be context-specific and may be informative at different points in the time-course of AKI (Fig. 302.1). An ideal biomarker would satisfy a number of unmet diagnostic needs (Box 302.1). While no individual biomarker may meet all of these requirements. a panel may provide complementary information on diagnosis and prognosis.

Box 302.1 Characteristics of an ideal biomarker of AKI

- Enables risk stratification for the development of overt AKI.
- Provides earliest possible diagnosis with high sensitivity and specificity enabling effective preventive intervention.
- Reliably distinguishes tubular injury from pre-renal causes of kidney dysfunction.
- Identifies the etiology of AKI.
- Prognosticates severity and duration of AKI, need for RRT, and risk of death.

Validation of biomarkers of AKI

Candidate renal biomarkers have been examined in observational studies assessing their ability to discriminate subsequent AKI, defined by consensus criteria based on serum creatinine and urine output. Combined sensitivity and specificity of biomarker measurements is often assessed by receiver-operating characteristic (ROC) analysis and expressed as the area under the curve (AUC). An AUC of 0.5 indicates no relationship between marker and outcome, while AUCs >0.8 and >0.9 represent, respectively, good and excellent predictive ability. Many biomarkers have been validated in the settings of predictable and time-defined risk in homogeneous populations, such as cardiopulmonary bypass in children [7]. Here, NGAL was exquisitely predictive of subsequent AKI as early as 2 hours after surgery with AUC values >0.9. However, the performance of NGAL and other biomarkers is not so strong in adults [8], in the presence of chronic kidney disease (CKD) [9], and in mixed critically-ill populations (8) with AUCs generally ranging between 0.7 and 0.8. NGAL measurements have been correlated with the severity of subsequent creatinine-defined AKI [10].

Any attempt to validate biomarkers of AKI is intrinsically limited by the use of a creatinine-based definition as a 'gold-standard' comparator [11]. Even the retrospective peak creatinine often underestimates the severity of AKI in patients with acute and chronic illness. Furthermore, kidney injury and tubular dysfunction could impact upon clinical outcomes that are not directly related to alterations in GFR. Apparent 'false negative' elevations in renal biomarkers may thus represent important biological phenomena. As a consequence, an important element of AKI biomarker validation is establishing an association with clinically relevant outcomes such as mortality and length of hospital or intensive care unit stay. In meta-analysis of prospective observational studies, plasma and urine NGAL predicted mortality with an AUC of 0.71 [8]. In an analysis of 2322 patients enrolled in these studies, increases in plasma or urinary NGAL were associated with increased hospital mortality in the absence of creatinine-defined AKI, while patients experiencing an elevation in creatinine without a raised NGAL had lower mortality [12]. These observations suggest that subclinical tubular injury may have a significant impact on outcomes, either because creatinine is imprecisely diagnosing renal dysfunction or because renal cellular injury affects organ function and survival by other processes. Novel biomarkers may thus allow definition of a new diagnostic category of sub-clinical AKI. It has been suggested that validated biomarkers may, in the future, be incorporated into consensus diagnostic criteria for AKI [13].

Experimental models may contribute to the validation of biomarkers. An NGAL reporter mouse has been developed that incorporates a fluorescent reporter protein for NGAL gene-expression. This model demonstrated a sensitive, rapid, dose-dependent, reversible, and organ—and cell-specific relationship between renal NGAL gene expression and tubular stress [14]. This elegant work further demonstrated that increases in creatinine induced by volume depletion were not associated with induction of renal NGAL, confirming its specificity for tubular injury.

Finally, validation of any novel diagnostic marker ultimately depends upon demonstration of clinical utility. To demonstrate that a biomarker provides a more effective diagnosis of AKI, evidence is required to show that measurements can be used to meaningfully improve patient outcomes.

Application of novel biomarkers of AKI

Renal biomarkers have been developed to detect patients with early AKI. After a timed insult, such as cardiac surgery, analysis of a panel of urinary biomarkers demonstrated sequential peaks in NGAL at 4 hours, liver fatty acid-binding protein (L-FAB) at 6 hours, interleukin-18 (IL-18) at 12 hours, and KIM-1 at 24 hours [7]. Very early prognostic information could identify patients at risk for continued close monitoring, avoidance of nephrotoxins, and/or haemodynamically-targeted therapy. In a cardiac surgery population, biomarker measurements significantly improved risk classification over conventional diagnostic models for AKI in the early post-operative setting [7]. Many specific interventions for early AKI that have not previously been proven to be clinically effective could be re-investigated if a homogenous patient population could be identified very early in the time course. Given that production of biomarkers such as NGAL has been associated with AKI severity [4] and predicts later use of renal replacement therapy (RRT) [8], there is also the potential to individualize treatment according to biomarker levels. These strategies will need investigation and validation in prospective randomized controlled trials.

There is significant clinical interest in the use of renal biomarkers to risk-stratify patients presenting to hospital or intensive care. In a study of 635 patients presenting to an emergency department [15], urinary NGAL was significantly better than serum creatinine at predicting AKI, the need for RRT, and intensive care unit admission. Urinary NGAL also successfully discriminated between groups of patients with normal renal function, stable CKD, pre-renal AKI, and sustained AKI. In a subsequent study of 1635 unselected emergency hospital admissions [16] that examined a panel of biomarkers, both urinary NGAL and urinary KIM-1 predicted a composite outcome of RRT or death in hospital. This study also identified a substantial sub-population with low serum creatinine at admission that was at risk of adverse events. These results suggest that patients could be risk-stratified to observation in a critical care area or to specific therapeutic interventions based on biomarker measurements taken at hospital admission.

As well as providing information on the timing of injury, measurements of multiple biomarkers may give useful clues to the quality and quantity of injury. In a study of 489 mixed intensive care unit admissions [17], prerenal AKI (defined as recovery within 48 hours and a fractional sodium excretion <1%) was associated with significant elevations in urinary KIM-18, IL-18 and Cys-c, but not urinary NGAL, which was only significantly elevated in patients

who developed sustained AKI. These observations suggest that a biomarker panel could be used to individualize therapy, but also that 'prerenal' AKI is likely to involve a degree of covert tubular injury.

Renal biomarkers are also being examined as outcome measures. KIM-1 has been suggested screening for nephrotoxicity in drug development [18]. This approach could be extended to monitoring sub-clinical nephroxicity from treatments such as chemotherapy or radiological contrast, allowing modification of subsequent treatment to reduce the risk of AKI. Biomarkers can also be used as secondary outcomes in interventional studies. This may be particularly beneficial in pilot studies of preventative interventions for AKI, where a positive effect on an AKI biomarker could justify larger trials to confirm a true clinical benefit.

Finally, biomarkers are being examined as markers of renal prognosis and recovery. A higher plasma NGAL at diagnosis of severe AKI correlated with non-recovery of renal function in survivors in a large cohort of patients with AKI following community-acquired pneumonia [19]. Biomarkers could thus provide information on renal prognosis and recurrent renal injury to aid ongoing management. Further data are required in this group of patients; it is also possible that novel biomarkers will be developed that are specific for the recovery phase of AKI.

Limitations of biomarkers

Interest in the use of renal biomarkers should be tempered by consideration of their limitations. For many, a direct causal link in the pathogenesis of AKI is unproven, and the mechanisms by which they are raised in AKI are uncertain or multifactorial. For instance, urinary NGAL is predominantly derived from the distal nephron [14], despite this not being the main site of pathological tubular injury. Furthermore, the majority of plasma NGAL is not renally-derived [4], but may arise from leukocytes, lungs, and other tissues. The relationship between biomarkers and AKI is thus complex and may reflect the strong link between local or systemic inflammation and AKI, and also the bi-directional interaction between AKI and distant organ injury. This suggests that renal biomarker performance will be highly dependent upon the clinical context with critical illness, age and CKD significantly impacting predictive ability [7,9]. In particular, as a marker of systemic inflammation, plasma NGAL correlates poorly with AKI in sepsis [20]. Monomeric NGAL may be more renal-specific, but does not enhance AKI discrimination in sepsis. Another factor in interpretation of urinary biomarkers is the variable effect of the urine concentration; conventionally, this is handled by expression of biomarker measurements as ratios to urinary creatinine concentration. However, soon after a decrease in GFR, creatinine excretion will fall. This will potentially cause an elevation in urinary biomarker:creatinine ratio unrelated to increased biomarker release. Finally, while many biomarkers have been strongly statistically associated with the occurrence of AKI in specific populations, such association does not prove that they are useful clinical tools. Utility very much depends upon the likelihood ratio for the outcome in question (ratio of post- to pretest odds). For many biomarkers this may be poor, particularly if AKI is relatively infrequent in a heterogeneous population. It is useful to consider the intensive care unit experience with well-established biomarkers in other areas of adult medicine. Cardiac troponins, brain natriuretic peptide, and D-dimers are excellent markers of, respectively, unstable coronary artery disease, cardiogenic pulmonary oedema and venous thromboembolism. However, interpretation crucially depends upon clinical context, history and ancillary investigation. All may be significantly elevated in septic multi-organ failure, but may be associated with different pathologies and not have their usual therapeutic implications. Thus, useful clinical application of renal biomarkers may require incorporation into risk prediction models for the occurrence or progression of AKI, allowing prospective validation of biomarker-led therapy in populations of critically-ill patients.

PART 14.3

Host response

CHAPTER 303

The host response to infection in the critically ill

W. Joost Wiersinga and Tom van der Poll

Key points

- Toll-like receptors (TLRs) are the first to sense invading pathogens and initiate the immune response.
- Pattern recognition receptors (PRRs) such as TLRs and Nod-like receptors (NLRs) recognize pathogen-associated-molecular patterns (PAMPs) such as LPS, peptidoglycan, lipopeptides, lipoteichoic acid, flagellin, and bacterial DNA, as well as danger-associated-molecular patterns (DAMPs) such as heat shock proteins, fibrinogen, hyaluronic acid and high-mobility group box-1 protein (HMGB-1).
- The systemic host response to infection results in activation of coagulation, due to tissue factor-mediated thrombin generation, downregulation of physiological anticoagulant mechanisms, and inhibition of fibrinolysis.
- Sepsis can be viewed as a PRR-mediated dysregulation of the immune system following pathogen invasion in which a careful balance between inflammatory and anti-inflammatory responses is vital.
- Severe sepsis (sepsis and organ dysfunction) and septic shock (severe sepsis plus fluid-refractory hypotension) are progressively severe stages of the host's immune response to infection.

Introduction

Among the many challenges facing the critically ill, infectious diseases stand out for both their omnipresence and their ability to have a profound impact on morbidity and mortality. When the body's response to an infection injures one's own tissues and organs it can become a life-threatening condition called sepsis [1]. Severe sepsis (sepsis and organ dysfunction) and septic shock (severe sepsis plus fluid-refractory hypotension) are progressively severe stages of the host's immune response to infection.

Moving away from the SIRS versus CARS dogma

The systemic inflammatory response syndrome (SIRS) is the predominantly cytokine-mediated, pro-inflammatory host response to invading pathogens that has always been considered the hallmark of sepsis [2]. Its molecular components can be divided into cytokines, plasma cascades, and acute phase proteins, while the cellular components include leukocytes and endothelium. However, simple inhibition of pro-inflammatory cytokines, such as tumour necrosis factor (TNF)-α and interleukin (IL)-1 has not provided clinical benefit to patients with severe sepsis [3]. Clearly, the hypothesis that excessive inflammation is the basis for adverse outcomes in sepsis requires reconsideration: the host response includes multiple concurrent and subsequent processes that involve both exaggerated inflammation and immune suppression. In general, pro-inflammatory reactions are held responsible for 'collateral' tissue damage in severe sepsis, whereas anti-inflammatory responses (meant to limit excessive activity of inflammation) may promote the development of secondary infections (Fig. 303.1) [4]. Anti-inflammatory cytokines, particularly IL-10 and transforming growth factor (TGF)-β, negative regulators of Toll-like receptor (TLR) signalling and various inflammatory mediators, such as prostaglandin E_2, epinephrine, and glucocorticoids are all likely to contribute to this inhibition of inflammation during severe infection. However, a clear separation between SIRS and the 'compensatory anti-inflammatory response syndrome' (CARS) does not seem to exist.

Historical perspective

Sir William Osler (1849–1919) was among the first to recognize that morbidity and mortality from sepsis were not directly caused by the invading pathogens, but mainly by the body's response. The original notion that sepsis mortality was due to an excessive stimulation of the immune system by high bacterial loads was based upon studies in animals infused with large doses of bacteria or bacterial products, in particular lipopolysaccharide (LPS), the toxic component of the Gram-negative bacterial cell wall. Such infusions result in a strong activation of different pro-inflammatory protein cascades that, although designed to protect the host against invading pathogens, can cause damage to tissues when produced in high amounts. In a landmark article published in 1985 Beutler and colleagues reported that neutralization of TNF-α, secreted after intravenous injection of an otherwise lethal dose of LPS, prevented death in mice [5]. Nearly two decades later, in 2011, the Nobel Prize in Medicine was awarded to Beutler and Hoffmann for their role in the discovery of the TLRs that form the front line of the host defences against invading pathogens.

The tremendous increase in our understanding of the interactions between the microbial world and our host defence system has led to the notion that sepsis is now considered an imbalance between pro-inflammatory reactions (designed to kill invading pathogens but, at the same time, responsible for tissue damage) and anti-inflammatory responses (designed to limit excessive inflammation but, at the same time, making the host more vulnerable to secondary infections) [3]. Here, the key components that define the host response to infection are discussed.

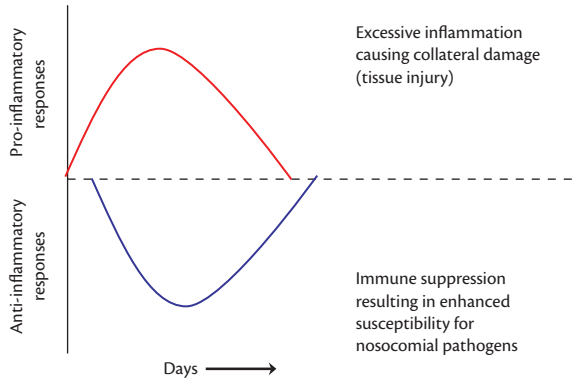

Fig. 303.1 The host response to infection during sepsis. The host response to sepsis is characteristically seen as an exaggerated pro-inflammatory response to invading pathogens. This tumour necrosis factor (TNF)-α and interleukin (IL)-1-driven early response is associated with fulminant sepsis and early mortality. In recent years more attention has been paid to the immunosuppressive phase in which IL-10 serves as an important anti-inflammatory cytokine; this phase of the septic response is associated with nosocomial infections, viral reactivation, and late mortality.

Data from Hotchkiss RS et al., 'The sepsis seesaw: tilting toward immunosuppression', *Nature Medicine*, 2009, **15**, pp. 496–7.

The virulence of invading pathogens

Gram-positive bacteria (e.g. *Streptococcus pneumoniae, Staphylococcus aureus*) have overtaken Gram-negative bacteria (e.g. *Escherichia coli, Klebsiella* spp., *Pseudomonas aeruginosa*) as the leading cause of sepsis. Polymicrobial infections, anaerobes and yeasts constitute <10% of responsible pathogens. These invading microorganisms have an impressive armoury of virulence factors to assault the host. To be successful, pathogens must adhere, traverse the mucosal barrier and multiply, while overwhelming the antimicrobial host defence systems [3,6]. Individual bacteria can affect the behaviour of surrounding bacteria by making use of the quorum sensing apparatus to coordinate their gene expression according to the density of their local population. This utilizes signalling molecules such as the *N*-acyl-homoserine-lactones (AHLs). Quorum sensing also plays an important role in the production and maintenance of biofilms; these slimy layers of bacteria are well-organized communities that can protect themselves against the immune system and antibiotics. Activation of quorum sensing can ultimately lead to production of proteins needed for tissue invasion and activation of toxins. Bacterial toxins are important mediators of sepsis by their capacity to damage natural barriers such as the mucosa to enable further bacterial spread. A well-known example is the toxin-mediated toxic shock syndrome caused by *S. aureus* and *S. pyogenes*. Bacterial toxins can be injected into the cytosol of host immune cells by specialized nanosyringes called type-III secretion systems. All these molecular components of invading pathogens that are recognized by host defence receptors are called pathogen-associated-molecular-patterns (PAMPs). Examples of bacterial PAMPs are LPS, peptidoglycan, lipopeptides (constituents of many pathogens), lipoteichoic acid (a cell wall component of Gram-positive bacteria), flagellin (factor in the mobility of bacteria) and bacterial DNA (Fig. 303.2) [7].

Pattern recognition receptors and the initiation of the immune response

The innate immune system can detect pathogens via a limited number of pattern-recognition receptors (PRRs) that recognize PAMPs

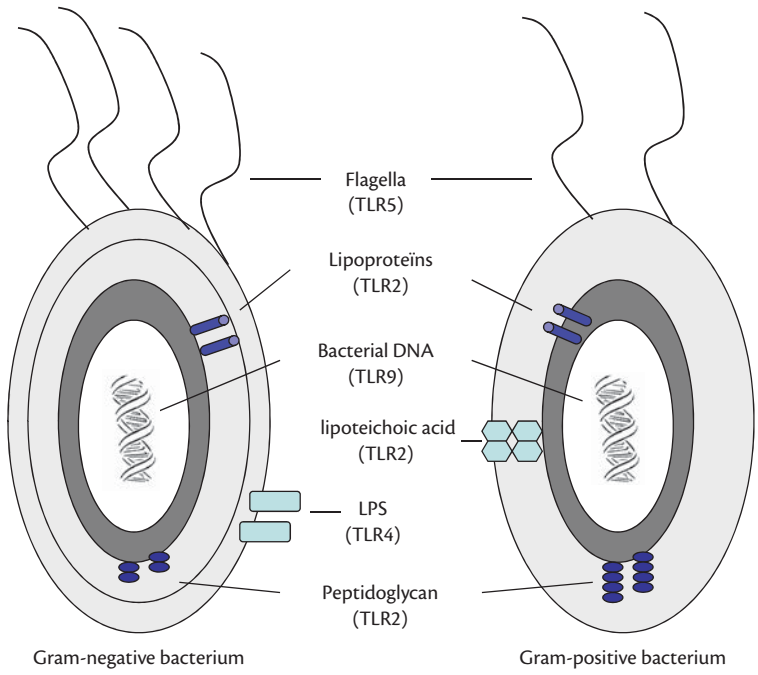

Fig. 303.2 Innate recognition of pathogens by Toll-like receptors (TLRs). Gram-positive and Gram-negative bacteria express distinct pathogen-associated molecular patterns (PAMPs) that are recognized by various, partly overlapping, TLRs. Lipoteichoic acid is exclusively expressed by Gram-positive pathogens, and lipopolysaccharide (LPS) by Gram-negative pathogens. Common PAMPs include peptidoglycan, lipoproteins, flagellin, and bacterial DNA.

(Fig. 303.2) [7]. The TLRs and intracellular (NOD)-like receptors (NLRs) are considered the most important PRRs.

Toll-like receptors

TLRs play a central role in the initiation of cellular innate immune responses during infection. Thirteen TLRs (TLRs 1–13) have been identified in mammals. Bacterial ligands have been described for most TLRs (Table 303.1). For instance, TLR4 functions as the LPS receptor (Fig. 303.3). The entire TLR family signals via four adaptor proteins, namely myeloid differentiation primary-response protein 88 (MyD88), TIR-domain-containing-adaptor-protein (TIRAP), TIR-domain-containing-adaptor-protein-inducing-IFN-β (TRIF) and TRIF-related-adaptor-molecule (TRAM). Together with a number of protein kinases, these take care of the recognition and response to microbial molecules. While TLRs are essential for the early detection of pathogens, they may also cause excessive inflammation after uncontrolled stimulation. As an example, TLR4-deficient mice are fully protected against LPS-induced lethality, but display an enhanced susceptibility to several Gram-negative infections. The clinical relevance of TLR signalling is reflected by the recent description of marked vulnerability to purulent infections in children with a genetic deficiency for MyD88 or IL-1 receptor-associated kinase (IRAK)-4, a kinase acting directly downstream from MyD88 [8]. Several single nucleotide polymorphisms in genes encoding TLRs have also been associated with an altered susceptibility to bacterial infections [9]. Of note, PRRs can also recognize endogenous mediators released upon injury, thereby warning the host of imminent danger. Such endogenous danger signals are called 'alarmins' or 'danger-associated molecular patterns' (DAMPs) (Table 303.1) [3,7]. Heat shock proteins, fibrinogen, hyaluronic acid, and high-mobility group box-1 protein (HMGB-1) are examples of DAMPs that cause further amplification of the pro-inflammatory response through PRRs.

Table 303.1 Important ligands for Toll-like receptors (TLRs) during the host response to infection. PAMPs (pathogen-associated molecular patterns) and DAMPs (danger-associated molecular patterns) with relevance to the host response against bacterial infection. endogenous mediators identified as TLR4 ligands

	Species	TLR
PAMPs		
LPS	Gram-negative bacteria	TLR4
LTA	Gram-positive bacteria	TLR2*
Peptidoglycan	Most bacteria	TLR2
Triacyl lipopeptides	Most bacteria	TLR1/TLR2
Diacyl lipopeptides	*Mycoplasma* spp.	TLR2/TLR6
Porins	*Neisseria*	TLR2
Flagellin	Flagellated bacteria	TLR5
CpG DNA	Bacteria	TLR9
Unknown	Uropathogenic bacteria	TLR11**
DAMPs**		
Heat shock proteins	Host	TLR4
Fibrinogen, fibronectin	Host	TLR4
Hyaluronan	Host	TLR4
Biglycans	Host	TLR4
HMGB-1	Host	TLR4, TLR2

*For detection of LTA from some pathogens TLR6 functions as a co-receptor for TLR2.

**TLR11 is not functional in humans.

***Recent studies describe a role for TLRs in acute injury using rodent models of haemorrhagic shock, ischaemia and reperfusion, tissue trauma, and wound repair, and various toxic exposures; these studies have implicated TLR4 as a major factor in the initial injury response.

The inflammasome

Whereas TLRs detect pathogens at either the cell surface or in lysosomes/endosomes, micro-organisms that invade the cytosol can be recognized by cytoplasmatic PRRs such as the nucleotide-binding oligomerization domain (NOD)-like receptors (NLRs) [10]. Several members of the NLR family can assemble multimolecular complexes termed 'inflammasomes' in response to various activators. Activation of the NLRP3 inflammasome by PAMPs or DAMPs induces activation of caspase-1, which stimulates processing of the pro-inflammatory cytokines IL-1β and IL-18 [10]. Although NLRs

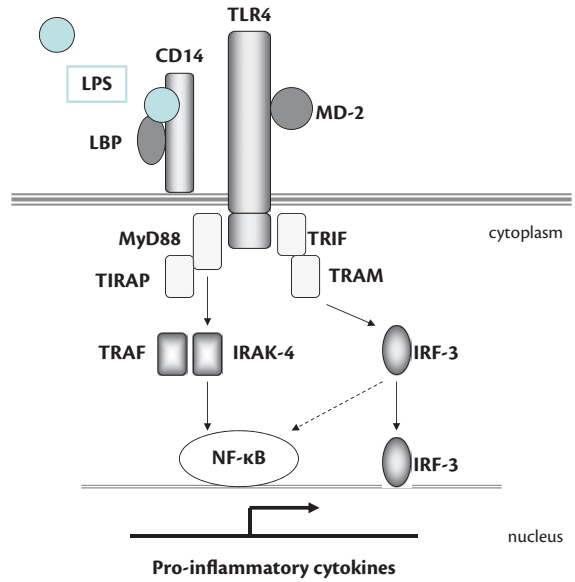

Fig. 303.3 The Toll-like receptor (TLR)-4 complex. The TLR family discriminates between specific patterns of microbial components. TLR4 recognizes lipolysaccharide (LPS). LPS first binds to LPS-binding-protein (LBP), which transfers LPS to CD14. Binding of LPS to CD14 leads to the association of CD14 with MD-2 and TLR4. After TLR stimulation, the adaptor molecule myeloid differentiation primary-response protein 88 (MyD88) is recruited. MyD88 associates with IL-1 receptor-associated kinase (IRAK)-4. This leads to release of nuclear-factor-κB (NF-κB), resulting in the transcription of a whole range of inflammatory genes. Next to MyD88, the adaptor molecules TIR-domain-containing-adaptor-protein (TIRAP), TIR-domain-containing-adaptor-protein-inducing-IFN-β (TRIF) and TRIF-related-adaptor-molecule (TRAM) have been identified. TIRAP is essential for MyD88-dependent signalling through TLR2 and TLR4. IRF-3 regulated TRIF is essential for TLR3—and TLR4-mediated activation of the MyD88-independent pathway. TRAM is involved in TLR4 mediated MyD88-independent/TRIF-dependent signalling pathways.

are of utmost importance for recognition of bacteria by the innate immune system, their exact role in sepsis pathophysiology is far from clear.

Regulation of the host response to infection

TLR signalling must be tightly regulated since a constant balance needs to found between activation and inhibition of the inflammatory response to avoid a detrimental inappropriate response [11]. Triggering receptor expressed on myeloid cells-1 (TREM-1) is an important amplifier of the TLR-and NLR-mediated inflammatory response to invading pathogens [12]. TREM-1 is specifically expressed on monocytes and neutrophils from patients with sepsis. Negative regulators of the TLRs designated to prevent excessive TLR signalling have been identified, including MyD88 short (MyD88s), ST2, single-immunoglobulin-interleukin-1 receptor-related (SIGIRR) molecule, toll-interacting protein (TOLLIP), suppressor-of-cytokine signalling (SOCS), A20, and IRAK-M [11].

Host–response proteins released upon infection

The interaction between pathogens and innate immune receptors triggers the release of a myriad of inflammatory mediators.

Cytokines

Cytokines are small proteins produced by various cell types (e.g. monocytes and macrophages) during infection that coordinate both local and systemic inflammation. In addition to TNF-α and IL-1, many other cytokines play an important role in regulating the septic host response. Many other cytokines are also important in regulating the septic host response. Novel cytokine mediators implicated in sepsis pathogenesis include IL-17, IL-33, and macrophage migration inhibitory factor (MgIF). Serum MgIF levels are elevated in patients with sepsis [13]. MgIF regulates innate immune responses through modulation of TLR4 [3,13]. MgIF-deficient mice challenged with LPS showed a defective response as a direct result of decreased TLR4 expression.

HMGB-1 and Mrp8/14

Cytokine activation trigger the release of numerous inflammatory response proteins, of which HMGB-1 and Mrp8/14 are prime examples. HMGB-1 is a nuclear protein released upon cell activation or injury [14]. Patients with sepsis have elevated circulating levels of HMGB-1. In preclinical sepsis models, HMGB-1 blockade protected against LPS-induced lethality, even when administration was delayed until after peak TNF-α and IL-1 levels had been reached [14]. Several receptors can mediate (directly or indirectly) the cellular effects of HMGB-1, including TLR2, TLR4, and the receptor for advanced glycation end-products (RAGE) [14]. RAGE is a promiscuous receptor that interacts with diverse ligands, such as advanced glycation end products (hence its name), S100 proteins, amyloid A, leukocyte adhesion receptors, and certain components of *E. coli*. It play various roles in the host defence against bacteria. Myeloid-related protein-8 (Mrp8 also called S100A8) and Mrp14 (also called S100A9) are members of the S100 protein family. Mrp8 and Mrp14 can form heterodimers that elicit a variety of inflammatory responses. Mrp8/14 complexes can activate TLR4 and amplify the LPS-triggered inflammatory responses of phagocytes [15]. In patients with sepsis and in healthy humans injected with LPS elevated Mrp8/14 plasma levels have been observed. Mice lacking Mrp8-Mrp14 complexes had increased survival following LPS-induced lethal shock and bacterial sepsis [15]. They displayed a reduced bacterial dissemination after intraperitoneal infection with *E. coli*.

Activation of complement

Complement factors are released as part of the inflammatory reaction to infection. Although the complement system has traditionally been considered a central part of the protective immunity against bacteria, complement activation may also contribute to an adverse outcome from sepsis [16]. Indeed, infusion of anti-C5a antibodies improved haemodynamic parameters in pigs infused with LPS or live *E. coli*, and reduced mortality in primates with *E. coli* sepsis and rats subjected to caecal ligation and puncture [16].

Bilateral interaction between inflammation and coagulation during infection

Sepsis is associated with multiple alterations in pro- and anticoagulant mechanisms [17]. The systemic host response to infection results in activation of coagulation, downregulation of physiological anticoagulant mechanisms, and inhibition of fibrinolysis. Coagulation activation in sepsis is primarily driven by tissue factor (TF). TF is a potent stimulator of the extrinsic coagulation cascade, and an essential mediator of coagulation. TF is not exposed to circulating blood in a resting state, but becomes exposed on the surface of mononuclear cells and endothelial cells when these cells are stimulated by bacteria or bacterial products such as LPS, or pro-inflammatory cytokines such as TNF-α. TF binds and activates factor (F)VII. The TF/VIIa complex so generated initiates coagulation activation by activation of FX, producing FXa that finally results in prothrombin conversion to thrombin. Procoagulant events are controlled by three major anticoagulant proteins: tissue factor pathway inhibitor (TFPI), antithrombin and activated protein C (AP-C) [17]. During severe sepsis the activities of TFPI, antithrombin and the protein C–AP-C system are impaired, together with enhanced TF-dependent coagulation, this results in a shift toward a net procoagulant state. The capacity of APC to control coagulation depends on inactivation of cofactors Va and VIIIa by this protease, while the anti-inflammatory effects of APC rely on its interaction with the protease-activated receptor-1 (PAcR-1). Proteolytic cleavage of PAcR-1 by APC induces genes known to downregulate pro-inflammatory signalling pathways and inhibit apoptosis. The relative contribution of the cytoprotective and anticoagulant effects of APC in the host defence against severe infections remains to be elucidated. PAcR-1 is a member of a family of receptors that also includes PAcR-2 to PAcR-4. Whereas APC signals through PAcR-1, the TF-FVIIa-FXa complex can activate PAcR-2. PAcRs can be activated by multiple other proteases (both host- and pathogen-derived), thereby markedly influencing inflammatory responses. PAcR-1 activation may be harmful during the early phases of endotoxaemia and sepsis, facilitating pulmonary leak and disseminated intravascular coagulation, but may be beneficial at later stages [17].

Conclusion

Taken together, the host response to infection can be seen as a PRR-mediated dysregulation of the immune system following pathogen invasion in which a careful balance between inflammatory and anti-inflammatory responses is vital (Fig. 303.4). A measured and rapid response to microbial invasion is essential to health; yet, the same immunological and coagulation systems that protect against localized infection can act to our disadvantage when these systems are activated systemically during generalized microbial infection [3]. Although systemic inflammation likely contributes to sepsis-induced death in some patients, recent insights have forced us to rethink the pure hyperinflammatory sepsis paradigm as many patients die during an extended period of immune suppression accompanying and/or following the initial septic response. Detailed knowledge of the interconnections between the host immune response programs will be essential in order to assist patients to prevent microbial invasion, limit the damage created by pathogens, and attenuate the injurious effects of the systemic host response. Further dissection of the role of host-pathogen interactions, the cytokine response, the coagulation cascade and their multidirectional interactions in sepsis should lead towards the development of new therapeutic approaches in the critically ill who are faced with infection. However, new approaches in clinical trial designs are also needed that take into account the considerable patient

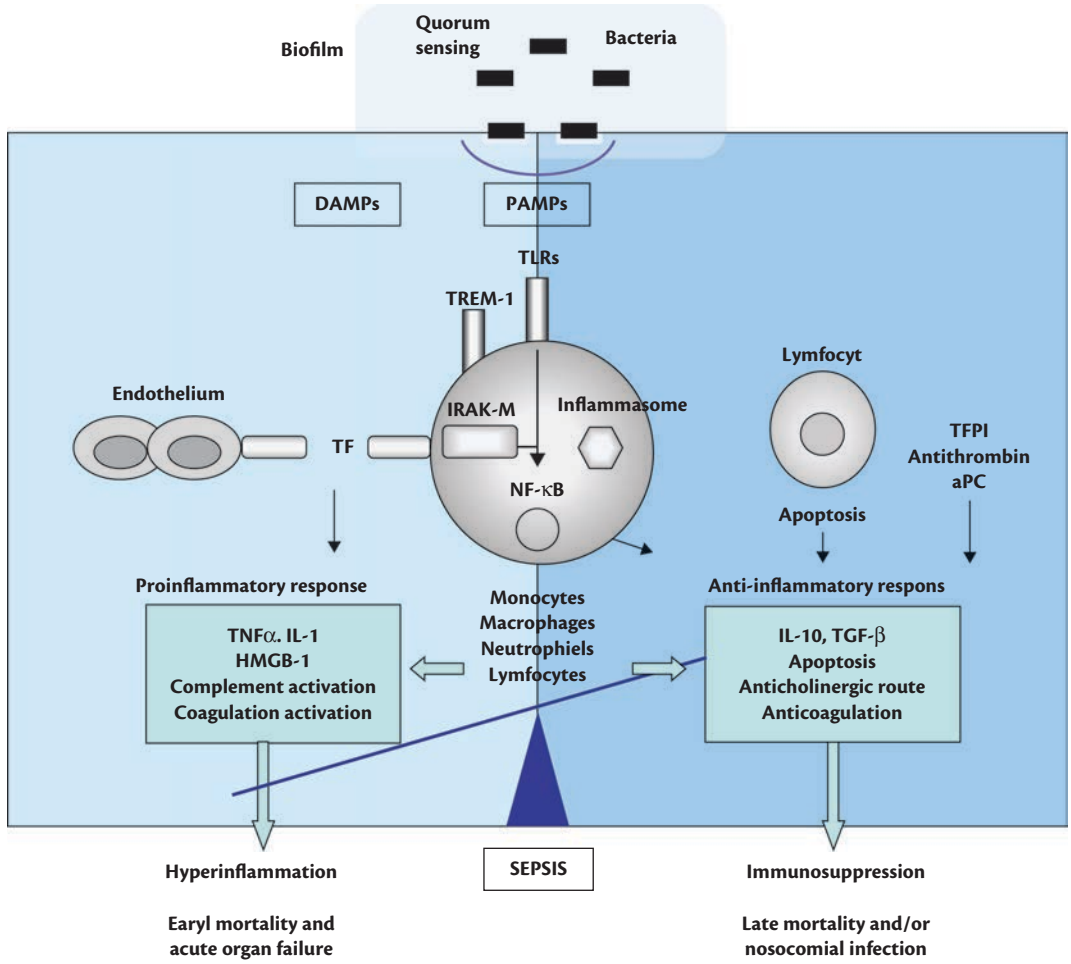

Fig. 303.4 The pro- and anti-inflammatory response during sepsis. The host response to infection starts with the initial interaction between PAMPs (pathogen-associated molecular pathogens) and pattern recognition receptors (PRR) such as the Toll-like receptors (TLR) and the inflammasome. Invading pathogens can communicate with each other via 'quorum sensing'. Biofilms are well-organized layers of micro-organism communities in which bacteria can protect themselves against the host's immune system and antibiotics. The PRR-initiated immune response can result in release of alarmins or DAMPs (danger-associated molecular patterns), e.g. high-mobility group box-1 protein (HMGB-1), that can further amplify the inflammatory response, at least in part via PRR. Pro-inflammatory cytokines, e.g. tumour necrosis factor (TNF)-α, interleukin (IL)-1, lead to hyperinflammation, initiation of the immune response and tissue factor (TF)-induced activation of coagulation. The directly activated anti-inflammatory response is characterized by upregulation of negative regulators of the TLR cascade e.g. IL-1 receptor-associated kinase (IRAK)-M, anti-inflammatory cytokines, e.g. IL-10 and transforming growth (TGF)-β, apoptosis of mainly lymphocytes, activation of a cholinergic anti-inflammatory response and the release of anticoagulant proteins. The resulting innate response of immune cells can result in a balanced reaction leading to pathogen elimination and tissue recovery or an unbalanced reaction that, on the one hand, can lead to exaggerated inflammation and tissue injury or, alternatively, to immune suppression caused by immune cell apoptosis and enhanced expression of negative regulators of TLR signalling.

CHAPTER 304

The host response to trauma and burns in the critically ill

Edward A. Bittner and Shawn P. Fagan

Key points

- Critical illness is associated with a broad spectrum of immunological derangements that defy simple characterization. Recent genomic studies have challenged the systemic inflammatory response syndrome/ compensatory anti-inflammatory syndrome paradigm regarding how the adult human responds to severe injury.
- Severe injury, whether a result of trauma, infection or burn, produces a genomic reprioritization ('genomic storm') in which up to 80% of the leukocyte transcriptome involving cell functions and pathways is altered. These changes occur rapidly after injury and can persist for days to weeks.
- Changes in both innate and adaptive immunity are established soon after injury; early, targeted therapy to either or both immune pathways may be the approach with the best possibility of improving patient outcomes.
- The prevailing assumption—molecular derangement results from current mouse models developed to mimic human diseases translate directly to human conditions—is challenged by recent genomic studies. New approaches should be explored to improve current models.
- Analysis of gene expression profiles may be useful in identifying not only patients at risk for complications after trauma, but also in allowing clinicians to focus on prevention of complications and identify those patients most likely to benefit from interventions.

Introduction

Following severe traumatic injury, patients enter a state of immune dysregulation consisting of both exaggerated inflammation and immune suppression with significant changes in inflammatory mediators and leukocyte cell populations. Many immune responses are common to trauma, burns, and sepsis; immunological dysregulation is thought to contribute to poor outcomes in these patient populations. The inflammatory response to trauma involves a wide variety of mediators (cytokines, chemokines, complement, oxygen radicals, eicosanoids, and nitric oxide) and effector cells (neutrophils, monocytes/macrophages, and endothelial cells). All these factors are interrelated and interconnected by up- and downregulatory mechanisms, leading to the systemic inflammatory response syndrome (SIRS). After massive trauma, uncontrolled systemic inflammation and an imbalance of these inflammatory factors results in organ dysfunction. The level of immunological alteration that leads to SIRS-associated multiple organ failure (MOF) is regulated by the degree of injury, the type of tissue injured, and various other factors including age, sex, genetics, and premorbid medical conditions.

Traumatic injury profoundly affects both innate and adaptive immune responses. The marked suppression in cell-mediated immunity following an excessive inflammatory response appears responsible for the increased susceptibility to subsequent sepsis. These responses are initiated and modulated by both pathogen- and damage-associated molecular pattern molecules detected through pattern-recognition receptors. Suppression of cell-mediated immunity may be caused by multifaceted cytokine/inhibitor profiles in the circulation and other compartments of the host. These may include excessive activation and dysregulated recruitment of neutrophils, induction of alternatively activated or regulatory macrophages that have anti-inflammatory properties, a shift in the T-helper (Th)1/Th2 balance toward Th2, appearance of regulatory T cells (potent suppressors of the innate and adaptive immune system), and lymphocyte apoptosis.

With recent advances in molecular biology and genetics, it is now possible to both characterize the inflammatory response to injury, and quantify the molecular mediators involved in this dynamic evolving process. Release of these mediators is dependent primarily on the severity of the 'first hit phenomenon' (injury) and, secondarily, on activation of the various molecular cascades during therapeutic or diagnostic interventions, surgical procedures and post-traumatic/post-operative complications ('second' or 'third' hits). Mediators involved in the sequelae of post-traumatic events are released from the cellular populations locally at the site of injury and, subsequently, systemically. The sequestration and activation of mainly neutrophils, monocytes, and lymphocytes triggers a multifocal molecular and pathophysiological process.

In addition to our capacity to evaluate the molecular events governing the immuno-inflammatory response to trauma, a growing body of evidence now suggests that genetic susceptibility influences the development of post-trauma complications. It is therefore possible that individual patients will react differently to major injury depending on their underlying genotype. Mapping of the actual gene information of each trauma patient and correlating this profile to the post-traumatic clinical course appears to be of paramount importance. DNA-chip technology is being used to clarify the different responses to the traumatic primary, secondary,

or tertiary hits, and to elucidate possible reasons for the transition of some patients towards complications and undesirable clinical outcomes.

SIRS/compensatory anti-inflammatory or immune-suppressive response syndrome/ multiple organ dysfunction syndrome paradigm

Injury due to major trauma or burns produces profound immunological dysfunction resulting in tissue injury, post-operative infection, and multiple organ dysfunction syndrome (MODS). The traditional paradigm of the host response has been viewed as an early SIRS followed temporally by a compensatory anti-inflammatory or immune-suppressive response syndrome (CARS). SIRS is mediated primarily by cells of the innate immune system, while CARS is primarily mediated by the adaptive immune system. This traditional paradigm argues that exaggerated inflammation contributes to early mortality. Complicated clinical courses are commonly associated with second hits or multiple inflammatory events induced by clinical episodes of infection or surgical stress. Much of this work is based on murine models of trauma, burns, and sepsis. Another component of the traditional SIRS-CARS paradigm is that the pro-inflammatory response occurs early and is terminated by the development of CARS. A model of early and late MODS based on the initial degree of injury severity has been described. An initial massive traumatic insult can create an early vigorous pro-inflammatory response and severe SIRS independent of infection ('one-hit' model), resulting in early MODS. In the 'two-hit' scenario, initially less severely-injured patients eventually develop late MODS as a result of the reactivation of their inflammatory response caused by an adverse and often minor intercurrent event, such as additional surgical stress, bacterial infections, or ischaemia/reperfusion injury. CARS often accompanies late MODS. An unbalanced compensatory anti-inflammatory response can result in anergy and immunosuppression, predisposing the host to opportunistic infection.

'Genomic storm' paradigm

Only recently has the human injury response been studied systematically at the genomic level. The 'Glue Grant' collaborative research programme (**Inflammation and the Host Response to Injury**) was the brainchild of its principal investigator, Tompkins, whose years of innovation in this field have contributed much to our present thinking [1]. Its investigators examined genome-wide expression patterns of blood leukocytes in the immediate post-injury period to better understand the overall priorities and patterns of gene expression. These patterns underlie not only the initial injury response, but also the development of complications and delayed clinical recovery [2]. The Glue Grant investigators have challenged the SIRS/CARS paradigm as to how the adult human responds to severe injury (Fig. 304.1). Major findings of their work include:

- Severe injury, whether as a result of trauma, infection, or burn injury produces a genomic reprioritization ('genomic storm') in which up to 80% of the leukocyte transcriptome involving cell functions and pathways is altered. These changes occur rapidly (within 4–12 hours) after injury, and can be prolonged from days to weeks.
- Similarities in gene expression patterns between different injuries (i.e. trauma, burns, and sepsis) reveal an apparently fundamental response to severe inflammatory stress, with genomic signatures that are surprisingly far more common than different.
- At the level of the leukocyte transcriptome, alterations in expression of classical inflammatory and anti-inflammatory, as well as adaptive immunity genes occur simultaneously, not sequentially after severe injury. Transcriptomic changes in the adaptive immune response occur very early and, often, simultaneously with the pro-inflammatory reactions found in innate immunity.
- The temporal nature of the current SIRS/CARS paradigm is not supported at the level of the leukocyte transcriptome. Complications such as nosocomial infections and organ failure are not associated with any genomic evidence of a 'second hit' and differ only in the magnitude and duration of this genomic reprioritization. Furthermore, the delayed clinical recovery with organ

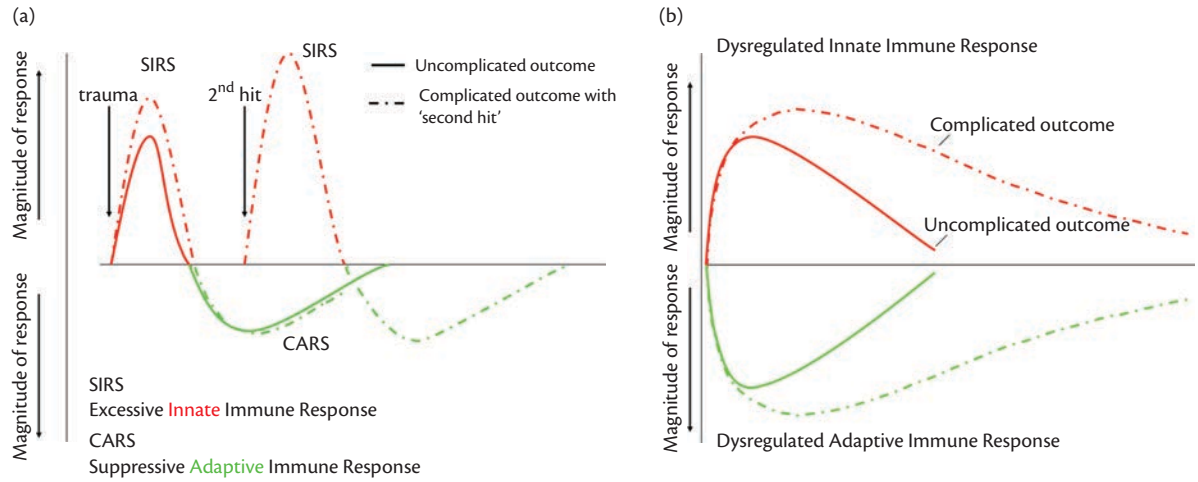

Fig. 304.1 Trauma-induced 'genomic storm': (a) Classic SIRS/CARS paradigm. (b) New paradigm of human response to injury. Genomic wide expression patterns of blood leukocytes following initial injury and the relationship between recovery and complications.

injury is not associated with dramatic qualitative differences in the leukocyte transcriptome. In examining recovery from injury, all genes moved in the same direction regardless of how complicated the patient's clinical course had been. There was no evidence of a single gene or cluster of genes whose expression changed uniquely, or any that dropped out in trauma patients with a complicated recovery versus those with an uncomplicated recovery.

Implications of the 'genomic storm' paradigm

Critically-ill patients with different underlying acute injuries have similar appearing physiological reactions, a condition known by consensus definition as SIRS. An unproven hypothesis central to the pursuit of drug targets for this syndrome has been that the molecular mechanisms underlying this syndrome are similar, regardless of initiating aetiology. The very high correlation in response between trauma, burns, and sepsis in humans strongly supports this hypothesis and suggests that such an approach may be possible. Furthermore, the commonality of genomic patterns in the human leukocyte transcriptome in patients with burn injury, trauma, and sepsis suggests a fundamental response to severe inflammatory stress in humans regardless of its origin, with far more similarities than differences. These findings are consistent with a genomic storm that is neither chaotic nor erratic, but rather highly coordinated and reproducible. This new paradigm has profound implications regarding the direction of future research, prediction of outcome, and the development of new therapeutics.

Need for new models of disease

A cornerstone of modern biomedical research is the use of murine models to explore basic pathophysiological mechanisms, evaluate new therapeutic approaches, and make decisions regarding whether to carry new drug candidates forward into clinical trials. An inherent assumption in the use of murine models to mimic human systemic inflammation is that the time course of injury and repair between the species is similar. Until recently, systematic studies evaluating how well murine models mimic human inflammatory diseases were non-existent. The Glue Grant collaborative research programme investigators performed a systematic comparison of the genomic response between human inflammatory diseases and murine models. This comparison challenges the assumption that mouse models developed to mimic human diseases translate directly to human conditions [3]. In their study, the investigators:

- Compared the correlations of gene expression changes with trauma, burns and endotoxaemia between human subjects and corresponding mouse models.
- Characterized and compared the temporal gene response patterns seen in these human conditions and models.
- Identified the major signalling pathways significantly regulated in the inflammatory response to human injuries and compared them against the human *in vivo* endotoxaemia model and three murine models.
- Evaluated patient and murine studies of several representative acute inflammatory diseases.

The study found that acute inflammatory stresses from different aetiologies resulted in highly similar genomic responses in humans, although the responses in the corresponding mouse models correlated poorly with the human conditions and with one another (Fig. 304.2). Among genes changed significantly in humans, the murine orthologs were close to random in matching their human counterparts.

Although there are many inherent flaws to using animal models in translational research, it is the reality of today's environment that they must be used. Therefore, existing animal models should be improved as new human data become available so that the models more closely mimic human immune responses. To date, many anti-inflammatory approaches to treat severe trauma and subsequent multi-organ failure have succeeded in mice, but failed in humans, probably due to differences in the complex nature of protective immunity between species.

As virtually every drug and drug candidate functions at the molecular level, one practical forward approach is to require molecular detail in the animal model studies. This would indicate whether the model mimics or fails to mimic the molecular behaviour of key genes, key pathways, or the genome-wide level thought to be important for the relevant human disease. These might first include requiring comprehensive genomic descriptions in patient studies to define the human disease, then using these as a guide to develop the animal model. The quality of the animal model could then be determined by how well it reproduces the human disease on a molecular basis, rather than simply phenotype. In addition, the development of synthetic human models by in vitro reconstitution of disease-related cell types or tissues might similarly improve current disease models. Furthermore, new genomic information, such as the availability of personal genomes or exomes to capture the disease heterogeneity directly from patients, or systematic interpretation of genome-wide signatures in human diseases, will probably complement or reduce the need for mouse models in disease discovery and drug development.

Prediction of outcome

Many patients have complicated recoveries following severe trauma due to the development of organ injury. Predictive models based on physiological and clinical parameters have had limited success in predicting clinical trajectories of individual patients at risk of developing organ injury or sepsis. Since changes in both innate and adaptive immunity are established soon after injury, early identification of severely injured patients who may have a complicated clinical course and targeting therapy to either or both immune pathways may be the approach with the best possibility of improving outcomes.

It is generally accepted that early interventional trials in trauma and sepsis patients have failed in large part due to the heterogeneity of the patient population. This is combined with the inability to select the sickest patients with the highest mortality, who are perhaps most likely to benefit from such therapy. Study inclusion criteria are primarily physiological and are often limited to non-specific inflammatory responses and overall organ injury, which may be too delayed to permit intervention to affect outcomes. Furthermore, the use of clinical criteria to enter patients into trauma or sepsis clinical trials inevitably results in the inclusion of individuals who will either not benefit from the therapy or may actually be harmed. The ability to identify and exclude those patients who will recover and not require intervention, while identifying those who may have

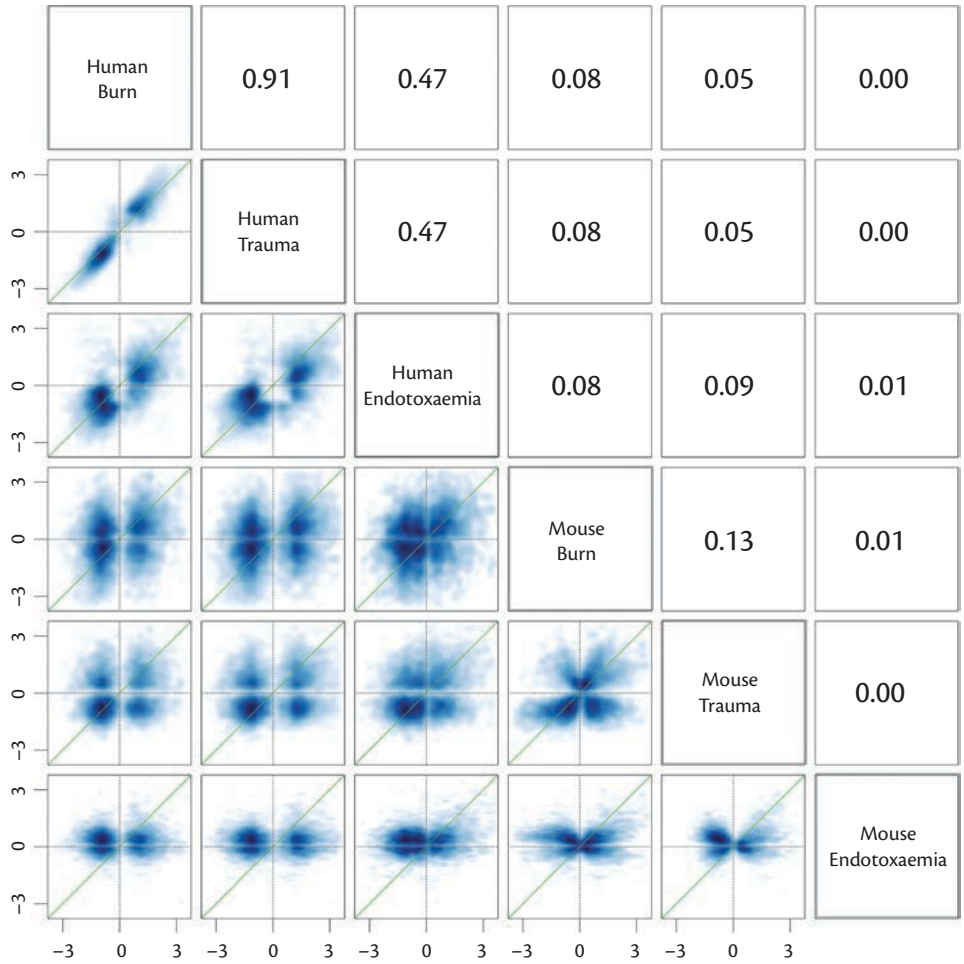

Fig. 304.2 Comparison of inflammation-induced genomic responses (burns, trauma, and endotoxin) between humans and their corresponding murine models. Scatter plots are presented of $\log_2$ changes of 4918 genes and their corresponding Pearson correlation coefficients (r).
Reproduced from Seok J et al., 'Genomic responses in mouse models poorly mimic human inflammatory diseases', *Proceedings of the National Academy of Sciences*, 2013, **110**, pp. 3507–12, doi 10.1073/pnas.1222878110.

a poor outcome and benefit from intervention would be a useful tool for future trials.

The development of prognosticators based on immunological measures has shown promise. The Glue Grant collaborative research program (**Inflammation and the Host Response to Injury**) developed and retrospectively validated a simple genomic composite score that can be rapidly used to predict clinical outcomes [4]. From previously identified families of genes involved in inflammation, antigen presentation and T-cell responses, the investigators identified 63 genes from 167 severely injured patients. The leukocyte gene expression in these patients was significantly different depending on whether the course was uncomplicated or complicated. The investigators then used a genomic tool to consolidate the gene expression profile of each patient into a single genomic score, which was able to discriminate patients that developed a poor clinical outcome from those who recovered. Based on the their findings, such a genomic score may be feasible as a prognostic tool in the clinical setting to identify trauma patients at risk for developing organ injury and adverse outcomes, and theoretically, identify those patients most likely to benefit from interventions. In the Glue Grant study, two-thirds of the 63 genes identified as being differentially expressed between uncomplicated and complicated trauma patients were genes associated with adaptive immunity in general, and specifically with interferon signalling. The expression of this subgroup of genes was suppressed in trauma patients with complicated courses, suggesting that this battery of genes may be useful in identifying not only patients at risk for complications after trauma, but also those who are responsive to biological response modifiers. This would allow the clinician to identify patients at risk of developing adverse clinical outcomes and focus care on the prevention of complications, such as secondary infections and multisystem organ failure.

CHAPTER 305

The host response to hypoxia in the critically ill

Raghavan Raju and Irshad H. Chaudry

Key points

- Severe haemorrhage causes whole body hypoxia.
- Hypoxia-inducible factor (HIF-1), an oxygen-sensing transcription factor, regulates the cellular response to hypoxia.
- The HIF-1 level is controlled by intracellular oxygen concentration.
- Hypoxia causes a decrease in mitochondrial oxidation, resulting in decreased adenosine diphosphate (ATP) production.
- Hypoxia also triggers endoplasmic reticulum stress.

Introduction

According to the US Centers for Disease Control, injury is a leading cause of death, while haemorrhage is the most common cause of preventable death [1]. Soft-tissue trauma and haemorrhage lead to decreased organ blood flow. The reduced tissue supply of nutrients and oxygen results in hypoxia, metabolic dysregulation, and organ dysfunction. Conditions such as trauma-haemorrhage (T-H) cause whole body hypoxia. Severe tissue hypoxia is also a frequent pathophysiological abnormality in severe sepsis [2]. The hypoxic response of the host is complex—during hypoxia, the oxygen-sensing intracellular machinery within mammals attempts to restore homeostasis by augmenting respiration and blood flow [3]. Although hypoxia plays an important role in various conditions, such as heart and lung diseases, cancer and stroke, contributing to the majority of deaths in the United States, this chapter will focus upon hypoxia produced by low flow conditions following T-H, and its consequences.

Hypoxia and haemorrhagic shock

Sustained tissue hypoxia contributes to the initiation of inflammatory processes, generation of excessive free radicals, and cellular apoptosis [4]. Specifically within the immune compartment, hypoxia modulates differentiation and function of T cells, dendritic cells and macrophages, as well as their cytokine profiles [5,6]. Hypoxia may also contribute to lipid accumulation within different cell types, including macrophages [7]. Serious immunological perturbations may occur following haemorrhagic shock in animal models, contributing to increased susceptibility to sepsis [8]. Our T-H animal model, wherein 60% of the blood volume is withdrawn in 45 minutes to induce haemorrhagic shock, induces severe hypoxia. Data from this model show significant reductions in blood flow in several organs, including liver, heart, kidney, and intestine, at 2 hours following haemorrhage and resuscitation. Haemorrhagic shock leads to increased production of pro-inflammatory cytokines, such as tumour necrosis factor (TNF)-α, interleukin (IL)-6, and IL-1. Hypoxaemia (low O_2 level in the circulation) has been suggested to be one of the reasons for this immunological response. When mice were exposed to low oxygen (95% N_2–5% O_2) for 60 minutes, significant hypotension occurred followed by an inflammatory cytokine release [9]. Thus, even in the absence of any blood loss or tissue injury, hypoxaemia induced systemic inflammation as evidenced by a significant rise in plasma TNF-α and IL-6 levels, and a significant decrease in antigen presentation capacity of peritoneal macrophages. This immune response is gender-dependent, with females in the pro-oestrus state being resistant to a pro-inflammatory response [8]. Indeed, oestrogen pretreatment protected males against a hypoxia-induced immune depression [8]. Hypoxaemia in male mice resulted in markedly depressed proliferation and IL-2 release capacity of splenocytes. However, in male mice pretreated with 17β-oestradiol, splenocyte function was preserved. Numerous studies have demonstrated a sex-dependent host response to T-H. This dichotomy was further confirmed by the finding that MyD88 and Src expression in Kupffer cells were significantly decreased after hypoxia in pro-oestrus females, but not in males. Elevated IL-6 production by Kupffer cells in response to hypoxia may be mediated by p38MAPK activation via a Src-dependent pathway [9].

Role of HIF-1 in hypoxia

As mentioned previously, haemorrhage and soft-tissue trauma impair tissue perfusion and cause microvascular injury, increased interstitial pressure, thrombosis, and local hypoxia [10]. Although some data show that hypoxia enhances macrophage phagocytosis, suppression of Kupffer cell phagocytosis has also been observed [11,12]. We compared the similarity of cellular hypoxia observed in T-H with that of a hypoxaemic animal model exposed to 5% O_2 for 2 hours. Using Pimonidazole as a marker of hypoxia, a similar percentage (80%) of Kupffer cells from T-H and hypoxia groups demonstrated a comparable hypoxic effect [11]. In another study, peritoneal macrophage phagocytosis was enhanced in animals subjected to hypoxia, but a reversed effect was seen when hypoxia-inducible factor (HIF)-1α mRNA was disrupted [12]. HIF-1α is an oxygen-sensing protein, the intracellular level of which is

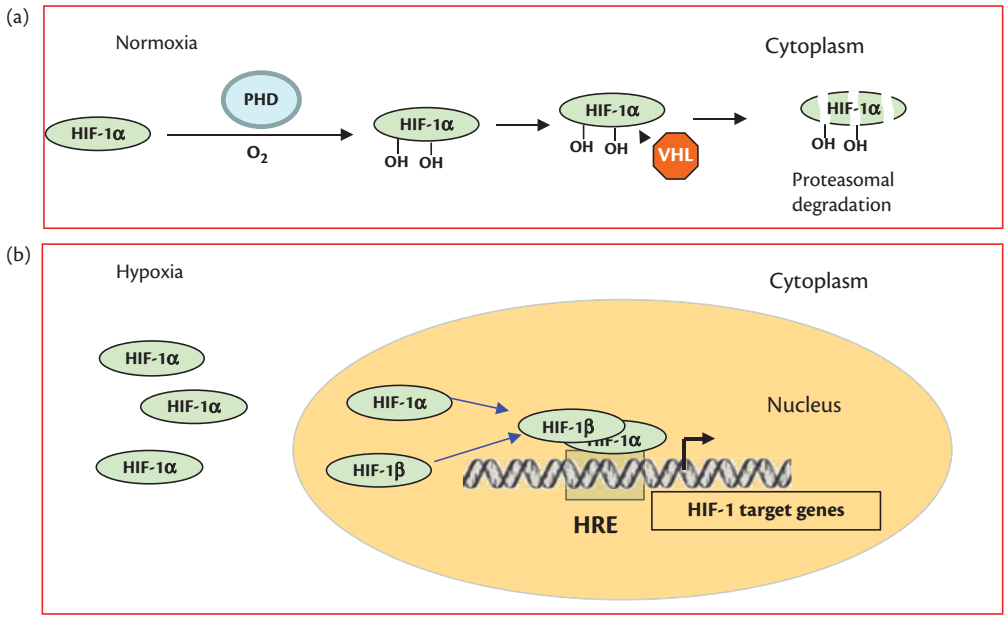

Fig. 305.1 Oxygen-regulated HIF-1 dynamics. (a) In the presence of oxygen, HIF-1α protein subunit is hydroxylated on one or two proline residues. The process is catalysed by the enzyme, prolyl hydroxylase (PHD) utilizing O_2. Hydroxylated HIF-1α, bound by von Hippel-Lindau protein (VHL) recruits E3 ubiquitin-protein ligase to the complex and targets for proteosomal degradation. (b) With deficiency of oxygen, hydroxylation of HIF-1α is inhibited, resulting in the build-up of HIF-1α in the cytosol. HIF-1α forms a heterodimer with HIF-1β in the nucleus, binds to hypoxia response elements (HRE) on gene promoters and regulates gene transcription. Over 100 genes are known to be regulated by HIF-1α.

Adapted from Carroll VA and Aschcroft M, 'Targeting the molecular basis for tumour hypoxia', Expert *Reviews in Molecular Medicine*, 2005, **7**, pp. 1–16, with permission from Cambridge University Press.

controlled by the oxygen level. When the mRNA was overexpressed there was a further increase in phagocytosis, demonstrating a direct relationship between the observed phenotypic effects and HIF-1α expression [12]. However, alongside the significant increase in HIF-1α expression, there was a marked reduction in mitochondrial function.

HIF-1 is a transcription factor, a heterodimer of HIF-1α and HIF-1β. Whereas HIF-1β expression is constitutive, the intracellular level of HIF-1α is highly regulated by the cellular oxygen concentration. In the presence of adequate oxygen, HIF-1α undergoes an oxygen-dependent hydroxylation at one or two proline residues, at positions 402 or 564. The hydroxylated HIF-1α is bound by von Hippel-Lindau (pVHL) protein and eventually targeted for proteosomal degradation (Fig. 305.1a). As the activity of the enzyme that hydroxylates HIF-1α is tightly dependent on oxygen availability, during oxygen deficiency the hydroxylation of HIF-1α declines. This results in an increased intracellular concentration of HIF-1α, allowing it to pair with HIF-1β. The dimer binds to promoter regions of more than 100 different genes (Fig. 305.1b). The nucleotide sequence on the promoters that bind HIF-1 is termed the hypoxia-responsive element (HRE) and is determined to be (A/G)CGTG [13]. HIF-2 and HIF-3 are also heterodimeric proteins with similar functions to HIF-1; however, HIF-1 is the most studied oxygen-sensing transcription factor.

Effect of hypoxia on cellular energetics

A primary role of HIF-1 is to assist a hypoxic cell to shift its energy reliance from aerobic respiration to glycolysis. Indeed, significant increases in HIF-1α expression have been observed in several organs after ischaemia-reperfusion injury, T-H, or soft tissue injury [7]. Mitochondrial ATP production relies on oxidative phosphorylation, which slows down under hypoxic conditions. The effect of hypoxia in promoting glycolysis, while reducing ATP production through decreased mitochondrial oxidation in cardiomyocytes subjected to hypoxia is well documented [14]. Anaerobic metabolism due to a low flow condition produces lactate as a by-product. This process is akin to the Warburg effect proposed in cancer, wherein oxygen-deprived cancer cells drive the less efficient glycolytic mechanism, with inhibition of fatty acid oxidation, conversion of acetyl CoA to pyruvate and mitochondrial oxidative phosphorylation, for survival. Decreased levels of the mitochondrial biogenesis factors, PGC-1α, PPAR, and NRF are reported following T-H. Consistent with this observation, decreased ATP and mitochondrial function have been observed in several organs. Hypoxia amplifies mitochondrial inhibition induced by nitric oxide during an inflammatory response [15]. To further understand mitochondrial gene expression changes following hypoxia, we studied the mitoscriptome profile (i.e. the transcriptome of mitochondrial DNA and nuclear DNA that play a role in the structure and function of mitochondria) in cardiomyocytes subjected to hypoxia [16]. A significant increase was observed in expression of aldolase (Aldoc) and another key glycolytic enzyme, hexokinase (HK1) in neonatal cardiomyocytes subjected to hypoxia. Expression of seven of the 10 tested genes involved in glycolysis was significantly increased. A key cellular response related to HIF-1 expression in hypoxia is facilitating a metabolic shift from oxidative phosphorylation to glycolytic production of ATP. Of note, expression of pyruvate dehydrogenase kinase, iso-enzyme 1 (Pdk1) also increased following hypoxia. Pdk1 phosphorylates the pyruvate

dehydrogenase complex (Pdh), which catalyses the conversion of pyruvate to acetyl CoA. The inhibition of Pdh therefore limits availability and entry of acetyl CoA into mitochondrial oxidation.

Among the genes upregulated following hypoxia were the HIF target genes, *Bnip3, HK1*, and *Pdk1*. Expression and accumulation of *Bnip3* mRNA and overexpression of *Bnip3*-activated cardiomyocyte death have been observed in chronic hypoxia [17]. *Bnip3* has also been implicated in hypoxia-mediated autophagy, although a recent study suggested that hypoxic induction of *Bnip3* may not be directly mediated by HIF-1 [18]. Nonetheless, *Bnip3* may play an important role in hypoxia-induced cell death.

Neutrophils are among the first responders and important mediators of any innate immune response. The dominant glycolytic metabolism of neutrophils allows these cells to function in hypoxic inflammatory foci. Furthermore, a hypoxic environment inhibits constitutive neurophil apoptosis. Murine neutrophils deficient in HIF-1α had decreased survival in oxygen deficiency conditions [19]. In addition, specific *in vivo* deletion of HIF-1α in myeloid cells resulted in reduced ATP pools and impairment of myeloid cell aggregation, motility and invasiveness, and reduced bacterial killing, further highlighting the need for hypoxic adaptation as part of the functional requirement of myeloid cells [19].

Another important cellular response to hypoxia is the induction of endoplasmic reticulum (ER) stress [20]. ER stress is one of the first and foremost responses of a cell in response to conditions such as hypoxia or hyperglycaemia; most injury situations elicit these conditions requiring the initiation of ER stress. ER is the first compartment of the protein secretory pathway; folding and post-translational modifications of newly-synthesized and transmembrane proteins are carried in this compartment. In response to ER stress-inducing signals, cells initiate an unfolded protein response. When misfolded or unfolded proteins accumulate, ER stress sensors IRE1, PERK, and ATF6 perched on the ER membrane activate various signalling pathways in order to restore cellular homeostasis. However, sustained stress may lead to apoptosis. Activation of the ER stress pathway has been observed following injuries such as T-H and burns.

Overall, there is a profound effect of hypoxia on metabolic homeostasis in the target tissues. The initial host response to hypoxia may be characterized as a survival response, although a sustained hypoxic condition may be suicidal to the host cells.

CHAPTER 306

Host–pathogen interactions in the critically ill

Guillaume Geri and Jean-Paul Mira

Key points

- Host–pathogen interactions are complex, precise, and varied.
- The innate immune response involves numerous pattern recognition receptors that detect pathogen-associated molecular patterns, leading to the production of cytokines, chemokines, and the development of adaptive immunity.
- Host–pathogen interaction diversity is increased by microbial variability.
- Genetic deficiencies may help physicians to understand and validate innate immune responses.
- Future therapeutic applications should be studied to adapt standard therapeutics to individual patients.

Introduction

Infection by a pathogenic micro-organism triggers a coordinated activation of both innate and adaptive immune responses that aim to control microbial growth and protect the host. The innate immune response, the first line of defence against micro-organisms, is either non-specific or directed against a group of micro-organisms, while the adaptive immune response is specific and targets a given pathogen. The innate immune response quickly triggers an antimicrobial response through the induction of various inflammatory cytokines and chemokines, and this will initiate development of a pathogen-specific, long-lasting adaptive immune response. Accurate recognition of microbial-associated molecular patterns (MAMPs) by pattern-recognition receptors (PRRs) is the cornerstone of this immediate response. PRRs are not only expressed on dendritic cells, macrophages and neutrophils, but also on endothelial and epithelial cells. These receptors sense various classes of molecules and activate different intracellular signalling pathways to produce an adequate initial response to the pathogen's aggression.

The importance of host genetics in the immune response is unequivocal. Hence, the same infectious challenge does not create a similar clinical phenotype in both humans and animal models. Familial clustering of severe infections, such as meningococcal disease, also argues for some inherited genetic susceptibility. Since the discovery of the double helical structure of DNA by Crick and Watson in 1953 to the completion of the human genome project, major advances have been realized in genetic medicine. These have allowed the rapid expansion of genetic-association, genome-wide association (GWA) and sequencing studies, leading to numerous publications on the host's genetic susceptibility. However, the two-way interactions that occur between host and pathogen also suggest that pathogen variability is another important piece of the puzzle, leading to a very complex two-sided relationship with numerous combinations. While immune-related genes are promising candidates for any infectious disease, genes encoding proteins involved in the pathogen life cycle within the host or in other pathways should also be considered.

This review aims to first describe the multiple determinants of the host's immune response and the influence of pathogen variability, and then to consider potential therapeutic applications for individualized medicine.

Host recognition of microbial-associated molecular patterns

Toll-like receptors

Toll-like receptors (TLRs) are major PRRs that trigger kinase cascades to activate nuclear transcription factors that induce gene expression and cytokine production. The TLR structure is composed of an extracellular domain that contains several leucine-rich repeats and an intracytoplasmic domain that shares significant sequence similarities with the corresponding domain of the interleukin-1 receptor. Myeloid differentiation factor-88 (MyD88) is the cornerstone protein for most of the pathways induced by the TLRs, with the exception of TLR-3. In particular, stimulation of TLRs triggers an intracellular signalling cascade leading to activation of NFκ-B, the central transcription factor of inflammation.

Thirteen TLRs have been described in mammalians. All these receptors act either as homo—or heterodimers with other members of the TLR family. The TLR-2/6 and TLR-1/2 heterodimers recognize Gram-positive bacteria through sensing of different bacterial surface lipoproteins. TLR-5 recognizes flagellin from both Gram-positive and Gram-negative bacteria, while TLR-7 detects bacterial RNA. CpG bacterial DNA stimulates only TLR-9. TLR-4 was initially described as recognizing lipopolysaccharide (LPS), a major pathogenic component of Gram-negative bacteria, although recent studies show that LPS does not bind directly to TLR4, but rather to a protein complex composed of LPS bound to MD2 and LPS-binding protein, which in turn activates TLR-4. The TLRs do not only recognize bacteria, but also fungi, parasites, and viruses. TLR-2 and TLR-4 recognize multiple ligands shared by different parasites. Viruses are recognized

by intracytoplasmic TLRs, namely TLR-3, -7, and -8 as they need to have access to viral nucleic acids.

In young children, rare autosomal MyD88 deficiencies lead to recurrent pyogenic infections and invasive pneumococcal diseases, including meningitis [1]. Similarly, serine-threonine kinase IRAK-4 (interleukin-1 receptor-associated kinase-4) deficiencies that affect TLR signalling also predispose to the same bacterial infections [2]. The common point between these two different genetic deficiencies is the host's inability to activate NF- κB and induce downstream cytokine release in response to TLR stimulation. Genetic mutations are also involved in severe viral infections. Hence, mutations in TLR-3 or in UNC93B1 (a protein involved in TLR-3 signalling) predispose to recurrent herpes virus encephalitis [3,4].

Other pattern recognition receptors

Besides TLRs, three others PRR families have been described. Two intracytoplasmic PRR families (RIG-I helicase receptors and NOD-like receptors (NLRs)) may be distinguished from C-type lectin receptors (CLRs), which constitute an extracellular PRR family like the TLRs.

CLRs recognize microbial polysaccharides and are important for recognition of bacteria and fungi [5]. The dectin-1 receptor is the major PRR for the beta-1,3-glucan, an important component of the fungal wall. This triggers phagocytosis and production of various inflammatory chemokines and cytokines via activation of the NLRP3 inflammasome. Dectin-1 deficient mice show great susceptibility to systemic fungal infections that is related to an impaired pro-inflammatory cytokine production and a decrease in neutrophil-mediated fungal killing [6]. However, patients with dectin-1 deficiency appear not to be more susceptible to severe fungal infections, even if they are more likely to colonized by fungi when undergoing stem-cell transplantation [7]. Hence, they are likely to need more frequent antifungal therapy than patients without dectin deficiency.

Intracytoplasmic RIG-1 receptors are efficient receptors for RNA viruses. The two main receptors of the RIG-1 family are retinoic acid-inducible gene 1 (*RIG-1*) and melanoma differentiation-associated gene 5 (*MDA5*), which are very efficient receptors for hepatitis C, Japanese encephalitis virus, dengue, and West Nile viruses. Until now, no mutation in this PRR family has been associated with an altered susceptibility to sepsis. NLRs are the second intracellular PRR family and play a major role in inflammasome activation. The inflammasome is a multiprotein complex that leads to production of inflammatory cytokines, such as IL-1ß, IL-18, and IL-33. The NOD receptors 1 and 2 (NOD1 and NOD2), are members of the NLR family and recognize the muramyl peptide moieties of the peptidoglycans of Gram-negative and Gram-positive bacteria [8].

Interactions between the different PRRs pathways are essential for optimal anti-pathogen responses. Synergy between the TLRs and NOD2, for example, is crucial for activation of defence system against mycobacteria and *Staphylococci*, while cross-talk between TLRs and CLRs is necessary for optimal antifungal responses [8].

Complement system

The complement system is a complex and diversified system composed of over 32 proteins. Complement is activated *via* three different pathways—classical, alternative, and lectin pathways—that activate C3 derived-components. C3 is the cornerstone of the complement system with activation leading to the release of C3a and C5a. These active forms have numerous functions, such as stimulating the inflammatory process, leucocyte chemotaxis, phagocytic cell degranulation, and an increase in vascular permeability. During complement activation, a membrane attack complex is formed allowing cell lysis. This system is tightly controlled and several inhibitors such as complement receptors 1 and 2 (CR1 and CR2), decay-accelerating factors (DAF) and membrane cofactor proteins (MCP) regulate this activation cascade. Factor H or factor I also inhibit complement system activation by shortening the half-life of the C3 and C5 convertases.

The absolute importance of the complement system in innate immunity is illustrated by recurrent and severe infectious events in patients carrying genetic deficiencies of some components of this system. Hence, recurrent meningococcal disease is frequently reported in patients with various complement deficiencies [9]. For example, factor H inhibits alternative pathway spontaneous activation and its deficiency leads to decreased C3 concentrations and an increased susceptibility to *Neisseria meningitidis* infections [10]. Host genetic variations of factor H, factor H receptor, and factor H-related protein-3 have been also reported in GWA studies (GWAS) performed on cohorts of patients with meningococcal infections, confirming the predominant role of these regulators in the pathogenesis of invasive meningococcal disease. Similar findings have been recently described for factor H in *Streptococcus pyogenes* infection [11].

Inflammatory host response after MAMPs recognition

Numerous factors mediate the inflammatory response after initial contact between the host and pathogen.

In viral infections, type 1 interferons are key cytokines inducing an antiviral response. Viral activation of TLRs and RLRs induce production of type 1 interferons and IL-12 to trigger specific antiviral actions.

Interaction between the host and bacteria leads to release of numerous pro-inflammatory cytokines (e.g. tumour necrosis factor-α (TNF-α), IL-1, IL-6, IL-17) but also neutrophil proteases, lactoferrin, myeloperoxidase, and specific antimicrobial peptides. The primordial role of these antimicrobial peptides has been seen in knock-out mice which are more susceptible to bacterial infections than their wild-type counterparts. TNF-α is a central pro-inflammatory cytokine involved in most of the antimicrobial defence processes. Patients carrying the TNF2 allele (a common G→A single nucleotide polymorphism (SNP) located at -308 from the transcription initiation site) have an increased risk of developing severe cerebral malaria and purpura fulminans [12]. TNF2 has also been associated with susceptibility of septic shock and is an independent risk factor for death due to septic shock [13].

Another part of the primary response to a host–pathogen interaction is the production of numerous chemokines that induce chemotaxis in target cells that express appropriate chemokine receptors. Apart from immune cell homing and maintaining inflammation, chemokines also have important antibacterial activity.

Influence of pathogen variability on infectious diseases presentation

Apart from host genetic variability, pathogen diversity also influences the phenotypic features of various infectious diseases. To illustrate this important aspect of the host-pathogen relationship, the pathogen diversity of *Pneumococcus, Meningococcus*, and *Plasmodium* will be briefly highlighted.

Genomic diversity of *Streptococcus pneumoniae*

Streptococcus pneumoniae may cause invasive lethal infectious diseases (bacteraemic pneumonia, septicaemia, and meningitis) or uncomplicated pneumonia, sinusitis, and acute otitis media. To partially explain this large diversity of invasiveness, immunochemical differences of the polysaccharide capsule have been performed, revealing approximately 90 different serotypes. Many of these strains are rarely recovered from serious diseases, and only 15 serotypes are implicated in the vast majority of invasive infections. Sandgren et al. evidenced 34 different serotypes out of 273 invasive isolates and 246 colonizing isolates—one group of serotypes was predominantly found in invasive isolates (type 1, 3, 4, 7F, and 9V serotypes), while another group was associated with both invasive pneumococcal disease, as well as carriage (type 6A, 6B, 14 and 19F isolates) [14]. More recently, multilocus sequence typing studies have revealed that one serotype does not really correspond to only one bacterium. In reality, it may contain bacteria from diverse ancestries, each having different consequences on the clinical phenotype. Interestingly, highly invasive isolates are less diversified than those isolated from carriage [15]. This diversity of pneumococcal invasiveness also includes varying susceptibility to antibiotics. In Sandgren's study, a decreased susceptibility to penicillin was most frequently observed in carriage-related compared to highly invasive isolates [14].

Hyperinvasive genotypes of *Neisseria meningitidis*

Neisseria meningitides is a frequent commensal bacterium of the human nasopharynx. It can be involved in severe, and sometimes fatal, disseminated disease. As with *Streptococcus pneumoniae*, the capsule is an important virulence factor in meningococci. To date, few genotypes of *Neisseria meningitidis* are known to be prominent in invasive infections. A strong association between invasive meningococcal disease and expression of serogroup C has been shown, with an odds ratio of 27.4. In the same study, ST-11, ST-41/44 and ST-269 clone complexes were strongly associated with invasive disease [16]. These findings have been confirmed in some subsequent reports. The ST-11 clonal complex has been specially reported to correlate with fatal outcome, higher virulence, more damage to human epithelial cells, and induction of apoptosis in epithelial cells.

Plasmodium diversity and severe malaria

As severe *Plasmodium falciparum* malaria is observed in only a small percentage of the infected population, this has led to a search for particular genotypes of the parasite. In parasite polymorphisms in Dakar (Senegal) a higher rate of *Pfdhfr* mutation was reported in severe compared with moderate malaria. An association was also noted between the presence of the msp-1 locus and malaria severity. Although the role of this gene product in malaria pathogenesis remains unclear, msp-1 is associated with greater plasma levels of TNF-α, which is central to the inflammatory response [17]. Similarly, increased expression of the *var-D* gene, involved in the primordial phase of parasite cyto-adherence, was also associated with malaria severity. On the other hand, some protective polymorphisms have been described. Some mutations in the control region of nitric oxide synthase-2 have been reported as protective and associated with less severe *P. falciparum* malaria.

Therapeutic applications and future challenges

In addition to improving our understanding of host-pathogen interactions, genomic analysis may assist in the development of targeted therapies or new therapeutic strategies based on the patient's genotype.

In HIV patients, a conformational change of the CC chemokine receptor CCR5 (CCR5Δ32) led to an inability for the receptor to be expressed on the cell surface, thus preventing virus entry into lymphocytes. Genetic studies revealed that patients who are homozygous for this genetic variant were resistant to HIV entrance, maintained a normal lymphocyte count for a long time after infection, and were long-term survivors even in the absence of treatment. This enabled the development of new drug specifically targeting the CCR5 co-receptor. Another example of genomic analysis application in clinical practice is the use of abacavir in HIV patients. Abacavir is a reverse transcriptase inhibitor used to treat HIV-1 infection and is responsible for severe adverse hypersensitivity reactions that are clearly linked with the *HLAB5701* allele [18], leading to screen this allele before prescription in order to reduce the risk of hypersensitivity reactions

Genomic knowledge may also increase the development of prophylactic strategies for infectious diseases. Indeed, several studies have shown that HLA subgroups may influence the response to immunization. This is most clearly illustrated by the responses to hepatitis B and measles immunization. A significant association was seen between HLA II (in particular HLA DRB1) and the response to primary hepatitis B vaccination, with HLADRB1*07 being strongly associated with a non-response to a full-dose immunization [19]. Likewise, some familial clusters of measles vaccination failures suggest that some HLA polymorphisms lead to different responses to immunization [20]. Identification of groups of patients with similar genotype risk may also improve outcomes through the use of specific targeted therapies such as anti-TNF-α for high TNF secretor patients.

Genomic medicine will play an increasingly larger role in clinical practice in the years ahead. In addition to becoming familiar with genetic analysis techniques, physicians should also look to adopt these new tools to improve patient outcomes.

CHAPTER 307

Coagulation and the endothelium in acute injury in the critically ill

Marcel Levi and Tom van der Poll

Key points

- Endothelial cells have a central role in the bidirectional relationship between inflammation and coagulation.
- Expression of tissue factor is the pivotal initiating event in the coagulation response occurring with systemic inflammation.
- Regulation of coagulation activation through physiological anticoagulant mechanisms occurs in large part at the endothelial cell surface.
- Activated coagulation proteases may bind and activate protease-activated receptors expressed by endothelial cells, and may elicit a pro-inflammatory effect.
- The endothelial cell-related glycocalyx is an important interface in modulation of the activation of coagulation and systemic inflammation.

Introduction

Acute inflammation, as a response to severe infection or trauma, results in systemic activation of the coagulation system [1].The principal initiator of inflammation-induced thrombin generation is tissue factor (TF). Since TF is expressed on cytokine-activated mononuclear cells, which play a pivotal role in the host response to infection, it was hypothesized that micro-organism-induced activation of mononuclear cells resulted in TF-mediated activation of coagulation. Cytokines mediate many of the responses triggered by severe inflammation, thereby placing cells other than circulating mononuclear cells in the spotlight. More complex mechanisms could thus be involved in the relationship between inflammation and activation of coagulation [2]. This relationship is not uni-directional; activation of coagulation will also affect inflammatory activity. In particular, vascular endothelial cells play a pivotal mediatory role in the procoagulant response to systemic inflammation and the cross-talk between coagulation and inflammation [3]. Endothelial cells respond to cytokines expressed and released by activated leukocytes, but can also release cytokines themselves. Furthermore, endothelial cells can express adhesion molecules and growth factors that may not only promote the inflammatory response further, but also amplify the coagulation response.

In addition to these mostly indirect effects of the endothelium, endothelial cells can also interfere directly with initiation and regulation of fibrin formation and removal during severe infection. In fact, endothelial cells play a prominent role in all three major pathogenetic pathways associated with coagulopathy in sepsis: TF-mediated thrombin generation, dysfunctional anticoagulant pathways, and blocked fibrinolysis.

Role of endothelial cells in the initiation of coagulation

TF plays a central role in the initiation of inflammation-induced coagulation. Blocking TF activity completely inhibits inflammation-induced thrombin generation in models of experimental endotoxaemia or bacteraemia [4]. The vast majority of cells constitutively expressing tissue factor are found in tissues not in direct contact with blood, such as the adventitial layer of larger blood vessels. However, TF comes into contact with blood when the integrity of the vessel wall is disrupted, or when endothelial cells and/or circulating blood cells start expressing tissue factor. The in vivo expression of TF is mostly dependent on IL-6, as studies show that inhibition of IL-6 completely abrogates TF-dependent thrombin generation in experimental endotoxaemia, whereas specific inhibition of other pro-inflammatory cytokines had less or no effect. Inflammatory cells in atherosclerotic plaques produce abundant TF; upon plaque rupture there is extensive TF exposure to blood [5].

In severe sepsis, mononuclear cells, stimulated by pro-inflammatory cytokines, express TF, thus leading to systemic activation of coagulation [6]. However, endothelial cells also play an important role in TF generation during severe infection. Under *in vitro* conditions, various cytokines (e.g. TNF-α and IL-1) induce TF expression in vascular endothelial cells. Ex vivo observations also support the notion of endothelial cell involvement in TF-mediated activation of coagulation during severe infection. The demonstration of circulating endothelial cells expressing TF in patients with sickle cell disease also suggests endothelial involvement in TF production.

Expression of TF by endothelial cells appears confined to certain organs and vascular beds [3]. It remains uncertain whether this

is genetically controlled in an organ-specific manner. Differential activation of endothelial cell TF expression may occur, in particular, during severe infection. Although not yet directly demonstrated, it is likely that in situations of tissue trauma (such as extensive surgery, brain trauma or burns) TF expressed constitutively at the site of injury (such as in subcutaneous tissue) contributes to, or is the primary source of, the procoagulant stimulation underlying disseminated intravascular coagulation (DIC).

Direct interaction between micro-organisms and endothelial cells can also occur, especially in the case of viral infections. Endothelial cell perturbation is a common feature of viral infection and can alter haemostasis both directly and indirectly. Endothelial cells can be directly infected by various viruses, e.g. Herpes simplex virus, adenovirus, parainfluenza, polio, echo, measles, mumps, cytomegalovirus, HTLV-1, human immunodeficiency virus, and in particular, by viruses causing haemorrhagic fevers, e.g. dengue, Marburg, ebola, Hanta, lassa.

Role of endothelial cells in the regulation of coagulation

Thrombin generation is limited by antithrombin (AT), the protein C system, and tissue factor pathway inhibitor (TFPI). During injury and inflammation, all three regulatory systems are defective, primarily as a result of endothelial dysfunction.

Antithrombin system

AT is the main inhibitor of thrombin and factor Xa. Endogenous glycosaminoglycans on the vessel wall, such as heparin sulphates, promote AT-mediated inhibition of thrombin and other coagulation enzymes. During severe inflammatory responses, AT levels are markedly decreased due to impaired synthesis (negative acute phase response), degradation by elastase from activated neutrophils, and—quantitatively the most important—consumption as a consequence of ongoing thrombin generation [2]. Pro-inflammatory cytokines can also cause reduced synthesis of glycosaminoglycans on the endothelial surface. This contributes to reduced AT function since these glycosaminoglycans can act as physiological heparin-like cofactors of AT.

Protein C system

Activated protein C (AcPC) plays a central role in the pathogenesis of sepsis and associated organ dysfunction [7]. Insufficient functioning of the protein C pathway contributes to coagulation derangement in sepsis [8]. The circulating zymogen, protein C is activated by endothelial cell-bound thrombomodulin once this itself is activated by thrombin. AcPC acts in concert with its co-factor, protein S, to proteolytically degrade the essential coagulation cofactors Va and VIIIa; in this manner, it functions as an effective anticoagulant. The endothelial protein C receptor (EPCR) not only accelerates activation of protein C several-fold, but also serves as a receptor for AcPC; binding of AcPC to this receptor may amplify its anticoagulant and anti-inflammatory effects. In patients with severe inflammation, the protein C system malfunctions at virtually all levels. First, plasma levels of protein C are (very) low due to impaired synthesis, increased consumption, and degradation by proteolytic enzymes, such as neutrophil elastase. Secondly, a significant downregulation of thrombomodulin, caused by pro-inflammatory cytokines, such as TNF-α and IL-1, has also been demonstrated, resulting in diminished protein C activation [9]. Low levels of free protein S may further compromise adequate functioning of the protein C system. Finally, but importantly, the EPCR is downregulated in sepsis, and this may further negatively affect functioning of the protein C system. Apart from these effects, sepsis may also cause resistance towards AcPC by other mechanisms that are dependent in part on a sharp increase in factor VIII levels (released from endothelial cells), but also through as yet unidentified mechanisms.

Tissue factor pathway inhibitor (TFPI)

A third inhibitory mechanism of thrombin generation involves TFPI, the main inhibitor of the tissue factor-factor VIIa complex. The role of TFPI in the regulation of inflammation-induced coagulation activation is not completely clear. Administration of recombinant TFPI (thereby achieving supra-physiological plasma concentrations of TFPI) blocked inflammation-induced thrombin generation in humans. Furthermore, the observation that pharmacological doses of TFPI can prevent mortality during systemic infection and inflammation suggests that high TFPI concentrations are capable of modulating TF-mediated coagulation [10].

Role of endothelial cells in fibrinolytic activity

Central regulators of plasminogen activators and inhibitors during inflammation are TNF-α and IL-1β. The presence of these cytokines in the circulation leads to release of plasminogen activators, in particular tissue-type plasminogen activator (t-PA) and urokinase-type plasminogen activator (u-PA), from storage sites in vascular endothelial cells. However, this increase in plasminogen activation, and subsequent plasmin generation, is counteracted by a delayed but sustained increase in plasminogen activator inhibitor type 1 (PAI-1). The resulting effect on fibrinolysis is a complete inhibition and, as a consequence, inadequate fibrin removal that contributes to microvascular thrombosis. Experiments in mice with targeted disruptions of genes encoding components of the plasminogen-plasmin system confirm that fibrinolysis plays a major role in inflammation. Mice deficient in plasminogen activators have more extensive organ fibrin deposition when challenged with endotoxin; on the other hand, PAI-1 knockout mice, in contrast to wild-type controls, exhibit no microvascular thrombosis upon endotoxin administration [11].

Cross-talk between coagulation and inflammation at the endothelial interface

Communication between inflammation and coagulation is bidirectional such that coagulation can also modulate inflammatory activity. Coagulation proteases and protease inhibitors not only interact with coagulation protein zymogens, but also with specific cell receptors to induce signalling pathways (Fig. 307.1). In particular, protease interactions that affect inflammatory processes may be important in the critically ill.

The pivotal mechanism by which coagulation proteases modulate inflammation is via binding to protease-activated receptors (PARs). Four types (PAR 1–4) have been identified, all belonging

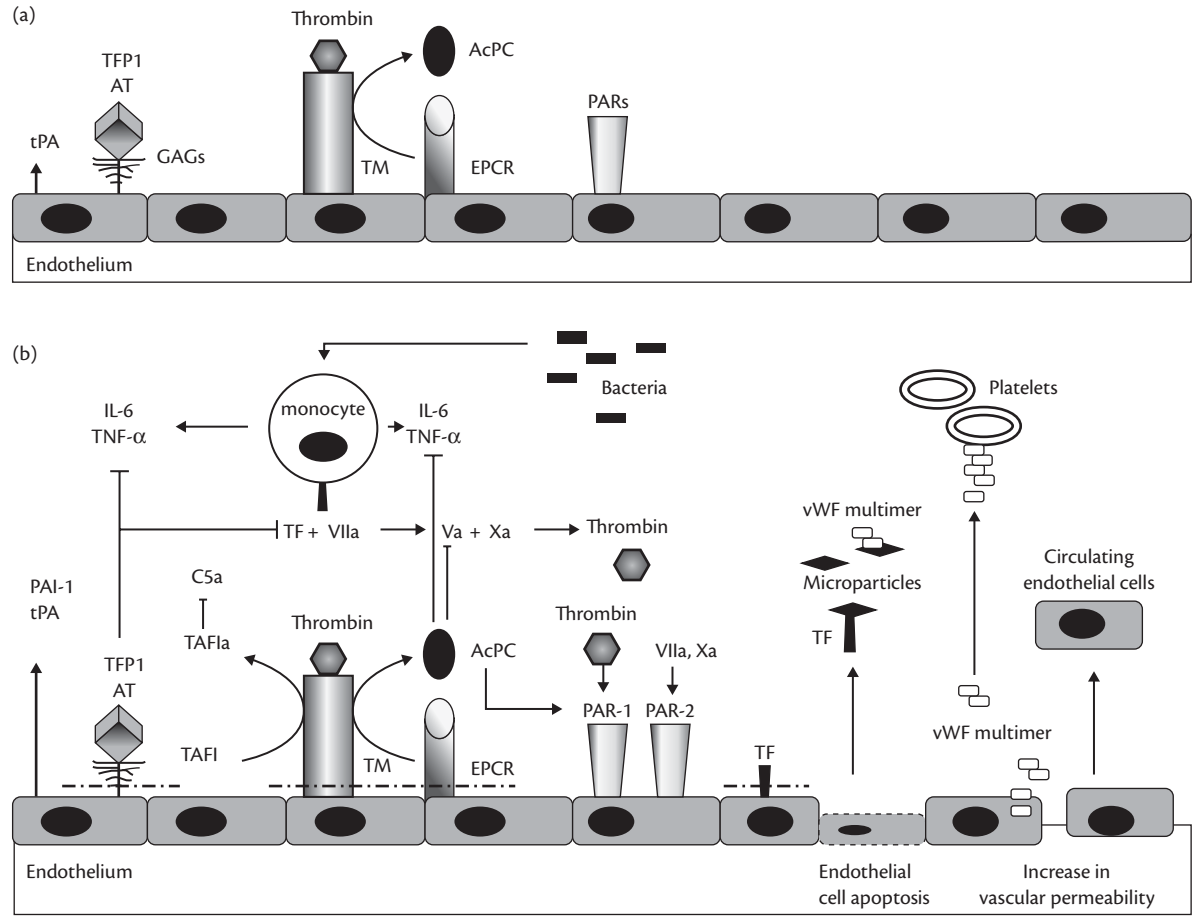

Fig. 307.1 Endothelium-associated mediators of coagulation and inflammation. (a) The normal situation by which the endothelium expresses thrombomodulin (TM) (activated by thrombin) and the endothelial PC receptor (EPCR), which then generate activated PC (AcPC). Other anticoagulant factors include tissue factor pathway inhibitor (TFPI) and antithrombin (AT), which attach to the endothelial surface, and endothelium-released tissue-type plasminogen activator (tPA), which promotes fibrinolysis. (b) Systemic activation of inflammation leads to cytokine release and endothelial perturbation, resulting in release of microparticles (MPs), apoptosis, detachment of endothelial cells, and loss of barrier function. Coagulation is activated by induction of tissue factor (TF) on monocytes, MPs, and endothelium, and by release of von Willebrand factor (vWF), which increases platelet adhesion to the subendothelial surface. Production of glycosaminoglycans (GAGs) is downregulated, and the anticoagulant proteins TFPI, AT, EPCR, and TM are cleaved from the endothelial surface, thus impairing their action. Fibrinolysis is impaired as a result of a rise in the main inhibitor of PA (PAI-1), which outweighs the rise in tPA. Complement activation is enhanced by loss of activation of thrombin-activatable fibrinolysis inhibitor (TAFI), which normally inhibits the complement factors C3a and C5a, and by increased bradykinin activity. In turn, anticoagulant proteins modulate cytokine release: tissue factor-factor VIIa (TF-FVIIa), factor (F) Xa, and thrombin exert pro-inflammatory activity by cleaving mainly protease-activated receptor (PAR)-1 and PAR-2. AcPC cleaves PAR-1 in an EPCR-dependent manner, thereby modulating inflammation and apoptosis.

to the family of transmembrane domain, G-protein-coupled receptors [12]. A typical feature of the PARs is that they serve as their own ligand. Proteolytic cleavage by an activated coagulation factor leads to exposure of a neo-amino terminus which activates the same receptor and, possibly, adjacent receptors, initiating transmembrane signalling. PARs are localized in the vasculature on endothelial cells, mononuclear cells, platelets, fibroblasts, and smooth muscle cells [12]. PARs 1, 3, and 4 are thrombin receptors, while PAR-1 can also serve as a receptor for the tissue factor-factor VIIa complex and factor Xa. PAR-2 cannot bind thrombin, but can be activated by the tissue factor-factor VIIa complex or factor Xa. Binding of thrombin to its cellular receptor may induce production of several cytokines and growth factors. Binding of tissue factor-factor VIIa to PAR-2 also results in upregulation of inflammatory responses (production of reactive oxygen species and expression of MHC class II and cell adhesion molecules) in macrophages, as well as modulating neutrophil infiltration and pro-inflammatory cytokine (TNF-α, IL-1β) expression. The *in vivo* relevance of the PARs has been confirmed in studies using PAR inhibitors or PAR-deficient mice [13].

Coagulation inhibitors regulate inflammation at the endothelial surface

Physiological coagulation inhibitors can also modulate inflammation. Antithrombin possesses anti-inflammatory properties, many of which are mediated by its actions in the coagulation cascade. Most importantly, thrombin inhibition by AT blunts activation of

many inflammatory mediators. For example, thrombin activates platelets and endothelial cells that, in turn, contribute to local inflammation. Activated platelets secrete inflammatory mediators such as IL-1, which stimulate leukocyte activity. In particular, recruitment and adhesion of neutrophils and monocytes to blood vessels within the microcirculation promote inflammation. Perhaps most importantly, AT induces prostacyclin release from endothelial cells. Prostacyclin inhibits platelet activation and aggregation, blocks neutrophil tethering to blood vessels, and decreases endothelial cell production of various cytokines and chemokines. Thus, AT directly hinders leukocyte migration and adhesion to endothelial cells and this, in turn, impacts upon the severity of capillary leakage and subsequent organ damage.

Components of the protein C system are also important modulators of inflammation [14,15]. AcPC plays an important role in attenuating the systemic inflammatory response in sepsis; indeed, blocking the protein C pathway exacerbated the inflammatory response in septic baboons. In contrast, AcPC administration ameliorated the inflammatory activation following intravenous infusion of *E. coli* [16]. Support for the notion that AcPC has anti-inflammatory properties comes from in vitro observations demonstrating an AcPC binding site on monocytes that may mediate downstream inflammatory processes, and from experiments showing that AcPC can block NF-kB nuclear translocation, a prerequisite for increases in pro-inflammatory cytokines and adhesion molecules. These in vitro findings are supported by in vivo studies in mice with targeted disruption of the protein C gene in whom endotoxaemia produced a greater increase in pro-inflammatory cytokines and other inflammatory responses, as compared with wild-type controls [17]. The effects of AcPC on inflammation are likely mediated by the EPCR [14]. Binding of AcPC to the EPCR influences gene expression profiles of cells by inhibiting endotoxin-induced calcium fluxes in the cell and by blocking NF-κB nuclear translocation. EPCR binding of AcPC may result in PAR-1 activation, and thereby affect cytokine responses [18]. In contrast, other experiments suggested a significant physiological role for PAR-1 activation by AcPC was less likely. Like AcPC, the EPCR itself may have anti-inflammatory properties. Soluble EPCR, the extracellular domain of the cell-associated EPCR shed from the cell surface by the action of an inducible metalloproteinase can bind to proteinase 3, an elastase-like enzyme. The resulting complex binds to the adhesion integrin macrophage 1 antigen (Mac-1). AcPC may protect against disruption of the endothelial cell barrier in sepsis, probably by interfering with the EPCR and PAR-1 on endothelial cells. Finally, AcPC can inhibit endothelial cell apoptosis, which also appears to be mediated by an EPCR-PAR-1-dependent mechanism [19].

The glycocalyx mediates coagulation in endothelial injury

Recent research points to an important role of the inner (luminal) layer of the endothelium, i.e. the glycocalyx, in the interaction between inflammation and coagulation. In sepsis, glycosaminoglycans are downregulated as a result of pro-inflammatory cytokines. This can impact on the function of antithrombin and TFPI, and on leukocyte adhesion and transmigration. Besides glycosaminoglycans and highly sulphated polysaccharides, the glycocalyx consists of glycoproteins, hyaluronic acid, and membrane-associated proteins. The glycocalyx may also play a role in other endothelial functions including maintenance of vascular barrier function, nitric oxide-mediated vasodilation and antioxidant activity, all processes known to be involved in sepsis. Specific disruption of the glycocalyx results in thrombin generation and platelet adhesion within a few minutes [20]. Moreover, loss of glycocalyx in vivo has been associated with subendothelial oedema formation. The role of the glycocalyx in modulating endothelial function, including anticoagulation, and the role of the endothelium in modulating the glycocalyx in situations of vascular injury and systemic inflammation suggest this may be an interesting point of impact for future therapy.

CHAPTER 308

Ischaemia-reperfusion injury in the critically ill

Mitchell P. Fink

Key points

- Although ischaemia is intrinsically deleterious, restoration of adequate blood flow, i.e. reperfusion can, paradoxically, make matters worse.
- ROS are capable of covalently modifying and damaging nearly all cellular constituents, including nucleic acids, proteins, and lipids.
- The electron transport chain in mitochondria is the principal source of ROS production, although cytosolic reactions catalysed by enzymes, such as xanthine oxidase, are probably also important under some conditions.
- Conflicting, but generally disappointing, results have been obtained in clinical trials of various ROS scavengers, such as tirilizad and edavarone, for the treatment of stroke.
- A small clinical trial of cyclosporin for acute myocardial infarction yielded encouraging results.

Introduction

Ischaemia describes a reduction in blood flow to a tissue or organ, leading to an inadequate supply of oxygen and glucose to support normal metabolism. If inadequate perfusion persists, then ischaemia can lead to cell death. This process occurs in commonly encountered conditions, such as myocardial infarction (MI) or stroke. Although ischaemia per se is intrinsically deleterious, restoration of adequate blood flow, i.e. reperfusion can, paradoxically, make matters even worse. Ischaemia/reperfusion (I/R) injury is an important pathophysiological process implicated in early and late graft dysfunction after solid organ transplantation. I/R injury is also an important cause of organ dysfunction after therapeutic interventions for stroke or MI, such as thrombolysis or coronary angioplasty. I/R injury involving multiple organs may play a role in the pathogenesis of critical illness after resuscitation from haemorrhagic shock.

Redox stress

The pathophysiology of I/R injury is complex and remains incompletely understood. However, redox-mediated events play a crucial role in the pathogenesis of cellular death or dysfunction related to I/R injury.

The term **redox** is a contraction of **reduction** and **oxidation**. A redox reaction involves transfer of electrons from a reducing agent to an oxidizing agent. Good reducing agents are elements or compounds that have a strong propensity to donate electrons. Conversely, good oxidizing agents avidly accept electrons. Molecular oxygen (O_2) is a very potent oxidizing agent. Two strong reducing agents, namely the reduced forms of nicotine adenine dinucleotide (NADH) and flavin adenine dinucleotide ($FADH_2$), are produced during glycolysis and the citric acid cycle. In mitochondria, these two reducing agents are oxidized by O_2, and the energy released is used to drive formation of adenosine triphosphate (ATP), the primary 'energy currency' of all cells. Substrate level phosphorylation of adenosine diphosphate (ADP) to form ATP during glycolysis also depends upon NADH oxidation. Thus, redox reactions are responsible for the generation of energy that drives all cellular processes. Redox reactions also play a key role in activation and modulation of key intracellular signalling pathways. While life is crucially dependent on various biochemical redox reactions, these are also capable of damaging cellular constituents or activating various maladaptive physiological responses, and thus can play an important role in disease pathogenesis.

Reactive oxygen and nitrogen species (NOS)

Reactive oxygen species (ROS) are reactive, partially reduced derivatives of O_2. Examples include superoxide anion radical ($O_2^{-}\cdot$), hydrogen peroxide (H_2O_2), and hydroxyl radical ($OH\cdot$). Closely related are various RNS, exemplified by the weak acid, peroxynitrous acid (ONOOH), and its anion, peroxynitrite ($ONOO^-$). Free radicals are atoms or molecules that contain an unpaired electron in an outer (bonding) atomic or molecular orbital. This usually renders such species extremely reactive. While many free radicals are ROS (e.g. $O_2^{-}\cdot$), not all ROS or reactive nitrogen species (RNS) are free radicals, e.g. H_2O_2 and $ONOO^-$.

Although many enzymatic processes can lead to ROS formation, the mitochondrial electron transport chain is considered the principal source of partially reduced forms of oxygen, at least in cell types richly endowed with these organelles, such as neurons, cardiomyocytes, and hepatocytes. Approximately 0.2% of cellular O_2 consumption is converted into ROS, and 90% of ROS generated are derived from mitochondria [1].

In addition to intramitochondrial reactions, various other enzymatic processes can generate ROS, including reactions catalysed by nicotinamide adenine dinucleotide phosphate (NADPH) oxidase

and xanthine oxidase. NADPH oxidase catalyses the one-electron reduction of O_2 to form $O_2^{-}\cdot$, using NADPH as the electron donor. NADPH oxidase is an enzyme complex that is assembled after activation of phagocytes by microbes or microbial products, such as lipopolysaccharide (LPS), pro-inflammatory mediators, such as tumour necrosis factor (TNF), or exposure to ROS. The reaction catalysed by NADPH oxidase is critical for the formation of ROS in macrophages and polymorphonuclear neutrophils (PMNs). NADPH oxidase isoforms are also present in other cell types, including vascular smooth muscle cells, neurons, epithelial, and endothelial cells [2].

XO catalyses the oxidation of xanthine (or hypoxanthine) to form uric acid and $O_2^{-}\cdot$. XO is a post-translationally modified form of another closely-related enzyme, xanthine dehydrogenase (XD), which utilizes NAD^+ as a cofactor, and coverts xanthine (or hypoxanthine) to uric acid without forming ROS. Conditions associated with XD-to-XO conversion include cellular hypoxia and/or exposure to various pro-inflammatory mediators [3].

The enzyme, nitric oxide synthase (NOS), is crucial for formation of RNS. NOS catalyses the formation of L-citrulline and a gaseous free radical, nitric oxide (NO·) from L-arginine in a complex five-electron redox reaction that requires O_2 and several co-factors. If L-arginine availability is limiting, NOS can generate $O_2^{-}\cdot$ [4]. Three isoforms of NOS have been identified: NOS-1 (neuronal NOS or nNOS), NOS-3 (endothelial NOS or eNOS), and NOS-2 (inducible NOS or iNOS). Both nNOS and eNOS are constitutively expressed, and their production of NO· is tightly regulated by changes in intracellular Ca^{2+} concentration. In contrast, iNOS, is expressed only after induction by various cytokines or microbial products. A fourth isoform, mitochondrial NOS (mtNOS), has been postulated, but this entity is probably a cytoplasmic isoform (mostly probably nNOS), which has been transported into mitochondria. Increased iNOS expression occurs when murine macrophages or PMN are stimulated by LPS and/or pro-inflammatory cytokines, e.g. interferon-γ (IFN-γ). Appropriately stimulated human macrophages can also produce NO· via an iNOS-dependent mechanism, as can other human cell types, such as intestinal and alveolar epithelial cells.

Although not exceptionally reactive per se, $O_2^{-}\cdot$ occupies a central place in the biochemistry of redox stress. It participates in the Haber–Weiss reaction ($O_2^{-}\cdot + H_2O_2 \rightarrow O_2 + OH\cdot + OH^-$), which combines a Fenton reaction ($Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + OH\cdot + OH^-$) and reduction of ferric iron (Fe^{3+}) by $O_2^{-}\cdot$, yielding ferrous iron (Fe^{2+}) and oxygen ($Fe^{3+} + O_2^{-}\cdot \rightarrow Fe^{2+} + O_2$). The hydroxyl radical is extremely reactive, combining very rapidly (~10^{-9} sec) with other molecules physically colocated. Under conditions commonly associated with upregulated iNOS expression, cells can produce both NO· and $O_2^{-}\cdot$ that can react with each other to produce the potent oxidizing and nitrosating agent, $ONOO^-$.

Molecular targets for ROS and RNS

General processes whereby ROS cause pathological changes in cells and tissues are collectively referred to as oxidative (or oxidant or redox) stress. Since ROS are being produced continuously, oxidative stress occurs not as a result of ROS production per se, but rather when ROS biosynthesis exceeds the detoxifying capacity of various intrinsic anti-oxidant (and free radical scavenging) defence systems.

At high concentrations, ROS can covalently modify most cell structures, including nucleic acids, lipids and proteins [6]. The hydroxyl radical reacts with all components of the DNA molecule, damaging both purine and pyrimidine bases and the deoxyribose backbone [6].

ROS also attack carbon-carbon double bonds in the polyunsaturated fatty acid (PUFA) residues of phospholipids, leading to formation of peroxyl radicals (ROO·). These can attack other targets (e.g. other PUFA residues), propagating a chain reaction and widespread damage to cellular constituents. ROS also oxidize sulphydryl groups of cysteine residues within proteins, forming intramolecular disulphides or mixed disulphides with other –SH-containing small molecules, notably glutathione. RNS, such as $ONOO^-$ can S-nitrosylate cysteine residues, leading to loss of function of key proteins.

Intrinsic anti-oxidant defence mechanisms

In view of the myriad potential deleterious effects of ROS and RNS, it is not surprising that eukaryotic cells have evolved various mechanisms to detoxify these reactive species. A key defence against oxidant stress is glutathione (GSH). Its oxidized form is glutathione disulphide. GSH is the major soluble antioxidant in cytosol, nuclei and mitochondria, offering protection against redox stress by acting as a co-factor for several ROS detoxifying enzymes, e.g. glutathione peroxidase, directly scavenging certain highly reactive species (e.g. OH·), and participating in the regeneration of other key endogenous antioxidants, e.g. ascorbate, vitamin E.

Another key group of endogenous ROS scavengers are the isoforms of superoxide dismutatase (SOD). These enzymes dismutate $O_2^{-}\cdot$, into O_2 and H_2O_2 at rates faster than $O_2^{-}\cdot$ can react with other potential targets [7]. There are three known SOD isoforms: the manganese-containing enzyme, SOD2 (localized to mitochondria); the copper and zinc-containing enzyme, SOD1 (localized to cytosol); and SOD3, which is present in the extracellular milieu. Knocking out SOD2 is lethal in mice, emphasizing its critical importance [7].

In addition to GSH-dependent and SOD-dependent mechanisms, other important cellular buffers against redox stress include small molecules such as ascorbate, vitamin E, carotenoids, and lipoic acid. Catalase, which catalyses the conversion of H_2O_2 to water and O_2, is also important.

Pathophysiology of I/R injury

The concept was first advanced by Jennings et al. in 1960 using a canine model of coronary occlusion. They showed that a short period of ischaemia followed by a short period of reperfusion produced as much histological damage as a much more prolonged period of ischaemia without reperfusion. For many years, experts debated whether reperfusion is independently responsible for tissue injury or simply hastens the demise of cells otherwise destined for necrosis. During the early 1980s, landmark publications led to the recognition that tissue injury caused by 'ischaemia' was also dependent on ROS production, notably $O_2^{-}\cdot$.

The McCord hypothesis and the role of XO

McCord hypothesized a central role for XO. While ATP is degraded in steps to hypoxanthine during tissue ischaemia, XDH is converted to XO, setting the stage for a burst of ROS production. On reperfusion the supply of abundant O_2 leads to oxidation of the accumulated store of hypoxanthine leading to $O_2^{-}\cdot$ formation. This hypothesis was supported by various studies showing organ protection in I/R injury utilizing intravenous SOD, molybdenum-depleted, and/or tungsten-rich diets (leading to loss of XD and XO activity) or XO

inhibitors (e.g. allopurinol, oxypurinol). Repine's group reported that XO released into the circulation after reperfusion of a previously ischaemic organ, such as the intestine, could lead to distant organ injury, e.g. lung [8]. This could be ameliorated by pretreatment with an allopurinol- or tungsten-enriched diet.

The PARP hypothesis

Single-strand breaks in nuclear DNA can activate poly(ADP-ribose) polymerase-1 (PARP-1), catalysing cleavage of NAD^+ into nicotinamide and ADP-ribose, with polymerization into branching poly(ADP-ribose) homopolymers. Simultaneously, poly-ADP ribose is degraded by poly(ADP-ribose) glycohydrolase. The concurrent actions of PARP-1 and poly(ADP-ribose glycohydrolase) constitute the functional equivalent of an NADase, thus massive activation of PARP-1 can lead to marked intracellular NAD^+ depletion.

In states of acute inflammation or after I/R, ROS and RNS, including H_2O_2 and $ONOO^-$, can induce single strand breaks in nuclear DNA, thereby activating PARP-1 and depleting cellular NAD^+/NADH content. Since NADH is the main reducing equivalent that supports oxidative phosphorylation, PARP-1 activation can markedly impair the ability of cells to utilize O_2 to support ATP synthesis. The notion that redox stress can lead to PARP-1 activation and metabolic inhibition was first articulated by Schraufstatter et al. [9]. Szabó et al. subsequently showed that both endogenous and exogenous $ONOO^-$ activated PARP-1 resulting in impaired mitochondrial respiration [10]. Genetic or pharmacological means of decreasing or ablating PARP-1 activity protected organs in various I/R injury models [7].

Role of the mitochondrial permeability transition pore

Mitochondria play a crucial role in cell death pathways. One key mechanism is the 'intrinsic' apoptosis pathway, whereby toxic events, such as overwhelming redox stress, induce translocation and integration of prodeath members of the Bcl-2 family of proteins (e.g. Bax, Bak, Bid) into the outer mitochondrial membrane [11]. Membrane permeability is increased, permitting the leakage of several pro-apoptotic proteins, including cytochrome c, Smac/DIABLO, and htrA2/Omi, into the cytosol which, in turn, activates the proteolytic enzymes, caspase-9, -3, and -8.

Severe redox stress secondary to I/R injury (or other triggers) also promotes opening of a large, non-specific channel in the inner mitochondrial membrane, the mitochondrial permeability transition pore (MPTP). MPTP opening leads to dissipation of the electrochemical gradient ($\Delta\Psi m$), normally present across the inner mitochondrial membrane, thereby decreasing ATP synthesis, further increasing ROS production, and ultimately causing swelling and rupture of the organelle. Mitochondrial rupture can lead to release of pro-apoptotic proteins and activation of the intrinsic apoptosis cascade. As the apoptosis programme requires ATP, MPTP opening of the MPTP can (somewhat paradoxically) inhibit apoptosis and instead promote necrosis.

During ischaemia mitochondria are damaged by various mechanisms, including overloading of the matrix with Ca^{2+} ions. Mitochondria, can no longer efficiently transfer electrons so components of the mitochondrial electron transport chain, notably complexes I and III, 'leak' electrons and generate $O_2^{-}\cdot$, particularly during reperfusion when abundant O_2 is available [11]. Thus, reperfusion is associated with the production of a burst of mitochondria-derived ROS.

The structure of MPTP remains controversial. A voltage-dependent anion channel (VDAC) in the outer membrane, an adenine nucleotide translocase (ANT) in the inner membrane and a protein, cyclophilin-D (CypD), in the matrix have been described. Three isoforms of VDAC are known called VDAC1, VDAC2 and VDAC3. Inhibitors of ANT, such as bongkrekic acid, CypD, such as cyclosporin or VDAC inhibitors inhibit MPTP function and protect against I/R injury. VDAC inhibitors also have been shown to block opening of the MPTP. However, the importance of the VDAC and ANT components have recently been called into question.

Role of the innate immune response

Microbial components—the so-called pathogen-associated molecular patterns (PAMPs)—are recognized by cells of the innate and acquired immune system, primarily through interaction with Toll-like receptors (TLRs) and other receptors. The interaction of a PAMP, e.g. lipopolysaccharide, with a TLR (TLR4 in this example) leads to activation of numerous intracellular signalling pathways and key cells, including macrophages and PMNs, which are recruited to the site of infection to destroy the invading pathogen and/or pathogen-infected cells. Additionally, an adaptive immunological response is initiated to produce and select specific T cell receptors and antibodies for pathogen recognition on a future occasion.

The innate and adaptive immune systems can also be activated by I/R injury. Cell and/or tissue damage leads to release of endogenous molecules, called damage-associated molecular patterns (DAMPs) or alarmins, which can activate inflammatory or immune responses. Like PAMPs, many alarmins can also interact with TLRs.

High mobility group box (HMGB)1 is an important alarmin. HMGB1 is released by necrotic, but not apoptotic, cells, and by immunostimulated macrophages, endothelial and intestinal epithelial cells. HMGB1 is both a chemotactic factor and activating agent for leukocytes, and can mediate key events in sterile inflammation. Activation of the complement system, another component of the innate immune system, has also been implicated in the pathogenesis of I/R-induced injury to the heart, intestine, kidneys, brain, and lungs. Pharmacological approaches for inhibiting complement activity, such as treatment with recombinant soluble human complement receptor type 1, have been efficacious in preclinical models.

Results from key clinical trials of interventions to ameliorate I/R injury

Unfortunately, efforts to translate our improved understanding of the pathophysiological mechanisms underlying I/R injury into interventions that clearly benefit patients have been largely unsuccessful. A few notable exceptions exist and are highlighted in the following sections.

Allopurinol

Allopurinol, which inhibits XO activity, ameliorates I/R injury in myriad animal models (*vide infra*). Apart from studies of ex vivo organ preservation solutions (not discussed here), most randomized clinical trials (RCTs) have been relatively small, mostly single-centre, and have focused on patients undergoing

cardiopulmonary bypass surgery. Pre-treatment with allopurinol before bypass provided significant benefit, as evidenced by lower mortality rate [12], higher post-operative cardiac index and a reduced need for post-operative inotropic support. Other studies, however, have reported no benefit. A recent meta-analysis of three small RCTs in perinatal hypoxia found insufficient data to determine whether allopurinol was beneficial or not [13].

Free radical scavengers

Three chemically dissimilar, but uniformly potent, free radical scavengers have been studied extensively for the treatment of stroke (Fig. 308.1). Edavarone (MCI-186), a lipophilic substituted 3-pyrazalone compound, was approved by the Japanese Ministry of Health, Labor, and Welfare in 2001 for treating acute ischaemic stroke, and was recommended as therapy by the Japanese Guidelines for the Management of Stroke 2004. A meta-analysis of clinical trials of edaravone for stroke concluded that 'edaravone appeared to increase the proportion of participants with marked neurological improvement' [14]. Phenyl-t-butylnitrone (PBN), a so-called 'spin trap', is protective in myriad animal models of I/R injury. A water-soluble derivative of PBN, NXY-059, was evaluated in a trial of 1722 patients with ischaemic stroke. While NXY-059 significantly reduced disability at 90 days, other outcome measures, such as neurological functioning, were not improved. A repeat study in 3195 patients, using a similar design, also found no difference between drug- and placebo-treated groups for any important outcome measure, including mortality or disability score at 90 days. Tirilazad (U74006F), a 21-aminosteroid devoid of classical steroid hormonal activities, can potently inhibit radical-mediated lipid peroxidation. Tirilazad and related compounds ameliorated I/R injury in animal models. However, a meta-analysis of six double-blind RCTs that enrolled a total of 1747 patients with presumed ischaemic stroke found no survival benefit and a worsening of functional outcomes [15].

Complement inhibitors

Two agents that target the complement system, namely TP10 and pexelizumab, have been investigated. Complement receptor 1 (CR1) is a cell surface glycoprotein expressed on erythrocytes, leukocytes and other cell types. CR1 inhibits both the classic and alternative pathways of complement activation. The soluble form of CR1 inhibits both complement pathways in a manner similar to that of the cell-bound protein. The recombinant form of soluble CR1, TP10, inhibits C3 and C5 activation and enhances proteolysis of activated C3b and C4b by plasma factor I. A double-blind RCT that enrolled 564 high-risk patients undergoing cardiac surgery and CPB showed no difference between TP10 and placebo in the primary composite endpoint (death **or** post-operative MI **or** requirement for prolonged support with an intra-aortic balloon pump **or** requirement for prolonged mechanical ventilation). Pexelizumab is a neutralizing humanized monoclonal antibody against C5. More than 15,000 patients undergoing treatment for ST segment elevation MI (STEMI) or coronary artery bypass graft surgery were enrolled in seven RCTs of pexelizumab. A meta-analysis showed no benefit from pexelizumab in rates of adverse events, death, MI, stroke, or heart failure [16]. Although pexiluzimab was associated with a significant (26%) reduction in risk of death after cardiac bypass surgery ($p = 0.01$), the number needed to treat was 100.

Ischaemic post-conditioning

Post-conditioning, i.e. deliberately causing short periods of ischaemia during the reperfusion phase of an I/R insult, ameliorated organ damage in various animal models. Mechanism(s) remain poorly understood, but probably involve inhibition of apoptosis, possibly by promoting activation of signalling via the phosphatidylinositol 3-kinase pathway. Several recent studies have yielded encouraging results in terms of infarct size, ejection fraction, cardiac enzyme rise, and long-term complications from post-conditioning after percutaneous coronary intervention (balloon angioplasty and stent placement) for the treatment of STEMI [17]. In contrast, negative results were reported from two other relatively small studies and one 700 patient RCT [18]. In view of these conflicting findings, the value, if any, of post-conditioning in the management of STEMI remains to be elucidated.

Therapeutic hypothermia

Hypothermia, i.e. deliberate lowering of core temperature to subnormal levels, is another therapeutic intervention extensively evaluated in various forms of I/R injury. Abundant evidence from preclinical studies support the value of therapeutic hypothermia in

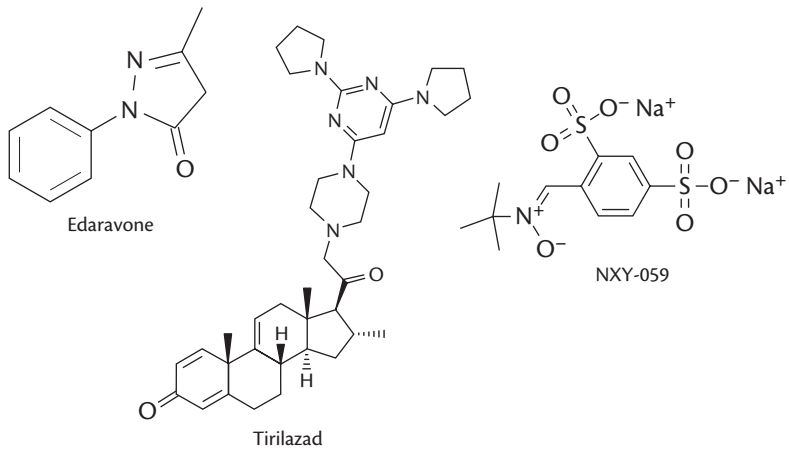

Fig. 308.1 Chemical structures of three free radical scavengers that have been evaluated in clinical trials for the treatment of stroke.

conditions including stroke, cardiopulmonary arrest and MI. Until the recent publication of negative data from a large RCT [19] induction of therapeutic hypothermia was a component of the standard management of patients, who have return of circulation, but loss of consciousness after successful resuscitation from cardiopulmonary arrest. Data are lacking from clinical trials of therapeutic hypothermia for stroke and results from several trials of therapeutic hypothermia for STEMI, mostly using endovascular cooling, have yielded largely negative results.

Cyclosporin

This compound was developed as an immunosuppressive agent in the 1970s, but is now known to exert its immunological effects by inhibiting signalling mediated by calcineurin. In 1988, cyclosporin was shown to block opening of the MPTP, acting by binding to cyclophyllin D. In various preclinical models of, treatment with cyclosporine- improved post-reperfusion myocardial performance and/or inhibited cell death. The positive results with cyclosporin in animal models of cardiac I/R injury have been supported by a small RCT of 58 patients with acute STEMI which showed superior outcome advantages [20].

CHAPTER 309

Repair and recovery mechanisms following critical illness

Geoffrey Bellingan and Brijesh V. Patel

Key points

- Critical illness represents a perpetuated state of inflammation and injury, with abnormal resolution and recovery.
- Resolution of inflammation is an active process involving a highly coordinated series of events, involving multiple molecular and cellular mediators.
- Stages of resolution and recovery involve the prevention of further insults, timely removal of infiltrated immune cells, clearing up of debris, and ultimately, recovery of tissue structure and function.
- The enhancement of proresolving mechanisms, rather than anti-inflammatory strategies may be a more amenable therapeutic strategy in critical illness.
- Abnormal resolution of inflammation may also lead to long-term functional deficits seen after critical illness.

Introduction

The ideal response to injury should ensure removal of any harmful stimuli, followed by a decline in the inflammatory response limiting damage to the host. In parallel, there should be successful repair of tissue(s) enabling return to normal structure and function. There is now convincing evidence that inflammation does not just simply 'fizzle out'. In contrast, resolution of inflammation and recovery involves a highly coordinated and actively controlled series of events. States such as sepsis and the acute respiratory distress syndrome (ARDS) show overwhelming inflammation due to disturbances in mechanisms that control the resolution of inflammation.

Injury, inflammation, and resolution

The cascade of events that govern inflammation, injury and resolution are showcased using an experimental model of resolving ARDS (Fig. 309.1) [1]. Injurious insults such as infection and acid aspiration lead to (**A**) classical activation of tissue macrophages through pathogen—and damage-associated molecular patterns (PAMPs and DAMPs). Activated macrophages release a host of pro-inflammatory mediators including cytokines, reactive oxygen/nitrogen species (ROS/RNS) and lipid mediators (**B**) (listed in Box 309.1), which upregulate cell adhesion molecules on the endothelium of the microcirculation triggering the rolling, activation, and firm adhesion of blood leukocytes (neutrophils and monocytes) (**C**). Barrier dysfunction occurs due to epithelial and endothelial disruption leading to the translocation of serum proteins and oedema (**D**). Migrated blood-derived leukocytes release opsonins (e.g. complement), which facilitate the recognition and phagocytic removal (**E**) of the offending trigger. The ideal inflammatory response should be confined to the affected region, be specific, and terminate after the injurious stimulus has been cleared, with little collateral damage.

This termination of the immune response is typically deranged in critical illness. The hallmarks for tissue recovery and resolution of inflammation can be described in three overlapping phases.

Phase 1: 'The stop signal'

First, the early phase of resolution removes the inciting stimulus, ceases further pro-inflammatory leucocyte recruitment, and promotes the reduction of pro-inflammatory mediators with a controlled anti-inflammatory response.

Increasing evidence exists that this phase of resolution is triggered earlier than previously thought. Within hours of the initial stimulus there is a switch from formation of pro-inflammatory eicosanoids (e.g. prostaglandins, leukotrienes, and platelet activating factor) to anti-inflammatory eicosanoids (including lipoxins, resolvins, and protectins). This switch is triggered by the neutrophils themselves (via neutrophil-platelet interactions) in an attempt to limit the inflammatory response (**F**). More importantly, these mediators also prevent further neutrophil trafficking, reduce vascular permeability, promote exudative monocyte entry, and the ingestion/clearance of debris and apoptotic neutrophils, which are integral to the later stages of resolution.

The ability to initiate this shutdown of pro-inflammatory leukocyte activity is an important checkpoint for the resolution of inflammation. Indeed, the resolution interval is an experimental index defined by the time taken for numbers of infiltrated neutrophils in the inflamed tissue to decline by half [2]. This decline depends upon constitutive apoptosis of neutrophils that consequently imparts a limited lifespan of ≤24 hours. Perpetuated neutrophil-mediated inflammation as a result of abnormal (delayed) apoptosis can

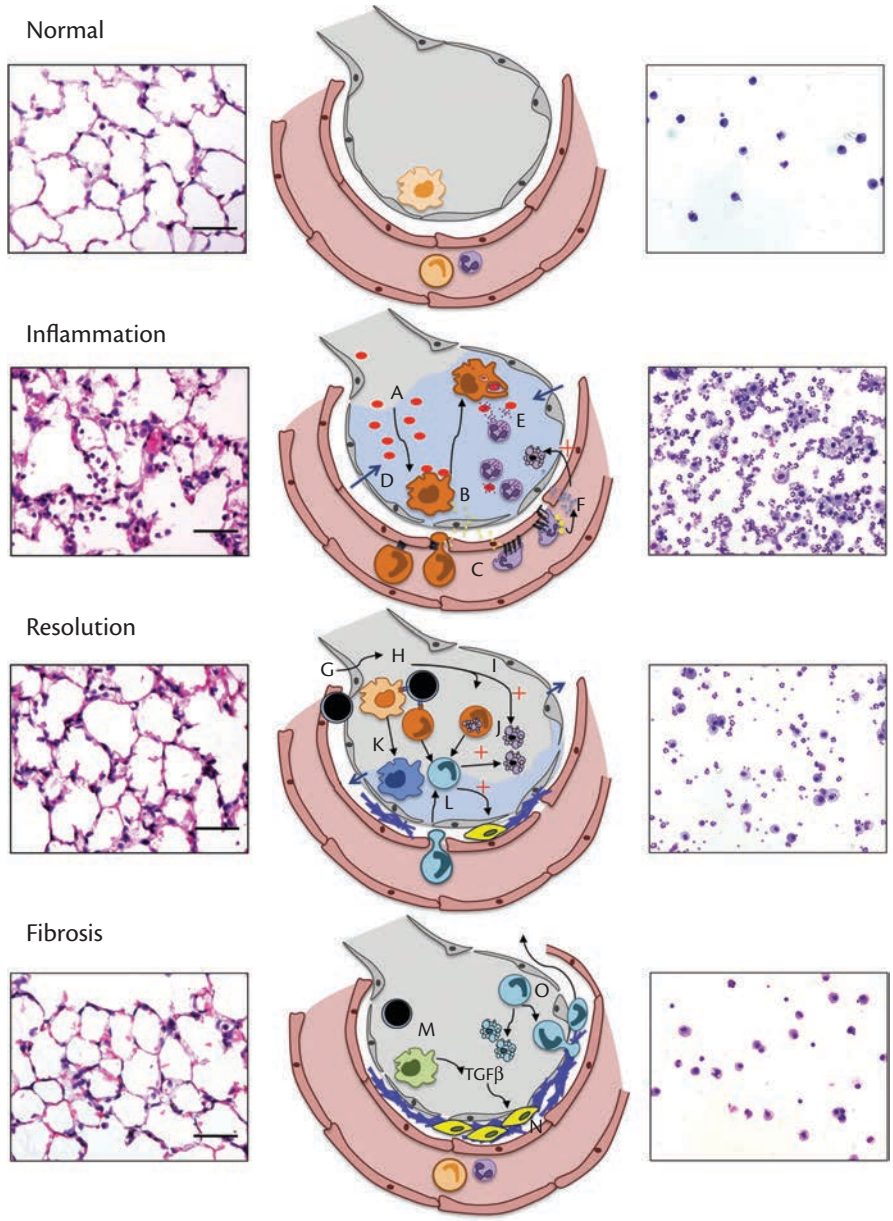

Fig. 309.1 Histology (left) and bronchoalveolar lavage cytology (right) after acid-induced lung injury to represent the events of injury, inflammation, resolution and fibrosis (middle). The events A-O are described in the main text. Scale bar represents 50 μm.

indeed be detrimental in the overzealous inflammatory processes that occur in critical illness. For example, bronchoalveolar lavage fluid from patients with established ARDS prolongs the survival of neutrophils through disrupted apoptosis [3].

Various cytokines and their receptors are implicated in this phase, including IL-1 receptor antagonist, soluble TNF receptors, IL-4, IL-10, and IL-13. One of the most studied, IL-10, blocks the synthesis of various pro-inflammatory cytokines (including IFN-γ, IL-1, TNF, IL-12) and chemokines (e.g. IL-8, CCL2), and is often released from macrophages that have changed their phenotype response having ingested debris and apoptotic neutrophils [4,5] (Fig. 309.2). IL-4 and IL-13 also influence the monocyte/macrophage phenotype by increased endocytic activity through increased expression of scavenger receptors to recognize and increase parasite killing, and stimulation of mRNA of proteins such as matrix metalloproteinases and collagen types, all of which are crucial in enhancing tissue repair and fibrosis. IL-10 and TGF-beta can deactivate monocytes and reduce expression of MHC class II molecules used for antigen presentation to cytotoxic T-cells.

Phase 2: 'Clearing up the mess'

A clearance phase of resolution is then initiated. Shortly after neutrophil infiltration into damaged/infected tissue the adaptive system is activated with T-cell infiltration (**G**). A cell–cell interaction with resident macrophages, exudative monocytes, and dendritic cells (DC) (**H**) leads to the release of mediators such as TGF-β and IL-10, promoting apoptosis of neutrophils (**I**) and their uptake by macrophages (**J**).

Box 309.1 Pro-inflammatory and proresolving mediators during inflammation.

Pro inflammatory mediators

- Coagulation products: fibrin.
- Fibrinolytic products.
- Amines: histamine, bradykinin, serotonin.
- Complement system: C3a, C5a.
- Eicosanoids: PGE_2, PGI_2, leukotrienes, thromboxane A_2, PAF.
- Cytokines: TNF, IL-1, IL-6.
- Chemokines: IL-8, CCL-2.
- Cell adhesion molecules: E-/P-selection, ICAM.
- Reactive oxygen species.
- Reactive nitrogen species: NO, peroxynitrite.

Anti-inflammatory/proresolving

- Cytokines: TGFβ, IL-10, IL-1RA, IL-6.
- Eicosanoids: lipoxins, resolvins, protectins.
- Transcription factors: NF-κB, FoxP3.
- Cell adhesion molecules: $\alpha_v\beta_3$ integrin, thrombospondin, phosphatidylserine.
- Glucocorticoid/annexin A1 pathway.

Cell death can proceed through a spectrum ranging from the programmed form (apoptosis) to a less ordered process (necrosis). Apoptosis is the ideal way for cells to die as it prevents activation of a pro-inflammatory response against intracellular molecular patterns released with necrotic cell death. Neutrophil apoptosis can be modulated by various agents, including granulocyte-macrophage colony-stimulating factor, lipopolysaccharide, and TNF-alpha, all of which are upregulated in sepsis and initially delay apoptosis. Mechanisms that dictate neutrophil apoptosis are beyond the scope of this chapter, but it is important to recognize that apoptotic neutrophils are non-functional, yet retain their histotoxic cellular constituents.

More importantly, apoptotic cells upregulate recognition signals facilitating their uptake by macrophages. These include thrombospondin-1, annexin-1, phosphatidylserine, and lysophosphatidylcholine. Indeed, mechanisms through which apoptotic cells signal their own disposal is crucial for the macrophage switch from pro-inflammatory to pro-resolving phenotypes (**K**) [6]. This plasticity to their environment makes macrophages vital regulators and effectors of local immune responses (Fig. 309.2). Influx of blood-derived monocytes (**L**) increases total tissue macrophage numbers to help initially fight the inflammatory battle, but then to subsequently switch their phenotype to clear debris and apoptotic neutrophils (**J**).

After clearance of neutrophils and debris, T-cells continue to be present, producing T_H2 cytokines such as IL-4 and IL-13 that regulate resident tissue macrophages (**M**). As a consequence, these resident macrophages take on a wound-healing phenotype leading to myofibroblast proliferation and collagen deposition (**N**). The extent is most likely dependent on the severity of damage. The fate of these exudative macrophages is still uncertain, but there is

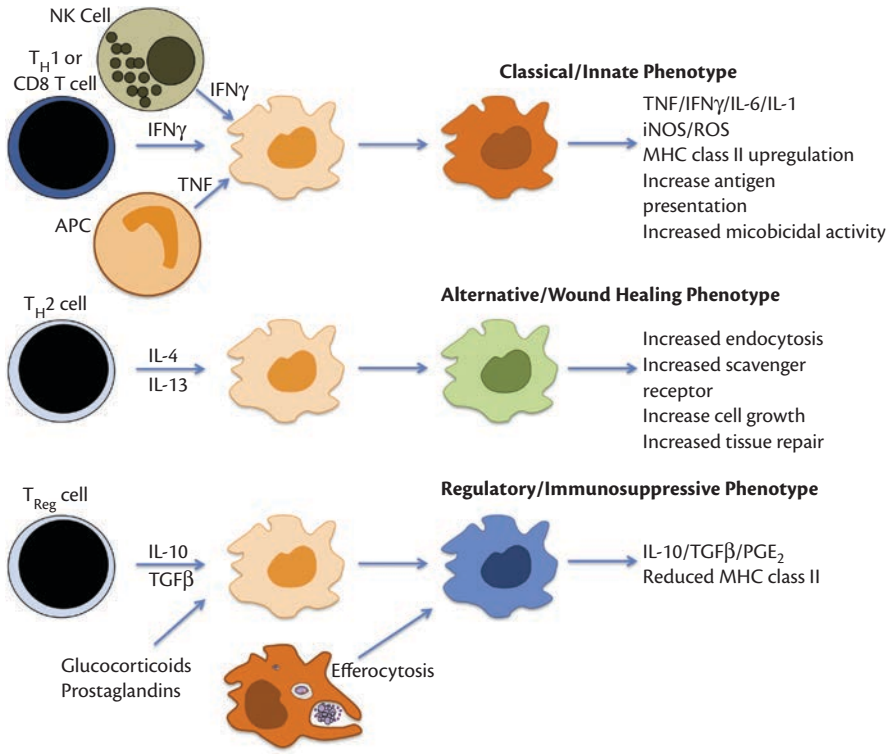

Fig. 309.2 The interactions and plasticity of activated macrophages.

evidence to suggest that they too undergo constitutive apoptosis, and that this may occur either locally or after migration to local lymph nodes (**O**).

Phase 3: 'Re-establishing order and function'

So, once the battlefield has been cleared, we return to the overall goal, i.e. functional recovery and catabasis, which requires recovery of cellular bio-energetics, controlled apoptosis and proliferation of damaged parenchymal cells. It remains unclear as to why certain patients heal while others repair through fibrosis. For instance, ARDS can lead to a protracted fibrotic phase. It is also clear that fibrosis occurs much earlier (at the onset of inflammation) and, factors such as TGF-β that regulate resolution, also influence fibrosis. Increasing evidence suggests that parenchymal cell death may dictate acute and chronic fibrotic responses. Hence, while leukocyte apoptosis is crucial for inflammatory resolution, parenchymal apoptosis also influences whether the tissue heals or is scarred. Furthermore, inflammation can worsen parenchymal cell death perpetuating fibrotic responses.

Translational avenues promoting resolution therapies in critical care

It is unclear why an initial focused inflammatory response goes awry in critical illness. There are significant challenges to bedside translation of biological therapies to treat conditions, such as sepsis and ARDS. A major hurdle is that patients do not present at time zero and often have overwhelming inflammation on presentation.

Prevention is better than cure

Much of the recent improvement in mortality is a result of improved delivery of care attenuating perpetuated inflammation as a result of iatrogenic insults, such as ventilation, invasive monitoring and nosocomial infection. The first significant breakthrough was the use of low tidal volumes to prevent iatrogenic ventilator-induced lung injury.

Anti-inflammatory strategies

A major focus of research over the past few decades has been to elucidate effective anti-inflammatory strategies. This has been fraught with difficulty, as such agents may promote an immunocompromised state with augmentation of an uncontrolled 'compensatory anti-inflammatory response syndrome'. For instance, low levels of pro-inflammatory mediators such as nitric oxide, TNF-alpha and IL-6 are pro-resolving and reparative. This may explain why the bench-to-bedside translation of cytokine-based therapies in the absence of mechanistic insights has increased mortality in some sepsis studies. The temporal relationship between this initial anti-inflammatory response and the progression of the first and second phases of resolution may determine susceptibility to nosocomial infection.

Enhancing active resolution phase mediators

The notion of active resolution mechanisms is so recent that well-known agents, such as glucocorticoids and aspirin have been labelled as anti-inflammatory, whereas in actual fact, they are significantly proresolving in nature. For instance, glucocorticoids delay neutrophil apoptosis yet influence the macrophage phenotype and have important resolving effects through induction of annexin A1. Overall, this leads to reduced pro-inflammatory cytokine release, reduced neutrophil trafficking and thus, overall, promotes the resolution of inflammation [7].

More recent advances have discovered the lipoxin, resolvin, and protectin classes of the eicosanoid family, which serve to actively promote homeostasis and resolution of inflammation. For instance, lipoxin A2 restitutes epithelial barrier function in experimental ALI [8], while resolvin D2 improved survival in a model of polymicrobial sepsis [9]. Hence, enhancing the effects of endogenous proresolving mediators may prove a better therapeutic option. Interestingly, aspirin influences resolution within hours of the onset of inflammation through the production of lipoxin A4 precursors.

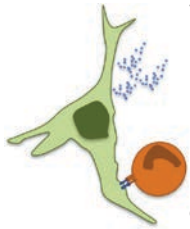
In addition to molecular mediators, cellular mediators also direct the path through which inflammation may proceed. This involves a concerted cross-talk between the acute innate and the regulatory adaptive arms of the immune system. More recently, regulatory T-cells, which are identified by the cell surface markers CD4, CD25 and the transcription factor FoxP3, have recently been shown to reduce pro-inflammatory cytokine production, increase TGF-β levels and increase neutrophil apoptosis in experimental ALI, and were also found to be present in human ALI [10].

Further insights into mechanisms through which infiltrating cells die have also improved understanding as to how leukocyte apoptosis can be manipulated to promote resolution. There is potential scope for manipulating neutrophil apoptosis and enhancing their uptake by macrophages, thus promoting proresolving reparative macrophage phenotypes. Additionally, the diagnostic evaluation of the macrophage phenotype may give insights into the immune status of patients allowing the implementation of personalized therapies to promote resolution.

Most excitingly, the future role of cell therapy has been significantly fuelled by the application of mesenchymal stem cells (MSCs) in experimental models of critical illness (Fig. 309.3). The heterogeneous and plastic nature of these cells, allowing them to adapt and respond appropriately to various inflammatory milieus in a reparative fashion, has shown significant therapeutic potential. MSCs have improved experimental ALI, bacterial pneumonia, and Gram-negative sepsis. Unfortunately, the application of MSCs in critical illness is still relatively devoid of mechanisms. There is emerging evidence that these may include paracrine effects such as secretion of growth factors (e.g. keratinocyte growth factor) and anti-bacterial proteins, as well as immunomodulatory effects on circulating monocytes, tissue macrophages and T-cells [11].

Aiming for full functional recovery

Mitochondrial dysfunction is integral to the pathogenesis of sepsis and multi-organ failure, and can be induced by various soluble mediators including nitric oxide and reactive oxygen species (ROS), as well as through activation of apoptosis signalling. Mitochondrial biogenesis most likely occurs at a transcriptional level involving nuclear regulators such as PGC-1alpha [12], which integrates multiple external signals including ROS and reactive nitrogen species (RNS). Furthermore, endocrine factors, such as thyroid hormones also influence mitochondrial recovery. Hence, strategies aimed at 'jump-starting' mitochondria are attractive as repair and recovery would undoubtedly require energy [13]. Another approach involves mesenchymal stem cells that have more recently been visually captured to adopt a 'trojan horse' strategy to deliver mitochondria, packaged in microvesicles, to injured alveolar epithelial cells, improving tissue bioenergetics, and thereby preventing injury and promoting recovery [14].



Soluble mediators released by MSCs

- IL-6 inhibits neutrophil respiratory burst and prevents DC maturation
- Stem cell factor
- GM-CSF
- VEGF promotes angiogenesis
- Hepatocyte growth factor
- Adrenomedillin
- PGE_2 inhibition of proliferation and cytotoxicity of NK cells

Cellular interactions with MSCs

- Monocytes – inhibited differentiation into mature DCs.
- DC – reduced TNF production and reduced antigen presentation.
- Reduces CD8 T-cell cytotoxicity.
- DC induced IL-10 production increases regulatory T-cell differentiation.
- Parencymal cells – mitochondrial transfer.

Fig. 309.3 The heterogeneous resolving and reparative potential of mesenchymal stem cells.

Conclusion

Despite discharge from critical care and hospital, many patients continue to have significant underlying physiological and chronic organ dysfunction. These have been particularly highlighted in ICU-acquired weakness post-ARDS [15], the risk of chronic kidney disease after sepsis-induced AKI [16], and neuropsychiatric complications including post-ICU delirium [17]. Future work to investigate the extent of underlying chronic immune activation and its resolution in patients post-ICU may uncover insights into the full temporal course of ICU-acquired inflammation.

CHAPTER 310

Neural and endocrine function in the immune response to critical illness

Gareth L. Ackland

Key points

- Bidirectional links between neurohormones and immune effectors contribute essential mechanisms that limit organ dysfunction.
- The persistence of the 'fight or flight' response is increasingly seen as a detrimental feature of critical illness.
- Iatrogenic factors introduced by critical care therapy may exacerbate neurohormonal dysregulation.
- Neurohormonal responses are dysregulated in chronic diseases, predisposing patients to an increased risk of sepsis and multi-organ failure.
- Off-target local immune effects may explain the failure of clinical trials aimed at altering systemic neurohormonal physiology.

Introduction

The neurohormonal physiological response is pivotal for effective defence against a range of insults that trigger critical illness, in an effort to maintain homeostasis. The acute and chronic phases of critical illness are characterized by distinct neurohormonal and immune profiles. While Cannon pioneered the concept that stressors elicit a coordinated response to maintain homeostasis, the advent of modern critical care has generated an entirely new (patho)physiological embodiment involving both direct and off-target effects of neurohormonal control on immune function, and vice versa [1]. Selye provided a prescient conceptual biological framework for established critical care states. He suggested that maladaptive responses to triggers of critical illness follow an initial phase of alertness, leading to habituation processes that may either not resolve, or become dysregulated. In turn, this leads to a prolonged or irreversible pathophysiological phenotype (Fig. 310.1).

The first phase of the effector response requires detection of afferent signals through various non-exclusive pathways [2]. Peripheral immunogenic stimuli activate neurons of the circumventricular organs, via fenestrated endothelium, or trigger phylogenetically-conserved immune signalling pathways in 'hard-wired' components of the afferent autonomic nervous system that detect both pathogen- and danger-associated molecular patterns (Fig. 310.2). The molecular mediators of acute critical illness are detected by both the carotid body and vagus nerves, which transduce inflammatory mediators and/or pathophysiological derangements into neural signals to key central nervous system substrates, such as the nucleus tractus solitarius. Afferent neural pathways mediated by pain (c-fibres) may also play an important role in conveying molecular information from damaged remote tissue, initiating CNS autonomic reflex neuro-immunomodulatory mechanisms.

The medial parvocellular region of the paraventricular nucleus within the hypothalamic pituitary axis integrates various afferent signals, or through direct/indirect neuronal activation via a pathologically compromised blood–brain barrier, to trigger the release of glucocorticoids [3]. Corticotropin-releasing factor is released into the portal circulation of the anterior pituitary gland, stimulating the systemic secretion of the melanocortin adrenocorticotrophic hormone by pituitary corticotrophs. Concomitantly, neural reflex circuits are activated that innervate the principal organs of the immune system, including spleen, lymph nodes, and reticuloendothelial organs.

The adrenal gland consists of two functional units—the medulla and cortex. Production of sympathetic system hormones (epinephrine and norepinephrine) is localized within the medulla. The adrenal cortex consists of three zones:

- The superficially located zona glomerulosa produces mineralocorticoids (aldosterone and, to a lesser extent, corticosterone).
- The zona reticularis produces androgens (dehydroepiandrosterone, dehydroepiandrosterone sulphate, and 11β-hydroxyandrostenedione).
- The zona fasciculata generates glucocorticoids (cortisol and cortisone).

Once adrenocorticotropic hormone (ACTH) reaches the zona fasciculata, cortisol and cortisone are released into the bloodstream to limit synthesis of pro-inflammatory mediators by various effector cells. The neurohypophysial hormones vasopressin and oxytocin maintain cardiovascular and metabolic homeostasis through central and peripheral sites of action. Arginine vasopressin stimulates ACTH secretion weakly, but strongly promotes CRH action.

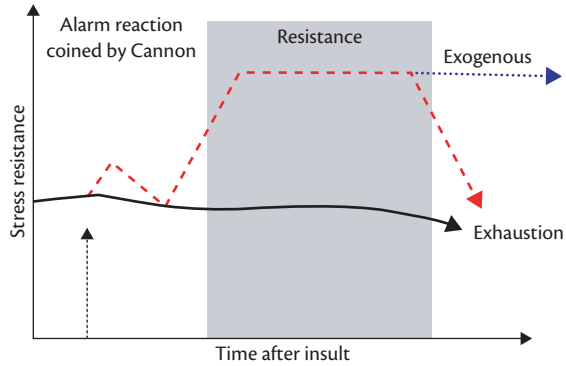

Fig. 310.1 Conceptual framework for neuroendocrine dysregulation in response to critical illness. Acute pathological insults trigger a coordinated neuroendocrine alarm reaction, as described by Cannon. In chronic pathologies characterized by persistent neuroendocrine activation, e.g. heart failure, the alarm reaction is muted (solid black line), leading to rapid exhaustion of cellular signalling in the presence of dysregulated pathophysiological control mechanisms (e.g. hypocortisolaemia). In patients without major chronic morbidity (dashed red line), the alarm reaction triggers a coordinated neuroendocrine response, which may become exhausted in the face of additional or iatrogenic insults, or downregulation of cellular signalling and metabolic pathways, leading to immunosupression. Apparent continued resistance (dotted blue line) achieved by exogenous delivery of various neuroendocrine modulators may perpetuate the resistance phase, often at the expense of off-target effects including immunosuppression.

Catecholamines, angiotensin II, serotonin, and vasoactive intestinal peptide also stimulate ACTH secretion.

The dysregulation of this initial neuroendocrine response, and the persistent failure to regulate the reciprocal exchange of signals between the immune, endocrine, and nervous systems that is required for effective immunoregulation and central nervous system function, is associated with the establishment of chronic critical illness [4]. While acute mechanisms regulating neuroendocrine control of immunity are becoming clearer, the habituation phenotype is less well understood. Furthermore, the acutely critically-ill patient frequently presents with this chronically disordered neuroendocrine phenotype prior to the onset of further acute deterioration as a feature of underlying co-morbidity: established neurohormonal dysregulation is a core feature of cardiac failure, diabetes mellitus, and malignancy.

Central and cellular autonomic regulation of immunity

Immunomodulatory neurotransmitters rapidly fine-tune the spatial and temporal control of innate and adaptive immune cellular function by specific molecular mechanisms. Catecholamines modulate immune function through both local cellular and neural origins. In addition to catecholamines derived from the adrenal medulla and presynaptic neurons, T lymphocytes, macrophages, and neutrophils synthesize and release catecholamines [5]. Autocrine/paracrine regulation by such diverse effectors provides a complex catecholaminergic influence on inflammatory mediators. Some of the deleterious effects of acute sympatho-excitation may result from direct tissue injury releasing danger-associated molecules, for example, from cardiomyocyte injury. While experimental and clinical models provide conflicting results, the detrimental effects of hyperacute and/or prolonged beta-adrenergic receptor stimulation may be targeted to ameliorate dysglycaemia, and hepatic and immune cell generation of inflammatory mediators. Sympatholysis with alpha-2 agonists, such as the sedative dexmedetomidine, reduces systemic inflammation, while a similar potential protective role for beta-1 blockade beyond cardioprotection is also plausible [6]. Consistent with the deleterious effects of catecholamines, dopamine predominantly exerts immunosuppressive effects, including inhibition of phagocytic chemotaxis and impaired T cell proliferation. The lack of clinical benefit with beta-2 agonists in acute lung injury, despite

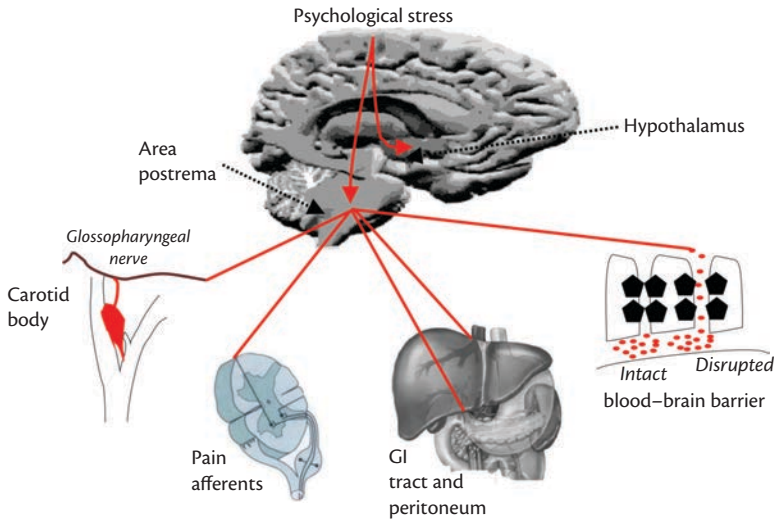

Fig. 310.2 Afferent detection by the neuroendocrine system of inflammation. Acute critical illness is detected by both central and peripheral substrates. The carotid body chemoreceptor, vagus nerve, and pain afferents nerve can directly detect cytokines. The carotid body can also detect neurohormones, danger-associated molecular patterns, and metabolic dysregulation. The area postrema and other circumventricular organs (characterized by their extensive vasculature and lack of a normal blood–brain barrier) permit inflammatory mediators to central nervous system neuroendocrine responses directly, as does breakdown of the blood–brain barrier. Psychological stress, a common feature to acute critical illness regardless of aetiology, also drives neuroendocrine activation.

cellular anti-inflammatory effects, illustrates the complex interplay between sympathetic modulation of immunity and off-target effects.

Parasympathetic neuromodulation

Similar to catecholamines, parasympathetic neurotransmitters innervate immune cells following both neural and local immune cell release [7]. Upregulation of endogenous acetylcholine synthesis in mononuclear leukocytes occurs following pathophysiological insults in vivo. Through nicotinic alpha-7 receptors, acetylcholine reduces the release of pro-inflammatory cytokines by human macrophages via inhibition of NF-κB and Janus kinase (JAK) and Signal Transducer and Activator of Transcription pathways (JAK–STAT). Human peripheral blood lymphocytes also possess M2-M5 muscarinic cholinergic receptors, in addition to the full range of neuronal cholinergic synthetic machinery. The activation of neural-immune reflexes appears to be a strongly conserved evolutionary mechanism to enable rapidly controlled immune responses to pathogens, chiefly through the release of acetylcholine from the vagus nerve to attenuate the release of pro-inflammatory mediators [8]. Central activation of the peripheral anti-inflammatory actions of cholinergic ligands, mediated by the vagus nerve, limit the pathological sequelae of a range of pathologies that leads to acute critical illness. Activation of central nervous system pathways by distant tissue injury or inflammation results in efferent neural regulation of infiltrative immune cell function through diverse signalling and effector molecules acting through the cholinergic anti-inflammatory pathway. Adrenocorticotropin (ACTH-1–24), another melanocortin endogenously produced from pro-opiomelanocortin in the anterior pituitary gland, reverses organ dysfunction after haemorrhagic shock, the benefit of which is lost in vagotomized animals [9]. Ghrelin is an endogenous orexigenic neurohormone produced chiefly by gastric endocrine cells [10], but also within the hypothalamus. Ghrelin inhibits pro-inflammatory cytokine production in experimental intra-abdominal sepsis. This anti-inflammatory effect is abrogated by surgical vagotomy, which is consistent with the potent pro-kinetic properties of ghrelin. However, as with many of these neural-immune interactions, ghrelin also directly inhibits cytokine release from monocytes and T cells. Several, as yet unidentified, clinically relevant triggers are likely to contribute to the vagal immunomodulatory release of acetylcholine, including gut-mediated afferent pathways through which enteral lipids release cholecystokinin [11].

The loss of parasympathetic activity in critically ill patients is associated with increased mortality. The vagus nerve also releases vasoactive intestinal peptide (VIP), a potent anti-inflammatory molecule that promotes Th2 cytokine production while reducing proliferation of activated Th1 cells [12]. Macrophage phagocytic activity, migration, and release of nitric oxide and prostaglandins are inhibited by VIP. The principal cyclic AMP/protein kinase A-mediated anti-inflammatory pathway activated by VIP is shared by other non-related neuropeptides, including pituitary adenylate cyclase-activating polypeptide, urocortin, adrenomedullin, cortistatin and ghrelin, all of which are GPCR-ligands produced by various immune cells. The pleiotropic immunomodulatory properties of these neuropeptides, including direct antibacterial actions in the case of adrenomedullin and ghrelin, and the induction of regulatory T cells that suppress activity against autoreactive T cell effectors, suggests that complex time and location specific functional changes drive the development, resolution and persistence of critical illness [13].

Hypothalamic regulation of immunity

Under normal conditions, glucocorticoids are secreted in a pulsatile fashion, driven by circadian and ultra-radian patterns in hypothalamic pituitary neuronal activity. Once released from the adrenal cortex, apparently normal or frequently elevated circulating levels of glucocorticoids may fail to execute normal physiological actions due to the development of glucocorticoid resistance. Reduced expression or binding affinity of glucorticoid receptor, and interference by other transcription factors may impair counter-regulatory control of the immune response. Epigenetic changes in the glucorticoid receptor gene, precipitated by common comorbidities including chronic exposure to inflammation and exogenous glucocorticoids, induce glucocorticoid resistance. Acute infections, including bacterial toxins, also directly impair glucocorticoid receptor function [14].

Glucocorticoids exert an ubiquitous, anti-inflammatory effect on immune function, driving a Th2 adaptive immune phenotype and suppressed cellular immunity characterized by decreased interferon-γ synthesis and promotion of interleukin-4 secretion. This anti-inflammatory profile extends to reducing adhesion molecule expression on endothelial cells. Consistent with this immunosuppressive phenotype, the CORTICUS trial in septic shock patients demonstrated that exogenous supplementation with hydrocortisone increased the risk of subsequent infection and failed to reduce mortality [15].

Leptin

Glucocorticoids are also potent regulators of leptin expression, an adipocyte-secreted hormone that links nutritional status with neuroendocrine and immune function. Leptin reduces cortisol synthesis by downregulating the steroid-producing enzyme cascade in the adrenal cortex, and also counteracts glucocorticoid-induced apoptosis of lymphocytes. Circulating leptin levels increase early during infection and inflammation, with direct stimulatory effects on chemotaxis and bactericidal capacity in phagocytes, enhanced production of pro-inflammatory cytokines, and the promotion of survival of thymic T cells accompanied by a switch to Th1-cell immune responses characterized by IFN-γ and TNFα secretion [16]. Acute starvation and reduced caloric intake, common features of both critical illness and comorbidities that predispose to its development, result in leptin deficiency and impaired immunity. Genetic ablation of leptin increases mortality in experimental murine sepsis, chiefly through impaired neutrophil function. Exogenous leptin administration can restore immune competence, reinforcing the link between energy homeostasis and immune function. Compatible with a critical neural mechanism, genetic rescue of leptin signalling specifically within the CNS improves mortality and dampens inflammation following experimental sepsis. Notably, acute elevations in plasma leptin that may occur at the onset of critical illness contrast with the suppression of leptin in established critical illness.

Vasopressin

Preprovasopressin is synthesized within magnocellular neurohypophyseal neurons, but stored and released from axonal

terminals in the posterior pituitary gland. Vasopressin is synthesized as a prohormone, which is then cleaved to form the mature active hormone. The release of vasopressin is triggered by hypotension and hyperosmolality of extracellular fluid, both familiar clinical features of acute critical illness. Regulatory changes in synthesis, release, and metabolism control serum levels of vasopressin. Feedback to the corticosteroid axis is mediated by the AVPR1b receptor, the stimulation of which releases ACTH. Thus, vasopressin and corticotrophin-releasing hormone synergistically promote ACTH release, albeit through distinct cellular signalling. This accounts, in part, for the preservation of vasopressin stimulation of corticotrophic cells in response to increased cortisol levels, in contrast to concomitant downregulation of the corticotropin-releasing hormone/ACTH response. A further bidirectional control mechanism is conferred by corticosteroids increasing vasopressin mRNA, with the preservation, or restoration, of circulatory pressor responses to vasopressin. Interestingly, the Vasopressin and Septic Shock Trial (VASST) study suggested a clinically relevant, physiological interaction between the vasopressin-corticosteroid axis, since low-dose vasopressin infusions combined with corticosteroid treatment decreased mortality compared to corticosteroids plus norepinephrine [17]. In established critical illness, including sepsis, vasopressin receptor expression is downregulated.

Consistent with the remarkable parallels between neural and cellular immunoregulatory control by many neurohormones, vasopressin is expressed and release from immune cells, including T cells, B cells and monocytes/macrophages [18]. Furthermore, vasopressin interacts with the CRH/ACTH axis within immune cells to potentiate CRH-induced ACTH release from peripheral blood monocytes. Pulmonary inflammation in experimental sepsis is decreased by administration of vasopressin. However, the precise contributions of systemic (particularly circulatory) effects of vasopressin and local immune actions remain unclear.

Conclusion

The complex, bi-directional interplay between neural and humoral influences on immune function impacts on the development and resolution of critical illness. There is increasing recognition that apparently acutely beneficial neurohormonal anti-inflammatory mechanisms may become deleterious during the progression to established critical illness. The loss of immunoregulatory function through impaired CNS and local cellular signalling, combined with the dysregulation of counter-regulatory mechanisms between various neurohormones, is likely to underpin several key features of the chronic critical illness phenotype.

CHAPTER 311

Adaptive immunity in critical illness

Sean F. Monaghan and Alfred Ayala

Key points

- Genomic responses after critical illness simultaneously include changes to the innate and adaptive immune responses, thus suggesting they are not unique events, but intertwined.
- B and T cells play a critical role in the development of many critical illnesses.
- Human lymphocyte antigen (HLA) is a biomarker implemented in critical illness that bridges the innate and adaptive immune response.
- Immune modulating proteins, such as CTLA-4 and PD-1, lead to alterations in the adaptive immune response in critical illness.
- Targeted immune modulating therapies may reverse the immune suppression seen after critical illness. They can target the adaptive immune response potentially leading to improved outcomes.

Normal adaptive immunity

Adaptive (acquired) immunity is an evolutionarily young system that appears to be restricted to vertebrates. It relies on the function of recombinase (RAG) genes for somatic recombination of gene segments that code for antigen receptors, i.e. novel immunoglobulin (Ig) by/on B-lymphocytes and/or unique T-cell receptor (TCR) molecules on T-lymphocytes. Clonal distribution/selection from randomly generated/highly diverse repertoire of specificities allows for development of selective 'memory' (vaccination). This 'memory' is in the form of specific antibodies (humoral immunity) to a given microbe (vaccine target) and/or selective cytotoxic effector lymphocytes (cell-mediated immunity) against viral and/or cancer cells (tumour proteins or non-self-proteins). The development of such memory allows for selective targeting of specific pathogens (especially upon their re-appearance), as well as the host cells infected with them, thereby leading to their rapid clearance via orchestrated effector systems.

Importantly, the activation/initiation of an adaptive immune response is intimately linked to activity and function of cellular components of the innate arm of the immune response. This is because microbial pathogens and their respective proteins must be captured/cleared (phagocytosed) by antigen-presenting cells, such as macrophages, dendritic cells, etc., and those pathogen proteins dissociated/fragmented and presented to CD4 T cells in a process called antigen presentation (Fig. 311.1). Typically, after such a microbial challenge, there is an initial expansion and differentiation of the CD4+ T-lymphocyte/cell into a T-helper-type 1 (Th1) cell. This supports not only the selective development of humoral and/or cell-mediated immune memory required to clear the foreign pathogen/antigen providing sterile immunity, but also for ensuring the innate immune system adequately handles the initial insult [1]. However, over time, even as a memory response is developing, there is a shift from the Th1 response toward a Th2 response that is orchestrated by sub-populations of 'regulatory' CD4+ T cells. The best known of these cell types are the Th17 and T regulatory cell subpopulations (Fig. 311.1) [2]. It is important to appreciate that, as foreign antigens are processed by macrophages/dendritic cells and presented to cells of the adaptive immune system, a Th2 (anti-inflammatory) response allows the development of memory of the event [3].

From a temporal/theoretical perspective the adaptive response was thought to occur in a sequential manner after the innate response. However, recent genomic studies of severely-injured patients have shown that both systemic inflammatory response syndrome (SIRS) and compensatory anti-inflammatory response syndrome (CARS) involve both innate and adaptive systems, and appear to occur simultaneously during critical illness [4].

Adaptive immune cells in critical illness

Although changes in total white blood cell count and neutrophils have been previously described, little has been written specifically on the role of lymphocytes in critical illness. The typical response for leukocytes and neutrophils are elevations in order to respond to the acute insult. In trauma patients who survived at least three days, three distinct patterns of lymphocyte (T and B cells) expression are noted. One-third never alter their lymphocyte count. Most, however, suffer a loss of lymphocytes (lymphopenia), of whom half show a recovery of lymphocyte count to normal levels within 4 days whereas the other half remain lymphopenic and have an increased mortality at 21 days. This inability of the critically ill patient to replenish cellular components of the adaptive immune response, such as T and/or B cells, suggests a need to retain such immunological capacity if the individual is to survive [5]. The accepted explanation for loss of these cells is through the process of lymphoid apoptosis.

From a functional perspective the development of immune suppression/anergy in critically ill patients (while not a routinely

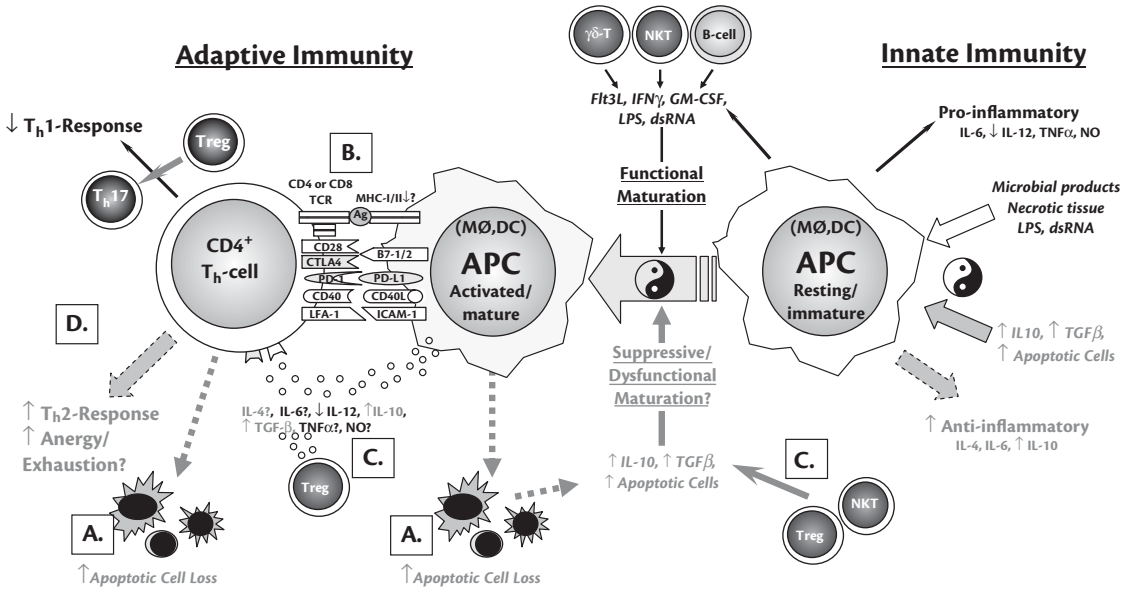

Fig. 311.1 The antigen presenting cell (APC, which could be a dendritic cell [DC] or macrophage/monocyte [MØ]):T cell interaction plays a major role in determining the type of T lymphocyte immune response that predominates following an antigen challenge/presentation. This is highly dependent on initial stimuli present at the time of APC maturation/activation. On the one hand, inflammatory stimuli such as microbial products may induce pro-inflammatory cytokine production by DC/MØ s (IL-12), as well as up-regulation of co-stimulatory receptors on their surface (B7–1/2). This may lead to a shift towards the Th1 type of immune response. On the other hand, anti-inflammatory/deactivating stimuli may induce incomplete maturation of DCs, their production of anti-inflammatory cytokines (IL-10, TGF-β, etc.) and expression of regulatory receptors such as PD-L1 at their surface. This type of stimulation may rather induce a Th2 type of immune response; this latter quiescent/suppressive state is often the default condition for the APC normally. After sepsis, APCs exhibit several alterations of both their phenotype and function: (A) increased apoptosis of both CD4 T-cells as well as mature/activated and immature/resting DC/MØs; (B) changes in surface molecule expressions (e.g., ↑co-inhibitory molecules vs. ↓co-stimulatory molecules); (C) changes in cytokine production, and; (D) impairment in capacity to induce Th1 type/pro-inflammatory T cell activation (reduced Cell-Mediated Immune responsiveness). Other Abbreviations: Flt-3L, Fms-like tyrosine kinase ligand 3; GM-CSF, granulocyte-macrophage colony stimulating factor; LPS, lipopolysaccharide.

measured outcome) has been described thirty years ago [6]. While apoptotic cell loss was identified as a contributor to this response, there are several other secreted and/or cell-associated mediators and regulatory cell types that also contribute to this state of immune suppression (Fig. 311.1)).

In patients with sepsis, the role of the adaptive immune cells is ever-expanding. The innate and adaptive responses were previously considered to be distinctly separate. However, both B and T cells (and their subtypes) are now recognized to play a prominent role in the clearance of pathogens (innate immune process) and the transition to the adaptive response. CD4+ cells, particularly the Th1 subset, are key players in the clearance of pathogens by providing cytokines, and these are known to undergo apoptosis in sepsis [7]. Spleens from patients who died from sepsis show a decrease in CD4 and CD8 cells; this correlates with data seen in trauma patients, further implicating the role of adaptive immune cells in sepsis [8].

At the far end of the spectrum of critical illness is end-organ failure such as acute respiratory distress syndrome (ARDS). Like sepsis, this was once thought to be caused only by an uncontrolled innate immune response. Again, recent research has demonstrated a role for the adaptive immune response in ARDS. In an animal model (haemorrhagic shock followed by polymicrobial sepsis via caecal ligation and puncture), CD4 cells were specifically recruited to the lung and this was regulated by T regulatory cells [9]. In human acute lung injury, T regulatory cells also appear to play a role in the pathophysiology of the end-organ disease (Fig. 311.1)) [10].

Immune modulating proteins in the adaptive immune system

Although the impact of cell types from the adaptive response have been studied in critical illness, numerous molecules such as cytokines, steroids and catecholamines have been studied extensively regarding their role in critical illness. Much of the work has focused on the shift towards a Th2 response, particularly in sepsis (Fig. 311.1)). The cytokines interleukin (IL)-4 and IL-13 shift the immune system towards the Th2 response. In addition soluble receptor antagonists, such as tumour necrosis factor (TNF) and IL-1, can block the primary function of the cytokine (Th1 response for TNF and IL-1), thereby shifting to the adaptive Th2 response [11]. Catecholamines and steroids (both endogenous and exogenous) shift the immune system towards a Th2 response [12].

Recent work has focused on specific cell-surface proteins that alter the immune response. Human leukocyte antigen (HLA) is the monocyte protein that presents antigens to the T cells, and is the bridge between the innate and adaptive immune response. HLA is decreased in patients who die from sepsis [8], however its utility as a biomarker has been questioned even though patients with critical illness have decreased levels of HLA [13].

As an appropriate adaptive immune response to a foreign antigen requires the T cell to receive proper co-stimulation during antigen presentation, there has been growing interest in understanding how cell-surface co-stimulatory molecules are antagonized by

co-inhibitory cell surface molecules such as CTLA-4 and PD-1 (Fig. 311.1)). These have been shown in other disease states to have the capacity to produce a state of T and B cell anergy/exhaustion that looks similar to what is encountered in the critically ill. CTLA-4 levels in human sepsis correlated with CD4 cell apoptosis [14]. In mice who underwent caecal ligation and puncture to model polymicrobial sepsis, increased expression of CTLA-4 was seen on adaptive cells; when CTLA-4 antibodies were given survival was improved [15]. Interestingly, this survival benefit was seen in a dose-dependent manner where survival was improved at low dose, but worsened with high doses. This finding speaks to the delicate balance of the immune system in critical illness.

In critically-ill surgical patients (from either trauma or surgical stress), PD-1 expression was significantly increased on T cells in those patients with severe physiologic dysfunction as noted by an APACHE II score >20 [16]. In an animal model of sepsis (caecal ligation and puncture) PD-1 expression was increased on adaptive immune cells while administration of an anti-PD-1 antibody improved survival [17]. Survival was also increased in mice lacking PD-1 who underwent caecal ligation and puncture compared with wild type animals. However, this benefit was attributed to the expression of PD-1 on macrophages, a cell of the innate immune system [18]. This again shows the cross-talk between adaptive and innate immune systems. In humans, increased PD-1 expression was seen in CD4 T cells in the days soon after onset of sepsis. Interestingly, this increased expression also correlated with an increased risk of nosocomial infection, highlighting the immune suppressive effects of PD-1 [19]. In animal models of ARDS (haemorrhagic shock followed by caecal ligation and puncture) PD-1 expression was increased on both innate and adaptive cells in the lung. In addition, lack of PD-1 was associated with improved survival when compared to wild-type mice. In humans with ARDS, those who survived had reduced expression of PD-1 on T cells compared to those who died [20].

Future directions

HLA, CTLA-4 and PD-1 have an impact on the adaptive immune system in critical illness. Other immune modulating proteins, such as BTLA, may also have similar effects. These proteins can enhance our understanding of the immune system in ICU patients, however, they may also provide an opportunity for therapeutic intervention.

Past efforts to treat critical illness, particularly sepsis, have failed in part due to the limited nature of the targeted therapy. When an antibody to one cytokine was given, the native immune system adapted with compensation by another combination of cytokines. This is evident by the long list of failed therapies [7]. Targeting immune modulating proteins such as PD-1 may be better able to treat a critical illness such as sepsis. Antibodies to both CTLA-4 and PD-1 have been trialled for cancer treatments and a CTLA-4 antibody has been approved for melanoma treatment. It is thus tempting to speculate about their potential application in the critically-ill patient sometime in the future.

CHAPTER 312

Immunomodulation strategies in the critically ill

Aline B. Maddux and Gordon R. Bernard

Key points

- Severe sepsis is the result of an infectious stimulus that triggers a hyper-inflammatory response and results in multiple organ failure. This hyperimmune response triggers a phase of immunoparalysis that results in the patient's inability to resist and clear infections, causing the delayed mortality observed in some septic patients.
- The inflammatory and coagulation cascades are closely linked such that a significant aspect of the disease process is attributed to the activation of the coagulation cascade by circulating inflammatory mediators.
- Therapeutic approaches to sepsis have targeted the hyper-inflammatory response, inhibition of the subsequent coagulation cascade, and immunostimulation during the immunoparalysis phase.
- Proven beneficial therapies for sepsis are limited to the mechanical eradication of the source of infection, antibiotics to clear the organism, the judicious use of fluids to support organ perfusion, and oxygen supplementation. Studies evaluating immunotherapeutics for the treatment of severe sepsis have failed to show efficacy in clinical trials.
- Further research may demonstrate effectiveness using a strategy of targeting therapies based on an improved identification of the patient's phase of sepsis, use of combination therapies, a better understanding and strategy aimed at specific host-organism interactions, and/or better specified therapies in relation to identified biomarkers.

Introduction

Severe sepsis is a hyperimmune response to an infectious stimulus resulting in a surge of cytokines and other mediators of inflammation. High circulating levels of pro-inflammatory cytokines, especially TNFα, lead to shock, multiple organ failure, and death in septic patients [1]. More recently, it has been recognized that patients with sepsis enter into a state of immune paralysis as their disease worsens and organ failures emerge. This subsequent anti-inflammatory response is characterized by apoptosis of immune cells and high levels of anti-inflammatory cytokines (IL-10, IL-13 and TGF-ß) inhibiting the function of macrophages as well as T and B lymphocytes [1,2]. These anti-inflammatory cytokines also suppress production of pro-inflammatory cytokines and inhibit the ability of monocytes to present antigens to other immune cells. This immune paralysis likely leads to the patient's inability to resist and clear infections resulting in the delayed mortality observed in some septic patients [1].

The proven beneficial therapies for sepsis are limited to the mechanical eradication of the source of infection, antibiotics to clear the organism, the judicious use of fluids to support organ perfusion, and oxygen supplementation during the initial hyperinflammatory phase of illness [3]. Outside of these effective therapies, strategies to counteract the hyper- and hypo-immune phases of sepsis have been tried thus far with only minimal success.

Antagonism of microbes and microbial products

The use of antibodies to target different components of the endotoxin molecule has been a strategy in sepsis therapy for many decades. The therapies tested have included both monoclonal immunoglobulin preparations targeting a specific antigen as well as polyclonal immunoglobulin preparations. Cellular mechanisms for recognizing and reacting to endotoxin have also been therapeutic targets [4].

Antagonism of endotoxin or cell activation through interference with endotoxin receptor/transduction apparatus

The activity of endotoxin is primarily due to the lipopolysaccharide (LPS) component of the Gram-negative bacterial cell wall. LPS has three components including the Lipid A moiety, core polysaccharide, and O-specific side chains. LPS activates the immune response when the Lipid A moiety binds to the TLR-4 receptor on monocytes and macrophages via the LPS-binding protein. Studies designed to block this interaction using antibodies to LPS have been conducted [5].

The first trial using anti-endotoxin human immunoglobulins in severe sepsis patients was performed by Ziegler et al. in 1982 [6]. This study showed improved survival when bacteraemic patients as well as those with septic shock were treated with human antibodies against the LPS core component of endotoxin. This small trial showed very promising results but its findings have never been replicated.

Further anti-LPS monoclonal antibody studies have utilized HA-1A, a monoclonal IgM LPS anticore antibody, and E5,

a monoclonal antibody directed against the lipid A moiety of LPS [5]. In 1991, Ziegler et al. compared HA-1A to placebo in a randomized, controlled trial [5]. This study of 543 septic patients showed no effect on the overall patient population, although a subset of 200 patients with culture-proven, Gram-negative bacteraemia showed improved survival in patients treated with HA-1A. In 1994, a follow-up randomized, placebo-controlled trial of 621 patients with Gram-negative bacteraemia and shock failed to confirm the positive results of the previous subset analysis. An additional trial in 1999 evaluating HA-1A in 269 children with meningococcal septic shock also failed to show improvement [4].

Greenman et al. published the first large trial evaluating therapy with E5 in 1991. This study of 316 patients with confirmed Gram-negative sepsis showed no survival difference at 30 days. However, a subgroup of 137 patients who were not in shock at the time of study entry showed improved mortality, decreasing from 43% in the placebo group to 30% in those given E5 ($p = 0.01$). In an attempt to confirm the positive results of this subset analysis, Bone et al. randomized 530 patients with Gram-negative sepsis. While this study did not show an improvement in survival, in the 139 patients who presented with organ failure there was better resolution of organ failure compared to placebo. In a final attempt to prove the efficacy of E5, a large RCT enrolled 1090 patients with documented ($n = 915$) or probable Gram-negative infections ($n = 175$) and severe sepsis, but again, showed no difference in 28-day all-cause mortality [4]. Currently, no single anti-endotoxin therapeutic strategy has been shown to provide benefit in patients with sepsis.

Further investigation has been undertaken to evaluate the efficacy of pooled serum containing polyclonal immunoglobulin preparations (IVIG). The exact mechanisms of action are not known though immunoglobulins may improve phagocytosis by coating bacteria, as well as eliciting neutralization and opsonization that inactivates bacterial endotoxins and exotoxins. It is also speculated that interaction between IVIG and the complement cascade, as well as its effects on the release of cytokines and cytokine antagonists by endotoxin, improves the immune response [4].

Two meta-analyses published by Kreymann et al. and Turgeon et al. in 2008 concluded that polyclonal IVIG improved survival. However, both analyses caution a significant amount of heterogeneity between trials. Furthermore, when Turgeon et al. eliminated studies of poor quality, the remaining trials showed no benefit from treatment [4]. A Cochrane review published in 2010 evaluated 42 studies including 17 studies of polyclonal IVIG in adults with sepsis. It reported a significant reduction in 30-day mortality, but again, noted heterogeneity across trials. Furthermore, when this analysis was restricted to trials with a low risk of bias, no mortality reduction was shown. Studies that evaluated long-term mortality (>60 days) did not show any effect of treatment. Polyclonal immunoglobulins provide some promise as an adjuvant therapy in sepsis but large, multicenter studies are needed to confirm efficacy [4].

IVIG in the paediatric population has a theoretical greater potential for benefit due to the immaturity of B cells in patients <5 years old. A prospective case-controlled study published in 2005 of 100 paediatric patients aged 1–24 months showed a significant improvement in lengths of stay, development of complications and mortality (28% treated versus 56% placebo) [3]. Due to this study, the Surviving Sepsis Guidelines published in 2008 recommend consideration of IVIG treatment in paediatric patients with severe sepsis [3]. However, the authors note the low trial quality and weak evidence base to support this recommendation. IVIG in the neonatal population is also controversial. Although the Surviving Sepsis guidelines cite evidence that IVIG decreases mortality in neonates with septic shock, the Cochrane review could not confirm this [4].

Antagonism of pro-inflammatory cytokines

Antagonism of the effects of TNFα

TNFα is a significant pro-inflammatory cytokine that acts early in the cascade of the hyperimmune response causing downstream elevation of IL-1, IL-6, and IL-8. Injection of TNFα into animals and humans triggers signs and symptoms closely resembling severe sepsis including hypotension, activation of the clotting cascade, and organ system dysfunction. Furthermore, persistent elevation of plasma TNFα levels during sepsis was associated with high mortality [7]. However, blockade of the effects of TNFα worsened the immune system's ability to clear microbes in animal models [8].

Strategies to reduce TNFα-initiated systemic inflammation have adopted multiple approaches. Trends toward improved survival have been noted, particularly in certain subgroups of patients. For example, those patients with severe sepsis as defined by failure of more than two organ systems and early hypotension responded to administration of p55 TNF receptor fusion protein. A study performed by Pittet et al. showed more organ-failure free days, a decreased incidence of new organ dysfunctions and a trend towards reduced 28-day mortality in severe sepsis patients treated with TNF neutralizing-receptor fusion protein p55 [7]. The INTERSEPT study, reported in 1996, showed improvement in shock reversal and organ dysfunction in the treatment arm, although failed to show benefit in treatment of patients without shock or improvement of 28-day mortality. The NORASEPT trial similarly showed a non-significant trend towards improved survival in those patients with septic shock. IL-6 levels are considered to be a surrogate for overall TNFα activity because of the much longer half-life of this cytokine compared to the more rapidly cleared TNFα. The MONARCS trial enrolled patients with elevated IL-6 levels and found that treatment with an anti-TNFα antibody fragment lowered TNFα and IL-6 levels, accelerated the resolution of organ dysfunction, and improved 28 day mortality though the effect was not robust enough to result in FDA approval [7]. In conclusion, most trials attempting to antagonize the effects of TNFα show a small, non-significant increase in survival. Further studies are needed to determine the true efficacy of these pharmaceutical approaches.

Antagonism of the effects of IL-1

IL-1 is another pro-inflammatory cytokine thought to work in concert with TNFα to induce the hyperimmune response of sepsis [9]. The counter-regulatory IL-1 receptor antagonist (IL-1ra) protein occurs naturally in humans [10]. This receptor antagonist functions by competitively and reversibly occupying the IL-1 receptor. However, stimulation of as few as 5% of IL-1 receptors is sufficient to trigger an inflammatory response. It thus requires 100–10,000 fold excess of IL-1ra relative to IL-1 to inhibit the effects of IL-1 [9].

A randomized controlled trial of 893 patients with sepsis syndrome published by Fisher et al. in 1994 evaluated human recombinant IL-1ra treatment versus placebo. No significant increase was seen in overall survival, but secondary and retrospective analyses showed an increased survival time among patients with sepsis who

also had organ dysfunction and/or a predicted risk of mortality of ≥24% [10]. Based on this finding, Opal et al. pursued a follow-up trial reported in 1997, which enrolled patients with severe sepsis defined as end-organ dysfunction and/or septic shock. This study was stopped early after enrolling 696 of the planned 1300 patients due to a low likelihood of finding a significant difference in 28-day mortality. As discussed by the study authors, it seems plausible that maintenance of the 100–10,000 fold excess of rhIL-1ra relative to IL-1 is needed to inhibit the immune response and this could not be consistently maintained in an ICU population [9].

Inhibition of the coagulation cascade

Intense activation of the coagulation cascade occurs in severe sepsis. The coagulation response can be used to assist in the isolation of infected areas to prevent spread of infection to other parts of the body. Unfortunately, in severe sepsis, the systemic nature of the process makes the isolation effort somewhat futile, and possibly, counterproductive. The over-exuberant coagulation response can result in microvascular thrombosis, widespread endothelial damage, and organ failure.

Tissue factor (TF) is a cell surface receptor, which, under normal circumstances, is not exposed to plasma, blood cells, or endothelium. However, bacteria and pro-inflammatory mediators cause endothelial cells and monocytes to express TF, resulting in activation of the extrinsic coagulation pathway. TF pathway inhibitor regulates this coagulation pathway [11]. Recombinant TF pathway inhibitor was tested in the OPTIMIST trial, a phase III trial of 1754 patients with severe sepsis [11]. This trial failed to show an improvement in mortality and, unfortunately, showed a trend towards harm in those treated concurrently with heparin.

Similarly, severe infection is associated with a decreased level of the endogenous anticoagulant, antithrombin (AT). AT inactivates multiple clotting enzymes to contribute to the hypercoagulation of sepsis [11]. Multiple small studies published in the 1990s suggested promising effects of AT in patients with severe sepsis. KyberSept, a multi-national phase III trial of AT in 2,314 patients however showed no difference in 28- or 90-day mortality. Further investigation of AT as a treatment for sepsis will need to focus on identification of a target population who will have the greatest potential for benefit while having minimal risks for bleeding [11].

Activated protein C (aPC) has anti-coagulant, anti-inflammatory, and anti-apoptotic effects that led to its use in sepsis. Its anticoagulant mechanism is via inactivation of factors Va and VIIIa, preventing generation of thrombin. This, in turn, decreases inflammation by reducing mast cell degranulation, platelet activation, and neutrophil recruitment. The results of the PROWESS trial generated great excitement as treatment with recombinant aPC reduced absolute 28 day mortality by 6.1% (p = 0.005). It was subsequently approved for use in the most severely septic patients with APACHE II scores ≥25 due to observations by the FDA that this subgroup derived the most benefit [12]. However, a subsequent trial, PROWESS-SHOCK, failed to replicate the positive results of the PROWESS trial causing aPC to be withdrawn from the market [13]. Activated protein C is also not recommended for use in children based on a study reported by Nadel et al. in 2007 [14]. This study evaluated 477 children with sepsis and failed to show improvement in mortality.

Corticosteroids

Steroids inhibit production of pro-inflammatory cytokines (e.g. TNFα, IL-1, IL-2, IL-6, IFN-gamma), chemokines, bradykinins, and eicosanoids while increasing the release of anti-inflammatory mediators (e.g. IL-10, IL-1ra, and TNF receptor antagonists). They also inhibit inducible nitric oxide synthase (iNOS) and decrease the function of inflammatory cells and their migration to sites of inflammation [1].

Smaller studies published by Bollaert et al. and Briegel et al. in the late 1990s showed trends to resolution of hypotension and improved mortality in patients treated with replacement dose glucocorticoids. However, these studies were underpowered to detect a significant mortality benefit [1]. In 2002, further studies of replacement dose glucocorticoids were published by Annane et al. who reported improved resolution of refractory hypotension and a decrease in absolute mortality in patients with relative adrenal insufficiency treated with hydrocortisone and fludrocortisone. In contrast, those who responded to ACTH, and thus deemed to be without adrenal insufficiency, gained no benefit and trended towards harm from glucocorticoids [2,3]. Subsequently, the CORTICUS trial compared treatment of patients with 11 days of hydrocortisone versus placebo. This trial failed to show any mortality benefit in patients treated with steroids, regardless of ACTH response, though reversal of shock was accelerated [2].

Currently, consensus is lacking with regard to steroid therapy in septic shock. The Surviving Sepsis Guidelines recommend steroids only in vasopressor-refractory shock [3]. ACTH stimulation tests are not recommended. The enthusiasm for steroid use is further dampened by concern over secondary infections, as reported by CORTICUS, and myopathy [3]. Minimal paediatric data exist regarding sepsis and steroid therapy. Currently, hydrocortisone is recommended only for children with catecholamine-resistant shock and suspected or proven adrenal insufficiency [3].

Prostaglandins

NSAIDs inhibit synthesis of prostaglandins, thus decreasing plasma levels of arachidonic acid-derived eicosanoids, particularly thromboxane A2 and prostacyclin. Thromboxane A2 is associated with bronchoconstriction, platelet aggregation, and vasoconstriction. Prostacyclin acts as a vasodilator and antagonist of thrombosis. Eicosanoids have been associated with abnormalities of airway mechanics particularly bronchoconstriction, pulmonary hypertension, hypoxaemia, cardiovascular collapse, and multiple organ failure in patients with sepsis syndrome. Additionally, the NF- κB cellular signalling pathway is inhibited by NSAIDs [15].

In 1997 Bernard et al. published a trial designed to evaluate treatment with ibuprofen versus placebo in 455 patients with severe sepsis. Despite finding a rapid decline in urinary levels of prostacyclin and thromboxane, temperature, heart rate, oxygen consumption and lactic acidosis, there was no improvement in either the incidence or duration of shock, nor development of the respiratory distress syndrome, and no significant effect on all-cause mortality [15]. The subset of patients entering the ibuprofen trial in a state of hypothermia were evaluated separately and reported in 1999. There were 44 (10%) such patients and they had significantly greater elevations in urinary thromboxane A2, urinary prostacyclin, serum TNFα, and serum IL-6 concentrations compared to the

febrile cohort. The hypothermic patients also had a worse mortality (70% versus 35%). In this subset, those treated with ibuprofen showed a beneficial effect as evidenced by an improvement in organ failure-free days, ICU-free days, ventilator-free days, and mortality. The study authors suggested that ibuprofen therapy may show benefit in high-risk patients with hypothermic sepsis [15].

Statins

Statins inhibit the HMGCoA reductase enzyme that, in turn, inhibits its synthesis of isoprenoid units necessary for the activity of multiple proteins, such as the GTP binding protein, Rho. This action subsequently affects transcription factors such as NFκB and AP-1 leading to decreased levels of inflammatory cytokines such as IL-6 and IL-1. HMGCoA-reductase also induces caspase-dependent apoptosis in smooth muscle cells that could lead to less inflammation during severe sepsis by avoiding the necrotic cell death pathway. In addition, statins inhibit the reduction of HMGCoA to mevalonate. This process is involved in synthesis of bile acids, some steroid hormones and Vitamin D. Statins also inhibit production of the cyclooxygenase (COX)-2 protein, the biosynthesis of ubiquinone (mitochondrial respiration) and haeme-A (oxygen transport), and prenalation of small G proteins. These are considered to be far-reaching effects with regard to inflammation and acute infection. Thus, though there are many potential mechanisms by which statins could alter the inflammatory response in sepsis, the precise mechanism remains to be elucidated [16].

A cohort study published by Christensen et al. in 2010 showed that patients on statin therapy immediately prior to ICU admission had a reduced risk of death within 30 days and at 1 year after ICU admission. The cohort design of this study limits the ability to infer causation but suggests positive effects of statin therapy [16]. A large meta-analysis published in 2010 by Bjorkhem-Bergman et al evaluated the potential therapeutic effects of statins in bacterial infections, reporting that statins were associated with improved survival (odds ratio 0.52, p <0.0001). However, the 15 studies analysed were of observational design and further analysis suggested significant publication bias [17]. Another meta-analysis by Janda et al. evaluated 20 studies including mostly cohort studies and one RCT. A protective effect for 30-day mortality, in-hospital mortality, pneumonia-related mortality, bacteraemia-related mortality, sepsis-related mortality, and mixed infection-related mortality were associated with statin use. This study was again limited by inclusion of mostly observational cohorts with significant heterogeneity between studies. The randomized controlled trial included in this review was done by Tseng et al. [18]. It included 80 patients with aneurysmal subarachnoid haemorrhage who were randomized to treatment with pravastatin or placebo and showed reduced mortality from sepsis as a secondary outcome. Phase II and III studies are currently in progress to evaluate the role of statins in the treatment of sepsis.

Immunostimulation

G-CSF/GM-CSF

The immunological effects of G-CSF and GM-CSF are thought to counteract the immunoparalysis state of sepsis. G-CSF use in non-neutropenic patients may act via improving the host defence response through enhancing chemotaxis and neutrophil adhesion, increasing superoxide production, and improving bacterial killing activity. It also improves the production of pro-inflammatory cytokines and increases intracellular uptake of antibiotics [19]. A trial performed by Root et al. evaluated 701 adult patients with severe sepsis due to bacterial pneumonia. While treatment with G-CSF increased white blood cell count, it did not show an improvement in mortality, occurrence of organ dysfunction, nor ICU length of stay [20]. Further studies are in progress to better identify the subset of patients with immunoparalysis with plans to evaluate the effect of immune stimulating therapies in this population.

Conclusion

Studies evaluating the use of immunotherapeutics for severe sepsis are plagued with multiple confounding factors including the predominant phase of sepsis (hyperimmune versus hypoimmune), differing offending organisms, differing host-organism interactions, heterogeneity in the patient populations, and underpowered study designs. Perhaps the correct immunotherapy will need to be tailored in order to decrease the immune response in the hyperimmune phase and increase it during the hypoimmune phase. In order to do so, better markers of these phases of sepsis are needed. Further studies may also find more efficacy in using multiple therapies simultaneously to obtain best results. Finally, there exists a close interaction between the immune and coagulation systems. Further study of this link and therapies to temper the coagulation cascade may prove to be a successful modality of therapy in order to halt the body's progression to multiple organ failure.

CHAPTER 313

Immunoparesis in the critically ill

Fabienne Venet and Alain Lepape

Key points

- Critically-ill patients develop immune dysfunction that affects both innate and adaptive immune responses.
- Two main outcomes are potentially associated with immunoparesis, all-cause mortality, and secondary infections.
- Therapeutics aiming at restoring immunological functions are currently being tested in patients.
- Colony-stimulating factors (G-CSF and GM-CSF) have been used in a limited number of randomized clinical trials.
- Further studies are urgently needed.

Introduction

Severe injuries induce immune alterations that have, for a long time, been solely considered as an overwhelming pro-inflammatory syndrome. Enormous efforts have been expended over the last 20 years to find new therapies (mostly anti-inflammatory) that decrease the mortality from sepsis [1,2]. However, with the recent withdrawal of activated protein C (drotrecogin alfa) due to the lack of beneficial effect on 28-day mortality, severe sepsis, and septic shock represent one of the most costly therapeutic failure areas in medicine.

This repeated failure has led to the re-evaluation of our understanding of septic shock pathophysiology and, more generally, of the post-injury immune response. It is now well accepted that, in parallel with an exaggerated pro-inflammatory response, critically-ill patients develop an immunosuppressive phase, termed immunoparesis/immunoparalysis or immune reprogramming, that is associated with significant immune dysfunction [3,4]. The goal of this chapter is to provide a comprehensive overview of injury-induced immune dysfunction, and of potential immunostimulatory therapies.

Immunoparesis

The place of immunoparesis in the post-insult immune response

Severe injuries induce a major pro-inflammatory response through interaction between Toll-like (and other) receptors on immune cells and danger- or pathogen-associated molecular patterns (DAMPs, PAMPs). Due to numerous, incompletely understood mechanisms, this response may not be contained after severe injury at the local level but becomes systemic, leading to shock and organ dysfunction [1]. To maintain immune homeostasis, anti-inflammatory mechanisms controlling the initial pro-inflammatory response also develop. This compensatory phase rapidly becomes predominant at the systemic level and is associated with injury-induced immune dysfunction in intensive care unit (ICU) patients (Fig. 313.1) [3,4].

Immunosuppression in ICU patients is evidenced by the frequent occurrence of infections with relatively avirulent germs (i.e. *Candida* or cytomegalovirus) that normally occur solely in immunosuppressed hosts [3]. Importantly, in septic patients, immune dysfunction is not only observed at the systemic level, but also in organs distant from the site of infection [5]. The intensity and duration of this injury-induced immune dysfunction have been associated with an increased risk of death and of secondary nosocomial infections after admission [6].

Injury-induced innate immune dysfunctions

The innate immune response represents the first line of defence after an infection and thus is rapidly mobilized after release of DAMPs or PAMPs. Innate immune cells (i.e. neutrophils, monocytes, and dendritic cells) are affected at different levels in critical illness. In particular, neutrophil reprogramming is manifest by impaired recruitment to infection/injury sites, abnormal accumulation to remote sites, and dysregulation of effector responses [7]. An anarchic recruitment of activated neutrophils to organs distant from the injury site is thought to contribute towards organ dysfunction.

Monocyte dysfunction is a hallmark of immunoparalysis in ICU patients. In particular, decreased pro-inflammatory and increased anti-inflammatory cytokine production and a decreased antigen presentation capacity have been repeatedly described in severely-ill patients. Importantly, decreased expression of human leukocyte antigen-DR (mHLA-DR) has emerged as a reliable marker of monocyte dysfunction and immunoparalysis in ICU patients [4]. Several clinical studies have linked decreased mHLA-DR with an increased risk of death and nosocomial infection; this biomarker is now being used in clinical trials to stratify patients before initiating immunostimulation therapy [8]. Finally, the number of circulating dendritic cells is decreased and cytokine production is oriented toward production of anti-inflammatory mediators with a reduction in IL-12 secretion after injury [9].

Injury-induced adaptive immune dysfunction

Far less work has been dedicated to the study of lymphocyte alterations in ICU patients. Critically-ill patients often present with a

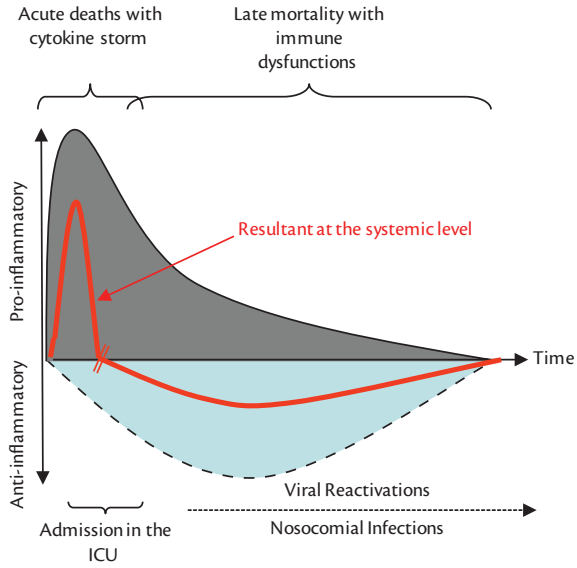

Fig. 313.1 Schematic representation of post-injury immune response.

dramatic lymphopenia that is present from admission and affects every lymphocyte subpopulation [10]. This is associated with a major induction of apoptosis [1]. Remaining lymphocytes present with functional alterations, such as decreased proliferation and cytokine production in response to stimulation. Phenotypic alterations such as increased co-inhibitory receptor expression and decreased co-stimulatory receptor and CD3 expression have also been described on circulating lymphocytes taken from septic shock patients [4]. This is associated with a decrease in T cell receptor diversity. Finally, an increased percentage of circulating $CD4^+CD25^+$ regulatory T cells has been repeatedly shown in ICU patients [11].

Is immunoparesis a target for treatment in the critically-ill patient?

The answer to this question is still unclear. Two outcomes—increased mortality and occurrence of secondary infections—are related to immune dysfunction, notwithstanding the nature of the initiating insult (trauma, surgery, infection). Studies on secondary infection in ICU patients have focused on the relationship to exposure to invasive devices, selection of resistant micro-organisms by antimicrobials and cross-transmission. There is an obvious variability in ICU-acquired infections that is not explained by the duration of ventilation nor catheterization. Immunoparesis is a probable risk factor for secondary infection; however, since this concept is more recent, and perhaps because of the numerous anti-inflammatory agent trial failures, this promising path has not been fully explored. There is a need for randomized clinical trials (RCTs) to address this question in appropriately selected patients.

Colony-stimulating factor therapy in non-neutropenic ICU patients

Two candidate drugs have been tested—granulocyte colony-stimulating factor (G-CSF) and granulocyte–macrophage colony-stimulating factor (GM-CSF). Both are potent immunostimulators, inducing leukocytosis and augmenting the activity of granulocytes.

G-CSF has been used to date in eight placebo-controlled trials [12]. Overall, 2044 patients were included in these trials however the results did not favour a reduction in mortality (relative risk = 0.95, 95% confidence interval: 0.80–1.14). Although not always clearly described, G-CSF appears to have few side-effects.

Despite far fewer patients studied to date—only four randomized controlled studies (RCTs) totalizing 158 patients) (Table 313.1) [8,13–15]—GM-CSF does seem to be an interesting candidate to stimulate immune function in the context of critical illness. Besides the same immunostimulation effects as G-CSF, GM-CSF has specific actions on monocyte functions, namely stimulation of monocytes/macrophages and induction of monocytic cytokine expression (e.g. TNF-α or IFN-γ induction seen in ex vivo models after stimulation by endotoxin). GM-CSF also induces antigen presentation (increased mHLA-DR). An interesting approach used by Meisel et al is to stratify patients according to their immune dysfunction as measured by mHLA-DR and, hence, to restrict the use of GM-CSF to patients at risk [8].

Overall, despite these trials not showing any effect on 28-day or hospital mortality, a positive effect was seen on the initial infection with a higher rate of reversal (RR 1.34, 95% CI 1.11–1.62, $p = 0.002$). However, as stated by Schefold [16], this effect is globally described within a meta-analysis containing many more patients enrolled into G-CSF trials. Whereas G-CSF increases antimicrobial defences, GM-CSF has a predominant role in restoring immunocompetency, especially antigen presentation, and may play an important role in the prevention of secondary infections after the initial infectious episode.

Interferon-gamma therapy (IFN-γ) in ICU patients

The beneficial effects of IFN-γ on monocyte deactivation in septic patients were first described in 1997 by Docke et al. in a limited open-label study [17]. In 2002, Nakos et al. confirmed these results in trauma patients [18], although no RCTs have yet been conducted in ICU patients.

Anti-apoptotic therapies in ICU patients

Given the extensive apoptosis-induced depletion of immune cells, including lymphocytes, another potential strategy is to use the anti-apoptotic immunostimulatory cytokines IL-7 and IL-15. Both have shown efficacy in sepsis models [19], although no clinical experience is yet available.

Intravenous immunoglobulin therapy (IVIg) in ICU patients

The immune effects of IVIg are far too complex to be depicted here. Among its effects, improvement of bacterial clearance is clearly an important role, and this is associated with inhibitory effects upon upstream mediators of the host response plus scavenging of downstream inflammatory mediators. Several meta-analysis and systematic reviews have been published, however the heterogeneity of the RCTs and the conflicting results of the meta-analysis have been recently described [20]. The use of IVIg is still not recommended; further studies are needed before this therapeutic can be used in sepsis. Only toxin-mediated bacterial diseases, such as severe *Staphylococcus* and *Streptococcus* infections, are currently given as examples of indications for IVIg therapy in infection, even though sufficiently powered RCTs are lacking.

Table 313.1 Description of randomized clinical trials of GM-CSF versus placebo in adult human sepsis

Study	Population	Intervention	Comparison	Outcome
Presneill [15], Australia	Single centre, 18 patients within 24 hours of severe sepsis with ≥2 SIRS criteria, clinically suspected infection, and sepsis-related pulmonary dysfunction	Randomized, double-blind, placebo-controlled phase II trial of low-dose (3 μg/kg) iv GM-CSF daily for 5 days versus conventional therapy in 10 patients and 8 receiving placebo	◆ **Primary outcome**: patient survival to 30 days ◆ **Secondary outcomes**: assessed at D5 • Oxygenation (PaO_2/FiO_2) • Occurrence of ARDS. • SOFA score: number and functional status of blood and bronchoalveolar leukocytes	◆ No difference in survival, rate of ARDS or SOFA score ◆ Improvement in PaO_2/FiO_2 ◆ Increased peripheral neutrophils, decreased alveolar neutrophils
Rosenbloom[13], USA	Single centre, 40 patients with SIRS and defined focus of infection, 33 evaluable	Randomized, unblinded, placebo-controlled, prospective study; 72-hour infusion of GM-CSF (125 μg/m^2) (n = 18) or placebo (n = 15)	◆ Survival, cure of infection, leukocyte count ◆ Functional markers of inflammation on circulating neutrophils and monocytes	◆ Increase in leukocyte count and cure/improvement in initial infection ◆ No difference in survival or organ failure ◆ Upregulation of immunological markers
Orozco [14], Mexico	Single centre, 58 patients with abdominal sepsis	Daily dosage of 3 μg/kg for 4 days (group 1) or placebo (group 2)	Time to improvement, duration of antibiotic therapy, hospital stay, complications, mortality, and adverse reactions to drugs	◆ **Median time to clinical recovery and improvement**: 2 days versus 4 days (p < 0.005) ◆ **Median hospital stay**: 9 versus 13 days (p < 0.001) ◆ **Median time with antibiotic therapy**: 9 versus 13 days p < 0.001) ◆ **Episodes of infectious complications**: 1 versus 16 (p = 0.02) ◆ **Fatal outcome**: 2 versus 2 (NS)
Meisel [8], Germany	Multicentre (n = 3), 38 patients with sepsis-induced immune suppression (reduced mHLA-DR levels <8000 monoclonal antibodies (mAb) per cell in two consecutive measures)	GM-CSF 4 mg/kg/day or placebo, sc for 5 days, then GM-CSF or placebo for 3 days at either 8 mg/kg/day GM-CSF (if mHLA-DR ≤15,000 mAb per cell at Day 5), or 4 mg/kg/day (mHLA-DR >15,000 mAb per cell)	◆ **Primary outcome**: mHLA-DR expression ◆ **Secondary endpoints**: course of disease severity, cellular immunity, inflammatory markers, length of hospital/ICU stay	mHLA-DR normalized in 19/19 treated patients versus 3/19 controls (p < 0.001); shorter time of mechanical ventilation (148 ± 103 versus 207 ± 58 hours, p = 0.04); improved APACHE score (p = 0.02); shorter length of both intrahospital and ICU stay (59 ± 33 versus 69 ± 46 and 41 ± 26 versus 52 ± 39 days, respectively, both not significant)

Data from various sources (see references).

Conclusion

Critically-ill patients develop immune dysfunction, and this is collectively called immunoparesis/immunoparalysis or immune reprogramming. Both innate and adaptive immune responses are affected. The intensity and duration of injury-induced immune dysfunction is associated with an increased risk of death and secondary infections. Innovative therapeutic strategies aiming at restoring immunological functions are currently being tested. Only G-CSF and GM-CSF have been used in a limited number of RCTs while IFN-γ and IL-7 represent novel future therapeutic approaches. Importantly, there is an urgent need for further clinical trials, which should include large cohorts of ICU patients stratified by relevant markers of immune dysfunction.

PART 14.4

Anaphylaxis

CHAPTER 314

Pathophysiology and management of anaphylaxis in the critically ill

James Keegan and Charles D. Deakin

Key points

- Anaphylaxis is a severe life-threatening systemic hypersensitivity reaction.
- Life-threatening symptoms include airway compromise, bronchospasm, hypoxia, and cardiovascular collapse.
- Common triggers include foods, insect stings, latex, and drugs.
- Intramuscular epinephrine (adrenaline) is the primary treatment of anaphylaxis. Treatment is time critical.
- Plasma tryptase levels should be measured immediately and 1–2 hours post-onset of symptoms.

Definition

Anaphylaxis is a 'severe life-threatening, generalized or systemic hypersensitivity reaction' [1] characterized by rapidly developing airway, breathing, and/or circulation problems with associated skin and mucosal changes [2]. It most commonly results from immunologically-mediated reactions to foreign antigens.

History

Although Egyptian hieroglyphics describe the sudden death of a Pharaoh following a wasp sting in 2640BC, the first clinical record of an anaphylactic reaction was published in 1836 by the French physiologist, Magendie. In 1902, Portier and Richet used the term 'anaphylaxis' to describe the reaction of dogs to injection of sea anemone venom. Subsequently, anaphylactic reactions to many substances have been described. Early reports of histamine release following tubocurarine and thiopentone were published in 1936 and 1952 [3].

Epidemiology

Anaphylaxis occurs in approximately 10–20 per 100,000 population per annum, with 3–4 per 100,000 of these admitted to hospital. Between 2005–2009 anaphylaxis accounted for 1269 (0.3%) adult and 81 (0.1%) paediatric UK critical care admissions [2]. Ninety-two per cent of adults and 95% of children admitted to critical care survive to hospital discharge, with a mean length of critical care admission of 1.2 days in survivors.

In children, foods are the most frequent cause of anaphylaxis, while drug reactions are more common in adults. Incidence of anaphylaxis during anaesthesia is estimated at between 1 in 10,000 and 1 in 20,000 anaesthetics [4,5].

Anaphylaxis occurs more commonly in female adults (65%), but exhibits an even sex distribution in children [2]. Patients who suffer from asthma or atopy, and those on beta-blockers may have a predisposition to more severe reactions.

Pathophysiology

Hypersensitivity reactions

Hypersensitivity reactions are classified in Box 314.1. Anaphylaxis is classified as a type I hypersensitivity reaction.

Anaphylaxis

Anaphylaxis occurs due to an exaggerated reaction to foreign protein associated with release of vasoactive substances. It is characterized by release of inflammatory mediators from mast cells or basophils triggered by the interaction of an allergen with IgE bound to the Fc epsilon R1 receptor [6].

In response to IgE-mediated activation, mast cells release multiple mediators, including histamine, tryptase, arachidonic acid metabolites, leuktotrienes, prostaglandins, eosinophil, and neutrophil chemotactic factors, platelet activating factor, complement, and kinins. The roles and interactions of these agents are complex and not fully elucidated.

Anaphylactoid reactions

These are clinically identical to anaphylactic reactions, but are mediated by substances other than IgE, e.g. IgG, complement or direct stimulation of histamine release. These mechanisms again result in release of vasoactive mediators and produce a clinical picture indistinguishable from anaphylactic reactions.

The European Academy of Allergy and Clinical Immunology has proposed that the classification of anaphylactic and anaphylactoid reactions be replaced with the terms allergic anaphylaxis (IgE, IgG, complement-mediated) and non-allergic anaphylaxis [1], however this proposal has not been universally accepted [7].

Box 314.1 Classification of hypersensitivity reactions

- **Type I**: anaphylactic, with previous sensitization. Mediated via mast cells and IgE.
- **Type II**: cytotoxic; antibodies directed against the cell membrane.
- **Type III**: immune complex.
- **Type IV**: delayed-type hypersensitivity, T-cell mediated.

Reproduced from Deakin C, *Clinical Notes for the FRCA*, Copyright 2011, with permission from Churchill Livingstone. Data from Gell PGH and Coombs RRA (eds), *Clinical Aspects of Immunology*, First Edition, Oxford, England: Blackwell; 1963.

Presensitization

Predisposed individuals are exposed to many agents that may result in cross-reactivity. For example, quaternary amine groups found in neuromuscular blocking agents (NMBAs) are present in toothpastes, washing detergents, and cough medicines, e.g. pholcodine in cough syrups. IgE antibodies to pholcodine may be responsible for some NMBA anaphylaxis. Removal of pholcodine-containing products from the market in Norway was associated with a decreased number of cases of NMBA anaphylaxis [8].

Causative agents

A broad range of agents including foods, insect stings, latex, and drugs can trigger anaphylaxis. Common food allergens include nuts, shellfish, milk and eggs. Anaphylaxis to insect stings commonly occurs from hymenoptera (bees, wasps, ants) venom, and mosquito bites.

Latex allergy

Latex is a common rubber material used in health care equipment. It occurs naturally in the sap of the rubber tree *Hevea brazilensis* or can be produced synthetically. It contains protein allergens, including the natural rubber elongation factor Hev b. These act as antigens to cross-link membrane-bound IgE and cause mast cell degranulation.

Latex is associated with three clinical syndromes—irritant dermatitis, allergic contact dermatitis (type IV hypersensitivity reaction), and anaphylaxis (type I hypersensitivity). Anaphylaxis is often delayed 30–60 minutes after exposure.

Latex accounts for 20% of anaphylactic reactions during anaesthesia [5]. The increase in use of universal precautions in health care settings over recent decades has resulted in a significant rise in latex reactions in healthcare workers. Other high-risk groups include patients regularly exposed to latex, e.g. repeated bladder catheterizations & multiple surgical procedures. Male gender, non-Caucasian race, atopy (asthma, allergic rhinitis, contact dermatitis, and hay fever) and food allergies are all risk factors.

Latex fruit syndrome

Some fruits (e.g. bananas, kiwi fruit, avocados, chestnuts, tomatoes) contain proteins that cross-react with latex proteins; those allergic to these fruits are at risk of latex allergy [9].

Drugs

Neuromuscular blocking agents (NMBAs)

Approximately 50–60% of cases of anaphylaxis during anaesthesia are due to NMBAs [5,7]. Suxamethonium is the most frequently implicated in terms of total number of reactions, sharing a similar incidence per drug use as rocuronium. Data on the relative frequency of anaphylaxis to the non-depolarizing muscle relaxants are inconclusive, although cis-atracurium demonstrates consistently low rates of reaction. The benzolisoquinoliniums (atracurium, mivacurium) cause histamine release and are also associated with anaphylactoid reactions. Cross-reactivity can occur between individual drugs and also across the aminosteroid and benzolisquinolinium groups; consequently, no agent should be considered 'safe' in a patient with a history of anaphylaxis to NMBAs without formal testing.

Anaesthetic agents

Anaphylactic reactions have been reported with all commonly used hypnotic agents (thiopentone, propofol, etomidate, midazolam, ketamine). As a group they are implicated in 1% of anaesthesia-related reactions [5]. Twenty per cent of reactions to thiopentone are anaphylactic; the remainder are anaphylactoid (90% direct histamine release, 10% complement activation). Specific IgE interaction may occur against the isopropyl groups on propofol, although most adverse reactions to propofol are non-immunological.

Antibiotics

Antibiotics cause 15–20% of anaesthesia-related reactions. Most commonly, reactions occur to penicillins, cephalosporins, and vancomycin [5]. Patients who are allergic to penicillin or amoxicillin have a higher incidence of allergic reaction to first generation cephalosporins (cephalexin, cefadroxil, cephradine), but not later generations.

Opioids

Opioids, most frequently morphine, account for 2% of perioperative reactions. Morphine, pethidine and codeine also cause non-specific histamine release, which may be associated with anaphylactoid reactions.

Colloids

Colloids are implicated in 2% of reactions. Gelatins are the most common cause, but reactions to dextrans and hydroxyethyl starches are also implicated. Reactions may be immediate or delayed.

Others

Chlorhexidine is a common topical antiseptic. Anaphylactic reactions have been reported to topical and parenteral exposure, including chlorhexidine-impregnated intravascular catheters.

Reactions to intravenous contrast media and vital dyes (e.g. patent blue) are increasing, probably due to their increased use. Reactions to dyes often occur 30–60 minutes after administration, due to the rate of absorption from subcutaneous tissue at the site of dye injection.

Clinical features

Anaphylaxis typically causes rapidly developing (within minutes) features, with airway, breathing and circulation problems. There are usually associated skin and mucosal changes [6].

- **Airway**: pharyngeal and laryngeal oedema, hoarse voice, and stridor.

- **Respiratory**: bronchospasm, hypoxaemia, pulmonary oedema and respiratory arrest.
- **Cardiovascular**:
  - *Hypotension*—systemic vascular resistance is decreased by as much as 80% due to the direct effect of histamine.
  - *Tachycardia*—due to chronotropic effects of histamine and secondary release of epinephrine and norepinephrine. Bradycardia occurs in 10% of cases.
  - *Myocardial ischaemia and ECG changes*—can occur in individuals with normal coronary circulation.
  - *Cardiac arrest*—can occur due to direct myocardial depression, vasodilation, capillary leak and relative hypovolemia.
- **Gastrointestinal**: nausea and vomiting, diarrhoea, abdominal colic.
- **Neurological**:
  - Awake patients may experience a metallic taste and a sense of impending doom.
  - Decreased conscious level.
- **Skin and mucosal changes**: present in over 80% of anaphylaxis cases, these can occur together or in isolation:
  - Erythema.
  - Urticaria.
  - *Angioedema*—eyelids, lips, mouth, or throat.

Patients may present with signs from one system in isolation, e.g. cardiovascular collapse. The time course of reactions varies with the causative agent. Fatal food reactions commonly result in respiratory arrest 30–35 minutes after ingestion; insect stings cause cardiovascular collapse after 10–15 minutes, while cardiorespiratory arrest following intravenous medication typically occurs within 5 minutes [6].

Treatment

Treatment of anaphylaxis should follow European Resuscitation Council guidelines [6] (or similar) using an ABC approach (Airway, Breathing, Circulation) (Fig. 314.1).

Patient positioning

Awake patients should be positioned carefully. Sitting or standing may precipitate cardiovascular collapse, although those with breathing problems may find sitting more comfortable. Elevate the patient's legs if there is hypotension.

Remove trigger

The trigger agent may be unclear so removal of all potential causative agents should be targeted. If anaesthetized, maintain anaesthesia with an inhalational anaesthetic agent.

Airway

Maintain the airway and administer high flow oxygen. Anaphylaxis can cause airway swelling and obstruction—if necessary intubate the trachea and provide controlled ventilation.

Cardiopulmonary resuscitation

In the event of cardiac arrest perform cardiopulmonary resuscitation according to Advanced Life Support Guidelines.

Epinephrine (adrenaline): intramuscular

Epinephrine is the primary treatment for anaphylaxis. It is an agonist at both alpha and beta-adrenoreceptors. The alpha-receptor action reverses peripheral vasodilation and oedema, while the beta-receptor action causes bronchodilation, increases myocardial contractility and suppresses histamine and leukotriene release. Beta-2 adrenoreceptors on mast cells attenuate mast cell degranulation [6].

The European Resuscitation Council guidelines recommend that epinephrine be given to all patients with life-threatening features. The intramuscular (im) route is recommended as the default due to a greater margin of safety, and ease of administration. The anterolateral aspect of the middle third of the thigh is the best site for im administration.

The recommended doses for im epinephrine (equivalent volume of 1:000 epinephrine) are [6]:

- **>12 years/adult**: 500 μg im (0.5 mL).
- **6–12 years**: 300 μg im (0.3 mL).
- **6 months–6 years**: 150 μg im (0.15 mL).
- **<6 months**: 150 μg im (0.15 mL).

Epinephrine: intravenous

The intravenous route has a lower margin of safety and is prone to significant side effects due to dosage or misdiagnosis errors. Side effects include severe hypertension, myocardial ischaemia, tachycardia, and arrhythmias. However, intravenous epinephrine may be used in monitored patients (electrocardiogram (ECG), oxygen saturation, and blood pressure) by those expert in its use. Indeed, intravenous (iv) epinephrine may be needed in those patients that require repeated im doses. The critical care unit is often best placed to provide this expertise.

In adults, epinephrine should be titrated in 50 μg boluses. An infusion may be used if repeated doses are required. Use of iv epinephrine in children requires careful titration in a specialist setting. A dose as low as 1 μg/kg may be effective [6].

Fluids

Patients may exhibit profound hypovolaemia due to capillary leak and vasodilation. Give a fluid challenge of 500–1000 mL (20 mL/kg in children). There is no evidence to suggest superiority of crystalloid or colloid in this setting, but colloid administration should be considered a possible trigger in patients receiving it at the time of onset of anaphylaxis.

Antihistamines

H_1-receptor antagonists, e.g. chlorphenamine maleate, are useful to alleviate histamine-induced vasodilation and bronchoconstriction. H_2 receptor antagonists are not recommended for the initial treatment of anaphylaxis [6].

Steroids

Corticosteroid administration may be useful to shorten anaphylactic reactions, but evidence of efficacy and optimum dose is limited.

Others

Bronchodilators

Bronchodilator therapy is useful in those patients with respiratory symptoms. Inhaled salbutamol and ipratropium, alongside

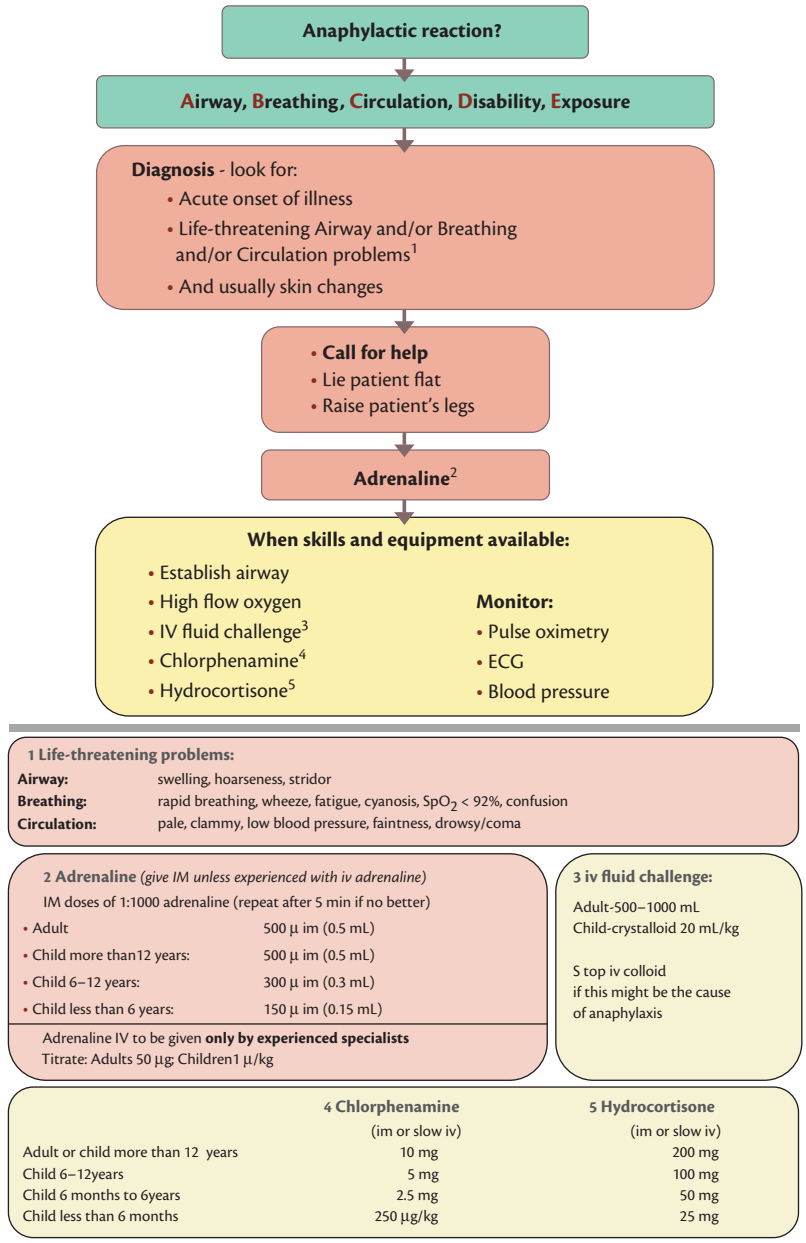

Fig. 314.1 Anaphylaxis treatment algorithm.
Reproduced with the kind permission of the Resuscitation Council (UK).

iv therapy (salbutamol, aminophylline, magnesium) may be considered.

Vasopressors

Use of second-line vasopressors and inotropes including vasopressin, norepinephrine, terlipressin, metaraminol, methoxamine and glucagon have been described [6]. Their use may be considered in the critical care unit by those experienced in their use. Glucagon may be particularly useful in anaphylaxis to beta-blockers [6]. In severe cases, cardiopulmonary bypass may be beneficial.

Rocuronium and sugammadex

The modified gamma-cyclodextrin sugammadex acts to encapsulate rocuronium and other aminosteroid NMBAs. Case reports are described of its use to treat aminosteroid-induced anaphylaxis [10–12].

Investigations

Standard investigations for all medical emergencies should include 12-lead ECG, chest X-ray, urea, and electrolytes, and arterial blood gases. Some specific tests are also applicable.

Tryptase

Mast cell tryptase is the major protein component of mast cell secretory granules. Together with histamine and other amines, tryptase is released in anaphylactic and anaphylactoid reactions. The normal basal plasma tryptase is <1 ng/mL. Peak concentrations >20 ng/mL

occur 1–2 hours after onset of anaphylaxis. Mast cell tryptase has a half-life of approximately 2 hours; therefore, levels may return to normal within 8 hours.

Measurement of mast cell tryptase is essential to diagnose anaphylaxis. These should be taken:

- As soon as possible after resuscitation.
- 1–2 hours post-onset of symptoms.
- At 24 hours (or in follow-up clinic) to define basal levels.

Skin prick testing

In patients who have suffered from IgE-mediated anaphylaxis, efforts should be made to identify the trigger. Sensitization to potential trigger agents can be detected through skin prick tests, which demonstrate the presence of specific IgE antibodies. These should be performed 4–6 weeks after the reaction.

Methylhistamine

Histamine is principally metabolized to methylhistamine, which is then excreted in the urine. Raised urinary concentrations can be detected following reactions that involve systemic release of histamine.

RAST/CAP

In vitro testing systems can be used to measure specific IgE, e.g. radio-allergosorbent test (RAST). The CAP system has replaced RAST testing in some laboratories. This fluoroimmunoassay measures antigen-specific antibodies and is often more sensitive than RAST.

Follow-up and prophylaxis

Following successful treatment of suspected anaphylaxis, patients should be observed in an appropriate clinical area with facilities for treatment of acute medical emergencies.

Up to 20% of patients may suffer from a biphasic reaction. Consequently, all patients should be reviewed by a senior clinician, educated on the signs and symptoms, and advised to return if they recur. The European Resuscitation Council recommends consideration of discharge with 3 days of antihistamine and steroid treatment to minimize the risk of recurrence [6]. An epinephrine auto-injector should also be considered for those at risk of idiopathic anaphylaxis, or in whom the trigger is difficult to avoid, e.g. insect stings, food reactions. Education on the appropriate use of an auto-injector is vital.

Follow-up

The patient's general practitioner should be informed and follow-up in an allergy clinic is required. The aim of follow-up is to identify the cause, reduce the risk of further reactions, and educate the patient on diagnosing and initiating management themselves if appropriate.

SECTION 15

Poisoning

PART 15.1

Principles of management

CHAPTER 315

Role of toxicology assessment in poisoning

Albert Jaeger

Key points

- Diagnosis of acute poisoning is based on history, symptoms, biomedical investigations, toxicological analyses, and sometimes therapeutic tests.
- An accurate and useful toxicological analysis needs good collaboration between the physician and the analytical toxicologist.
- Toxidromes, electrocardiographic disturbances, and biomedical abnormalities may provide diagnostic clues for specific poisons.
- Indications for toxicological analysis include assessment of diagnosis, evaluation of severity and prognosis, indication and evaluation of treatments, and medicolegal implications.
- Interpretation must take into account kinetic and toxicodynamic variation, type of poisoning, and factors such as age and underlying diseases.

Introduction

Diagnosis of acute poisoning is based on history, symptoms, biomedical investigations, toxicological analyses, and sometimes therapeutic tests [1]. Toxicological analytical methods are now widely available, but extensive and specific quantitative analyses are expensive. Therefore, the indications should be carefully considered by the physician according to assessment of diagnosis, evaluation of severity and prognosis, indication and evaluation of treatments, and medicolegal implications. The interpretation needs to take several factors into account depending on the poison and the patient.

Methods

Before a toxicological analysis is performed, the physician and the analytical toxicologist should discuss the following points [2]:

- Which substance (the parent compound and/or the metabolite(s)) should be analysed and in what biological sample(s)?
- What type of analytical method (qualitative or quantitative) and what specificity are needed?
- Is the analysis useful for the management of the patient?
- Within what time limit should the results be available for the physician?

A qualitative or semiquantitative analysis of the parent compound (or the active or non-active metabolites) may be adequate for diagnostic assessment. A quantitative analysis of the parent compound is mandatory for kinetic studies. Analysis of the parent compound and the active metabolite(s) is needed for toxicodynamic assessment (symptom–concentration relationship) [2,3]. For instance, in ethylene glycol poisoning, analysis of ethylene glycol concentrations is useful for the diagnosis, but glycolate concentrations are more relevant for the evaluation of the severity and prognosis. Therefore, the analytical toxicologist should be precisely informed about the indications and the objective of the analysis.

Indications

Assessment of diagnosis

The usefulness of systematic toxicological screening in poisoned patients has not been established. In several reports, the concordance between the drug(s) suspected clinically and the drugs detected by toxicological screens ranged from 26 to 96%, and were dependent on the physician, the age of the patient, and the drug ingested [2]. The results rarely contributed to the management of the patient. Toxicology screens give qualitative or semiquantitative results for drugs that are frequently involved in poisonings, but they do not usually include toxins that induce severe poisoning, and for which analysis is essential for the prognosis or the treatment (e.g. theophylline, digoxin, lithium, carbon monoxide, methanol, ethylene glycol, etc.) [2,3].

In practice, four different situations may be observed:

- **Poisoning is definite, the toxin(s) is known according to the history, and the symptoms are related to the toxin(s) and dose**: a toxicological analysis is not absolutely necessary if it has no prognostic, therapeutic, or medicolegal implications.
- **Poisoning is definite and the toxin(s) is known, but the symptoms are not related to the suspected toxin(s) or to the dose**: a toxicological analysis is indicated in order to detect other toxins that may have been ingested.
- **Poisoning is suspected because of symptomatology (toxic symptoms or syndromes), but the toxin(s) is unknown**: only a toxicological analysis can confirm or refute poisoning.
- **Poisoning must be excluded by toxicological analysis**: in patients presenting with disturbances of the central nervous

system (trauma, brain death, in elderly patients), cardiovascular symptoms, or convulsions.

According to the history, the symptoms and biomedical abnormalities, the analysis should be directed towards specific drugs or groups of drugs.

Groups of symptoms (or toxidromes), such as those involving the autonomic nervous system, electrocardiogram (ECG) disturbances, and biomedical abnormalities may provide diagnostic clues for toxins that are not usually included in routine screens. They reflect directly the toxic effects and are often more useful than the measurement of plasma drug concentrations in the management of the patient [1,2]. Some examples of toxidromes, ECG disturbances, and biomedical abnormalities in specific poisonings are given in Tables 315.1, 315.2, and 315.3.

Therapeutic tests, such as naloxone in opiate and flumazenil in benzodiazepine poisoning, may also confirm the diagnosis [1].

Evaluation of severity and prognosis

In order to establish the relationship between the severity and the blood/plasma concentrations, the analysis must be specific and quantitative and sometimes include the active metabolites. The relationship is dependent on the mechanism of toxicity [3].

Functional toxins (e.g. barbiturates, benzodiazepines, meprobamate, cardiotropic drugs, lithium, theophylline, etc.) impair the function of one or more organs. Patients recover without sequelae if no complications occur during the poisoning. Their toxicity is directly related to the concentration at the target organ or receptor, Symptoms appear when the plasma concentration exceeds a threshold level, and the severity increases with the concentration (Fig. 315.1). The duration of the toxicity is dependent on the plasma half-life and the decrease of the concentration at the target organ. For instance, in barbiturate, meprobamate, or ethanol poisoning, the severity of disturbances of the central nervous system and coma is closely related to the plasma concentration. In acute theophylline poisoning, toxicity is minor at concentrations between 20 and 40 mg/L, moderate at concentrations between 40 and 100 mg/L, and severe at concentrations above 100 mg/L. If the parent compound is metabolized into active metabolites that have not been analysed, there is not usually a relationship between plasma parent drug concentrations and symptoms [3].

Lesional toxins (paraquat, paracetamol (acetaminophen), colchicine, amatoxins, heavy metals, etc.) induce cellular or organ damage. The severity depends on the maximum concentration that has been (or will be) reached at the target organ. If cellular damage has occurred, symptoms may not improve even though the toxin has been eliminated from the target organ. The interpretation has to

Table 315.1 Toxidromes involving the autonomic nervous system

Syndrome	Mechanism	Symptoms	Toxins
Cholinergic Muscarinic	Stimulation of cholinergic receptors ↑ acetylcholine production or ↓ acetylcholine degradation	Sweating, hypersalivation, bronchorrhea, diarrhoea, vomiting, miosis, bradycardia	Acetylcholine, pilocarpine, mushrooms (Clitocybe), organophosphate and carbamate insecticides
Nicotinic		Tachycardia, hypertension, fasciculation, paralysis	Nicotine, nicotinic, and organophosphate insecticides
Anticholinergic (or atropinic)	Cholinergic receptors blockade	Dry skin, hyperthermia, mydriasis, tachycardia, confusion, hallucinations, hyperventilation, agitation	Atropine, *Atropa belladonna*, Datura, mushrooms (*Amanita muscaria*, *A. pantherina*), TCA, antihistamines, antiparkinson-drugs
Sympathomimetic (or adrenergic)	Stimulation of α and β-adrenergic receptors	Agitation, convulsion, hypertension, tachycardia, hyperglycaemia, hypokalaemia, leucocytosis, hyperlactataemia	Caffeine, xanthines, theophylline, amphetamines, cocaine, LSD, phencyclidine
Narcotic (or opioid)	Opiate receptors agonist effect	CNS depression, hypoventilation, hypotension, miosis	Heroin, morphine, codeine, dextropropoxyphene
Withdrawal	Adrenergic stimulation	Insomnia, hallucinations, agitation (convulsion), diarrhoea, mydriasis, sweating, tachycardia, cramps	Withdrawal of alcohol, benzodiazepines, opiates
Antabuse	Acetaldehyde accumulation	Cutaneous flush, tachycardia, headache, hypotension, hyperventilation	Disulfiram, dithiocarbamates, mushrooms (Coprinus), dimethylformamide
Serotoninergic	↑ Serotoninergic brain activity, increased activity of 5-HT1A réceptors	Hyperthermia, dysautonomia, tachycardia, consciouness disturbances, hypertonia, hyperreflexia, myoclonia	Serotonin reuptake inhibitors, serotonin receptor agonists
Neuroleptic malignant	Dopaminergic receptors antagonism, acute depletion of dopamine	Hyperthermia, dysautonomia, tachycardia, consciousness disturbances, hypertonia, rhabdomyolysis, hyperleucocytosis	Piperazine-type neuroleptics
Ecstasy (MDMA)	Disturbances of dopaminergic and serotoninergic neurones, ↑ production of serotonin	Hyperthermia, dysautonomia, tachycardia, consciousness disturbances, hypertonia, disseminated intravascular coagulation, rhabdomyolysis, renal failure	MDMA

LSD, lysergic acid diethylamide; CNS, central nervous system; MDMA, 3-4-methylene dioxymethamphetamine.

Table 315.2 ECG disturbances induced by poisons

Disturbances	Effects	Toxins
Tachycardia	Anticholinergic	Atropine, *A. belladona*, Datura, anti-H1 histaminines, TCA, quinidine, disopyramide
	Betamimetic	Salbutamol, theophylline, xanthines, caffeine
	Alphamimetic	Amphetamines, cocaine, ephedrine
Bradycardia	Cholinergic	Acetylcholine, some opiates, organophosphates
	Beta-blockade	Beta-blockers
	Na-K-ATPase inhibition	Digoxin, digitoxin
	Ca channel blockade	Class IV AAR
	Na channel blockade	Class I AAR, chloroquine, TCA, some beta-blockers
	Alphalytic	Clonidine, methyldopa
Ventricular dysrhythmias (VES, VT, VF, torsades de pointes)	Betamimetic	Salbutamol, theophylline
	Alphamimetic	Amphetaminines, cocaine, ephedrine, trichloroethylene
	Na-K-ATPase inhibition	Digoxin, digitoxin
	Na channel blockade	Class I AAR, chloroquine, TCA, some beta-blockers
Atrioventricular block	Na-K-ATPase inhibition	Digoxin, digitoxin
	Na channel blockade	Class I AAR, chloroquine, TCA, some beta-blockers, ciguatoxin, tetrodotoxin
Intraventricular block (QRS > 0,10 s)	Na channel blockade	Class I AAR, chloroquine, TCA, some beta-blockers, thioridazine
Increased QT interval	K channel blockade	Amiodarone
	Na channel blockade	Class I AAR, chloroquine, TCA, some beta-blockers

TCA, tri-tetracyclic antidepressants; AAR, anti-arrhythmics; VES, ventricular extrasystoles; VT, ventricular tachycardia; VF, ventricular fibrillation.

Table 315.3 Biomedical disturbances in specific poisonings

Disturbances	Toxin
◆ Anion gap	◆ Methanol, ethylene glycols, acetone
◆ Osmolal gap	◆ Ethanol, methanol, ethylene glycols, acetone
◆ Hypoglycaemia	◆ Insulin, oral antidiabetics
◆ Hypokalaemia	◆ Chloroquine, theophylline
◆ Hyperkalaemia	◆ Digoxin, digitoxin
◆ Hypocalcaemia	◆ Fluoride
◆ Pseudohyperchloraemia	◆ Bromine and bromide
◆ Decreased prothombin level	◆ Oral anticoagulants, rodenticides, snake venoms
◆ Methaemoglobinaemia	◆ Methaemoglobin-forming agents
◆ Decreased plasma or erythocyte cholinesterase level	◆ Organophosphate and carbamet insecticides
◆ Oxalate crystals in urine	◆ Ethylene glycol
◆ Gastric opacities on radiographs	◆ Metals, halogenated hydrocarbons

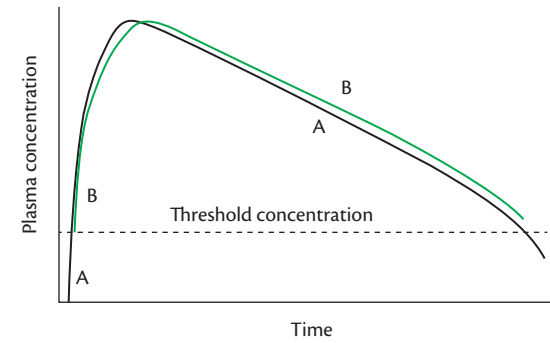

Fig. 315.1. Toxicokinetic–toxicodynamic relationship for a functional poison (monocompartment kinetics).

Curve A, concentration; curve B, toxic effect.

take into account the plasma concentration and the time at which this concentration has been measured. Depending on the delay following ingestion, the same plasma concentration may be non-toxic, toxic, or lethal (Fig. 315.2). In these poisonings, plasma concentrations have a prognostic value: risk of lethal outcome in paraquat poisoning [4], and risk of hepatitis in acetaminophen poisoning [5].

Some toxins act by both mechanisms: the parent compound is a functional toxin, but after a delay cellular damage due to prolonged cellular hypoxia (carbon monoxide, cyanide) or to the accumulation of cytotoxic metabolites (methanol, ethylene glycol) may occur. The interpretation is based on the kinetic data (plasma concentrations of

the parent compound and metabolites) and on the time after ingestion or the duration of the exposure [3]. In acute short exposure to carbon monoxide, the symptoms correlate well with carboxyhaemoglobinaemia levels. In prolonged exposure, the severity depends not only on the carboxyhaemoglobin level, but also on the duration of the cerebral hypoxia. The potential toxicity of methanol is related to the methanol concentration measured in the early phase of the poisoning. The real toxicity depends on the concentrations of the toxic metabolites. If the patient is seen in a later phase, severe symptoms may be present despite low methanol concentrations.

Indication and evaluation of treatments

The management of the poisoned patient is mostly supportive and based on anamnestic, clinical, and biological data. Toxicological quantitative analyses are mandatory for some treatments [3]. Depending on the analytical results and clinical data, the physician will estimate the indication of the following:

- Alkaline diuresis in salicylate poisoning.
- Repeated dose of oral activated charcoal in phenobarbital or theophylline poisoning.
- Haemodialysis in lithium, methanol, ethylene glycol, and salicylate poisoning, and haemoperfusion in carbamate or theophylline poisoning.
- Ethanol or 4-methylpyrazole in ethylene glycol or methanol poisoning, *N*-acetyl cysteine in acetaminophen poisoning.
- Chelating agents in metal poisoning or deferoxamine (desferrioxamine) in iron poisoning.

In digitalis poisoning, the indication for Fab fragments is essentially based on clinical and biochemical (hyperkalaemia) criteria, but previous confirmation of the diagnosis by measurement of digitalis plasma concentration is recommended.

Evaluation of the methods used for decontamination or enhancing elimination must be based not only on clinical improvement but also on precise kinetic data which vary depending on the technique used.

Medicolegal implications

Quantitative and specific analyses are indicated if the poisoning may have medicolegal consequences (e.g. occupational or criminal poisoning).

Interpretation

Apart from the mechanism of toxicity, other factors must be taken into account in the interpretation of analytical and kinetic data [2,3].

Type of poisoning

Similar plasma concentrations may be associated with different severity, depending on the type of poisoning: acute, acute on chronic, or chronic. Toxic symptoms appear at lower plasma concentrations in chronic theophylline poisoning than in acute poisoning; convulsions and severe dysrhythmias may appear at concentrations between 40 and 70 mg/L, and the probability of developing convulsions is 50% when the peak concentration exceeds 40 mg/L whereas in acute poisoning the same probability is only observed if the peak concentration is above 120 mg/L. In chronic lithium poisoning, severe disturbances of the central nervous system may appear at supratherapeutic plasma concentrations (>1.2 mmol/L), whereas in acute poisoning no toxicity has been reported at concentrations ranging up to 8 mmol/L [3]. Similar severity of digoxin poisoning is observed at lower plasma digoxin concentrations in chronic overdose than in acute poisoning.

With some toxins (barbiturates, ethanol), a tolerance may be observed in patients treated or poisoned chronically. In acute ethanol poisoning with similar blood ethanol levels, symptoms are less severe in chronic alcoholics than in non-tolerant individuals. Patients treated chronically with barbiturates are more tolerant to acute barbiturate toxicity and the duration of coma is often shorter because of an increase in hepatic elimination by enzyme induction.

Age

In chronic theophylline overdoses with the same plasma concentrations, symptoms and prognosis are more severe in elderly patients than in young adults. For a given plasma concentration, the cardiotoxic effects of digoxin are more severe in adults than in children.

Underlying diseases and toxic symptoms

An underlying disease or toxic symptoms, such as hypoxaemia and shock, may strongly modify the toxicodynamics [3]. In theophylline poisoning, the risk of toxicity and the plasma half-life are increased in patients with congestive heart failure because of impaired elimination by hepatic metabolism. Patients with epilepsy are at higher risk of developing convulsions in poisoning with drugs that may induce convulsions. In poisoning with cardiotropic drugs, the toxicity is increased in patients with chronic heart diseases. In acute meprobamate overdoses, the plasma half-life is increased in patients with shock.

Concurrent ingestion of other drugs

The ingestion of drugs with anticholinergic effects may prolong the gastrointestinal absorption of other drugs. In poisoning with several cardiotoxic drugs with synergistic effects severe symptoms may appear even if the plasma concentration of each drug individually is at a therapeutic level.

Dose ingested

Dose-dependent kinetics, with a change from first-order to zero-order kinetics, have been reported in massive theophylline and salicylate poisoning.

Acknowledgements

The editors were saddened to hear of the death of Dr Albert Jaeger since writing this chapter of the book.

CHAPTER 316

Decontamination and enhanced elimination of poisons

Darren M. Roberts

Key points

- Decontamination or enhanced elimination should not be used routinely for the treatment of acute poisoning. They are initiated on a case-by-case basis after consideration of the type of poison, amount and time since exposure, anticipated clinical benefit, and other factors.
- Decontamination aims to decrease the severity and, potentially, duration of poisoning. Activated charcoal is the most common form used and, in most cases, should be administered within 1–2 hours of poison ingestion.
- Enhanced elimination aims to decrease the duration and other consequences of poisoning. It is most commonly used in severe poisoning with an agent that has a long elimination half-life.
- Elimination of a poison can be enhanced with extracorporeal therapies, multiple doses of activated charcoal, sodium polystyrene sulphonate and urinary alkalinization. Data support their use in selected cases.
- To maximize poison clearance by haemodialysis or haemofiltration, the prescribed regimen may differ to that used for renal replacement therapy.

Introduction

Assessing the need for and implementation of urgent resuscitation is the first priority in the management of the poisoned patient. This is followed by the simultaneous consideration of decontamination, enhanced elimination, antidotes, and ongoing monitoring and disposition.

The term poison is used to describe any medicine, drug, chemical, natural toxin, or other xenobiotic capable of inducing poisoning. Decontamination and enhanced elimination have the principle roles of decreasing the body burden of the poison, thereby reducing the severity and/or duration of poisoning. Such treatments are administered on a case-by-case basis after consideration of clinical, physicochemical, and pharmacokinetic factors. As with any intervention, the potential risks and benefits must be considered.

Concepts in kinetics

Kinetics refers to the absorption, distribution, metabolism and excretion of a poison following an exposure [1].

The rate and extent of absorption depends on the physicochemical properties of the poison and the biological membrane. Intravenous administration bypasses absorption processes. Absorption is largely complete within 2 hours following oral exposure, although absorption may be prolonged or erratic in the following cases:

- Ingestion of modified release formulations.
- Co-ingestants that retard intestinal motility, e.g. opioids or anticholinergics.
- If the poison is poorly soluble in the intestinal fluid, including the case of massive ingestions.
- Conditions that impair intestinal function, including hypotension, hypothermia, hypoxaemia, or autonomic neuropathy.

Distribution refers to the physiological process where a poison crosses from the central compartment (plasma) into peripheral (extravascular) compartments, including adipose tissue, the intracellular fluid, or the cerebrospinal fluid. The rate and extent of this depends on the poison and time since the exposure. A poison may distribute into a compartment where it does not have a clinical effect (a 'sink') or a compartment where it can mediate a clinical effect (a 'toxic compartment').

Elimination is the sum effect of metabolism and excretion. Excretion may occur via the kidney, gastrointestinal system (e.g. biliary system) or, less commonly, via respiration.

Decontamination

General comments

The decision to perform decontamination is based on the history of exposure. Decontamination must be commenced prior to completion of absorption, which is usually within 1–2 hours of ingestion, with the exceptions outlined previously. This opportunity is uncommon in clinical practice.

Fig. 316.1 shows the effect of gastrointestinal decontamination on the concentration–time curve. Effective decontamination decreases the amount of poison absorbed into the systemic circulation. This has the effect of decreasing the severity of poisoning due to a decrease in the maximum concentration (C_{max}) and also the area under the concentration–time curve (AUC). Decontamination may also decrease the duration of poisoning, particularly when there is extensive distribution of the poison to the extravascular space.

A number of different interventions may be used for decontamination following oral exposure, including activated charcoal, whole

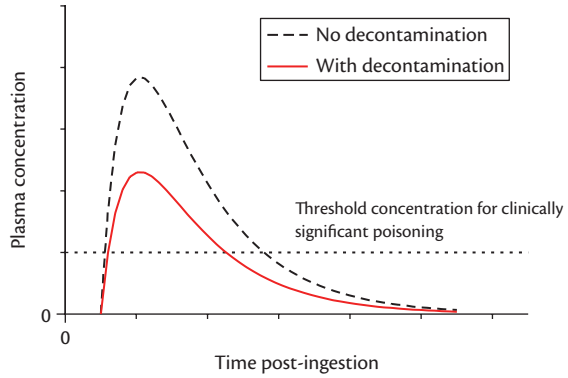

Fig. 316.1 The effect of gastrointestinal decontamination on the concentration–time curve. Gastrointestinal decontamination decreases the bioavailability of a toxic exposure. This shows how a 40% decrease in bioavailability decreases the C_{max} and the duration of poisoning. This simulation is likely to exaggerate the actual effect of gastrointestinal decontamination in clinical practise because patients rarely present to hospital within 1 hour when the maximal effect of decontamination is expected.

bowel irrigation, gastric lavage, and Fuller's earth. The usual indications and contraindications for these treatments are summarized in Table 316.1. Forced emesis is unlikely to be useful for patients admitted to hospital.

In other exposures, decontamination involves washing/irrigating the skin with dermal or ocular exposures, and moving the patient to fresh air with respiratory exposures.

Activated charcoal

Enteral activated charcoal is the most common method of decontamination. It reversibly adsorbs poisons via hydrostatic bonds so its use is limited to organic poisons, while alcohols, acids, and metal ions are not adsorbed. The dose is 50–100 g (or 1–2 g/kg in children) mixed with water, and ingested by the patient or instilled into a gastric tube. Activated charcoal is usually given as a single dose, although multiple doses may be given for ingestion of modified release formulations or for enhanced elimination.

Randomized controlled trials have not demonstrated a clinical benefit from the routine administration of activated charcoal in predominantly pharmaceutical [2] or pesticide poisoning [3]. However, in early presentation of highly toxic exposures it may be beneficial. Other studies have suggested benefits for clinically relevant measures when activated charcoal is administered early to patients with a significant exposure, including paracetamol (acetaminophen) [4], and psychotropic agents including citalopram [5], venlafaxine [6], promethazine [7], and quetiapine [8]. Although activated charcoal appears to have a favourable effect on the kinetics on *Thevetia peruviana* cardenolides [9], two randomized controlled trials reported conflicting results in terms of clinical benefits from multiple doses [3,10].

The risk of activated charcoal appears to be low. It is prudent to give it only to patients with a protected airway (including patients who are alert and willing to self-administer it) to minimize aspiration.

Enhanced elimination

General principles

Enhanced elimination is used for the purpose of increasing removal of the poison from the body. The decision to perform it is usually based on confirmed exposure, e.g. an elevated blood concentration or clinical features of poisoning, and does not depend on the

Table 316.1 Choices for decontamination following ingestion of a potentially toxic dose of a poison

	Activated charcoal	Whole bowel irrigation	Gastric lavage	Fuller's earth
Poisons to consider	Organic poisons (not acids, alkalis, metals or alcohols)	Modified release formulations; poisons not absorbed by activated charcoal, 'body packers'	Highly toxic liquids	Paraquat, any confirmed exposure
Indications	Ingestion within 1–2 hours; potentially up to 4 hours if impaired gastric emptying	Up to 24 hours post-exposure depending on the poison	Ingestion within 1 hour	Ingestion within 1–2 hours
Risks	Aspiration (uncommon if airway protected) or bowel obstruction (rare)	Aspiration (uncommon if airway protected)	Aspiration (airway must be protected); oesophageal trauma, particularly with caustic ingestions	Aspiration due to emesis (uncommon)
Dose	50–100 g in adults; 1–2 g/kg in children	1–2 L/hour of polyethylene glycol until the rectal effluent is clear	Not specified	150 g in adults
Evidence supporting intervention	In vitro studies support binding. Volunteer studies show effect if administered within 1 hour. Clinical studies support a benefit with selected, but not routine use; mortality benefit not reported	Observational studies, largely case reports	Observational studies, largely case reports. A quasi-randomized controlled trial suggested no benefit with routine use in predominantly pharmaceutical poisoning [12]	In vitro studies support binding
Other comments	Admix with water according to manufacturer guidelines. See discussion in text	Admix with water according to manufacturer guidelines	Wide-bore orogastric tubes may remove tablet fragments, but this is usually a small proportion of the dose	Admix with water according to manufacturer instructions. Infrequently available, use activated charcoal instead

route of administration. Candidate poisons have the following characteristics [1]:

- **Small volume of distribution (generally <1 L/kg) with single compartment kinetics**: for poisons with a larger volume of distribution, enhanced elimination may still be beneficial, but should be commenced prior to significant distribution from the vascular compartment (i.e. as soon as possible post-exposure) and a prolonged course may be necessary.
- **Low endogenous clearance, including renal impairment for poisons that are renally cleared**: this is reflected in a prolonged elimination half-life (although this may also occur with large volumes of distribution).
- **Binds minimally to plasma proteins**: in overdose there may be saturation of protein binding which increases the effect of enhanced elimination, e.g. valproate, salicylate, chlorophenoxy herbicides.
- **The clinical effect is reversible**: if irreversible then treatment should be commenced before they occur to a significant extent

Enhanced elimination decreases the duration of poisoning due to a shortening in the apparent elimination half-life (Fig. 316.2). If performed prior to the C_{max}, or prior to distribution of the poison from the central compartment to a toxic compartment, then it may decrease both the severity and duration of poisoning, similar to the representation shown in Fig. 316.1. Enhanced elimination may also decrease the severity of poisoning by removing the poison from the central compartment prior to distribution to a toxic compartment, for example minimizing salicylate-induced uncoupling of oxidative phosphorylation.

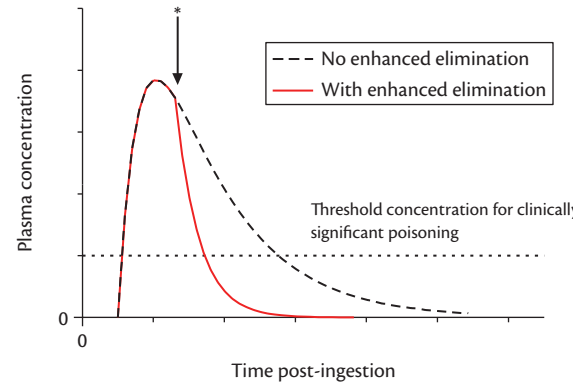

Fig. 316.2 The effect of enhanced elimination on the concentration-time curve. An enhanced elimination technique that increases clearance by 40% is initiated as indicated by the arrow and asterisk (*). This has the effect of decreasing the apparent elimination half-life and the duration of poisoning.

A number of interventions may enhance the elimination of a poison, including multiple dose activated charcoal, sodium polystyrene sulphonate, extracorporeal treatments (in particular haemodialysis, haemofiltration, or haemoperfusion), urinary alkalinization, antidotes, and high flow oxygen. The usual indications and contraindications for these treatments are listed in Table 316.2. Clinical studies confirm a kinetics benefit for most of these treatments, but clinical benefits are less clearly reported. Examples of antidotes include antivenom (various snakes and spiders), antidigoxin Fab antitoxin (digoxin, oleander, other cardioactive steroids) and chelators such as desferrioxamine, hydroxocobalamin,

Table 316.2 Choices for enhanced elimination following exposure to a potentially toxic dose of a poison

	Multiple doses of activated charcoal	Haemodialysis or haemofiltration	Haemoperfusion	Urinary alkalinization	Sodium polystyrene sulphate	High flow oxygen
Mechanisms of action	Gastrointestinal dialysis, interruption of enterohepatic recirculation	Direct extraction from the vascular compartment	Direct extraction from the vascular compartment	Decrease reabsorption in the distal tubule	Cation exchange resin promoting gastrointestinal dialysis	Promotes dissociation of carbon monoxide from haemoglobin
Poisons to consider	Carbamazepine, aspirin, theophylline, phenobarbital, digoxin, dapsone, colchicine, modified release tablets, valproate, *Amanita phalloides*	Toxic alcohols, aspirin, lithium, valproate, potassium, phenobarbital. Also if renally cleared in the context of kidney impairment (e.g. metformin)	Theophylline, paraquat (within 2 hours), phenobarbital	Aspirin, chlorophenoxy herbicides, methotrexate	Lithium and potassium	Carbon monoxide
Risks	Aspiration (uncommon if airway protected) or bowel obstruction (rare)	Procedural complications, electrolyte abnormalities	Procedural complications, electrolyte abnormalities, thrombocytopaenia	Electrolyte abnormalities, blood alkalinization	Aspiration (uncommon)	
Dose	12.5 g hourly, or 25 g every 2 hours	Maximize blood flow rate, dialysate flow rate, filter surface area, duration	Maximize blood flow rate and change the column every 2–3 hours	Intravenous sodium bicarbonate to achieve urine pH >7.5	30 g every 4–6 hours depending on severity	15 L/min via a non-rebreathing mask until recovery
Other comments	Admix with water as per manufacturer guidelines		Clearance decreases with time due to column saturation	Ensure normokalaemia	Mix with diluent as per manufacturer guidelines	

succimer, and ethylenediaminetraacetic acid (EDTA). Acid diuresis and forced diuresis are not performed.

Lithium

Lithium fulfils many of these characteristics so enhanced elimination is commonly considered in the treatment of poisoned patients. However, because of other kinetic characteristics of lithium the indications and benefits of such treatments are poorly defined at present [13].

Neurotoxicity is the most important clinical manifestation of severe lithium poisoning and it is uncommonly observed following acute poisoning. This is because of slow distribution of lithium from the plasma compartment to the brain (the 'toxic' compartment), relative to the rate of distribution to non-toxic compartments and elimination. So, despite potentially high plasma concentrations of lithium initially, the resultant concentration in the brain is lower (Fig. 316.3). However, the risk of neurotoxicity is increased with renal impairment or ingestion of a sustained release formulation, in which case enhanced elimination can be considered.

Acute overdose on a background of therapeutic dosing, or repeated supra-therapeutic dosing may lead to lithium accumulation in the brain and neurotoxicity. Although enhanced elimination techniques can decrease the plasma concentration of lithium, because the rate of redistribution out of the brain is slower than the rate of decrease from the plasma, neurotoxicity can persist despite normalization of the plasma concentration. Furthermore, following high efficiency haemodialysis, there is often a rebound in the lithium plasma concentration due to the slower rate of redistribution to the central compartment. Data demonstrating the effect of enhanced elimination on the duration of neurotoxicity are not currently available.

Extracorporeal therapies

To optimize clearance by an extracorporeal treatment the blood flow rate, filter surface area and pore size and effluent (dialysate and/or ultrafiltrate) production should be maximized. Special considerations include the following:

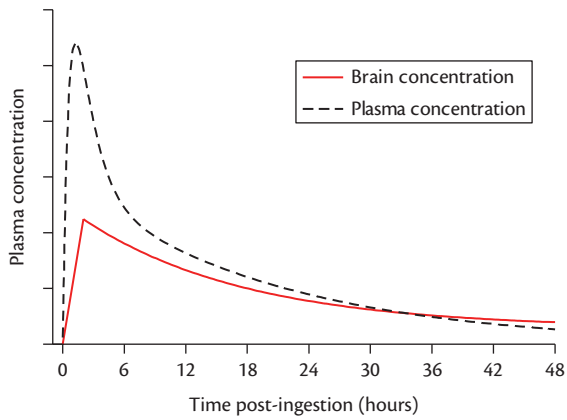

Fig. 316.3 Representation of the kinetics of lithium in the plasma and brain following an acute poisoning. The slower rate of distribution of lithium into the brain causes a lower C_{max} in the brain compared to that observed in the plasma. The rate of redistribution back to the plasma compartment is slower than the rate of systemic elimination leading to a relative accumulation in the brain. Despite this, because the concentration in the brain remains relatively low neurotoxicity is unlikely to develop.

- When a poison displays significant extravascular distribution, an increase (rebound) in the plasma concentration may be observed when the extracorporeal treatment is completed. This rebound may be accompanied by a clinical deterioration so close monitoring is required. Fig. 316.4 shows the relative effect of two extracorporeal regimens in valproate poisoning. A rebound in the plasma concentration is seen following cessation of the intermittent technique.
- In the case of haemodynamic instability a continuous extracorporeal technique may be better tolerated, although this is at the expense of poison removal.
- Charcoal haemoperfusion can achieve high clearances, including poisons that are bound to plasma proteins such as theophylline. However, supply of the cartridges is frequently limited

Determination of the endpoint of therapy or the optimal dose requires consideration of the desired effect of an enhanced elimination technique. The following factors can be considered:

- A clinical end point, such as recovery from unconsciousness or extubation.
- Confirmed removal of the poison by blood tests.
- A kinetic end point, such as the percentage change in clearance or half-life. A minimum change of 30% has been considered significant, although this value was based on therapeutic dosing. A lesser percentage increase may be clinically significant for a poison with a prolonged elimination half-life.

These assessments are complicated by variability in the time since and amount of exposure, co-ingestants, patient demographics, and endogenous organ function.

Removal of poison from the toxic compartment

It is claimed that some treatments enhance elimination from a toxic compartment. The rationale is that if a relatively small concentration

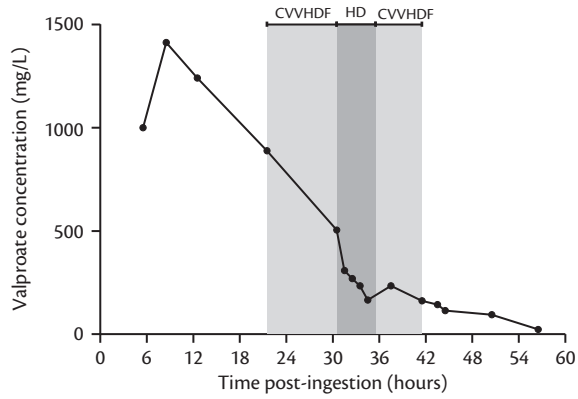

Fig. 316.4 The apparent elimination half-life of valproate is seen to be shorter during haemodialysis (HD) compared with during continuous venovenous haemodiafiltration (CVVHDF), suggesting that HD is a relatively more efficient method of enhanced elimination. Note the rebound in the plasma concentration of valproate after HD, reflecting faster elimination from the blood compartment during HD compared to the rate of redistribution from extravascular tissues. A similar phenomenon is reported with lithium and barbiturates.
Reproduced from TD Kay et al., 'Hemodialysis versus continuous veno-venous hemodiafiltration in the management of severe valproate overdose', *Clinical Nephrology*, **59**(1), pp. 56–8, copyright 2003, with permission from Dustri-Verlag.

of poison at the toxic compartment is sufficient to cause poisoning, then a treatment that decreases that concentration may be clinically useful, even if it does not significantly alter the total body burden. This had been suggested with haemoperfusion for cardiotoxic poisons with a large volume of distribution (e.g. tricyclics antidepressants). However, supporting data are lacking and this treatment is no longer recommended [14].

The intervention that has received much attention in this area is intralipid emulsion (ILE). Here, the poison is thought to be distributed from the toxic compartment into a lipid sink created by ILE (there are other proposed mechanisms of action). Animal studies are limited, case reports of life-saving effect of ILE are published, while others report a less dramatic effect; these observations are likely to reflect at least in part a publication bias. A very small randomized controlled trial reported an improvement in consciousness and decrease in blood glucose by ILE with non-local anaesthetic drug poisoning [11]. Furthermore, the complications of ILE may not be negligible.

At present, the use of ILE in the management of acute poisonings is limited to bupivacaine-induced cardiotoxicity, and life-threatening cardiotoxicity due to other poisons unresponsive to usual therapies—it is not first-line therapy. More data are required that confirm the time-course response to ILE on dynamic measures of toxicity, such as haemodynamics or the electrocardiogram.

Conclusion

Consideration of decontamination or enhanced elimination in a patient always follows acute resuscitation and the risk assessment. Decontamination and enhanced elimination aim to modify the kinetics of a poison and decrease the severity and/or duration of poisoning. The decision to perform these treatments is determined on a case-by-case basis. Poison information centres and clinical toxicologists are available in many parts of the world to provide advice.

PART 15.2

Management of specific poisons

CHAPTER 317

Management of salicylate poisoning

Brenna M. Farmer and Neal Flomenbaum

Key points

- Salicylates are weak acids that work as neurotoxins. The goal of management is to keep salicylates out of the brain and enhance elimination.
- Acute salicylate toxicity manifests as tinnitus, nausea, vomiting, and hyperventilation in a patient who takes a single large ingestion.
- Chronic salicylate toxicity is associated with long-term use, has a more insidious onset, and symptoms tend to be less severe, resulting in delayed diagnosis. It is more commonly seen in elderly patients.
- Therapeutic interventions for toxicity include gastrointestinal decontamination, serum and urine alkalinization, and haemodialysis.
- Mechanical ventilation may lead to clinical deterioration and death in a salicylate-poisoned patient, due to worsening acidosis from respiratory failure. This results in severe acidosis, cerebral oedema, pulmonary oedema, and cardiac arrest.

Introduction

Salicylates are widely used as analgesics, antipyretics, anti-inflammatories, and antiplatelet agents for cardiovascular prophylaxis. Salicylates can cause severe poisoning and death, thus every case of ingestion must be taken seriously. Acute and chronic toxicity may occur with salicylate poisoning. Deaths occur because of misdiagnosis, lack of understanding of the complexity and severity of salicylate overdose, and lack of appropriate management. Salicylates are found in many products including aspirin (acetylsalicylic acid), methyl salicylate (oil of wintergreen; found in liniments and rubifacients), choline salicylate (found in some teething gels), and salicylic acid, which has keratolytic properties. Aspirin comes as tablets or capsules (75–500 mg). It can be in enteric-coated products and in combination products with caffeine, paracetamol, barbiturates, and opioids.

Toxicity and mechanisms

Therapeutically, salicylates are used for their inhibition of cyclo-oxygenase (COX) leading to decreased prostaglandins, prostacyclin, and thromboxane. By decreasing these substances, salicylates produce analgesia, anti-inflammatory and antipyretic effects, and reduce platelet aggregation.

Salicylates are absorbed in the stomach and small intestine. Enteric-coated products can have delayed toxicity as the coating slows absorption. Once absorbed, aspirin is rapidly converted to salicylic acid, which is further metabolized to five main metabolites—salicyluric acid, salicyl phenolic glucuronide, gentisic acid, acyl glucuronide, and gentisuric acid. The pathways for the first two metabolites involve saturable hepatic enzymes. Normally, at therapeutic doses, these liver enzymes eliminate the majority of the salicylate. However, when a large amount of salicylate is ingested, these routes quickly become saturated. This results in a change from first-order kinetics, where elimination is proportional to the plasma concentration, to zero-order kinetics, where only a certain amount is eliminated irrespective of the plasma concentration. Thus, salicylate may accumulate following mild therapeutic overdoses, particularly in children or the elderly, and prior therapeutic use of the drug may increase the toxicity of an acute overdose. In toxic doses, renal clearance becomes more important and is very sensitive to pH changes. Salicylic acid is a weak acid that is mainly ionized at serum pH of 7.4 or urine pH that is alkaline. By increasing the pH, i.e. making more alkaline, more of the ionized form of salicylic acid may be trapped in the serum and urine. The ionized form in the urine leads to increased excretion of the salicylic acid and thereby increased elimination. This is the basis of urinary alkalinization in salicylate overdose.

Patients develop hyperventilation from direct stimulation of the central nervous system (CNS) respiratory centre leading to a primary respiratory alkalosis, rarely seen in infants and young children. Aspirin uncouples oxidative phosphorylation, which interferes with oxidative adenosine triphosphate (ATP) production. In the mitochondria, anaerobic metabolism increases to produce ATP, leading to lactate production and an anion-gap metabolic acidosis. The energy normally used to create ATP in oxidative phosphorylation is shunted to heat production and causes hyperthermia. Furthermore, salicylates interfere with glucose and fatty acid metabolism leading to ketosis and further metabolic acidosis. Capillary leak eventually occurs, leading to cerebral and pulmonary oedema. Altered platelet function and coagulopathy occurs due to extension of therapeutic effects of salicylates.

Clinical features

The therapeutic serum concentration of salicylate is 15–30 mg/dL (150–300 mg/L). Toxicity can occur at doses greater than 150 mg/kg or serum concentrations greater than 30 mg/dL (300 mg/L). Acute and chronic toxicity can occur with salicylate poisoning.

Acute toxicity from salicylates occurs from a one-time exposure, usually as an intentional ingestion, resulting in early signs and symptoms of toxicity. Nausea, vomiting, hyperventilation, sweating, and tachycardia are seen. Tinnitus and hearing loss are also common. Chronic toxicity usually occurs in older patients from therapeutic misadventures in trying to treat inflammation or pain and due to increased accumulation from impaired elimination. It usually results in less severe and slower onset of symptoms that are frequently unrecognized as salicylate poisoning. It can be misdiagnosed due to a high prevalence of altered mentation with up to 25% mortality due to delayed diagnosis and treatment [1].

Common early features of salicylate overdose are irritability, tinnitus, hyperventilation, nausea, vomiting, and abdominal pain. Further symptoms include sweating, flushing, deafness, tremor, hypokalaemia, and hypernatraemia. The combination of vomiting, hyperventilation, and sweating may lead to severe volume depletion. Other findings may include hypoprothrombinaemia (due to inhibition of the vitamin K-dependent coagulation pathway), pyrexia (usually in children), confusion, drowsiness, delirium, coma, and seizures (more common in children).

Respiratory alkalosis, metabolic acidosis, ketosis, hypoglycaemia, and hyperglycaemia may all occur. The biochemical pattern of a primary respiratory alkalosis together with primary metabolic acidosis is characteristic of salicylate poisoning. The patient usually presents with a combined respiratory alkalosis and metabolic acidosis, with a blood pH in the range 7.40–7.46, low serum bicarbonate, and low PCO_2. These symptoms may be improved by correction of metabolic acidosis with sodium bicarbonate. Respiratory alkalosis is uncommon in younger children, but the likelihood of respiratory alkalosis increases with age until 12 years, when the adult picture of respiratory alkalosis, followed by metabolic acidosis occurs. The underlying mechanisms for these age-dependent differences in acid–base balance are poorly understood. Since acidosis enhances transfer of the salicylate ion across the blood–brain barrier, it is necessary to employ more active therapy at lower salicylate concentrations in children.

Confusion and depressed consciousness are serious signs, usually indicating that salicylate has entered the CNS and that the patient is at high-risk of death due to large CNS burden of salicylate. Death is usually due to cardiorespiratory arrest; attempts at resuscitation are unlikely to be successful.

Management

Assessment of the severity of salicylate intoxication involves clinical assessment, metabolic assessment (e.g. a plasma pH of 7.45 bodes well, but a pH of 7.30 indicates severe toxicity and concern for impending death), and measurement of the plasma salicylate level.

Every patient suspected of salicylate toxicity should be detained until the severity has been assessed biochemically. The plasma salicylate level should be measured on presentation and every 2–4 hours after confirmed ingestion, until levels are below detection. Absorption may continue for many hours, leading to a delay of up to 24 hours before the peak salicylate concentration is reached, especially with enteric-coated tablets. At the same time, arterial or venous blood gases, and plasma biochemistry should be checked.

Gastric decontamination should be performed. Gastric lavage may be useful if the patient presents with an acute ingestion and is expected to still have some salicylate in the stomach. However, due to enteric coating, salicylate tablets can form concretions and be difficult to remove with gastric lavage. Activated charcoal (1 g/kg) should be given and repeated doses of activated charcoal (0.5–1 g/kg every 4 hours) may be considered because salicylate may be retained in the stomach for many hours after ingestion. This treatment has been shown to shorten the plasma half-life of salicylate. Activated charcoal adsorbs salicylate but desorption may occur [2]. This regimen also appears to enhance passage of the salicylate ion from the blood back into the gut ('gastrointestinal dialysis') [3]. As this procedure is effective and non-invasive, it is recommended for mild to moderately severe salicylate toxicity. If repeated doses of activated charcoal are given, ensure that the activated charcoal does not contain a cathartic, since cathartics can cause electrolyte abnormalities.

Ensure that the patient is adequately rehydrated with intravenous fluids and remains normovolaemic. Any patient with altered mental status should have their serum glucose evaluated and hypoglycaemia corrected as it occurs.

Patients, with serum salicylate concentrations greater than 30 mg/dL (300 mg/L), should receive intravenous sodium bicarbonate for serum and urinary alkalinization to enhance elimination [4]. The aim is to produce a serum pH of 7.5–7.55 to keep the salicylate from entering the CNS and urinary pH of over 7.5. This enhances renal salicylate elimination by trapping the salicylate ion in the renal tubule. Renal elimination of salicylate is enhanced 10–20-fold when urine pH increases from 5 to 8 [5]. Urinary alkalinization is difficult to obtain in the setting of hypokalaemia. Therefore, patients should receive potassium supplementation, while undergoing serum and urine alkalinization. In the past forced alkaline diuresis (i.e. fluid plus alkali) was recommended. However, this method has led to non-cardiogenic pulmonary oedema, particularly in smokers and the elderly, with risks of hypokalaemia and/or hypernatraemia. It is no longer currently recommended [6].

Haemodialysis is recommended for severe salicylate intoxication. This includes any patient with markedly raised salicylate concentration, altered mental status or other neurological dysfunction, inability to tolerate a sodium bicarbonate infusion (such as patients with renal failure or acute lung injury (ALI)), renal failure (cannot eliminate salicylate), and those patients not responding to conservative management with sodium bicarbonate infusion. In the past, charcoal haemoperfusion was also used as an extracorporeal method of salicylate removal. However, it is usually not readily available.

Airway management is sometimes considered in patients with salicylate toxicity. However, it is a dangerous and sometimes, deadly procedure if not done with extreme caution [7]. The concern with airway management in these patients is due to the mechanical ventilator's inability to match the patient's respiratory function (both primary respiratory alkalosis and compensation from the metabolic acidosis). The likelihood of the patient developing an acidaemic serum pH, from respiratory acidosis, during the procedure can lead to increased CNS salicylate and thereby increased toxicity to the patient. If intubation and mechanical ventilation is necessary for further management such as safe placement of a haemodialysis catheter, precautions must be taken. The patient should receive a bolus of intravenous sodium bicarbonate (1–2 mmol/kg) to provide an extra buffer against respiratory

acidosis. The most experienced provider should perform the procedure on an unparalysed patient. Once intubated and connected to the mechanical ventilator, the ventilator settings should be set to maintain an increased minute ventilation (increased tidal volume and respiratory rate) to try to match the patient's previous respiratory function. Frequent blood gases should be performed to ensure an alkalaemic serum.

Conclusion

Salicylates result in both acute and chronic toxicity with death as a possible outcome. All suspected ingestions must be taken seriously. Treatment is based on the patient's clinical picture and blood analysis. It includes gastrointestinal decontamination, serum and urine alkalinization, and haemodialysis in the most severe cases. Airway management and mechanical ventilation should be performed with extreme caution with steps taken to ensure the patient maintains serum and urine alkalinization.

CHAPTER 318

Management of acetaminophen (paracetamol) poisoning

Michael Levine

Key points

- Acetaminophen toxicity results from accumulation of the metabolite N-acetyl-para-benzoquinoneimine, which results in centrilobular necrosis.
- Acetaminophen toxicity is primarily characterized by liver toxicity.
- Fulminant hepatic failure from acetaminophen is frequently characterized by markedly elevated transaminases and impaired synthetic function, along with encephalopathy, renal failure, metabolic acidosis, and hypoglycaemia.
- N-acetylcysteine (NAC) is the preferred antidote.
- If NAC is started within 8 hours post-ingestion, the rate of hepatic failure is near zero.

Epidemiology

It has been nearly 120 years since acetaminophen, or paracetamol, was first marketed as an analgesic and antipyretic. Nonetheless, the first cases of hepatic toxicity were not recognized until the 1960s. Today, acetaminophen is one of the most widely used analgesic and antipyretic medications, and is often co-formulated with other medications.

Much of the increased popularity of acetaminophen can be traced back to the desire to find a safer analgesic after salicylates were linked with Reye's syndrome in the 1980s [1]. In 2011, US Poison Control Centers received more than 137,287 calls involving acetaminophen, including 260 fatal cases involving acetaminophen [2].

Furthermore, nearly half of all cases of acute liver failure in the USA are believed to be due to acetaminophen [1].

In recent years, there has been increased attention focused on the potential for hepatotoxicity following acetaminophen overdose. This concern is not, however, based on new data. An extensive review of acetaminophen toxicity was conducted in 2002. The same group rereviewed the literature in 2009 and concluded there were no new data [3].

Pharmacokinetics/Pharmacodynamics

Following ingestion, acetaminophen is absorbed rapidly from the gastrointestinal tract. The half-life of acetaminophen is approximately 1.5–2.5 hours, although it can be slightly prolonged at supratherapeutic concentrations [4].

Acetaminophen is primarily metabolized in the liver, with a small portion (approximately 4%) being excreted unchanged in the urine. In adults, glucuronidation accounts for the majority of acetaminophen's metabolism, followed by sulphation [4] Together, these two processes account for nearly 90% of acetaminophen's metabolism, when consumed in therapeutic doses. The remainder of acetaminophen is metabolized via the cytochrome P450 isoenzyme CYP2E1 to form the metabolite N-acetyl-para-benzoquinoneimine (NAPQI). Normally, the body's endogenous glutathione supplies are able to bind to NAPQI, resulting in a water-soluble, non-toxic metabolite that is subsequently excreted in the form of cysteine or mercaptopuric acid conjugates [4]. In the setting of overdose, however, glucuronyltransferases and sulfotransferases are saturated, resulting in increased production of NAPQI with subsequent glutathione depletion, and ultimately hepatotoxicity [4].

Histology of liver failure

Similar to several other toxins, acetaminophen can result in a distinctive histological pattern—centrilobular (zone III) necrosis with passive congestion and scattered leukocytes without fatty infiltration [5]. These areas of necrosis are characteristically followed by rapid disappearance of necrotic cells, resulting in reticulin collapse. Among those who survive, there is a marked histological recovery.

Risk for liver failure

Acetaminophen's toxicity results from the accumulation of NAPQI by the cytochrome P450 isoenzyme CYP2E1. Thus, any xenobiotic that induces the P450 isoenzyme CYP2E1 can theoretically increase the risk for acetaminophen-induced hepatotoxicity. Perhaps one of the best studied agents for inducing CYP2E1 is ethanol. Chronic ethanol consumption increases CYP2E1 activity, thereby theoretically increasing the risk of hepatotoxicity [6]. Conversely, the co-ingestion of ethanol with an acetaminophen overdose may result in inhibition of the microsomal oxidation thereby providing some degree of protection from acetaminophen-induced hepatotoxicity. The strongest risk factor for developing hepatotoxicity, however, is the time from a toxic ingestion until the antidote, N-acetylcysteine (NAC), is administered. The risk of hepatotoxicity if NAC is started within the first 8 hours of the overdose is exceedingly low, while the risk increases substantially with delays longer than eight hours and longer [7].

Clinical presentation

Acute acetaminophen toxicity has traditionally been divided into four stages, although the exact times of each stage are somewhat arbitrary. The first stage, which lasts up to 24 hours post-ingestion, is characterized by mild gastrointestinal symptoms shortly after the ingestion with frequent resolution of these symptoms. Patients may remain asymptomatic during the first stage. Right upper quadrant pain can begin towards the end of this stage. The second stage, which occurs from 24 to 72 hours post-ingestion, is characterized by the initial development of hepatic dysfunction. Vomiting and anorexia, if present in the first stage, have typically resolved, and right upper quadrant pain develops. Transaminitis and coagulopathy begin. The third phase, which can begin as early as 72 hours post-ingestion, is characterized by hepatic failure. Metabolic acidosis, coagulopathy, renal failure, hypogycaemia, and encephalopathy can occur [7,8]. At this stage, the patient will either improve or will continue to worsen until either death or hepatic transplantation occurs. The fourth stage is characterized by complete hepatic recovery. Unlike other causes of hepatic injury (e.g. alcohol-induced cirrhosis), acetaminophen-induced liver injury is not associated with long-term liver damage, assuming recovery occurs.

Typically, the transaminases are markedly elevated, with the aspartate aminotransferase (AAST) often exceeding 10,000 IU/L. Hypophosphataemia is relatively common and there are some data suggesting that the degree of hypophosphataemia is directly correlated with the severity of the overdose. While the degree of transaminase elevation does not predict outcome, metabolic acidosis, impaired synthetic function, renal insufficiency, and hepatic encephalopathy are independent predictors of death without transplant [9].

Uncommonly, a significant anion-gap metabolic acidosis can occur early following massive acetaminophen ingestion. It has been postulated that this early acidosis is the result of accumulation of pyroglutamic acid (5-oxoproline) [10]. This acidosis is distinct from the acidosis that can develop late as part of fulminant hepatic failure, in which accumulating lactic acid is the primary aetiology. Other uncommon features of acetaminophen poisoning are the development of pancreatitis or renal failure. Renal failure is most commonly encountered in patients with fulminant hepatic failure, but is occasionally encountered in the absence of hepatic dysfunction. In treating a patient with a metabolic acidosis following acetaminophen ingestion, it is prudent to exclude other potentially fatal causes of metabolic acidosis, such as salicylate, metformin, or toxic alcohol ingestion before attributing the acidosis to 5-oxoprolline accumulation.

Diagnosis and treatment

The diagnosis of acetaminophen toxicity relies on history and laboratory studies. Because of vague symptoms in the early stage of acetaminophen toxicity, together with patient confusion between acetaminophen, ibuprofen, and salicylates, it is recommended that all overdoses have an acetaminophen level obtained. In addition, when one encounters a new diagnosis of hepatitis without a clear aetiology, a history regarding acetaminophen use should be obtained.

The need for treatment depends on the history, physical examination, and laboratory studies. If treatment is required, the preferred antidote is NAC. An original paracetamol nomogram was developed in Scotland, in which a line on a semi logarithmic graph joined two points: 200 μg/dL at 4 hours and 30 g/dL at 15 hours [11]. In an effort to improve sensitivity in the USA, the line was reduced by 25% to a threshold of 150 μg/mL 4 hours after ingestion, and 75 μg/mL at 8 hours post-ingestion [12]. Treatment with NAC is indicated when the acetaminophen concentration is above the line on the Rumack Matthew nomogram. In 2012, the United Kingdom's Medicine and Healthcare Products Regulatory Agency (MHRA) changed their treatment recommendations, such that any acetaminophen concentration above 100 μg/mL at 4 hours warrants treatment.

As with most overdoses, the topic of gastrointestinal decontamination remains controversial. There is no role for the routine administration of syrup of ipecac or gastric lavage in the emergency department. The use of activated charcoal with oral NAC probably results in a mild decrease in NAC absorption, but this is unlikely to be of any clinical consequence [7].

N-acetylcysteine acts both as a free radical scavenger, as well as a glutathione substrate. Many different treatment durations have been proposed. One such treatment regimen involves the oral administration of 140 mg/kg, followed by 70 mg/kg every 4 hours for 17 doses. More recently, other dosing strategies have been developed, with shorter durations of therapy [13]. Because both acetaminophen poisoning and oral NAC administration can cause nausea and vomiting, the intravenous administration of NAC is appealing. The major adverse effect associated with intravenous therapy is the development of anaphylactoid reactions. One common regimen for intravenous administration of NAC involves a loading dose of 150 mg/kg intravenously over 1 hour, followed by 12.5 mg/kg/hour for 4 hours, followed by 6.25 mg/kg/hour for 16 hours. While the anaphylactoid reactions are usually mild, at least one report of death in a 'brittle asthmatic', as the authors describe, has resulted from the intravenous administration of NAC [14]. Nonetheless, most anaphylactoid reactions due to NAC are minor, and can be easily treated by temporary discontinuation of NAC, and administration of diphenhydramine. Once symptoms improve, NAC can typically be restarted, often at a somewhat slower infusion rate. The incidence of anaphylactoid reactions appears to be inversely related to the acetaminophen concentration [15]. If an intravenous preparation of NAC is not available, the oral formulation can be administered intravenously, if administered through a 0.22-μ filter.

After a patient has received at least 21–24 hours of therapy, NAC can be discontinued if the patient is asymptomatic, liver function, including the prothrombin time (PT), are normal, and a repeat acetaminophen concentration, if obtained, is not detectable.

The Rumack–Matthew nomogram was designed for a single, acute ingestion, when the time of ingestion is known to have occurred between 4 and 24 hours prior to phlebotomy. Many times patients present following multiple ingestions over several hours. In these cases, technically the nomogram cannot be utilized. However, some toxicologists will still use the nomogram by assuming plotting all pills based on the earliest and latest times of ingestion, and treat if either point exceeds the treatment line. For example, if a patient ingested 20 tablets of acetaminophen at 01.00 hours and an additional 20 tablets at 03.00 hours, an acetaminophen level should be obtained at 05.00 and 07.00 hours, and treatment should be started if either concentration is above the treatment line.

Not uncommonly, patients will present with an unknown time of ingestion. In these cases, an acetaminophen level and liver function tests, including PT should be obtained. If there is no detectable acetaminophen, and the liver functions and PT are normal, no treatment for acetaminophen ingestion is needed. If there is any detectable acetaminophen, or if there are abnormal liver function tests, treatment with NAC is indicated. Chronic ingestion, where the patients have taken supratherapeutic doses for several days should be managed the same as when the time of ingestion is not known.

Because of its low volume of distribution and minimal protein binding, acetaminophen can be removed via haemodialysis. However, because NAC is highly effective if started early, the role for extracorporeal removal is minimal. In cases of massive acetaminophen ingestion, extracorporeal elimination can be considered, especially if there is a co-existing metabolic acidosis.

Differential diagnosis

While the diagnosis of acetaminophen-induced liver failure may be obvious in a patient who presents with a suicide note and an empty bottle of acetaminophen, the clinician is frequently confronted with a patient in liver failure with no history of overdose. In these cases, the acetaminophen concentration is often negative, as it has been metabolized completely prior to the onset of severe liver dysfunction. Therefore, it is important to consider acetaminophen in the differential diagnosis of any patient with hepatic failure.

While many drugs can cause a toxin-induced hepatitis, there are fewer xenobiotics that can cause acute fulminant hepatic failure. Among these drugs are acetaminophen, amoxicillin-clavulanate, isoniazid, iron, phenytoin, valproic acid, propylthiouracil, nitrofurantoin, and herbal preparations, including pennyroyal and chaparral. Cocaine, 3,4 methylenedioxymethamphetamine (MDMA, or ecstasy), together with carbon tetrachloride, white phosphorus, arsenic, thallium, and borates can cause acute hepatic failure.

The emergency physician should always consider infectious aetiologies, vascular aetiologies (e.g. Budd–Chiari syndrome, ischaemic hepatitis, veno-occlusive disorders), and miscellaneous aetiologies such as Wilson's disease, autoimmune hepatitis, fatty liver of pregnancy, heat stroke, and haemolysis elevated liver enzymes and low platelets (HELLP) syndrome.

While the history may be helpful in distinguishing the aetiology of fulminant hepatic failure, several additional laboratory features might be helpful as well. Frequently, the AAST rises faster and peaks sooner than the alanine aminotransferase (ALAT). In addition, unlike some other aetiologies of hepatic failure there is also synthetic dysfunction that results in a rise in the prothrombin time.

Liver failure

The greatest concern following acetaminophen ingestion is the potential to develop hepatotoxicity, which is characterized by the combination of transaminitis, encephalopathy, acidosis, renal failure, coagulopathy, and hypoglycaemia. The proximate cause of death in acetaminophen-induced hepatic failure is usually cerebral oedema or sepsis.

N-acetylcysteine should be continued until one of three major endpoints happens; clinical and laboratory improvement, liver transplant, or death.

Raschke and colleagues published a protocol for management of patients in fulminant liver failure. In their series of 22 patients with fulminant liver failure and a grade 3 or 4 encephalopathy, 12/22 (55%) were due to acetaminophen [16]. In addition to NAC, their protocol involved placement of an intracranial pressure monitor, aggressive management of intracranial hypertension, and vasopressor titration. This strategy was associated with good clinical outcomes among the 18 transplant candidates, including those who did not ultimately receive a liver transplant. Importantly, none of the patients died from cerebral oedema.

Special populations

Pregnancy

Acetaminophen readily crosses the placenta, which places the fetus at potential risk of hepatotoxicity [17]. However, because NAPQI does not cross the placenta, the fetus itself must metabolize the acetaminophen in order for hepatotoxicity to occur. The fetus is able to start metabolizing acetaminophen beginning at approximately 18 weeks gestational age [17]. Fortunately, NAC does cross the placenta. The indications for NAC are not different between pregnant and non-pregnant individuals. Fetal outcome appears to be worse with delays in commencing NAC [18].

Alcoholics

Chronic alcohol consumption results in depletion of hepatic glutathione, and upregulation of CYP2E1 [6], the isoenzyme that metabolizes acetaminophen to NAPQI. Consequently, chronic alcoholics might be at increased risk for acetaminophen-induced hepatotoxicity. Therapeutic dosing does not appear to increase the risk of hepatotoxicity [19], although chronic alcohol abuse may be associated with poor outcomes in acute acetaminophen poisoning.

Prognosis

In general, patients who have NAC started within 8 hours of the overdose will do well. Once hepatic injury occurs, the King's College Criteria can be used to help predict which patients may benefit from liver transplant [20]. According to these criteria, patients should be considered for liver transplant if the arterial pH is less than 7.25 after fluid resuscitation, or if there is a combination of a prothrombin time longer than 100 seconds, grade III or IV encephalopathy, and a serum creatinine higher than 3.4 mg/dL [9].

Conclusion

Acetaminophen overdose remains a common cause of hepatic failure. In order to ensure optimal care, the diagnosis must be made early, and treatment started within 8 hours. With prompt treatment with NAC, the incidence of hepatic failure can be reduced.

CHAPTER 319

Management of opioid poisoning

Alison L. Jones

Key points

- The physiological action of an opioid depends on the drug type, dose, and degree of prior opioid tolerance.
- Management of opioid poisoning consists of effective respiratory support and appropriate use of an antidote, usually naloxone intravenously.
- The half-life of opioids is longer than the antagonist naloxone—hence, ongoing infusions of naloxone are often required after the initial 'wake up' bolus and titrated to clinical signs with close ongoing clinical monitoring.
- Acute withdrawal syndrome may be precipitated by overzealous administration of in opioid dependent patients. Naloxone can be used, but should be titrated slowly, aiming for a Glasgow Coma Score of 13–14.
- Patients with opioid toxicity are at risk of respiratory, septic, and central nervous system complications, e.g. anoxic encephalopathy.

Opioids

Opioids are 'morphine like' substances that have pharmacological actions at specific opioid receptors in the central nervous system (CNS) and gastrointestinal tract. There are subclasses of opioid receptor including μ, δ, and κ receptors [1]. Stimulation of the μ receptor is responsible for most of the clinical effects caused by opioids and the extent of pharmacological action is determined by the factors illustrated in Fig. 319.1 [2].

Opioid tolerance and acute withdrawal syndrome

Over time, chronic opioid users need increased doses to achieve the same pharmacological effect, i.e. tolerance occurs [3]. Tolerance of respiratory depression develops at a slower rate than analgesic tolerance, placing patients with a long history of opioid use at particular risk for respiratory depression [3]. Stimulation of the μ receptor is responsible in part for tolerance (due to uncoupling of the μ receptor from the G-protein) [4].

If chronic users stop taking opioids abruptly, due to lack of supply or illness, they develop an acute withdrawal syndrome (AWS) which lasts 24–48 hours [5]. This is characterized by lacrimation, piloerection, rhinorrhoea, salivation, shivering and yawning, and progresses to agitation, fluctuations in blood pressure, diarrhoea, and vomiting [5]. Although AWS is not usually life threatening per se [5], there is a risk of aspiration pneumonitis if emesis occurs with an unprotected airway. Controlled detoxification programmes from opioids involve sedation with benzodiazepines, or even administration of a general anaesthetic in 'ultrarapid' techniques [6].

Epidemiology

Most opioid toxicity is the result of inadvertent overdosage during recreational use or due to opioid ingestion in self-harm. Trials are under way in the UK to send the antidote naloxone home with patients who use opioids recreationally. In other cases, opioid toxicity may be due to a variety of routes of exposure and circumstances including medication misuse and drug errors (Table 319.1).

Broadly, the number of opioid analgesic overdoses is proportional to the number of opioid prescriptions [4]. Death is more common as an outcome if benzodiazepines or cocaine are co-intoxicants. Opioids accounted for 107,000 of toxic exposures reported to Poison Control Centers in the USA and more than 27,500 admissions to health care facilities in a US population close to 260 million [7].

It is important not to miss underlying paracetamol toxicity in patients presenting with features of opioid toxicity (due to ingestion of a combined opioid-paracetamol) product [8]. Therefore, initial plasma blood paracetamol concentration should be determined in all patients who have ingested excessive opioids, and repeated at 4 hours to not miss an overdose [4]. If a patient has presented with an opioid overdose and subsequently develops abnormal liver function tests, then a paracetamol-opioid co-ingestion or shocked liver due to impaired circulation, or hepatitis due to viruses, e.g. hepatitis B or C in an intravenous (iv) drug user should be considered.

There is little point undertaking a urine drug screen for opioids, as it will not guide clinical management, unless the diagnosis of opioid poisoning is in doubt or there is a medicolegal imperative.

Assessment of degree of opioid poisoning

Opioid poisoning is characterized by three main clinical features (all may not be consistently present) [4,9]:

- Depressed respiratory rate (the *sine qua non* of opioid poisoning) and respiratory volume and consequential reduced arterial oxygen desaturation (<90% on air).
- **CNS depression**: usually described by the (unvalidated in poisoning) Glasgow Coma Scale.
- Small or pin-point pupils.

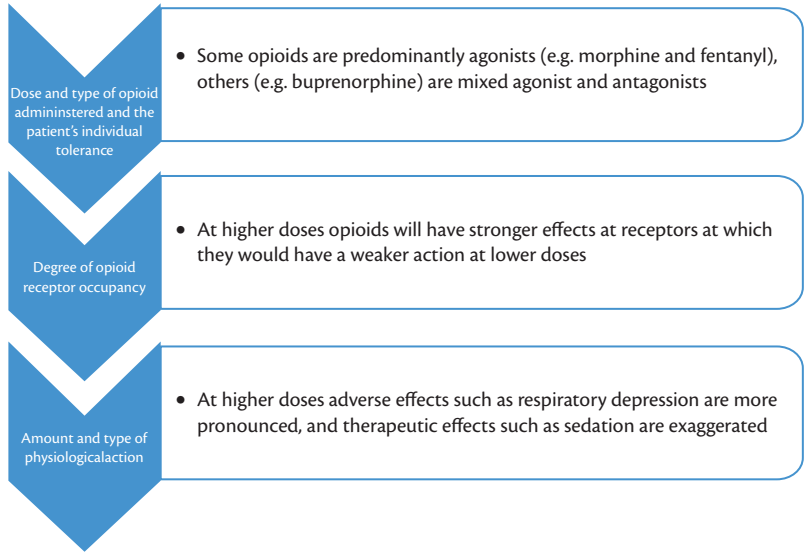

Fig. 319.1 Factors influencing amount and type of physiological action of opioids.
Data from Negus S, Bilsky E (eds) *Opioid Receptors and Antagonists: from Bench to Clinic*. Humana Press 2009. Chapter 27, pp. 511–38. DOI: 10.1007/978-1-59745-197-0.

Table 319.1 Opioid poisoning by route and circumstances of exposure

Exposure route	Circumstances	Details	References
Oral	Accidental and deliberate poisoning in children	Methadone poisoning in children is increasing paralleling its use, with 72% in one USA series requiring paediatric ICU (PICU) admission. A recent study demonstrates that patients in PICU are at increased risk of opioid adverse drug events, and a bar code-assisted opioid administration system reduced risks.	[15,16]
Oral and iv	Deliberate and accidental self-poisoning in adults	Risk profile: drug abusers or those with chronic pain. Note increasing methadone deaths with increasing methadone prescribing for pain. Note that individuals who have been incarcerated are at risk of opioid toxicity on release, due to diminished tolerance to opioids.	[7,17]
Gastrointestinal release	Body packers	Transportation of opioids within condoms or other packaging material: may leak from pack rupture and require ICU care as a prequel or sequel to abdominal surgery.	[18]
Transdermal or oral abuse of patches	Accidental in pain management or deliberate abuse	Transdermal absorption of fentanyl patches or oral abuse resulting in poisoning with is a concern.	[3]
Inhalational toxicity	Terrorism or accidental	Examples include the use of fentanyl in the Moscow theatre terrorism event. A recent case report of a pharmacy technician inhaling methadone powder in error for cocaine. The outcome was fatal with blood methadone concentration of 290 μg/L and death after 24 hours of ICU due to cerebral and pulmonary oedema.	[19]
Spinal		Spinal analgesia, mediated by opioid receptors, requires only a fraction of the opioid dose that is needed systemically. Risk is respiratory depression with long term use and recently reported, loss of opioid tolerance due to delayed pump refill may cause severe respiratory depression.	[20]

Data from Negus S, Bilsky E (eds) *Opioid Receptors and Antagonists: from Bench to Clinic*. Humana Press 2009. Chapter 27, pp. 511–38. DOI: 10.1007/978-1-59745-197-0; and various other sources (see references).

The differential diagnosis for these clinical features includes organophosphorus poisoning, or gammahydroxybutyrate (GHB) toxicity [2]. In the case of GHB, co-ingestion of opioids increases toxicity of the GHB.

The absorption, onset of action, and elimination half-life, which are known kinetic parameters for each specific opioid are often irrelevant in overdose. Opioids delay gastric emptying. Often first-order elimination kinetics changes to zero-order, as saturation occurs, leading to prolonged opioid toxicity [4].

Management of opioid poisoning

Meticulous supportive care

Opioid poisoned patients who reach hospital alive should not die, but data show death is still an outcome [10,11]. Patients require early clinical assessment, appropriate administration of naloxone and meticulous respiratory supportive care for sufficient time to allow the patient to fully metabolize and eliminate the opioid.

Most patients require temporary airway support (e.g. bag-valve mask, and chin-lift or jaw thrust) until a sufficient dose of the antagonist naloxone has reversed the opioid effect. Ongoing naloxone and close observation is then required until the opioid has been eliminated. Sometimes endotracheal intubation is required.

Rarely patients require intensive care unit (ICU) admission. This usually occurs as a result of a complication of the opioid toxicity, such as aspiration pneumonitis due to an unprotected airway, due to sepsis from iv opioid injection sites, or as a result of physical injury or trauma. In a recent retrospective chart review of a Greek intensive care unit (ICU) heroin overdose series, 19 of 42 patients (45%) were found in the field with a Glasgow Coma Scale (GCS) <8, and respiratory depression and 37 required intubation [11]. Of the patients requiring intubation 19 were extubated within the first 24 hours and 16 required assisted ventilation for 5 +/– 2 days, with a mean length of ITU stay of 8 +/– 1 days. Two patients died due to anoxic encephalopathy and brain death [11]. Complications seen across the 42 patients were acute respiratory distress syndrome in eight (19%), severe sepsis in four (9.5%), catheter-related bacteraemia in one (2.4%), iatrogenic pneumothorax in one (2.4%), and rhabdomyolysis in two (4.8%), while four (8.6%) died due to severe sepsis. The overall mortality was 14.2% [11].

Negative pressure pulmonary oedema has been reported either following reversal of opioid anaesthesia (e.g. for cardiac surgery) or with pre-existing cardiorespiratory disease [4]. Opioids can cause non-cardiogenic oedema and it is possible that use of the antidote naloxone unmasks this oedema [4]. In addition, co-administration of myocardial depressants such as propoxyphene are considered contributory. Mild cases of pulmonary oedema resolve with supportive care, but patients with more severe hypoxaemia require intubation and positive pressure ventilation [4]. Resolution of lung injury usually occurs within 24 hours, unless aspiration pneumonitis has occurred when recovery is delayed [11].

Seizures, arrhythmias, and rhabdomyolysis have also been associated with opioid overdoses, their co-ingestants or due to pre-existing disease [2].

Note, there is an emerging literature suggesting patients are not fit to drive for many days after recovering from an opioid overdose and should be advised accordingly [12].

The opioid receptor antagonist: naloxone

μ opioid receptor antagonists, such as naloxone (n-allylnoroxymorphone), competitively reverse the clinical features of toxicity by pure opioid agonists. They do not reverse opioid toxicity of partial agonist/antagonists like buprenorphine [13]. If opioid antagonists are given to regular opioid users in excess, they can precipitate acute withdrawal symptoms.

The pharmacokinetic features of naloxone include a time to clinical effect of approximately 2 minutes, if given iv, which lasts from 20 to 90 minutes [4], and an elimination half-life of approximately 60 minutes [2,4]. In clinical practice the effects may be shorter than the kinetic data suggest because its high lipid solubility creates a steep concentration gradient between brain and serum, leaching naloxone back into the serum. Because of the longer half-life of opioids than naloxone, repeated doses may be needed for long-acting opioids or large doses of shorter-acting opioids.

Optimal management of opioid poisoning consists of empirical titration of iv boluses of naloxone (0.04 mg increased to 0.5, 2, 4, 10, and a maximum dose of 15 mg each after 2 minutes to assess response to prior dose) so that patients maintain their airway and have effective ventilation [4]. In most overdose cases, an ongoing naloxone infusion is required according to the Goldfrank protocol of two-thirds of the total required 'wake up dose' given over each hour to maintain the antagonism and close clinical observation of the patient [2]. Naloxone infusions for many hours, e.g. 18–24 hours may be required. A clinical algorithm has been developed to summarize the clinical data to date.[4] Patients who had taken long-acting opioids may develop re-narcosis up to 2 hours after initial treatment and as the half-life of naloxone is 20–90 minutes it seems logical to observe patients for at least 2 hours after the last dose of naloxone has been given.

Cases have been reported where up to 20 times the recommended doses of naloxone have been needed to treat massive opioid doses, and even more with body packers with up to 50 mg used in a single patient over 24 hours (author's personal experience) [2]. Case histories reveal nearly 100-fold variation in the dose of naloxone infusions (0.125–12 mg/hour) given for prolonged overdoses [2]. Note that, in obese patients, the residence time for opioids may be increased as the opioid leaches out of fatty tissues over time and such patients may therefore require a longer duration of naloxone infusion [4]. Subcutaneous (sc) and intramuscular (im) routes for naloxone should only be used if iv access cannot be established. A recent report suggests nebulized naloxone may be effective in the prehospital environment [14].

Children often ingest a higher dose per kilogram than adults and may require larger doses of naloxone to reverse opioid toxicity than adults. Elderly patients have increased susceptibility to opioid respiratory and CNS depression effects and should be carefully monitored.

An observational study found a 0.7% complication rate within 5 minutes of naloxone administration (0.4–2.4mg), which included transient, mild fluctuations in blood pressure due to antagonism of opioid-mediated inhibition of noradrenaline release from the autonomic system [2]. An 8% complication rate occurred within 20 minutes of 2–4 mg boluses, including severe hypertension in patients with pre-existing essential hypertension [2]. Although all of the complications occurred soon after naloxone was administered, it does not mean that naloxone was the direct cause of complications [2].

Acute withdrawal symptoms can be caused by overzealous administration to chronic opioid-dependent patients. Therefore, titrating the dose of naloxone closely to the patient's respiratory rate (to maintain good arterial oxygen saturations) and coma score is recommended, aiming for a target GCS of 13–14, rather than 15.

Opioid receptor antagonists: nalmefene and naltrexone

These opioid antagonists have much longer half-lives and lower lipid solubility than naloxone and were introduced in the 1980s (half-life 10 hours for naltrexone and 8–9 hours for nalmefene) [2]. Their prolonged action means they are used for controlled, rapid detoxification of chronic opioid use, and to help former addicts abstain from further opioid use. If opioids are subsequently needed, it may be extremely difficult to achieve adequate analgesia for up to 72 hours afterwards [2].

Conclusion

Good outcomes after opioid poisoning are determined by meticulous supportive care and judicious use of appropriate doses of naloxone over time, recognizing the much shorter half-life of the antidote compared with the opioid. Even in 2012, the antidote treatment for opioid poisoning remains largely empirical and requires good observational clinical skills.

CHAPTER 320

Management of benzodiazepine poisoning

Philippe Lheureux and Marc Van Nuffelen

Key points

- Benzodiazepines are the drugs most frequently involved in acute self-poisoning.
- Benzodiazepine overdose usually has a good prognosis—most patients do well with careful observation and prevention of complications. Supportive care including oxygen, intubation, respiratory support, and fluid administration may be required in some cases.
- Care should be taken with elderly patients, or those with chronic obstructive pulmonary disease or liver disease. Fast-acting agents and ingestion of other central nervous system depressants, including alcohol, may present an additional risk.
- Early administration of activated charcoal in fully conscious patients who are able to protect their airway is only needed if there are co-ingestants.
- Flumazenil may help confirm the diagnosis, improve alertness, and prevent the need for respiratory support in some patients, especially after accidental poisoning in children. Contraindications include patients on long-term treatment and/or dependent on benzodiazepines, or those who have simultaneously ingested proconvulsant or prodysrhythmic substances, or at risk of increase intracranial pressure.

Introduction

Benzodiazepines were introduced 50 years ago. The first compound, chlordiazepoxide, was followed by multiple other agents and benzodiazepines are now among the most frequently prescribed drugs in many countries, due to their clinical efficacy and relatively good safety profile. They have replaced older sedative-hypnotics in clinical use, particularly barbiturates. They have a wide pharmacological profile including anxiolytic, muscle relaxant, amnestic, and anticonvulsant properties. Some benzodiazepines (e.g. diazepam, lorazepam) are also commonly used in clinical practice to control withdrawal symptoms, especially from alcohol. In anaesthesia, they are used as pre-anaesthetic agents and associated with other drugs for procedural sedation.

Unfortunately, due to their widespread availability, these agents are also frequently involved alone, or in combination with alcohol or other medications in drug-assisted suicide, as well as in accidental poisoning in children. Some of them, especially flunitrazepam, are known as date rape drugs.

There is also clear evidence that the prolonged use of even therapeutic doses of a benzodiazepine will lead to dependence. The risk of developing a significant withdrawal syndrome, which may be life-threatening seems related to dosage and duration of treatment.

Mechanism of action

The main action of benzodiazepines ('agonists') on the central nervous system (CNS) consists of potentiating the γ-aminobutyric acid (GABA) neurotransmission (the main inhibitory system in the CNS), and enhancing the frequency and duration of opening of the chloride channel, thereby inducing a post-synaptic hyperpolarization.

The pharmacokinetic profile of benzodiazepines is heterogeneous, because of variations of side chains around a similar basic chemical structure. Onset of action is highly variable; higher lipid solubility is associated with faster digestive absorption and distribution in the CNS through the blood–brain barrier [1,2], but peak concentrations are usually reached within 1–3 hours. Duration of action is related to redistribution to peripheral tissues, as well as to the elimination half-life of the parent compound and active metabolites. Biotransformation predominantly occurs in the liver (oxidation and/or conjugation) and may be impaired in elderly patients and those with hepatic disease. Genetic polymorphism of cytochrome P450 is also responsible for variations in the pharmacokinetics of benzodiazepines [3]. Co-ingestants, especially alcohol and drugs, enzyme induction, and acquired tolerance are other factors involved in individual variability

Assessment

Clinical evaluation

Pure benzodiazepine overdose is rarely severe, particularly in previously healthy people. It is characterized by progressive CNS depression, ranging from dizziness, drowsiness with slurred speech and blurred vision, confusion to stupor, and flaccid coma. Nystagmus may be present. Vital signs usually remain normal, although mild hypotension may be observed. Patients often remain arousable and able to provide some information when stimulated, but anterograde amnesia is common. Unresponsiveness or deep coma requiring respiratory support is infrequent, but snoring with flow limitation due to an increase in upper airway resistance and obstructive apnoea may be observed [4], even in somnolent patients. Paradoxical agitation, anxiety, disinhibition, and aggressiveness may occur. Ataxia is

a common presentation after accidental benzodiazepine ingestion in children. Alprazolam seems significantly more toxic than other benzodiazepines [5]. Benzodiazepine overdose has been anecdotally associated with atrioventricular block, perhaps mediated through an action on calcium channels [6] and bullous cutaneous eruptions [7].

A scenario of respiratory compromise due to CNS depression, hypotension, or hypothermia is more often present when a benzodiazepine is administered intravenously for procedural sedation, usually with other agents or when other central nervous system depressants (particularly alcohol) have been ingested. People with increased susceptibility include the elderly or patients with poor clinical condition, in who muscle weakness may be particularly prolonged. CNS depression may last in patients with liver disease, while the risk of respiratory depression is increased in those with chronic obstructive pulmonary disease. Other risk factors include massive ingestion, and short-acting or highly sedative compounds (midazolam, triazolam, temazepam, flunitrazepam) [1,8,9].

Despite the relative safety of benzodiazepines, morbidity and mortality of overdoses are not negligible, particularly in elderly people, but are usually related to complications, mainly respiratory problems [10]. Withdrawal syndrome may develop after acute poisoning in chronic users.

Analytical toxicology

Routine toxicological testing does not help in assessing the severity or the prognosis. It does not influence the management of benzodiazepine overdose, but may detect certain co-ingestants, especially paracetamol, when history is lacking or doubtful.

Qualitative urine testing for benzodiazepines, based on the detection of the oxazepam glycuronide, may help to confirm the presence of most 1,4-benzodiazepine derivatives. Some agents (e.g. alprazolam, clonazepam, temazepam, midazolam, lorazepam, or triazolam) and benzodiazepine-like substances are not easily detected.

Determination of benzodiazepine serum levels (parent drugs and metabolites) may occasionally help to differentiate drug-induced CNS depression from other aetiologies, although there is no strong correlation between serum concentrations and clinical presentation. In particular, very high levels with minimal impairment may be observed in tolerant people.

Other investigations

When multiple drug overdose is suspected or in coma of unknown aetiology, an electrocardiogram (ECG) should always be obtained, especially before considering flumazenil injection. Any abnormality of QRS or QTc intervals should suggest co-ingestion of cardiotoxic agents. A chest X-ray must be obtained in comatose patients or those with respiratory compromise to rule out aspiration pneumonia, which is the most frequent source of complications.

Usual chemistry values, EEG, CT scan, and analysis of cerebral spinal fluid may be helpful for excluding trauma, cerebrovascular accident, infection, or metabolic disturbances in comatose patients.

Management

General supportive care

Treatment of benzodiazepine overdose is mainly supportive. Airway, breathing, and circulation must be rapidly assessed. Repeated evaluation of neurological status and respiratory function are needed; oxygen, intubation, and ventilation support may be required to prevent hypoxaemia, hypoventilation, aspiration, and atelectasis. If present, hypotension usually responds to volume expansion alone. Usual measures must be undertaken to prevent ocular and pressure-induced complications during coma.

Prevention of digestive absorption and elimination procedures

Gastrointestinal decontamination should only be considered for patients who are at risk because they have self-harmed by ingestion of very large dose of benzodiazepines or have co-ingested dangerous drugs. If such cases are managed within the first hour after ingestion, a single dose of activated charcoal should be offered at the earliest opportunity, if the patient is conscious and able to protect the airway. Later administration of activated charcoal may still be considered if drugs in slow-release form or substances slowing gastric emptying are involved (e.g. cyclic antidepressants). If only low doses of benzodiazepine were ingested, it is unlikely that there will be any clinical benefit from the charcoal and the risk of pulmonary complications will be increased. Airway protection by endotracheal intubation must be ensured before activated charcoal is given (through a nasogastric tube) in those with significant impairment of alertness. More invasive techniques, such as induced emesis, gastric lavage, or whole bowel irrigation are never indicated in pure benzodiazepine overdose: the risks associated with these procedures outweigh their hypothetic clinical benefit, particularly in stuporous patients. In mixed overdoses, the need for gastric emptying before charcoal dosing must be carefully evaluated in each case [11].

Multiple doses of activated charcoal, enhanced diuresis, and extracorporeal techniques (e.g. haemodialysis, haemoperfusion) are never indicated for benzodiazepines, since they will not significantly improve the elimination of these agents.

Antidotes

Flumazenil is a benzodiazepine receptor competitive antagonist with no significant intrinsic effect. It rapidly antagonizes the effects of both agonist and inverse-agonist ligands. Flumazenil has proved useful in hastening reversal of benzodiazepine-induced CNS impairment after anaesthesia or procedural sedation. More debate surrounds the ability of flumazenil in reversing benzodiazepine-induced respiratory depression consistently [12].

After intentional overdose of benzodiazepine, judicious use of flumazenil may provide useful diagnostic information [13–16] and may sometimes obviate the need for invasive supportive measures or diagnostic procedures. Arousal usually occurs 30–60 seconds after intravenous administration, peaks after 5–10 minutes and may last for 1–2 hours. The rate of gradual relapse of sedation depends on the dose ingested, the substances involved, and their metabolites.

Slow injection is recommended because of the frequent side effects associated with sudden arousal, including anxiety, palpitations, nausea, and vomiting. Measures to prevent aspiration (lateral position, suction equipment) must be taken. In adults, the initial dose consists of 0.1–0.2 mg/minute intravenously over 30 seconds. It may be repeated after at least a 1-minute interval until sufficient alertness and adequate respiration are obtained or up to a maximum dose of 1–2 mg. Full recovery should not be the goal. To

prevent resedation, continuous infusion (usually 0.5–2 mg/hour) may be needed to maintain the effect [17] because flumazenil has a much shorter duration of action (0.7–1.3 hours) than most benzodiazepine agents, especially when ingested in large amounts. In children, an initial intravenous dose of 0.01 mg/kg and a maximal total dose of 0.05 mg/kg are recommended.

Although experience with flumazenil has shown good efficacy and relative safety in the management of benzodiazepine overdose [14], this antidote should not be administered to long-term benzodiazepine users, especially if they are being treated for epilepsy. They are probably benzodiazepine-dependent and flumazenil could precipitate an acute withdrawal syndrome, with associated tremor, anxiety, agitation, delirium, and seizures.

Controversy also exists regarding the use of this antidote in the setting of mixed drug overdose, particularly when substances that lower the seizure threshold are involved. Some observations, as well as animal studies suggest flumazenil precipitates cardiac arrhythmias when arrythmogenic drugs, such as cyclic antidepressants, monoamine oxidase inhibitors, isoniazide, theophylline, amfetamine, cocaine, antipsychotics, anti-arrhythmics, propoxyphene, chloral hydrate, halogenated hydrocarbons, etc., have been co-ingested. Flumazenil can unmask their toxic effects while suddenly antagonizing the protection ensured by benzodiazepines. It should not be used in patients who present with arrhythmias, or a prolonged QRS complex or QTc interval [11,17]. Moreover, flumazenil is contraindicated in patients who are suspected of increased intracranial pressure (e.g. head injury) due to its adverse effect on cerebral haemodynamics [18].

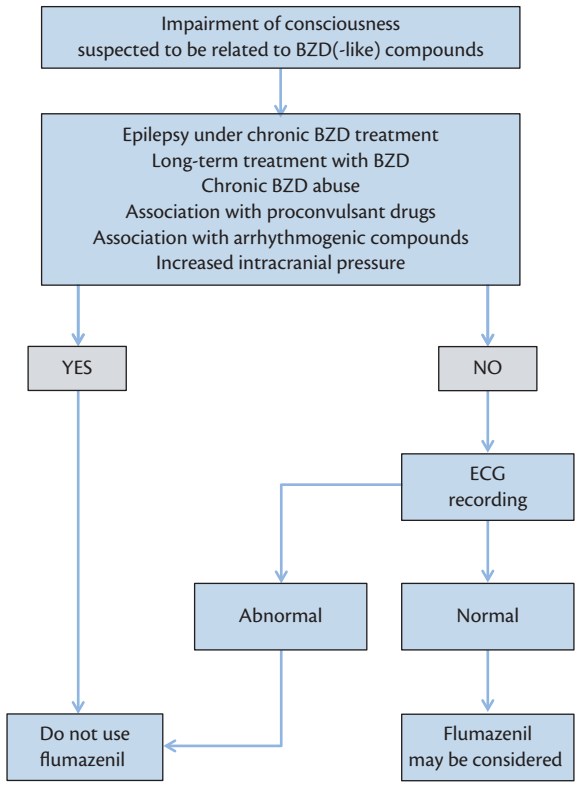

Fig. 320.1 Protocol for the rational use of flumazenil in patients suspected of benzodiazepine (BZD) intoxication.

Conclusion

Administration of flumazenil is rarely required in adult patients presenting with an overdose involving benzodiazepines or benzodiazepine-like substances and its adverse effects may unacceptably increase the risk associated with its use if contraindications are not considered [19,20]. An algorithm for its use is shown in Fig. 320.1. Flumazenil remains a very useful antidote in children presenting with accidental benzodiazepine ingestion, who are not dependent and when other drugs are commonly not involved.

CHAPTER 321

Management of tricyclic antidepressant poisoning

Giorgio Berlot and Ariella Tomasini

Key points

- Despite the introduction of newer antidepressants, tricyclic antidepressants (TCA) are still commonly used in the treatment of depressive disorders, anxiety, and neuropathic pain with the consequent risk of accidental or voluntary intoxication.
- TCA intoxication is a potentially life-threatening condition due to multisystem involvement.
- The presence of electrocardiogram (ECG) abnormalities associated with neurological symptoms, including alterations of consciousness and/or seizures, suggests the diagnosis of possible TCA intoxication.
- If TCA intoxication is suspected, treatment should start immediately without waiting for toxicological analysis.
- The administration of sodium bicarbonate is the cornerstone of treatment, with a target blood pH of 7.45–7.55. Other drugs, including benzodiazepines, magnesium sulfate, and catecholamines should be administered if needed.

Introduction

Although a number of more recent substances with fewer side effects have become available for the treatment of depression [1], tricyclic antidepressants (TCA) are still commonly used. In addition, they are used for the treatment of neuropathic pain [2]. The common basic mechanism of action is inhibition of reuptake of different neuromediators at the presynaptic terminal in both the central nervous system (CNS) and peripheral tissues, with the subsequent prolongation of their effect on the post-synaptic membrane [3]. The earliest drug of this class was imipramine. Despite a phenothiazine-like structure it was not effective for the treatment of schizophrenia; quite unexpectedly, it improved depressive symptoms. Consequently, these substances and the derived TCAs became the first line of treatment for depression until the development of the selective serotonin reuptake inhibitors (SSRI) [3]. Although all TCAs share the same mechanisms of action, there are some differences in terms of the mediator involved. Whereas imipramine and some of its derivates, including amitriptyline and doxepin, block the reuptake of noradrenaline and serotonin at the presynaptic terminals, clomipramine has a more selective action on serotonin. After oral administration, TCAs are promptly absorbed and achieve peak blood concentrations in 2–6 hours; their absorption is reduced by antacids and drugs with anticholinergic effects. Being highly lipophilic, TCAs are rapidly taken up by the CNS. They are metabolized in the liver through oxidation and glucoronization. Although they undergo a relevant enterohepatic circulation, they are primarily eliminated through the kidney, with a half-life of 12–24 hours depending on the specific drug.

Side effects

All the molecules belonging to the TCA class share some common side effects, the effect of which whose relevance somehow varies according to the substance used (Table 321.1) and the patient's clinical conditions [4]. There are three significant side effects.

Orthostatic hypotension

This can appear well before the onset of the antidepressive effects and that can be more pronounced in hypovolaemic patients.

Anticholinergic action

Anticholinergic action may cause problems such as urinary retention, constipation, dry mouth, and in more severe forms, confusional state, tachycardia, and dryness of other mucosal surfaces. Among the various TCA, amitriptyline, and protriptyline exert the more marked anticholinergic effects. The concomitant use of drugs with cardiodepressive properties such as β-blocking agents can prevent the occurrence of tachycardia.

Cardiac conduction

Cardiac conduction disturbances may lead to the occurrence of potentially harmful arrhythmias. The most relevant features are prolongation of the PR interval, the QRS complex and of the QT corrected for the heart rate (QTc). The action of TCA on the heart conduction systems resemble that exerted by the Class Ia of antiarrhythmic agents (e.g. quinidine and procainamide). These actions and are ascribed to the altered Ca^{2+} handling in the cardiac miocytes [5]. Although these alterations are unlikely to be a problem in patients without pre-existing cardiac conduction defects and/or arrhythmias, the administration of TCA should be avoided in patients with defects of the His-Purkinje tract, such as bifascicular block, bundle branch block with prolonged PR interval, alternating bundle branch block and second and third-degree atrioventricular (AV) block; conversely, their use is safe in patients with stable first-degree AV block and right bundle branch block (RBB). All these abnormalities can be triggered and/or worsened

Table 321.1 Main side effects of TCA

Relative potencies			
Agent	**Orthostatic hypotension**	**Anticholinergic effect**	**Arrhythmogenic effect**
Doxepin	Moderate	Moderate	Present
Amitriptyline	Moderate	High	Present
Imipramine	High	Moderate	Present
Trimipramine	Moderate	Moderate	Present
Protriptyline	Low	Low	Present
Nortriptyline	Low	Low	Present
Desipramine	Low	Low	Present

by concomitant electrolyte abnormalities, especially hypokalaemia and hypomagnesaemia.

Toxic effects

Although the symptoms of TCA-associated intoxication are commonly represented by an increased severity of the symptoms listed under 'Side Effects', some can occur even in their absence. It should also be noted that the severity of symptoms is often, but by no means always dose-related.

Relevant clinical presentation of TCA intoxication

Anticholinergic syndrome

The anticholinergic syndrome is caused by TCAs and other agents including antihistamines, antipsychotics, and cyclobenzaprine. The anticholinergic syndrome refers to an array of symptoms caused by their antimuscarinic effects, which include the combination of mydriasis, dry flushed skin, hyperthermia, tachycardia, urinary retention, and reduced or absent bowel movements. At higher doses the involvement of the CNS will occur, characterized by the onset of ataxia, agitation, hallucination, delirium, and coma [6]. The occurrence of coma is considered a valuable indicator of other impeding serious complication such as arrhythmias and seizures [7].

Acute liver injury

Acute liver injury of variable severity has been associated with TCAs as well as monoamine-oxidase inhibitors (MAOI) and selective serotonin-uptake inhibitors (SSRI). The occurrence of acute liver injury is supposed to be idiopathic and thus not related to the dose or other specific risk factors. As SSRIs have largely replaced the MAOI and TCA in the treatment of depression, fewer cases of TCA-related acute liver injury have been reported in the recent years [8]. Since there is no way to predict its occurrence, a high index of suspicion is warranted in patients receiving TCA and developing signs of declining liver function.

Cardiovascular toxicity

Cardiovascular toxicity is manifested by ECG abnormalities, arrhythmias, arterial hypotension and, in most serious cases, cardiogenic shock. Among TCAs, amitriptyline has been particularly associated with these abnormalities [9]. The underlying mechanism is disturbance of Ca^{2+} handling and Na^{+} channel blockade, which enhances the duration of the action potential, as well as the refractory period of cardiac miocytes, thus increasing the AV conduction. Besides the above ECG abnormalities, more severe abnormalities include non-specific ST and T waves changes, AV blocks of varying severity, right deviation of the terminal vector of the QRS complex in the frontal plane, and a Brugada-like pattern, that include the ST elevation in V1–V3 with elevated J point and marked downslope in association with RBB (Fig. 321.1) [10]. Although the most commonly encountered arrhythmia is sinus tachycardia, related to the anticholinergic effect caused by the inhibition of the reuptake of noradrenaline, bradyarrhymias (mainly due to an AV block), and supraventricular and ventricular tachyarrhythmias, including torsade de pointes, have been reported. The combination of depressed cardiac contractility and decreased vascular resistances leads to arterial hypotension. Potentially fatal cardiac arrhythmias usually occur within 24 hours of ingestion; the cardiac toxic effects appear to be better predicted by a QRS duration >100 ms and a rightward T 40 ms axis than blood levels of TCA [9,10].

Principles of treatment

As with many other life-threatening intoxications, an early diagnosis is essential. In order to hasten the treatment, the diagnosis of TCA intoxication should be based on the clinical presentation without waiting for their detection in blood or urine; moreover, a number of factors, including the increase in the extravascular volume, reduction of drug-carrier proteins and alteration of pH influence the pharmacokinetics and pharmacodynamics of practically every drug in the critically ill patients [12].

TCA intoxication should be considered in every patient with an consciousness associated with ECG abnormalities; ECG investigation should be repeated as harmful changes that may not be evident at admission may appear later; moreover, ECG is a valuable tool to assess the efficacy of the treatment [13].

Recently, new guidelines on the treatment of TCA intoxication have been issued [14]. These recommendation are based on studies with different levels of evidence; in the absence of large, controlled double blind trials enrolling sufficient numbers of patients, the strength of each of them varies from Grade C (based upon individual level 2a or 2b papers or multiple level 3a or 3b papers) to Grade E (based to consensus guidelines or studies of expert opinion).

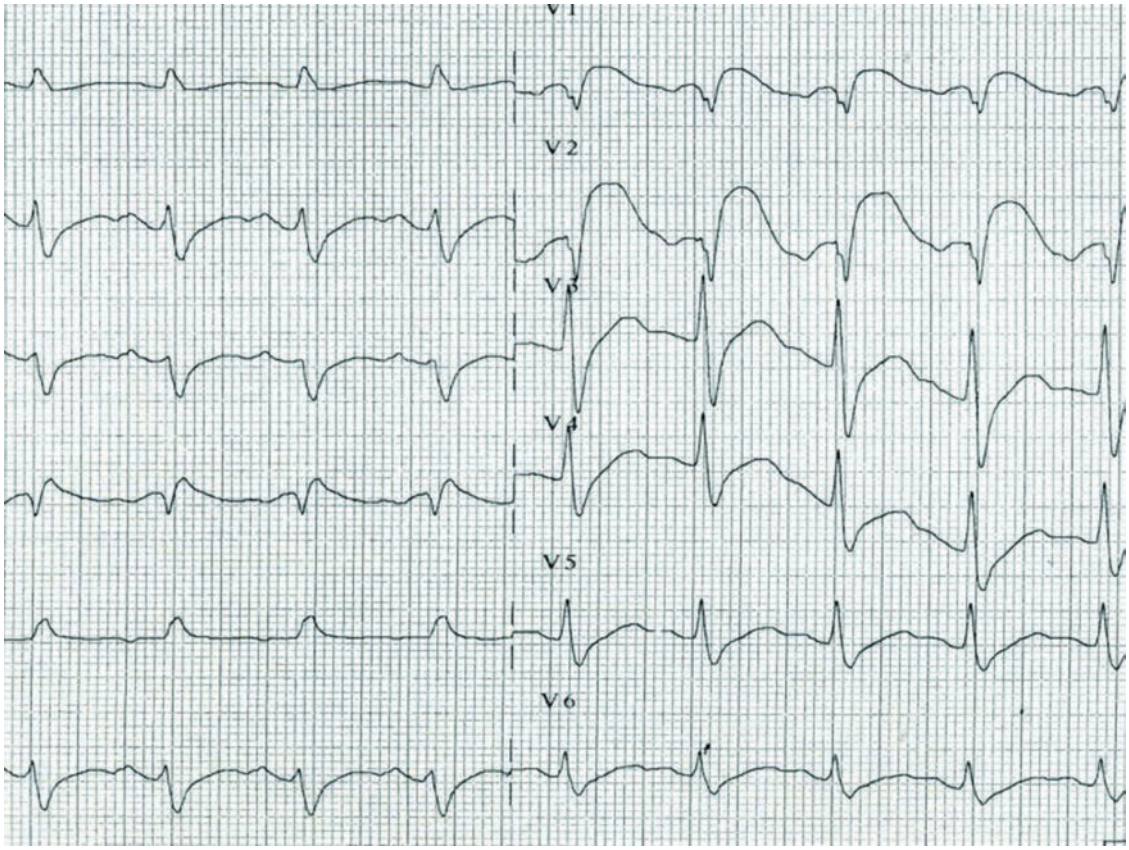

Fig. 321.1 Severe TCA intoxication, approximatively 4 hours after the ingestion of 7000 mg of amitriptyline.

Keeping these limitations in mind, the cornerstones of treatment basically consist in [14]:

- **Rapid sequence tracheal intubation** in patients with reduced levels of consciousness (Grade C), associated with volume resuscitation in the presence of arterial hypotension (Grade D); should hypotension be refractory to the administration of fluids, cautious intravenous administration of catecholamines is indicated (Grade D).
- **Prevention of (further) TCA adsorption**: in conscious patients, or after the airways have been secured, this goal can be accomplished with gastric lavage, possibly using activated charcoal; this measure appears valuable only in the early phase (within 1 hour from the ingestion) (Grade D).
- **Administration of sodium bicarbonate** to achieve a serum pH of 7.45–7.55 (Grade E); blood alkalization appears particularly valuable in the resolution of QRS widening, recovery of hypotension and the treatment of arrhythmias (Grade E), although its efficacy varies among different TCAs [15]. The underlying mechanism of action includes the reduction of cardiac toxicity and increased binding of TCA to serum proteins, which in turn decreases their free fraction.
- The **administration of magnesium sulfate** if arrhythmias persist during the administration of sodium bicarbonate and/or when the target pH value has been achieved, (Grade D).
- The **administration of benzodiazepine** to control seizures (Grade E); the use of phenytoin in this setting is contraindicated (Grade D) because its class Ia-anti-arrhythmic action could potentiate the similar effect exerted by TCA.
- The **administration of lipid emulsions**, which are supposed to sequester TCA inside an intravascular lipid compartment, is indicated when other measure fail to control the symptoms of TCA intoxication (Grade D).

Conclusion

Despite the introduction of newer drugs for the treatment of depression, TCAs are still largely used either with this indication or for the treatment of anxiety and chronic pain. A high index of suspicion is warranted, especially in patients with altered state of consciousness associated with arterial hypotension and/or ECG abnormalities. The treatment should be initiated before the confirmation of their presence in the blood or in the urine.

CHAPTER 322

Management of poisoning by amphetamine or ecstasy

Enno Freye

Key points

- Methamphetamine is a potent central nervous system stimulant affecting neurochemical mechanisms responsible for regulating heart rate, body temperature, blood pressure, appetite, attention, mood, and responses associated with alertness or alarm conditions.
- The only two approved indications for methamphetamine are attention-deficit hyperactivity (ADHD) and the short-term management of obesity.
- It is unclear if the toxic effects of ecstasy (MDMA) can be solely attributed to the pure agent or whether these are due to impurities.
- Hyperthermia and rhabdomyolysis commonly accompany MDMA intoxication.
- Since there is no specific antidote available, therapy for amphetamine or MDMA-related toxicity is purely symptomatic

Introduction

Already being abused in the years between the two wars to increase stamina and endurance, there was a widespread use of methamphetamine in the German army and the Allied Forces in order to avoid fatigue, stay alert, and to remove inhibition when faced with dangerous missions. Methamphetamine started to be known as speed in the early 1960s. Intermittently, during Vietnam and through Desert Storm, both the Air Force and the Navy made methamphetamine available for aviators with usage ranging from 3 to 96%.

The use of ecstasy or MDMA (3,4-methylendioxymethamphetamine) has significantly increased in the past years. Causing an intensified feeling of empathy and enhancement of senses, it is an agent of growing recreational misuse in discotheques, as well as the black market sales of ecstasy pills on the street have increased considerably in all Western countries over the recent years. Often ecstasy is not MDMA at all, as it tends to be diluted with almost any kind of drug powder ranging from amphetamines, LSD, cocaine, inert substances such as chalk or flour to rat poison (strychnine). Mixing with other drugs (e.g. alcohol), and drinking too little or too much water increases the risks associated with taking a drug that is already toxic.

Pharmacology of methamphetamine and ecstasy (MDMA)

Amphetamine is a simple synthetic derivative of phenylethylamine, which differs only in possessing a methyl group (-CH3) attached to the side chain. In methamphetamine, however, a second methyl group is attached protecting methamphetamine from degradation by monoamine oxidase (Fig 322.1). As a result, methamphetamine can persist in the bloodstream exerting a variety of biological effects. Amphetamines exist in two stereo-isomers. The dextro-isomer being far more biologically active than the levo-isomer.

Methamphetamine increases dopamine levels in the central nervous system (CNS) by as much as 2600 times, primarily by stimulating pre-synaptic neurotransmitter release rather than by re-uptake blockade [1]. Such increase has the effect of stimulating regions of the brain linked with vigilance and the action of the heart [1]. For a short period, the user feels sharper, stronger, and more energetic. It is believed that a significant proportion of the dopamine-producing cells in the brain can be damaged by prolonged exposure to even low levels of methamphetamine, being responsible for reduced levels of dopamine release. This can affect memory, attention, and decision-making functions.

MDMA belongs to a group of ring-substituted amphetamine congeners, called methoxylated amphetamines (Fig. 322.1). The drug is a potent indirect monaminergic agonist, acting both by increasing the release [2] and inhibiting the reuptake of serotonin and, to a lesser extent, of dopamine [3],with affinities to serotonin subreceptors of the 5-$HT2_A$ and 5-$HT2_C$ types [2,4].

Oral dosages range from 60 to 80 mg, with a benchmark standard dose of 2 mg/kg body weight. Even taken orally the effects manifest within 30–45 minutes; snorting, smoking, or injecting the agent result in a much faster onset of action (Box 322.1). With a plateau after 1 hour, the effects lasts for about 6 hours. The psychological effects largely disappear after 3 hours with the exception of some sympathomimetic residuals that last for 5 hours. A so-called 'afterglow' may be felt for days, and tertiary psychological effects (e.g. improved outlook) may even last indefinitely.

Acute effects of methamphetamine

The acute effects of the drug closely resemble the physiological and psychological effects of an adrenaline-provoked flight-or-fight

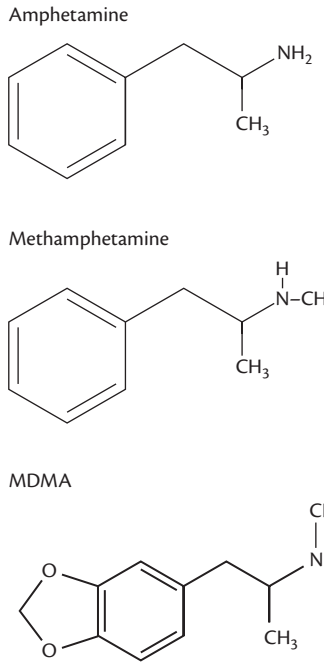

Fig. 322.1 The molecular structure of amphetamine, methamphetamine and ecstasy (MDMA, a ring substituted 3,4-methylendioxymethamphetamine).

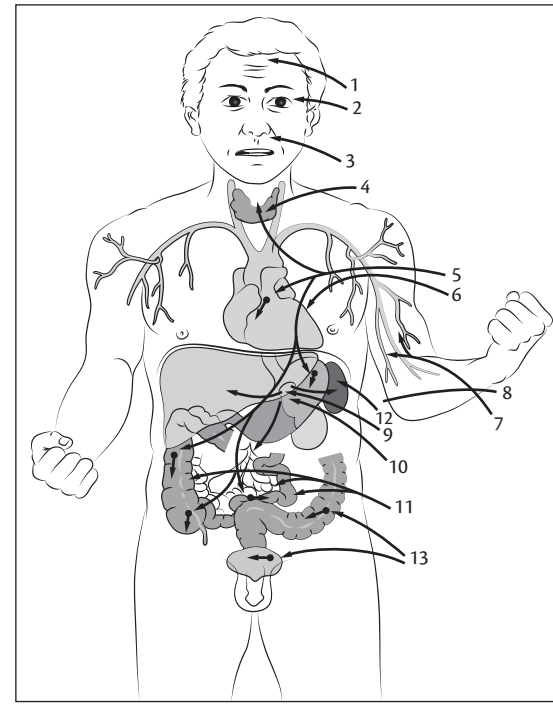

Fig 322.2 Summary of the negative effects of methamphetamine on body functions, which can be life-threatening once overactivated.
1, increase in vigilance, aggressive behaviour, insomnia, panic attacks, convulsions; 2, dilated pupils; 3, grinding of teeth; 4, release of thyreotropic hormones followed by increase of basal metabolic rate; 5, increase in heart rate, irregularity, ventricular extrasystoles; 6, increase in contractility of the heart, coronary vasoconstriction, heart attack; 7, dilatation of the vascular tree; 8, increase in muscle tension, hyperreflexia; 9, adrenal stimulation with release of epinephrine and norepinephrine; 10, glycogenolsis with raised blood sugar concentration, primary liver damage; 11, inhibition of propulsion of the gut; 12, increased lymphocyte production of the spleen; 13, urinary and bowel discharge.

Box 322.1 Summary of acute effect of MDMA

Ingestion of 50–150 mg of MDMA results in following effects:

- Perception of increased intimacy and trust with others.
- Enhanced communication.
- Increased insight into personal pattern/behaviour.
- Feeling of warmth, freshness, and love.
- Euphoria.
- Sensation of being more self-aware and at peace.

Common negative effects however can also be induced characterized by:

- Anxiety.
- Teeth grinding.
- Cheek biting.
- Anorexia.
- Sensations of being cold.
- Insomnia.
- Reduced feeling of thirst.

response, including increased heart rate and blood pressure, vasoconstriction, bronchodilation, and hyperglycaemia (Fig. 322.2). Users experience an increase in focus, increased mental alertness, and the elimination of fatigue, as well as a decrease in appetite.

Methamphetamine is a potent neurotoxin. Since dopamine and serotonin concentration, as well as dopamine and 5-HT uptake sites, together with tyrosine and tryptophan hydroxylase activities are reduced after the administration of methamphetamine [5], it has been assumed that dopamine plays a role in methamphetamine-induced neurotoxicity. This assumption is underlined by experiments, where the reduction of dopamine or the blockade for the release of dopamine decreased the toxic effects of methamphetamine. Since dopamine breakdown produces reactive oxygen species (ROS) such as hydrogen peroxide, it is probable that the oxidative stress that occurs with the intake of methamphetamine mediates its neurotoxicity [6]. In addition, recent research indicates that methamphetamine binds to a group of receptors called trace amino-associated receptors (TAARs) (7). This newly-discovered receptor system seems to be affected by a range of amphetamine-like agents, which have been shown to mediate the identification of social cues in mice, and are also present in humans and fish. To a lesser extent methamphetamine also acts as a dopaminergic and adrenergic re-uptake inhibitor and in high concentrations as a monoamine oxidase inhibitor (MAOI). Since it stimulates the mesolimbic dopaminergic reward pathway, causing euphoria and excitement, it is prone for abuse and addiction. Withdrawal is characterized with excessive sleeping, eating, and depression-like symptoms, often accompanied by anxiety and drug-craving [8].

In contrast to crack cocaine, the effects of methamphetamine are intense and persist longer than the brief 'high' of cocaine. Users

may become addicted quickly, and use it with increasing frequency and in increasing doses.

Crystal methamphetamine or 'ice' typically resembles small fragments of glass or shine-blue white 'rocks' of various sites. Unlike powdered methamphetamine, the other form of d-methamphetamine hydrochloride, which contains by-products from synthetic preparation, crystal methamphetamine has a higher purity level and produces longer-lasting and more intense euphoric effects than the powdered form of the drug.

Crystal methamphetamine is typically smoked using glass pipes similar to pipes used to smoke crack cocaine. Crystal methamphetamine may also be injected. A user who smokes or injects the drug immediately experiences an intense sensation followed by a high that may last for 12 hours or longer. Crystal methamphetamine is gaining popularity as a club drug in discotheques, but also as a stimulant in the upper and especially the middle management of big companies.

Acute effects of MDMA

Symptoms of acute intoxication with MDMA include agitation, tachycardia, hypertension, dilated pupils, trismus, and sweating, whereas more severe cases are characterized by hyperthermia, disseminated intravascular coagulation (DIC), rhabdomyolysis, and acute renal failure [9]. In such severe cases, an elevated creatinine kinase level may reach 12,200–555,000 IU/L [10].

It is important to note that serum MDMA levels do not correlate well with clinical symptoms and acute toxic reactions develop within 15 minutes to 6 hours after ingestion of MDMA.

The toxic reaction can be divided into three categories:

- Acute reaction at therapeutic doses.
- Overdose reactions.
- Residual effects.

At moderate doses (80–100 mg) the user will experience transient nausea, an increase in blood pressure, increased muscle tonicity with jaw clenching, and teeth grinding. At higher doses than 100 mg, susceptible individuals will experience numbness or tingling of extremities, luminescence of objects, increase in colour vision, and vomiting. Doses higher than 200 mg result in a classical toxic reaction with symptoms of paranoia, accompanied by auditory, as well as visual hallucinations.

Similar to cocaine and amphetamines, varying degrees of acute toxic effects may include sympathetic stimulation with arrhythmia, hypertension, tachycardia, and vasoconstriction resulting in an increase in myocardial oxygen demand. In severe cases there may be acute myocardial infarction and/or irreversible cardiomyopathy [11] accompanied by ECG changes with widespread ST-segment elevation [12]. In addition, MDMA use has been associated with intracerebral/subarachnoid haemorrhage, cerebral infarction, and venous sinus thrombosis [13], often in conjunction with an underlying malformation [11].

Chronic use of methamphetamine

Chronic methamphetamine abuse is reported to lead to significant reduction in the grey matter of the brain. Associated health risks involve social and family problems, including risky sexual behaviour. In addition, drug-induced psychosis may result. Methamphetamine effects last for days in the body, and some degree of neurological impairment may last up to 2 years or more after cessation of the drug

Continued use of high doses of methamphetamine produce anxiety reactions during which the person is fearful, tremulous, and concerned about his physical well-being, an amphetamine psychosis during which the person misinterprets others' actions, hallucinates, and becomes suspicious, sometimes resulting in a violent, aggressive behaviour. After the stimulatory phase, an exhaustion phase involves intense fatigue and the need for sleep, together with prolonged depression during which suicide is possible. Users of large amounts of methamphetamine over a long period of time develop an amphetamine-psychosis, a disorder similar to paranoid schizophrenia. Symptoms usually disappear within a few weeks after drug use stops followed by a recovery.

Tolerance of various effects develops unequally. For instance, tachycardia and enhanced alertness are diminished, but psychotoxic effects, such as hallucinations and delusions still occur. Also in contrast to cocaine, even massive doses are rarely fatal. Long-term users have reportedly injected as much as 15,000 mg of amphetamine in 24 hours without observable acute illness. One of the many prompts for repetitive abuse are the circumstances surrounding the drug taking (environmental cues) that trigger neuronal hypersensitivity, and exert a powerful influence leading to physiological arousal and increased craving at the mere sight of even the thought of the drug [5].

Addictive properties of methamphetamine

As with other psychoactive drugs, different routes of administration have different profiles of effects. For instance, oral methamphetamine ingestion tends to lack rushing, has less euphoric effects, and tends to cause far less of a feeling of wanting to do it again than other methods. Smoking or injecting methamphetamine is associated with compulsive/addictive user patterns. The most frequent route of administration among primary methamphetamine/amphetamine substance abuse treatment admissions was smoking (63%) followed by injection (19%). Thirteen per cent of primary methamphetamine/amphetamine admissions reported inhalation and only 5% reported oral consumption [14].

Withdrawal of methamphetamine

Abrupt interruption of chronic methamphetamine use results in withdrawal symptoms in almost 90% of all cases. Withdrawal of methamphetamine often causes a depression, which is even longer and deeper than the depression from cocaine withdrawal [8]. The length and the severity of the depression is related to how much and how often amphetamines had been used. Medical treatment includes the use of antidepressant agents.

Vigabatrin is a new treatment for methamphetamine. It is thought that mechanism of action is due to irreversible enzyme inhibition of γ-aminobutyric acid transaminase (GABA-T) resulting in increased levels of GABA, an inhibitory neurotransmitter [15].

Chronic use of MDMA

Synthesis of most street-sold MDMA pills (Fig. 322.3) is done in home laboratories with little chemical expertise resulting in the accumulation of by-products during the chemical reaction. Certain

Fig. 322.3 Examples of ecstasy pills with different logos, as they are being sold in the street, with unknown content of MDMA and possible adulterants.

reactions, such as hallucinations or visual distortion, are a sure sign of not ingesting pure MDMA. Taking the drug over a longer period of time, some report the desirable effect are no longer as pronounced (habituation), while others still found each MDMA session worthwhile.

It has been suggested that fluoxetine could prevent a chronic reduction in the serotonin system when taken before or even after MDMA.

Treatment of amphetamine and MDMA-related toxicity

Hyperthermia, with temperature >40°C is the most common adverse effect associated with acute MDMA toxicity. It is mostly caused by excessive heat production, due to sustained muscular hyperactivity and an increase in the metabolic rate, especially following strenuous long hours of dancing in discotheques, which may result in rigidity and seizures. Hyperthermia is considered the beginning of a cascade leading to DIC rhabdomyolysis, myoglobinuria, and renal failure [16]. This is probably the most important condition to treat immediately, since mortality has been correlated to the extent of hyperthermia and its duration. Treatment should include the following:

- Limit further heat production by cooling, using ice cubes at groin and axilla, applying cooling blankets, putting the patient in an ice bath, co-administering cold intravenous (iv) fluids, or ultimately, using peritoneal lavage with cool dialysate.
- Control agitation to prevent further heat production by sedative agents, such as diazepam, lorazepam, or midazolam.
- Administer dantrolene sodium (2.5 mg/kg repetitively) to limit muscle hyperactivity. Although being used for treatment of malignant hyperthermia it results in the inhibition of Ca^{2+}-release in the sarcoplasmic reticulum [17–19].
- Alternatively, use of non-depolarizing muscle relaxants (e.g. pancuronium bromide) is being advocated in treating the acute toxic MDMA-related reaction. This requires intubation and ventilatory support.
- Since some of the symptoms associated with acute MDMA toxicity are similar to findings in both malignant neuroleptic syndrome and the serotonin syndrome [20], additional pharmacological management is recommended (although not evaluated prospectively), such as methysergide maleate, a non-specific serotonin antagonist, the short-acting ß-blocker esmolol, a 5-$HT1_A$-antagonist such as buspirone, or the dopamine agonist bromocriptine.

Antipsychotic agents should not be used as they decrease the seizure threshold and may even affect the thermoregulatory system leading to an exacerbation of hyperthermia. In addition, SSRIs may further increase serotonergic transmission by reuptake blockade, raising the risk of a serotonin syndrome and aggravating the existing hyperthermia.

Contrary to MDMA, acute methamphetamine toxicity is characterized by a massive overstimulation of the sympathetic nervous system. Patients may be highly agitated and present a serious safety risk to themselves and prehospital personnel. If possible, one should seek additional help from police or other emergency medical services (EMS) providers before the patient

is transported. Since the cause of an altered mental status before a laboratory test is never clear, initial treatment should comprise the following:

- Ensure a patent airway, with sufficient breathing plus cardiovascular support.
- 100 mL of 50% glucose iv for reversal of a potential hypoglycaemia.
- Thiamine (vitamin B1) 100 mg intramuscularly (im) for potential alcoholic intoxication and prevention of a Korsakow syndrome.
- 2 mg of naloxone iv for reversal of a potential opioid overdose.

Box 322.2 Summary of treatment for metamphetamine intoxication

Agitation

Consider:

- Temporary physical restraint.
- Tranquillizers, such as droperidol, haloperidol, or butyrophenones, titrated iv.
- Benzodiazepines (enhance GABA neurotransmission).
- Antipsychotics (risperidone, olanzapine).
- Rapid sequence induction and muscle relaxation.

Seizures

Benzodiazepines iv:

- Diazepam 10–20 mg.
- Clonazepam 1–2 mg.
- Midazolam 5–15 mg.
- Phenobarbital 50–100 mg.

Early CT in view of intracranial haemorrhage risk.

Hypertension

Consider:

- Urapidil 25–50 mg.
- Sodium nitroprusside infusion.
- Glyeryl trinitrate infusion.
- Clonidine 0.15 mg slow iv.
- Labetalol 0.25 mg/kg.

Avoid propranolol since it is an α-stimulator.

Tachycardia

- Esmolol infusion 100 mg/kg/min.
- Metoprolol.

Myocardial ischaemia

GTN and standard acute coronary syndrome protocol.

Rhabdomyolysis

Fluid replacement, urine alkalinization.

Pre-hospital iv access is necessary for treatment of seizures and agitation using intravenous benzodiazapines. CNS overstimulation may lead to seizure-like activity and cardiovascular effects result in tachycardia with the possibility of ventricular fibrillation, systemic hypertension with intracranial/subarachnoid bleeding, and ischaemic stroke especially when three is a predisposing condition, such as an aneurysm or an ateriovenous malformation. Most cases of methamphetamine toxicity can be managed supportively. In the case of a severe overdose, immediate supportive care, including airway control, oxygenation and ventilation support, and appropriate monitoring is required. In severe overdoses, termination of methamphetamine-induced seizure activity and arrhythmias are of immediate importance. Correction of hypertension, hypotension, hyperthermia, metabolic, and electrolyte abnormalities, and control of severe psychiatric agitation are indicated. Also, consider health maintenance activities, such as testing for viral hepatitis and HIV disease and rehabilitation as a follow-up. The treatment protocol is described in Box 322.2

Conclusion

In summary, supportive care in MDMA intoxication (Table 322.1) primarily includes rehydration with iv crystalloid fluids and lowering the temperature with the aid of cooling blankets or an ice bath. Liver function should be monitored in patients with suspected MDMA intoxication with unexplained jaundice or hepatomegaly

Table 322.1 Summary of supportive management in acute MDMA intoxication

Prevent further absorption	Apply activated charcoal 50 g po if <1 hour of ingestion, apply cathartic techniques
Treat arrhythmias	Short-acting beta-blocker such as esmolol
Monitor	For at least 4 hours, heart rate, blood pressure, ECG, core temperature
Check	Electrolytes, creatinine, blood urea, creatinine phosphokinase, clotting profile, arterial blood gases
Urine drug screening (UDS)	Use specific drug screen multi sticks for methamphetamine, cocaine, opiates, etc.
Treat anxiety, agitation	Diazepam 0.1–0.3 mg/kg po or iv
Treat seizures	Diazepam 10–20 mg/70 kg iv, midazolam 5–15 mg/70 kg iv, or phenobarbital 50–100 mg/70 kg iv
Treat hyponatraemia	Fluid restriction, consider hypertonic solutions
Treat acidosis	Correct using sodium bicarbonate if QT-interval is prolonged
Treat severe hypertension with/without signs of myocardial ischaemia	Consider α/β-blocker labetalol, sodium nitroprusside, α-blocker phentolamine or, if severe, glyceryl trinitrate. Avoid propranolol because it is an α-stimulator
Treat hypotension	Volume expansion, central venous and cardiac output monitoring
Treat hyperthermia	Simple cooling methods. If temperature is >39°C give dantrolene, intubate, and ventilate
Treat renal failure	Promote diuresis with mannitol or furosemide

during supportive care. If, however, hepatic necrosis has appeared, liver transplantation would be the only option.

In methamphetamine intoxication, cardiovascular and CNS symptoms are the most prevalent signs and should be treated accordingly focusing on potential cardiac arrhythmias as they are the prodrome of detrimental ventricular fibrillation.

CHAPTER 323

Management of digoxin poisoning

Frédéric Lapostolle and Stephen W. Borron

Key points

- Poisoning by digitalis is primarily manifested as an exaggeration of its therapeutic effects. Cardiac effects include a wide variety of rhythm and conduction disturbances, with bradydysrhythmias predominating. They can be life-threatening.
- Non-cardiac effects include neurological and visual disturbances, generalized weakness, and gastrointestinal disturbances.
- The serum digitalis concentration is useful in assessing body burden of digitalis, but therapy for life-threatening poisoning should not be delayed while awaiting blood concentrations.
- The treatment of choice for serious poisoning is immediate administration of digitalis Fab fragments.
- Complete reversal of the digitalis body load with Fab fragments is indicated in life-threatening poisoning. Partial reversal with digitalis Fab immunotherapy is indicated in less serious poisoning.

Introduction

Indications for cardiac glycosides are restricted to heart failure, with or without associated supraventricular dysrhythmia. More appropriate maintenance regimens and widespread availability of serum digoxin concentrations have reduced morbidity in recent years. Nonetheless, digitalis toxicity remains frequent in patients chronically taking the drug (6–23% of patients, especially the elderly) [1,2]. In contrast, intentional digitalis poisoning occurs less frequently, but mortality may reach 25% in cases of acute overdose [3]. The treatment and outcomes for digitalis poisoning have been dramatically altered through use of digoxin-specific Fab fragments [4]. Antidotal treatment significantly reduces mortality rate when an anticipatory strategy is used [3,5].

Pharmacology

Two preparations of digitalis, digoxin and digitoxin, are in common use today. Digitoxin, still used in Europe but is no longer available in the United States. Both are passively absorbed from the small intestine. Digoxin has a half-life of 33–34 hours. Digitoxin is heavily protein bound and has a longer half-life (6–7 days). Drug action depends on tissue concentration, which is relatively constant in relation to serum concentration; the major depot in humans is skeletal muscle. The constant relationship of myocardial digoxin concentration to serum concentration supports measuring serum concentrations to monitor patients' compliance and toxicity. Dosage requirements and the likelihood of toxicity are better anticipated on the basis of muscle mass, rather than overall body weight. Digoxin is excreted primarily via the renal route, whereas digitoxin is metabolized in the liver. Enterohepatic circulation is important with both drugs, thus biliary production affects digitalis elimination.

Digitalis inhibits the Na^+-K^+-ATPase transport system (Fig. 323.1). The net effect is a decreased intracellular K^+ concentration and an increased Na^+ and Ca^{2+} concentration. The increased Ca^{2+} augments positive inotropic action [6]. Na^+, K^+, or Ca^{2+} fluxes across cell membranes exert significant effects on conduction. Digitalis decreases the rate of sinoatrial (SA) node depolarization, and increases the refractory period of the atrioventricular (AV) node and the bundle of His. The negative chronotropic effect of digitalis is primarily mediated through an increase in vagal tone, associated with decreased sympathetic activity. Digitalis decreases the refractory period of both atrial and ventricular cells, and improves conduction within the muscle, as reflected in a shortened QT interval. Digitalis increases myocardial automaticity (the ability of tissue to undergo spontaneous depolarization) and excitability (the ability of tissue to respond to a given stimulus).

Digitalis toxicity

Toxicity is related to exaggerated therapeutic effects and the status of the patient at the time of drug administration/overdose. Toxic effects can occur in any condition that increases the amount of digitalis in the body or modifies cardiac sensitivity to digitalis.

Drug interactions are an important consideration, because introducing or discontinuing these drugs without changing the digoxin dose may lead to digitalis toxicity. The most common interactions are listed in Table 323.1.

By far, the most important and dangerous drug interactions with digoxin are caused by the antidysrhythmics. Quinidine causes a substantial increase in serum digoxin in up to 90% of patients, beginning immediately. Other Class 1 antidysrhythmics (procainamide, disopyramide, lidocaine, mexiletine, and flecainide) do not increase serum digoxin concentrations.

Amiodarone increases digoxin concentrations by 25–70% within 24 hours of adding amiodarone. The addition more frequently results in bradydysrhythmias or heart block, rather than tachydysrhythmias.

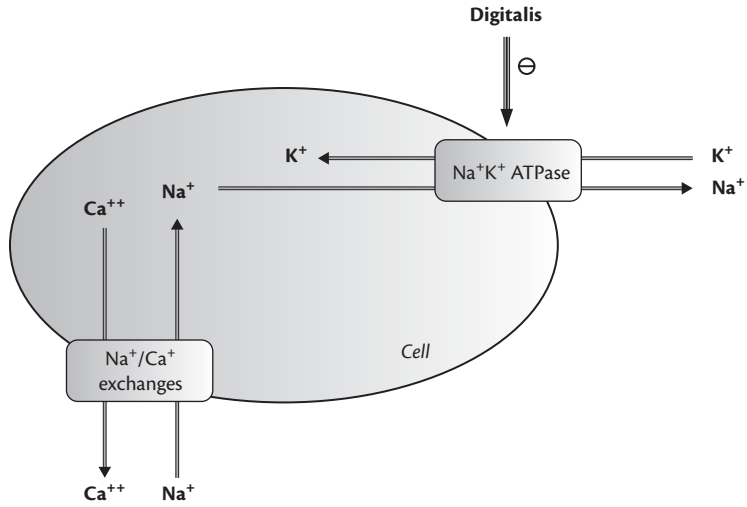

Fig. 323.1. Digitalis: mechanisms of action and toxicity.

Table 323.1 Agents affecting digitalis pharmacology

Alteration	Agents
Increased absorption (less of a problem when the capsule form is used)	Antibiotics inhibiting gut flora (erythromycin and tetracycline), anticholinergics
Decreased absorption	Antacids, antibiotics (neomycin, sulfasalazine, p-aminosalicylic acid), bran, colestyramine, cytotoxic, kaolin-pectin
Inhibited protein binding	Clofibrate, phenobarbital, phenylbutazone, prazosin, warfarin
Decreased extrarenal clearance	Diltiazem, quinidine, verapamil
Decreased volume of distribution	Quinidine
Increased renal excretion	Hydralazine, levodopa, nitroprusside
Increased serum digitalis concentration	Amiodarone, aspirin, bepridil, diltiazem, flecainide, ibuprofen, indometacin, nifedipine, nicardipine, nisoldipine, nitrendipine, propafenone

Reproduced from *Clinical Pharmacokinetics*, **15**(3), 1988, pp. 165–79, 'Digitalis. An update of clinical pharmacokinetics, therapeutic monitoring techniques and treatment recommendations', Mooradian AD, with kind permission from Springer Science and Business Media.

The interaction between calcium channel blocking drugs and digoxin varies greatly. Verapamil increases serum digoxin concentrations as much as 70%, which can lead to lethal cardiotoxicity, while the dihydropyridines (nifedipine, amlodipine, isradipine, nicardipine) and diltiazem interact minimally. Other antidysrhythmics, such as sotalol, aprindine, ajmaline, and moricizine do not affect digoxin concentrations.

Apart from drug interactions, renal dysfunction reducing excretion is the major factor leading to an increased body load of digitalis. Dialysis does not cause much body loss of digitalis.

Toxicity from digitalis may also occur in any condition that modifies the cardiac sensitivity to digitalis, such as myocardial infarction or ischaemia, myocarditis, cardiomyopathy, amyloidosis, and other trauma, including surgery. Electrolyte abnormalities, especially hypokalaemia, and hypocalcaemia are well known contributors to digitalis toxicity, but aberrations of magnesium may increase myocardial sensitivity to digitalis as well.

Acidosis, alkalosis, hypoxaemia, and hyperthermia may alter digitalis effect, but are probably not independent risk factors. Diseases of other organ systems, especially chronic lung disease and hypothyroidism, predispose patients to digitalis toxicity. Acute cerebrovascular events may lead to toxicity by large sympathetic discharge, which may lower the dysrhythmia threshold.

Clinical presentation

Cardiac manifestations are frequent and dangerous presentations of digitalis toxicity [7,8]. A healthy heart rarely demonstrates any signs of toxicity unless the ingested quantity is high. Therefore, accidental overdoses, especially in children, rarely present any cardiac findings, but may show AV conduction disturbances. On the other hand, a diseased heart is prone to lethal dysrhythmias. No dysrhythmias are pathognomonic of digitalis toxicity because similar rhythms may represent underlying disease. A change in the rhythm, especially decreased pulse rate, may be the most important clue. Toxicity should be suspected in any patient exhibiting evidence of depressed conduction, alteration of impulse formation (automaticity), or both.

Blocks of all types may be observed. SA nodal block is relatively common. The resultant bradycardia may be quite severe,

Table 323.2 Comparison of clinical features and main prognostic factors in chronic and acute digitalis poisonings

	Chronic (*n* = 722)		Acute (*n* = 116)		
	n	**%**	***n***	**%**	***p***
Male sex	247	34	34	29	NS
Age > 55 years	697	96	59	51	<0.0001
Past cardiac history	712	99	63	54	<0.0001
HR < 60 beat/min	126	17	48	41	<0.0001
HR < 40 beat/min	23	3	3	3	NS
Second or third degree atrioventricular block	81	11	17	15	NS
All degree atrioventricular block	165	23	37	32	<0.05
Ventricular fibrillation or tachycardia	11	1	5	4	<0.05
Cardiogenic shock (SBP < 100 mmHg)	52	7	10	9	NS
Serum potassium > 5.0 mmol/l	168	23	25	22	NS
Serum potassium > 4.5 mmol/l	369	51	49	42	NS

Reproduced from *Intensive Care Medicine*, **34**(8), 2008, pp. 1448–53, 'Assessment of digoxin antibody use in patients with elevated serum digoxin following chronic or acute exposure', Lapostolle F et al., with kind permission from Springer Science and Business Media and European Society of Intensive Care Medicine.

especially in the elderly and those with SA node disease. First- and second-degree AV blocks of Mobitz types I or II may be observed. The resultant heart rhythm may be complicated by accelerated junctional escape beats. Third-degree block, or complete AV dissociation, is usually associated with a narrow QRS escape focus at adequate rates, and haemodynamic alterations are rare in the absence of other cardiac abnormalities. As digitalis is usually prescribed in patients with atrial fibrillation, slow bradydysrhythmia is frequent in chronic poisoning [8].

Alterations of impulse formation may be divided into those that suppress higher pacemakers or those that excite lower pacemakers. The combination of suppression of higher pacemakers (SA node) and excitation effects (increased frequency of discharge of junctional or ventricular pacemakers) should be considered digitalis toxicity until proved otherwise. Premature ventricular contractions (PVC) and more complex ventricular dysrhythmias, including ventricular tachycardia, may be observed.

Conduction and rhythm disturbances can be seen in combination, resulting in various electrocardiographic presentations. The rhythms are usually manifested by an increased sinus rate with block or second-degree AV block with accelerated lower pacer. Examples are atrial fibrillation with slow ventricular response, resulting in irregular bradycardia or Wenckebach block with accelerated junctional escape beats. Even though non-specific, digitalis toxicity should always be considered when this type of dysrhythmia is encountered.

Gastrointestinal manifestations are seen in both acute and chronic digitalis intoxication. Anorexia, nausea, and vomiting often occur early, and may be the presenting complaint. Neurological manifestations are also frequent and range from headache, fatigue, and weakness, to depression, confusion, disorientation, aphasia, delirium, and hallucinations. Visual disturbances of blurring and alteration in colour are less common. Digitalis intoxication should always be considered in patients, particularly the elderly, who are receiving digitalis therapy and present with vague gastrointestinal complaints, malaise or altered mental status [1]. Clinical features of acute and chronic digitalis poisoning are quite similar (Table 323.2). As expected, patients under chronic digitalis treatment (and chronic overdose) are generally older with more significant past medical history [8].

Diagnostic studies

Digitalis toxicity induces hyperkalaemia, which is significantly correlated with digitalis poisoning severity and mortality. In acute poisoning, mortality was greater in patients with serum potassium >4.5 mmol/L, approaching 35% in patients with serum potassium >5 mmol/L and 100% in patients with concentrations greater than 6.4 mmol/L [9]. Renal function appears partially responsible for hyperkalaemia seen in patients with chronic digitalis poisoning. Hyperkalaemia correlates better with serum creatinine level than with digoxin concentration in chronic digitalis poisoning [10].

Digitalis concentration

Clinical correlation of therapeutic and toxic digitalis concentrations are determined at steady-state concentrations, measured 6–8 hours after administration. Measurements made before this time may give values two to three times steady-state concentration. The therapeutic range is 0.5 to 2.0 ng/mL for digoxin and 10 to 30 ng/mL for digitoxin. Serum concentrations of patients with and without clinical toxicity overlap considerably. Multiple factors predispose patients to toxicity at concentrations well below the upper limit of normal. Hypokalaemia is the most important of these. Thus, serum concentrations are not always diagnostic. False-positive elevations may occur due to chronic renal failure, caused by an endogenous circulating digoxin-like substance.

Serum concentrations should be used as a guide to appropriate therapeutic doses and as an indication of toxicity. It must be emphasized that toxicity **cannot** be diagnosed from serum concentrations alone. Physicians must maintain a high index of suspicion

for digitalis intoxication, especially in patients with predisposing factors, such as old age, renal disease, chronic lung disease, or quinidine use. In general, an increased serum digitalis concentration indicates digitalis toxicity in patients chronically-treated with digitalis who are manifesting cardiac or non-cardiac symptoms. In contrast, if a digitalis poisoning is strongly suspected, specific therapy should not be delayed on the basis of a 'therapeutic' digitalis concentration or to obtain a digitalis concentration. A blood sample should be obtained and analysed while antidotal treatment is underway. Successful treatment of digitalis intoxication depends on early recognition.

Therapy of digitalis intoxication

Supportive care

A single dose of activated charcoal should be administered within the first 2 hours following ingestion in acute poisoning. Neither repeated charcoal administration nor any extracorporeal removal technique has been demonstrated to be of value in acute or chronic digitalis poisoning.

Correction of hypokalaemia and dehydration are important in chronic toxicity. However, the pathophysiological mechanism of hypokalaemia should be kept in mind and secondary hyperkalaemia avoided. Hyperkalaemia is best treated with antidotal treatment with Fab fragments [11].

Severe bradydysrhythmias are often related to increased vagal tone. Treatment is crucial, as bradydysrhythmias increase the risk of for life-threatening ventricular dysrhythmias. Atropine is the treatment of first choice. Adrenergic agonists should be avoided because of the risk of precipitating more severe dysrhythmias.

Intravenous magnesium sulfate in digitalis-induced dysrhythmias is of theoretical benefit. Magnesium may be considered even when the magnesium concentration is normal or high if the serum potassium is elevated. Hypermagnesaemia may occur in patients with renal dysfunction, but is unlikely to result from a bolus of 10–20 mmol.

Other anti-arrhythmic drugs, such as lidocaine and phenytoin, quinidine, procainamide, disopyramide, calcium channel blockers, beta-blockers have limited efficacy, and carry a high risk of side effects.

Cardiac pacing has been used to treat bradycardia and bradydysrhythmias and to prevent ventricular dysrhythmias, but did not reduce mortality in digitalis poisoning [3,5,7]. As a rule, pacemaker use should be considered only if treatment by Fab fragments is not rapidly available.

Direct current counter shock should be performed as a last resort for life-threatening dysrhythmias, only if treatment by Fab fragments is not rapidly available. If used, the lowest effective energy level is suggested.

Antidotal therapy

High degree conduction disturbances and ventricular dysrhythmias in digitalis toxicity result in increased mortality, reaching 25% in recent studies [5,7,9,12]. The safest and most efficacious method for treating acute and chronic digitalis poisoning is the use of digoxin-specific antibody fragments (Fab). The fragments neutralize toxicity by reversing tissue binding of digitalis. Antibody-bound digitalis is eliminated by glomerular filtration and rapid excretion.

Two approaches to antidotal treatment with Fab fragments may be considered [13]. Equimolar 'curative' neutralization is used in patients with life-threatening poisoning (asystole, ventricular dysrhythmia, heart rate <40/min after intravenous atropine or serum potassium >5.0 mmol/L). Semi-equimolar 'prophylactic' neutralization is used in patients with less severe intoxication and/or poor prognostic risk factors alone (age >55, cardiac disease, heart rate <60/min after atropine, second or third degree block or serum potassium >4.5mmol/L) [7,13–15]. The aim of early Fab therapy is to prevent evolution to life-threatening complications. The use of an antidotal prophylactic strategy is associated with lower mortality.

Antidotal treatment is efficacious in both cardiac and non-cardiac poisoning. Hyperkalaemia is best treated by Fab fragments.

The dose of Fab fragments to administer may be determined empirically or, ideally, by calculating digitalis body load [7,13]. Digitalis body load may be estimated, based on supposed ingested digitalis amount (in acute poisoning) or by measured digitalis blood concentrations. Total digitalis body load calculations and empiric dosing are described in Table 323.3.

Fab fragments are given over a few minutes in the presence of life-threatening toxicity and over 1–2 hours for prophylactic

Table 323.3 Empiric dosing of Fab fragments

	DigiFab™ (BTG International)	**Digibind™ (Smith Kline Beecham)**
How supplied (mg per vial)	40 mg	38 mg
Acute ingestion of unknown amount	800 mg (20 vials)	760 mg (20 vials)
Toxicity during chronic therapy	240 mg (6 vials)	228 mg (6 vials)
Ingestion of known amount	40 mg DigiFab© digoxin immune Fab will bind approximately 0.5 mg of digoxin*	38 mg Digibind© digoxin immune Fab will bind approximately 0.5 mg of digoxin or digitoxin
Dose of Fab based on **steady state** digitalis concentration	Dose (# of vials) = serum **digoxin** concentration (ng/mL) × weight (kg)/100*	Dose (# of vials) = serum **digoxin** concentration (ng/mL) × weight (kg)/100
		Dose (# of vials) = serum **digitoxin** concentration (ng/mL) × weight (kg)/1000

For 'prophylactic' or semi-equimolar therapy, reduce calculated dose by one-half.

Brand names are included only to distinguish between the two available therapeutic antibody products and instructions for use, and do not constitute an endorsement of either product.

*DigiFab package insert does not address digitoxin, as the latter has been removed from the US market. It should effectively bind digitoxin as well.

indications. Resolution of digitalis poisoning after Fab fragments infusion is rapid. Reversal, including correction of serum potassium concentration, has been reported in 75% of the patients within 1 hour [11]. Vital signs, electrocardiogram, and serum potassium monitoring during Fab fragments infusion are methods of assessing treatment efficacy and safety.

Prior history of allergy after Fab fragment administration is the sole contraindication to administration. Allergic reactions have been reported in <1% of cases [11]. Side effects associated with Fab fragments administration are rare and minor. Hypokalaemia or withdrawal of digitalis therapeutic effects may rarely exacerbate congestive heart failure.

CHAPTER 324

Management of cocaine poisoning

Nicholas J. Johnson and Judd E. Hollander

Key points

- Common clinical manifestations include agitation, euphoria, tachycardia, hyperthermia, hypertension, and chest pain.
- Life-threatening sequelae include stroke, intracranial haemorrhage, seizures, myocardial infarction, dysrhythmias, and rhabdomyolysis.
- Six per cent of patients with cocaine-related chest pain will have myocardial infarction.
- Beta-blockers should not be used in cocaine intoxicated patients.
- Many manifestations of cocaine intoxication, including agitation, hypertension, and chest pain, are effectively treated with benzodiazepines.

Introduction

Cocaine (benzoylmethylecgonine) is an alkaloid compound and a powerful central nervous system (CNS) stimulant derived from the South American coca plant, *Erythroxylum coca*. It is a widely-abused illicit drug that produces a variety of clinical effects.

Epidemiology

Between 14 and 21 million people worldwide (0.3–0.5% of the population aged 15–64 years) were estimated to have used cocaine at least once in 2009 [1]. Of the estimated 4.6 million drug-related Emergency Department visits during 2009 in the USA, cocaine was involved in nearly 10% [2]. Limited data exist on cocaine-related intensive care unit admissions, but a small cohort study identified nearly 50% hospital mortality [3].

Pharmacology

Cocaine affects the body via a number of mechanisms, including blockade of fast sodium channels, increased catecholamine release, inhibition of catecholamine reuptake, and increased concentration of excitatory amino acid concentrations in the CNS. Fast sodium channel blockade produces a local anaesthetic effect, as well as a quinidine-like antiarrhythmic effect on the myocardium. Increased catecholamine levels produce a sympathomimetic effect.

Cocaine is well absorbed through the aerodigestive, respiratory, gastrointestinal, and genitourinary mucosa. The cocaine hydrochloride salt is the form most often abused transnasally or parenterally. Crack and free base cocaine are alkaloids that can be smoked, and are absorbed via the pulmonary route.

When injected intravenously or inhaled, cocaine is rapidly distributed throughout the body and CNS, with peak effects in 3–5 minutes. With nasal insufflation, absorption peaks in 20 minutes. The half-life of cocaine is approximately 1 hour. It is primarily metabolized to ecgonine methyl ester by plasma cholinesterases. Benzoylecgonine, the other major metabolite, is excreted in the urine and is the compound for which most urine toxicology screens routinely test. Cocaethylene is a long-lasting metabolite formed when cocaine is used in combination with ethanol.

The effects of cocaine are widespread and impact nearly every organ system, particularly due to the drug's ability to stimulate the sympathetic nervous system. In addition, cocaine causes direct vascular effects best described in the heart [4–6]. These include arterial vasoconstriction, thrombus formation, and inhibition of endogenous fibrinolysis. The direct local anaesthetic effect may be responsible for disturbances in cardiac conduction and dysrhythmias [7].

Clinical manifestations

Central nervous system

Common CNS effects include agitation, euphoria, and mydriasis. These effects are typically short lived and without sequelae. Less common, but more severe stimulatory effects of cocaine include seizures, ischaemic stroke, transient ischaemic attacks, focal vasospasm, intracranial haemorrhage, headache, cerebral vasculitis, spinal cord infarction, and psychiatric manifestations. Increased psychomotor activity during acute intoxication may lead to severe hyperthermia.

Cocaine-induced seizures are typically single, brief, generalized, self-limited, and not associated with permanent neurological damage [8]. These seizures may occur in the presence or absence of structural disease, such as infarction or haemorrhage. Choreaoathetosis and other repetitive movements (termed 'crack dancing') are associated with cocaine intoxication, and appear to be related to dopamine dysregulation.

Chronic heavy cocaine users can present with the 'cocaine washout syndrome', which is characterized by lethargy and depressed mental status. This self-limited syndrome typically resolves within 24 hours and is thought to result from depletion of essential neurotransmitters [9].

Cardiovascular

There are numerous cardiovascular manifestations of cocaine use. Of cocaine-related emergency department visits, chest pain is the most common presenting complaint. Although most of these patients do not have a serious underlying aetiology, 6% of patients with cocaine-related chest pain will have myocardial infarction [10,11]. Among those with cocaine-associated acute coronary syndrome, mean age is 33 years (range 18–52 years), male:female ratio is 7:1, >80% smoke cigarettes, and almost 90% are regular cocaine users. Two-thirds present within 3 hours of cocaine use, and atherosclerotic coronary artery disease was found in 31%.

Disruption in cardiac conduction (e.g. prolonged QRS and QTc) and dysrhythmias (e.g. sinus tachycardia, atrial fibrillation and flutter, supraventricular tachycardias, idioventricular rhythms, ventricular tachycardia, torsade de pointes, and ventricular fibrillation) may also occur with cocaine use. Cocaine-induced left ventricular hypertrophy can lead to a hypertrophic, and eventually a dilated cardiomyopathy and congestive heart failure.

Pulmonary

The effects of cocaine on the lungs largely depend on how the drug is abused. Smoking cocaine may induce exacerbation of asthma, alveolar haemorrhage, pulmonary hypertension, and acute respiratory failure. Forceful insufflation to maximize drug delivery may cause pneumothorax, pneumomediastinum, and non-cardiogenic pulmonary oedema.

Musculoskeletal/renal

Cocaine use may precipitate rhabdomyolysis, leading to acute renal failure in up to one-third of patients [12]. Risk factors for rhabdomyolysis include altered mental status, seizures, dysrhythmias, and haemodynamic compromise, including cardiac arrest.

Gastrointestinal

The intestinal vascular system is particularly vulnerable to the effects of cocaine due to the large numbers of α-adrenergic receptors. Acute intestinal infarction has been associated with all routes of cocaine administration.

The deadliest gastrointestinal manifestations are seen in patients who present after ingesting packets filled with cocaine, termed 'body packers' or 'body stuffers'. Body packers are patients who swallow carefully prepared latex or plastic packets filled with large quantities of highly purified cocaine to smuggle it into the country. Body stuffers are typically 'street' drug dealers who swallow poorly constructed packets of cocaine while fleeing the police. Toxicity can develop from cocaine leaking out of the ingested packets [13].

Pregnancy

Cocaine is a potent vasoconstrictor that alters placental blood flow [14]. Cocaine abuse during pregnancy increases the chance for spontaneous abortion, premature delivery, eclampsia, and placental abruption. Maternal cocaine use is associated with low birth weight, small head circumference, developmental problems, and birth defects in the neonate. Neonates exposed to cocaine in utero may experience withdrawal, which typically begins 1 or 2 days after delivery, and is characterized by irritability, jitteriness, and poor eye contact.

Diagnostic evaluation

Cocaine intoxication should be suspected based on the symptoms and signs of the sympathomimetic toxidrome—agitation, mydriasis, diaphoresis, tachycardia, tachypnoea, hypertension, and possibly hyperthermia. Further evaluation should be based on the patient's presenting complaints or symptoms.

Mildly-intoxicated patients without focal complaints or exam findings may be briefly observed. When a patient manifests severe toxicity, a laboratory evaluation may be warranted and should include a complete blood cell count, serum electrolytes, cardiac biomarkers, and creatine kinase. Patients with altered mental status, an abnormal neurological examination, or seizure should undergo computed tomography (CT) of the head. Lumbar puncture should be considered in patients with suspected subarachnoid haemorrhage. Patients who are suspected of body stuffing or packing should be evaluated by abdominal radiographs or CT and cavity searches (digital or visual examination of the oropharynx, rectum, or vagina).

If the patient has chest pain, an ECG, chest radiograph, and measurement of cardiac biomarkers should be performed. Nonspecific or non-diagnostic changes on initial ECG are common with cocaine-associated chest pain [10,15]. Cardiac troponin is the preferred method to evaluate for myocardial infarction as false elevations can be seen in the creatine kinase-MB fraction [16]. Observation for a 9–12-hour period is a useful tool with patients with cocaine-associated chest pain. Patients without new ischaemic changes on ECG, a normal troponin test, and no cardiovascular complications (e.g. dysrhythmia or recurrent symptoms) can be safely sent home with follow-up and planned outpatient work-up [17]. Patients with an abnormal electrocardiogram, concerning clinical history or elevated biomarkers will require admission and further management.

Urine drug screens to confirm cocaine use are readily available, but should be interpreted with caution. Commercial urine drug screens are sensitive to 300 ng/mL, and cocaine use within the past 24–72 hours is typically detected. In chronic users, cocaine metabolites may occasionally be detected for 2–3 weeks after last use.

Management

Initial management of patients with suspected cocaine intoxication should focus on airway, breathing, and circulation. If endotracheal intubation is required, neuromuscular blockade may be achieved with a non-depolarizing agent. In theory, suxamethonium may increase the risk of hyperkalaemia. Initial management should also focus on lowering of the core body temperature, when it is elevated. Treatments should be directed at specific signs, symptoms, or affected organs, and are summarized in Table 324.1.

Central nervous system

Patients who present with sympathetic excess and psychomotor agitation are effectively treated with benzodiazepines (1C). The role of antipsychotics is controversial, but it is generally thought that they should be avoided. Antipsychotics may lower the seizure threshold and contribute to both hyperthermia and dysrhythmias. Seizures should be treated with benzodiazepines and phenobarbital. Controversy exists about the use of phenytoin in cocaine-related seizures. Theoretically, barbiturates are preferred because they also produce sedation. If these agents are ineffective, neuromuscular blockade with a non-depolarizing agent and general anaesthesia

Table 324.1 Treatment summary for cocaine-related medical conditions. Support of airway, breathing, and circulation should precede all specific treatments

Medical condition	Treatments (level of evidence/class of recommendation)
Cardiovascular dysrhythmias	
Sinus tachycardia	◆ Observation (IIa/C) ◆ Diazepam or lorazepam (IIa/C)
Supraventricular tachycardia	◆ Diazepam or lorazepam (IIa/C) ◆ Consider diltiazem, verapamil, or adenosine (IIa/C) ◆ If haemodynamically unstable, cardioversion (IIa/C)
Ventricular dysrhythmias	◆ Diazepam or lorazepam (IIb/C) ◆ Consider sodium bicarbonate, lidocaine or amiodarone (I/C) ◆ If haemodynamically unstable, defibrillation (I/C)
Acute coronary syndrome	◆ Aspirin (I/C) ◆ Diazepam or lorazepam (I/B) ◆ Glyceryl trinitrate (I/B) ◆ Heparin (IIa/C) ◆ **For** ST elevation myocardial infarction (STEMI): • Percutaneous intervention (I/C) • Consider fibrinolytic therapy (IIb/C) • Consider morphine (IIa/C), phentolamine (IIb/C), verapamil (IIa/C), or glycoprotein IIb/IIIa inhibitors (IIa/C) • Avoid β-antagonists (III/C)
Severe hypertension	◆ Observation (IIa/C) ◆ Diazepam or lorazepam (I/C) ◆ Consider glyceryl trinitrate (I/C), phentolamine (I/C), and nitroprusside (I/C)
Pulmonary oedema	◆ Furosemide (I/C) ◆ Glyceryl trinitrate (I/C) ◆ Consider morphine sulphate (IIa/C) or phentolamine (IIb/C)
Hyperthermia	◆ Diazepam or lorazepam (I/C) ◆ Cooling methods (I/C) ◆ If agitated, consider paralysis and intubation (IIa/C)
Neuropsychiatric	
Anxiety and agitation	Diazepam or lorazepam (I/C)
Seizures	◆ Diazepam or lorazepam (I/C) ◆ Phenobarbital (IIa/C)
Intracranial haemorrhage	Neurosurgical consultation
Rhabdomyolysis	◆ Intravenous hydration (I/C) ◆ Consider sodium bicarbonate or mannitol (IIa/C) ◆ If in acute renal failure, haemodialysis (IIa/C)
Cocaine wash-out syndrome	Supportive care
Body packers	◆ Activated charcoal (IIa/C) ◆ Whole-bowel irrigation (IIa/C) ◆ Laparotomy or endoscopic retrieval (IIa/C)

are indicated. Patients with cerebrovascular complications or focal neurological findings should be managed as usual. The role of fibrinolytic therapy, however, in cocaine-associated ischaemic stroke is unknown.

Cardiovascular

Patients with suspected acute coronary syndrome should be managed with an aspirin (1C), benzodiazepine (1B), and glyceryl trinitrate (1B) as first line agents [4,15]. Antiplatelet agents (such as glycoprotein IIb/IIIa inhibitors), and unfractionated or low molecular weight heparin are reasonable to use in patients with documented ischaemia (1C). Patients who do not respond to these therapies can be treated with morphine, phentolamine (2b,C) or calcium channel-blocking agents (2b,C). β-adrenergic blockers should be avoided in the management of cocaine-associated myocardial ischaemia or infarction because unopposed stimulation of α-adrenergic receptors may worsen coronary and peripheral vasoconstriction, hypertension, and possibly ischaemia (3C). Although use of labetalol (a mixed α-adrenergic and β-adrenergic antagonist) has been proposed by some authors, labetalol increased seizures and mortality in an animal model of cocaine toxicity, and does not decrease cocaine-induced coronary vasoconstriction in humans [15]. If indicated for a STEMI, primary reperfusion therapy is best done with percutaneous interventions. The role of fibrinolytic therapy in the setting of cocaine use is controversial, and should be avoided in cases of severe hypertension, vasospasm, or suspected coronary dissection.

Supraventricular dysrhythmias should be treated initially with benzodiazepines. Calcium channel blockers may also be effective. Adenosine may be used, but its effects are often temporary. β-adrenergic blockers should be avoided. Ventricular dysrhythmias and QRS-complex prolongation may be treated with sodium bicarbonate, or lidocaine [4,15]. Benzodiazepines may also be useful.

Severe hypertension can be safely treated with benzodiazepines (1C). For patients with refractory hypertension, vasodilators such as glyceryl trinitrate, nitroprusside, or phentolamine may be used (1C). Blood pressure may be lowered if the patient is not suspected to have chronic hypertension.

Musculoskeletal/renal

Management of cocaine-associated rhabdomyolysis and renal failure should focus on decreasing agitation, lowering body temperature, intravenous hydration, and maintenance of adequate urine output. Patients whose initial serum creatine kinase level is <1000 IU/L with a normal serum creatinine level are unlikely to develop complications. Mannitol, alkalinization of the urine or haemodialysis may be considered in severe cases.

Gastrointestinal

Asymptomatic cocaine body stuffers and packers may be treated with activated charcoal and whole bowel irrigation to decrease absorption and enhance elimination. If toxicity develops, immediate surgical removal of ruptured packets may be life saving.

CHAPTER 325

Management of β-blocker and calcium channel blocker poisoning

Geoffrey Isbister and Colin Page

Key points

- β-blockers (βB) and calcium channel-blockers (CCB) can cause life-threatening toxicity due to cardiogenic shock.
- Both βBs and CCBs are heterogenous groups of drugs and particular drugs, such as propranolol, diltiazem, and verapamil are far more toxic than the others in their class.
- Like most overdoses, supportive treatment is the most important with emphasis on the primary pathophysiology, i.e. reduced cardiac output, systemic vascular resistance or both.
- Treatment of βB and CCB poisoning using absolute blood pressure as an endpoint can be misleading and measuring cardiac output can be more informative in gauging response to treatment.
- There are no specific antidotes, although β-agonists may be effective in βB overdose and calcium has been shown to be effective in CCB overdose.

Introduction

Beta blockers (βB) and calcium channel-blockers (CCB) are potentially lethal groups of drugs in overdose. Poisoning by these agents is uncommon and may only require minimal intervention and supportive care for many cases. However, large ingestions of some βB and CCB may result in life-threatening overdose requiring critical care intervention and cardiac support. The existence of slow release formulations, particularly for the CCBs, has meant that there may be delayed severe toxicity in some overdoses.

β-blockers are a heterogeneous group of drugs and can result in a range of effects in overdose. The most toxic βB are propranolol due to sodium channel effects and its ability to cross the blood–brain barrier and sotalol due to its potassium channel effects. The remaining βBs are relatively less toxic, and include atenolol, bisoprolol, carvedilol, labetalol, metoprolol, nebivolol, nadolol, and oxprenolol. The cardioselective CCB are potentially lethal and can cause cardiogenic shock refractory to treatment. The peripherally selective CCB are less likely to cause severe effects as cardiac output is often preserved. Any combination of CCB and βB, or a combination with other cardiovascular acting agents may result in severe toxicity.

Predictors of toxicity

Like all drug overdoses, dose is the most important predictor of toxicity. However, the toxic dose is poorly defined for most βBs and CCBs. One study showed that in propranolol overdose ingestion of greater than 2 g was associated with central nervous system depression, seizures, and sodium channel blockade [1]. Ingestion of greater than 10 higher-dose formulations of diltiazem or verapamil is associated with severe toxicity, although smaller amounts can be highly toxic in the elderly or in patients with underlying cardiac disease. Other predictors of toxicity are co-ingestion of another cardiotoxic drug(s) (βB, CCB, digoxin, and other vasodilators).

- **Type of β-blocker**:
  - *Propranolol*—seizures, coma, QRS widening (sodium channel blockade).
  - *Sotalol*—QT prolongation and torsades des pointes (Tdp).
- **Type of calcium channel-blocker**:
  - *Cardioselective agents*—verapamil and diltiazem.
  - *Peripherally selective agents*—nifedipine, felodipine, amlodipine, lercanidipine, and nimodipine.

Clinical effects

The clinical effects of (βB overdose and CCB overdose are compared in Table 325.1 [2,3].

Investigations

The most important investigations in (βB and CCB overdose are an electrocardiogram (ECG), blood glucose measurement and electrolytes. The ECG will identify QRS widening due to sodium channel effects with propranolol, QT prolongation with sotalol, and any arrhythmias resulting from severe toxicity. The QT nomogram should be used to determine if the QT interval is abnormal [4]. The measurement of cardiac output will often be useful in severe toxicity to determine if hypotension is due to myocardial depression, increased vasodilation or a combination of the two, and to assess the effect of inotropes and vasoconstrictors on the haemodynamics [5,6]. Serial blood glucose and potassium should be measured

Table 325.1 The clinical effects of βB overdose and CCB overdose

	β-blocker	Calcium channel-blocker
Haemodynamic effects	Hypotension due to both myocardial depression and bradycardia, progressing to cardiogenic shock	Hypotension due to both peripheral vasodilatation and myocardial depression, progressing to cardiogenic shock
Arrhythmias	Bradycardia with first degree AV block and interventricular conduction delays are the most common. Other bradydysrhythmias and asystole have been reported in fatal βB ingestions [14]. QRS prolongation with propranolol and QT prolongation and Tdp with sotalol	◆ **Verapamil/diltiazem**: sinus bradycardia, atrioventricular blocks (including complete heart block) progressing to idioventricular rhythms and asystole ◆ **Peripherally-selective CCB**: sinus rhythm and tachycardia
CNS effects	Coma and seizures can occur with lipophilic βB, e.g. propranolol	Drowsiness and confusion. Seizures are rare
Respiratory effects	Bronchospasm, pulmonary oedema	Pulmonary oedema (cardiogenic)
Gastrointestinal effects	Nil	Nausea and vomiting
Metabolic effects	Hypoglycaemia, hyperglycaemia, hyperkalaemia	Hyperglycaemia, lactic acidosis, hyperkalaemia

in all patients on insulin therapy and serial calcium in patients on calcium infusions.

Treatment

Treatment of βB and CCB poisoning can be complicated because of the potential combination of myocardial depression and vasodilation. There are no specific antidotes, although beta-agonists may be effective in βB overdose and calcium has been shown to be effective in CCB overdose. Calcium therapy should be considered before inotropic support. Its effect will often be short-lived unless an infusion is commenced to maintain a state of hypercalcaemia, but can provide support while other therapies are being instituted. More difficult is the choice of inotrope. This is best informed by knowledge about cardiac output to determine if an inotrope and/or a vasoconstrictor is required.

Treatment should initially follow standard advanced cardiopulmonary resuscitation guidelines with the institution of specific antidotes and inotropes as required. Hypotension should initially be treated with intravenous fluid replacement and if unresponsive inotropic support will be required. Unlike many other highly toxic medications, CNS depression may not be a major or early clinical feature so intubation and ventilation are not necessarily required for airway protection and ventilation, except for agents that enter the CNS (e.g. propranolol). In severe poisoning intubation and ventilation may facilitate monitoring and treatment of refractory circulatory collapse. Care needs to be taken with intubation, particularly in bradycardic patients with low cardiac output where atropine and/or adrenaline may be required temporarily with the institution of positive pressure ventilation.

Decontamination

Decontamination should be considered in βB and CCB poisoning because of the potential life-threatening nature of these overdoses. There is no specific evidence to guide the use and timing of decontamination, but like all overdoses a risk-assessment should be made based on the agent, dose, timing, potential for adverse effects and the willingness of the patient to cooperate with decontamination [7]. Single dose-activated charcoal should be used within 2 hours in any potentially severe poisoning with an immediate release preparation. Whole bowel irrigation should be used in large and potentially severe poisoning with slow release preparations, most importantly for slow release diltiazem and verapamil overdoses [8] However, once toxicity is evident, attempts at decontamination may be unsuccessful and will divert attention away from managing the primary toxicity.

Arrhythmias

Cardiac monitoring including serial 12-lead ECGs are essential in all βB and CCB poisoning. Bradycardia is the commonest arrhythmia and can be treated with a bolus of 0.5–1.5mg atropine if there is associated hypotension. In cases of severe bradycardia with persistent hypotension temporary transvenous pacing may be required. In CCB poisoning pacing will need to be ventricular and not atrial due to atrioventricular nodal blockade.

QRS complex widening can occur in severe propranolol toxicity. If associated with hypotension or tachyarrhythmias it can be treated with boluses of sodium bicarbonate similar to QRS complex widening associated with tricyclic antidepressant overdose.

QT prolongation and Tdp associated with sotalol toxicity (even therapeutic doses) should be managed with continuous ECG monitoring and regular 12-lead ECGs to determine if the QT is abnormal [4]. QT prolongation in isolation usually requires no specific intervention except to correct any electrolyte abnormalities. If Tdp occurs with haemodynamic instability then it should be treated as per standard advanced life support guidelines for ventricular fibrillation. In patients with QT prolongation and an episode of Tdp, magnesium sulphate or chronotropy (transvenous pacing or isoprenaline) should be considered. If isoprenaline is used then much larger doses may be required due to the β-blockade.

Inotropes

Selection of inotropes and/or vasopressors should be considered carefully and will differ for βB and CCB overdose with some similarities. Vasopressors (e.g. vasopressin) or inotropes with vasopressor properties (e.g. adrenaline, noradrenaline) are suitable for CCB overdose, but on their own are not suitable for βB blocker overdose where decreased cardiac output is the principle toxicity. High-dose insulin euglycaemia therapy (HIET), which increases cardiac output with less effect on systemic vascular resistance, is effective in

both βB and CCB overdose. If cardiac arrest occurs then prolonged cardiopulmonary resuscitation must be done (4–8 hours) because most patients are healthy prior to overdose. Cardiac assist devices and extracorporeal support should be considered, and will allow time for the drug to be eliminated.

β-blocker overdose

Glucagon has been recommended in the past with little evidence of effectiveness [9]. Glucagon is expensive and the large doses required for its inotropic effect are usually difficult to access. There are a number of potential inotropes for βB toxicity where the aim is to treat myocardial depression. These include isoprenaline, HIET, phosphodiesterase inhibitors (e.g. milrinone), and other catecholaminergic inotropes (e.g. dobutamine). The most commonly used are isoprenaline and HIET, but in resistant cases or where there is more familiarity with other inotropes the other agents can be used. All of these inotropes may initially cause hypotension when commenced and it is reasonable for small amounts of vasoconstrictors to be used to maintain blood pressure. However, recent animal studies in βB overdose suggest that the use of inotropes with vasopressor activity (adrenaline, noradrenaline) or vasopressors alone (vasopressin) may be associated with poor outcomes [10] and they should be only used in association with a pure inotrope.

HIET has become increasingly popular with both animal and anecdotal human evidence to support it as a first line agent or in combination with isoprenaline [11]. A short-acting insulin is given as an initial bolus of 1 U/kg followed by an infusion commencing at 1 U/kg/hour. Glucose needs to be administered simultaneously to prevent hypoglycaemia and can be done as either 10 or 50% infusions with boluses as required. The dose of insulin can be increased and doses of 2–10 U/kg/hour have been reported and appear to have been effective [6]. However, such high doses require large amounts of insulin, and can result in significant hypoglycaemia and hypokalaemia.

Isoprenaline can be used as an initial single agent or in combination with HIET. An initial dose of 20 μg is given, but repeat doses can be given up to 100 μg because large doses may be required to overcome the β–blockade. The bolus dose should be followed by an infusion (2–4 μg/minute), and again double, quadruple, or even higher doses may be required.

Milrinone and dobutamine have also been used to treat hypotension in βB overdose and may be used in combination with other inotropes. Low dose adrenaline, metaraminol, or vasopressin may be used in combination with an inotrope to maintain the blood pressure, but large doses or isolated use of vasopressors is not recommended in β-blocker overdose. With severe toxicity and refractory hypotension advice from a toxicologist is useful.

Calcium channel-blocker overdose

The choice of inotrope CCB overdose will be influenced by the type of CCB. A variety of different inotropes have been used with the aim to treat myocardial depression and/or peripheral vasodilatation. The commonest inotrope and most familiar is adrenaline (1 to 20 μg/min infusion), which can be used in combination with both calcium and HIET. The isolated use of vasopressors is also problematic in CCB overdose because severe toxicity with refractory hypotension (even with peripheral agents) is usually a result of myocardial depression [12].

Other inotropes or combinations of inotropes and vasopressors have been used for CCB overdose. The combination of dobutamine and noradrenaline is one such option and therapy should be guided by familiarity with various agents and toxicological advice. Similar to βB overdose, glucagon is no longer recommended.

Other pharmacological treatments

There are no specific antidotes for βB overdose although β-agonists are effectively an antagonist and inotrope. Although a specific antidote does not exist for CCB toxicity, calcium increases extracellular calcium and has been partially effective for arrhythmias and heart block in CCB overdose [8]. An initial dose of 1–3 g is recommended and if the patient is responsive, an infusion of 1–3 g/hour should be continued. However, initial doses of up to 10 g may be required in severe poisoning and for patients in cardiac arrest [13]. Serum calcium should be measured aiming for an ionized serum calcium above 2 mmol/L. Adverse effects from hypercalcaemia are uncommon.

Conclusion

Severe acidosis in CCB poisoning can be corrected with boluses of sodium bicarbonate in patients with adequate ventilation. Bicarbonate infusions are not appropriate because the body will simply buffer the changes. Seizures in propranolol overdose should be treated like any seizure in poisoning with benzodiazepines.

CHAPTER 326

Management of cyanide poisoning

Stephen W. Borron

Key points

- Cyanide poisoning is characterized by cytochrome oxidase inhibition, resulting in acute central nervous system and cardiorespiratory dysfunction. Hypoxic injury may result in lasting neural deficits.
- Smoke inhalation from enclosed space structure fires is the most common source of cyanide poisoning.
- Marked elevation of plasma lactate, in conjunction with a suggestive anamnesis and clinical presentation, are sensitive indicators of cyanide poisoning.
- A 'toxidrome' exists for cyanide, but may at times be confused with those of other toxicants and sources of CNS and cardiorespiratory instability.
- Treatment relies on rapid, supportive care and, in serious cases, specific antidotes. Hydroxocobalamin and sodium thiosulfate appear to provide a greater margin of safety when the diagnosis is ambiguous.

Introduction

Our bodies have adapted to cyanide (CN) by developing CN-detoxifying enzymes (thiosulphate sulfurtransferase or rhodanase) and nitric oxide [NO] inhibition of CN binding to cytochrome oxidase [1]. Humans are generally capable of detoxification and elimination of the miniscule quantities encountered in our daily environments (foods, tobacco smoke, industrial effluents). However, in the face of massive exposure, such as fire smoke inhalation, accidental or intentional poisoning with CN gas or salts, or iatrogenic prolonged administration of nitroprusside, life-threatening toxicity may occur in minutes to hours, depending on the specific cyanide-containing substance and route of entry. Cyanide reversibly inhibits cytochrome oxidase, resulting in markedly diminished oxygen utilization and energy production. Generation of reactive oxygen species may result in necrotic or programmed cell death. Highly oxygen-dependent organs (brain and heart) suffer earliest and most. If intervention is not rapid, death or permanent brain injury may ensue. The challenge is to recognize a relatively rarely seen entity quickly, in order to permit effective intervention. Moreover, the antidotes may be rather unfamiliar.

Sources of acute cyanide poisoning

Smoke inhalation, most often from an enclosed space fire (auto, home, or other structure), is the most common source of poisoning. The importance of CN toxicity relative to carbon monoxide (CO) and other combustion gases and particulates, varies from one fire to another and remains a subject of debate [2]. The combustible material (Table 326.1), the heat of degradation, and the availability of atmospheric oxygen determine, to a large extent, how much cyanide is produced. Unfortunately, **timely** measurement of cyanide in smoke atmospheres [3] and among patients [4,5] is rare outside research settings. When blood cyanide is sampled, it is often post-mortem and sometimes long after the event [6] This leads to confusion regarding cyanide's role in smoke inhalation. Nonetheless, cyanide was suspected as early as the 1960s of contributing to fire smoke mortality and has been demonstrated to do so in prospective clinical investigations [4,5]. These studies have shown the presence of altered mental status, soot in the mouth or nose, and elevated plasma lactate should strongly suggest CN toxicity in fire victims.

Hydrogen cyanide (HCN, a gas or liquid at room temperatures), CN salts (sodium, potassium, calcium, and others), and metallocyanides (gold, silver, mercury cyanide, and others) cause CN poisoning, respectively, within minutes to hours, the delay depending on the solubility, dose, and route of exposure. HCN and its salts are used extensively in industry, mining, metal recovery, jewellery cleaning, and electroplating, and in chemistry and medical laboratories as reagents. Sudden collapse occurring in these occupational settings should always raise suspicion of exposure to CN. HCN is also produced when strong mineral acids or even water come into contact with CN salts. Thus, stomach acid may turn ingested CN salts into both a respiratory exposure to the patient and an environmental risk to rescuers.

Foods and nutritional products, such as cassava, cycad seeds, *Prunus* spp. fruit pits containing laetrile ('vitamin B17'), occasionally

Table 326.1 Household products which may release cyanide during combustion

Cyanide-containing substance	Example household product
Melamine	Countertops, cabinets
Nylon	Clothing, carpets
Polyacrylonitrile	Furniture, clothing, rugs
Polyurethane	Furniture cushions, pillows, mattresses, surface finishes
Silk	Drapes, upholstery, clothing
Urea formaldehyde	Fibreboard, plywood, laminates, glues, and adhesives
Wool	Drapes, upholstery, clothing

produce acute CN poisoning when metabolized, as do industrial nitriles (R-CN, used in plastics and pesticide production) and cyanogens (employed as fumigants). It is critical to recognize that toxicity may be delayed for hours after exposure to nitriles and cyanogens.

Finally, nitroprusside may result in CN toxicity, typically when administered in high doses over several days.

Clinical presentation

Acute cyanide poisoning follows a distinctive progression of events. A careful history may elicit early signs that have passed by the time of patient presentation. The immediate clinical response to exposure to HCN or soluble cyanide salts may include dizziness or confusion, headache, a sense of malaise, or even impending doom, chest pressure, nausea, and vomiting. Initially, the pulse becomes rapid and strong, the blood pressure increases, and tachypnoea and hyperpnoea ensue. Central nervous system depression and, sometimes, seizures intervene. Eventually, gasping and bradypnoea give way to apnoea. A sudden drop in blood pressure is observed and, if intervention is not early and correct, death follows. In the case of ingestion or skin absorption of less soluble salts or of nitriles or cyanogens, the progression may be much slower. Deaths following a spate of acetonitrile ingestion in children resulted in symptoms several hours after accidental ingestion [7].

Toxidrome

An 'asphyxiant toxidrome' may be seen after cyanide or CO poisoning. While the presentations of these two poisonings share nervous and gastrointestinal system signs and symptoms, Baud [8] has pointed out important distinctions that are unique to cyanide poisoning—severely abnormal vital signs, cardiovascular compromise, abnormal respiratory pattern (particularly bradypnoea) and severe lactic acidosis.

Impostors

CO poisoning should be high in the differential diagnosis, but typically causes less severe acidosis and cardiovascular impairment [9]. Clenbuterol, a β2-adrenergic agonist and adulterant of heroin, has caused epidemic poisoning in the USA that very closely resembled CN poisoning, with nausea, agitation, chest pain, hypotension, hyperglycaemia, and lactic acidaemia [10]. Hydrogen sulphide poisoning resembles cyanide poisoning with tachypnoea and/or apnoea, loss of consciousness, and metabolic acidosis. However, a strong sulphur smell distinguishes this exposure [11]. Sodium azide poisoning (used in automotive air bags and herbicide manufacture) may inhibit cytochrome oxidase and result in symptoms similar to cyanide poisoning.

Diagnostic studies

Definitive diagnosis of cyanide poisoning is based primarily on the blood cyanide concentration, which is not immediately available in most hospitals. A point-of-care test is undergoing development, but is not currently commercially available [12]. For late presentations, the finding of high concentrations of thiocyanate in the urine strongly suggests cyanide exposure. This test is also rarely available in a clinically-relevant timeframe.

The plasma lactate is a useful, if non-specific, marker of cyanide poisoning. Plasma lactate associated with cyanide toxicity in smoke inhalation reliably exceeds 10 mmol/L [4]. In the setting of suspected 'pure' cyanide poisoning, a plasma lactate of 8 mmol/L or above strongly supports the diagnosis [13]. The question of CO's contribution to lactate is worth mention. While CO does result in lactic acidaemia, the lactate is generally lower than that seen in smoke inhalation [9,14].

Arterial and/or venous blood gases with co-oximetry are useful. A low blood pH, elevated anion gap, and low total CO_2 can be expected in the setting of moderate to severe CN poisoning. These are, of course, less specific than lactate. Comparing arterial to mixed venous oxygen saturation permits gross assessment of tissue oxygen extraction. In CN poisoning, it is not unusual for venous oxygen saturation to approach arterial saturation. Co-oximetry allows assessment of contribution of abnormal haemoglobins, such as methaemoglobin and carboxyhaemoglobin, to the clinical condition.

Some texts and antidote package inserts [15] recommend monitoring of methaemoglobin levels after sodium nitrite administration. The idea of administering sodium nitrite to reach some arbitrary 'therapeutic' level of methaemoglobinaemia must be strongly denounced. Cyanide very rapidly binds to methaemoglobin to form cyanmethaemoglobin, which is not detected by routine co-oximetry. Thus, any **measurable** methaemoglobin in the blood is **in excess** of therapeutic levels. Suggesting a maximum methaemoglobin level of <30% implies that, in addition to non-oxygen-carrying cyanmethaemoglobin and/or carboxyhaemoglobin, an additional 30% of the circulating blood volume is incapable of carrying oxygen. If methaemoglobin is to be measured, it should be done with the understanding that **any** measured methaemoglobin represents excess capacity to bind extant cyanide.

Treatment

The *sine qua non* of the treatment of cyanide poisoning is excellent supportive care, which has been successful without specific antidotes. Antidotes appear to offer additional benefits however, including toxicokinetic support of CN elimination. The strength of evidence for antidote treatment relies heavily on case series and a handful of open-labelled prospective trials. A proposed treatment guideline for 'pure' CN poisoning is found in Fig. 326.1. In the setting of smoke inhalation, significant CN poisoning is heralded by soot in mouth, nose or secretions, altered mental status (coma, confusion, slowness of ideation), and/or cardiovascular instability not due to associated trauma.

Oxygen administration appears almost paradoxical in CN poisoning, as oxygen utilization is diminished at the cellular level due to inhibition of cytochrome oxidase, but oxygen improves outcome in CN poisoning. Most severely-poisoned patients will require intubation and mechanical ventilation, with a goal of mild respiratory alkalosis. Hyperbaric oxygen has been used in severe cases but the evidence base remains limited.

CN poisoning induces sustained and sometimes severe lactic acidaemia which persists long after correction of haemodynamics [16]. Given the pKa of 9 of HCN, acidaemia implies that more of the CN is in a non-ionized form, facilitating its movement into sensitive cells. Grave cyanide poisoning may be further complicated by respiratory acidosis. Induction of an alkaline pH in such circumstances by hyperventilation reduces cerebral distribution of CN in an animal model by some 57% [17]. Sodium bicarbonate is

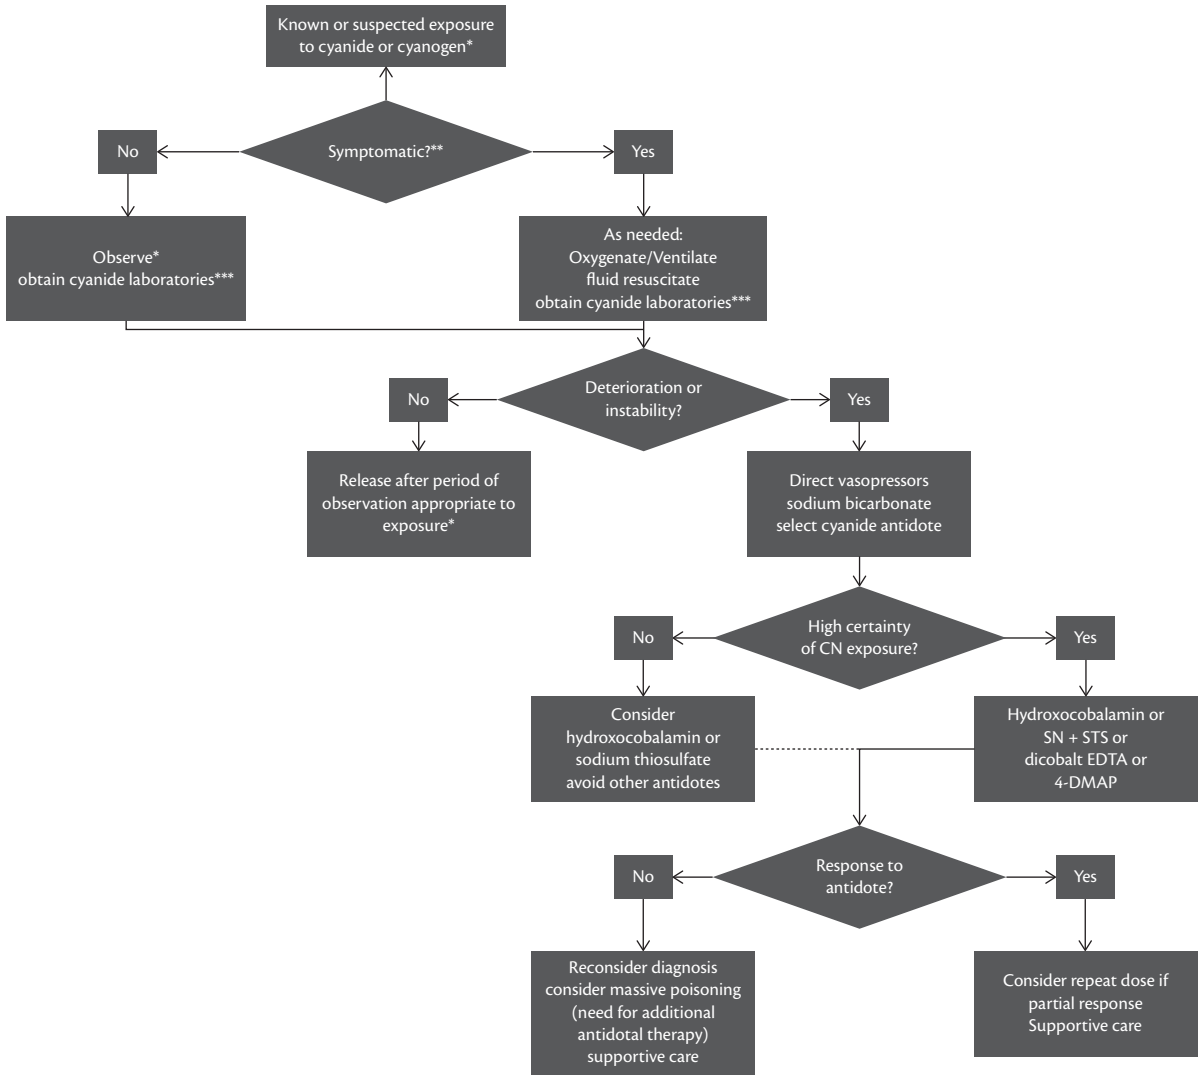

Fig. 326.1 Treatment guideline for suspected exposure to cyanide or cyanide-containing compounds.

*Cyanogens and nitriles may result in delayed toxicity. Observation for a minimum of 12–24 hours is recommended if exposure is thought to have occurred. Monitor for development of lactic acidaemia.

**Frightened non-exposed subjects may have tachypnoea, tachycardia, and hypertension. Look for evidence of mental status changes, abnormal breathing patterns (bradypnoea, hyperpnoea, apnoea) or hypotension.

*** Useful laboratories include serum electrolytes (to calculate anion gap), venous and/or arterial blood gases with co-oximetry (to assess acid-base status, presence of abnormal haemoglobins, and oxygenation/oxygen utilization), and plasma lactate (as a surrogate of significant inhibition of oxidative phosphorylation). Oxygen utilization is diminished in cyanide poisoning, giving falsely reassuring pulse oximetry values. Do not delay treatment of unstable patients while awaiting laboratory results.

CN, cyanide; dicobalt EDTA, dicobalt edetate; SN, sodium nitrite; STS, sodium thiosulphate.

frequently recommended, but appears to be supported purely on an anecdotal basis.

Vasopressors may be used as adjuncts to antidotes if fluid infusion fails to stabilize blood pressure. Bebarta and colleagues demonstrated increased survival in CN poisoned pigs treated with adrenaline versus saline alone after induction of severe hypotension (<30 mmHg) [18]. Other vasopressors were not tested. As CN poisoning results in both myocardial ischaemia and decreased systemic vascular resistance, noradrenaline or phenylephrine may be reasonable choices.

Antidotes

CN antidote availability varies by region and hospital.

Hydroxocobalamin

Hydroxocobalamin (OHCo) is vitamin B12a, which binds rapidly and irreversibly with cyanide to form cyanocobalamin (vitamin B12). Its therapeutic action likely derives from its binding of both cyanide and nitric oxide. OHCo is generally agreed to be safer than most other cyanide antidotes [19]. Adverse effects include a transient rise in blood pressure, reddish colouration of urine, plasma (leading to laboratory interference), and integument, and rare allergic reactions. It is administered via the intravenous (iv) or oral (po) route in a dose of 5 g (70 mg/kg in children). The dose may be repeated if response (haemodynamic or mental status) is incomplete. It is safe in the setting of smoke inhalation [5], as it does not form methaemoglobin or otherwise interfere with oxygenation.

Amyl nitrite, sodium nitrite, and sodium thiosulfate

Amyl nitrite, sodium nitrite, and sodium thiosulfate have been packaged in combination since the 1930s. Recently, a new antidote kit, with only the latter two drugs, has become available. The mechanism of action of the nitrites is still incompletely understood. They form methaemoglobin, which is capable of reversible binding of CN as cyanmethaemoglobin. Recent data suggest formation of nitric oxide may be important as well [1]. Unfortunately, overzealous administration of nitrites may result in hypotension or excess methaemoglobinaemia. Methaemoglobin does not carry oxygen so may aggravate hypoxaemia in smoke inhalation. Sodium thiosulfate provides a source of sulfane sulphur to the enzyme rhodanase, one of the body's innate systems of cyanide detoxification. Sodium thiosulfate appears to be quite safe, frequently causing vomiting, but there is limited experience with this drug used alone.

Amyl nitrite is generally considered a first aid measure, having little role to play in the intensive care unit. Sodium nitrite is administered iv as 300 mg over 2–4 minutes (0.2 mL/kg, not to exceed 10 mL, in children). It may be repeated once for incomplete response at one-half the original dose. Sodium thiosulfate is administered as 12.5 g (50 mL) by slow iv injection (1 mL/kg in children) and likewise may be repeated at one-half the original dose for incomplete response. The nitrite-thiosulfate combination seems most appropriate for confirmed or highly suspected pure CN poisoning. Sodium thiosulfate has been proposed for use alone in the setting of smoke inhalation, though evidence is anecdotal.

Dicobalt edetate

Dicobalt edetate, like hydroxocobalamin, is a cobalt-containing compound that chelates CN. It is recommended only for definite CN poisoning due to its adverse effect profile, which includes hypotension, anaphylactoid reactions, and ventricular arrhythmias. The iv dose is 300 mg over 1 minute in adults. Experience with children is lacking.

4-Dimethylaminophenol

4-Dimethylaminophenol is another inducer of methaemoglobinaemia. Unlike the other antidotes, it may be administered by the intramuscular route. Its use has been associated with severe toxicity, including haemolysis and multi-organ failure. The recommended iv dose is 250 mg over 1 minute in adults. Experience with children is lacking.

Cobinamide and sulfanegen

Cobinamide, a derivative of cobalamin is anticipated to soon undergo human trials in the USA. It benefits from being a smaller molecule than hydroxocobalamin and of binding two, rather than one CN anions per mole of drug, allowing smaller doses. Sulfanegen, a new sulfane sulphur donor prodrug is demonstrating promising results alone, and in combination with cobinamide in animal testing [20].

CHAPTER 327

Management of alcohol poisoning

Knut Erik Hovda and Dag Jacobsen

Key points

- Methanol and ethylene glycol poisoning share many characteristics, often presenting with a metabolic acidosis of unknown origin.
- A common mistake is delayed diagnosis of poisoning with fatal consequences, in spite of effective treatment available.
- The long-term prognosis of cerebral (unless hypoxic damage) and kidney function in ethylene glycol poisoning is good given adequate treatment.
- Diethylene glycol is also highly toxic, but the knowledge on toxicity is limited. We recommend treatment similar to ethylene glycol poisoning.
- Poisoning with other alcohols is less severe, and will usually present without pronounced metabolic acidosis.

Ethyl alcohol

Diagnosis

The most important diagnostic procedure in the patient with a suspected alcohol poisoning is to rule out other causes for the coma such as head injuries, hypoglycaemia (children) or co-ingestion of drugs or chemicals.

Ethanol is easily determined by standard enzymatic methods or gas chromatography, and ethanol elevates serum osmolality by 24 mOsm/kgH_2O per 1 g/L (100 mg/dL).

Assessment

The lethal ethanol dose for adults is about 3–5 g/kg in adults (75 kg), corresponding to a lethal serum concentration of 5–8 g/L; or 110–180 mmol/L, lowest among the chronic alcoholics with poor nutrition. The lethal dose in children is about 2–3 g/kg (1 g = 1.2 mL). Fatalities are often related to unsecured airways and, in adults, often to alcohol-induced organ complications, such as cardiomyopathy, malnutrition, and secondary infections.

Typical features of ethanol intoxication are central nervous system (CNS) depression, hypotension, hypothermia, and respiratory problems, including aspiration into the lungs.

Ethanol intoxication in children may be complicated by hypoglycaemia. Alcoholic ketoacidosis may occur due to complex mechanisms, including hypoglycaemia (ethanol replaces the ordinary calories in ethanol abusers), dehydration (low extracellular volume gives α-adrenergic stimulus, causing inhibition of insulin-release; hence, the liver oxidizes alcohol to ketones) and lack of thiamine, which gives an increased lactate production (thiamin acts as a co-factor for pyruvate in Krebs cycle to inhibit the production of lactate).

Management

If the patient is seen within the first hour after drinking a substantial quantity of ethanol, gastric aspiration and lavage could be considered. Activated charcoal is of no value in pure ethanol intoxication, but as many patients have co-ingested other drugs, which potentiate the toxic effects of ethanol, activated charcoal should be considered in these cases.

Symptomatic and supportive treatment should be given as needed and intravenous glucose should be administered to inebriated children with regular monitoring of blood sugar.

Haemodialysis effectively removes ethanol, but is rarely indicated.

Isopropyl alcohol

Diagnosis

The clinical diagnosis of isopropyl alcohol poisoning may be suspected from CNS depression and acetone smell on the breath. The specificity of ketostix (sensitive only for acetoacetate) is far too low to be of practical value.

Both isopropyl alcohol (1 g/L = 17 mmol/L; osmolal contribution 18 mOsm/kgH_2O) and it´s metabolite acetone (1 g/L = 18 mmol/L; osmolal contribution 19 mOsm/kgH_2O) will increase the osmolal gap. The anion gap is usually normal, but may be slightly increased due to ketosis (and some lactate) in the alcoholic and lactate in the hypotensive patient.

Isopropyl alcohol is best determined by a standard gas chromatographic method where ethanol, methanol, and acetone are determined as well.

Assessment

The lethal dose 1–4 mL/kg, i.e. about twice as toxic as ethanol.

Blood isopropanol levels in the range of 2–4 g/L (34–68 mmol/L) are often seen without complications other than coma and slight respiratory depression. Others have survived with levels as high as 5.6 g/L (95 mmol/L), although haemodialysis was then performed. Elimination is mainly due to hepatic metabolism to acetone with a serum half-life of isopropanol of 6–7 hours.

The typical patient will present with CNS depression, depressed respiration, gastritis with abdominal pain and slight hypothermia. (Aspiration) pneumonia may be present. Hypoglycaemia may be present in the very young and the most severe alcoholics.

Management

If the patient is seen within 1 hour, gastric aspiration and lavage could be considered, whereas activated charcoal is of no value. The symptomatic treatment should follow the established principles of intensive care when needed. Mechanical ventilation should be used if respiratory depression is accompanied by pneumonia.

Haemodialysis will effectively remove isopropyl alcohol and should be considered at blood isopropanol levels above 4 g/L (68 mmol/L), and on clinical criteria if coma and sustained hypotension are present. In the hypotensive patient, an infusion of norepinephrine may be necessary in order to perform dialysis. The effectiveness of continuous veno-venous haemodialysis has not been confirmed, but it may be considered in the hypotensive patient.

Methanol

Diagnosis

Methanol is most often determined by gas chromatography. Measurement of serum formate by a simple enzymatic method [1] is also a sensitive and specific indirect diagnostic method for methanol poisoning. A simple bedside dip-stick version is under development showing promising results [2]. The clinical diagnosis of methanol poisoning is difficult in the absence of a history of ingestion. The objective signs of ocular toxicity of methanol include dilated pupils, which are partially or non-reactive to light and optic disc hyperaemia with blurring of the disc margins ('pseudopapilitis'). The subjective visual disturbances are only reported in 40–60% of the patients.

If a specific analytical method for methanol is not available, the anion and osmolal gaps should be calculated. The **anion gap** (AG) should be calculated using the formula:

$$AG = (Na^+ + K^+) - (Cl^- + HCO_3^-). \quad \text{[eqn 1]}$$

The anion gap normally varies between 4 and 20 mmol/L [3]. In the absence of a circulatory failure, diabetes, alcoholism, and uraemia, an increased anion gap clearly indicates poisoning with salicylate, methanol or ethylene glycol, although other rare poisonings may also be present (e.g. cyanide). There is a clear 1:1 correlation between the increased anion gap and the formate concentration.

The **osmolal gap** (OG) is the difference between the measured osmols (Om) and the calculated osmolality (Oc) in serum.

$$OG = Om - Oc \quad \text{[eqn 2]}$$

Normally, sodium (and its accompanying anions), glucose, and urea determine the osmolality of serum as expressed by the formula (SI-units):

$$OG = (1.86 \times Na + urea + glucose) / 0.93 \quad \text{[eqn 3]}$$

The reference range for the osmolal gap is 5 ± 14 (mean±2SD) or, more simply below 20 mOsm/kgH_2O [3].

The intoxicants best able to increase the osmolal gap are those which have a low molecular weight and are present in high mass units, i.e. high molar concentrations. The lower alcohols and glycols are such substances. A methanol concentration of 1 g/L (32 mmol/L) increases the osmolal gap by (32/0.93) 34 mOsm/kgH_2O; and a 1:1 linear relationship exists between the OG and the serum methanol concentration. The osmolal contribution of methanol is so significant that interference from other causes (except ethanol), will only occur at low levels of methanol (<0.5 g/L; 16 mM).

Only methanol and ethylene glycol regularly cause severe metabolic acidosis and elevation of both the anion and osmolal gaps (Fig. 327.1). However, if ethanol is co-ingested with methanol or ethylene glycol, there will be no metabolic acidosis before most of the ethanol is metabolized due to the antidotal effect of ethanol (inhibits metabolism of the other two by alcohol dehydrogenase (ALDH)). In such circumstances, calculation of the gaps must be repeated until the ethanol level is zero.

In late stages of methanol or ethylene glycol poisonings, most of the alcohol or glycol may be metabolised to its acidic metabolite. In this situation there is a pronounced metabolic acidosis with a high anion gap. Due to low alcohol/glycol levels, the osmolal gap may now be close to normal values, especially in ethylene glycol poisoning due to its higher molecular weight and thus smaller molar contribution. In this situation, a small/normal osmolal gap does not eliminate the possibility of toxic alcohol ingestion (Fig. 327.1).

Assessment

The lethal dose of methanol is about 1 g/kg (1 g = 1.2 mL). The minimum dose causing permanent visual defects is unknown.

Methanol itself is rather non-toxic and there is usually a latent period of about 12–24 hours from the ingestion of methanol to the occurrence of symptoms. This is the time it takes for sufficient amounts of methanol to be metabolized to formic acid. Since ethanol inhibits this metabolism, concomitant intake of ethanol may lengthen the latent period.

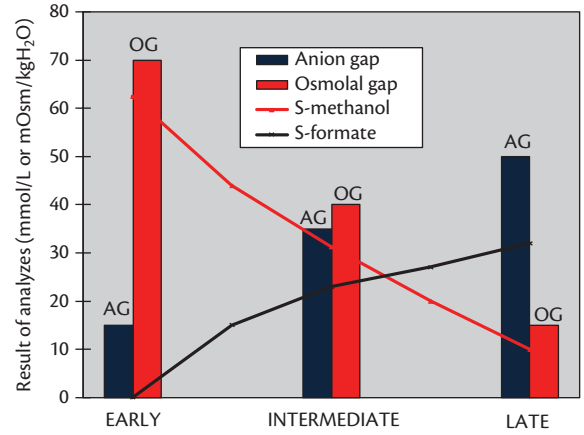

Fig. 327.1 The different stages of methanol poisoning (similar for ethylene glycol poisoning).

Reproduced from *Intensive Care Medicine*, **30**(9), 2004, pp. 1842–6, 'Anion and osmolal gaps in the diagnosis of methanol poisoning: clinical study in 28 patients', Hovda KE et al., with kind permission from Springer Science and Business Media and European Society of Intensive Care Medicine.

Clinical features are non-specific and include weakness, anorexia, headache, nausea, and chest pain, accompanied by increasing dyspnoea (hyperventilation) as the metabolic acidosis develops. Visual symptoms (blurred vision) may appear anytime during the course. A few cases may present with acute pancreatitis.

There is usually little improvement of impaired visual acuity **after** the acute stage, whereas early initiation of treatment will often reverse the symptoms. The patient should always be evaluated by an ophthalmologist as the incident may have legal and insurance implications. The most severely poisoned patients may suffer from a Parkinson-like syndrome due to methanol-induced symmetrical lesions in the putamen.

The possibility of methanol victims other than the patient treated should always be considered.

Management

The treatment should follow the established principles of intensive care when needed. If the patient is seen within 1 hour, gastric lavage should be considered. Activated charcoal is of no value.

The specific treatment of methanol poisoning includes administration of sodium bicarbonate to combat the metabolic acidosis, fomepizole [4] or ethanol to inhibit methanol metabolism to formic acid [5], and haemodialysis to remove methanol and formate, and correct the metabolic acidosis.

Aggressive bicarbonate treatment must be given to correct the metabolic acidosis and decrease the amount of undissociated formic acid and its access to the central nervous system.

Fomepizole should be given intravenously as a loading dose of 15 mg/kg, followed by bolus doses of 10 mg/kg every 12 hours (from the 5th dose and onwards; use 15 mg/kg as fomepizole induces its' own metabolism). Alternatively, give orally in equal doses. During haemodialysis dose every 4 hours. No serum monitoring of fomepizole is necessary.

If ethanol is used as the antidote, aim for a blood ethanol concentration of 22 mmol/L (1 g/L). Keeping ethanol at a constant level is difficult, especially during dialysis (double the dose as a rule of thumb), and close monitoring of the blood levels is necessary (e.g. every 1–2 hours). Start by giving a bolus dose of 0.6 mg/kg of absolute (96%) ethanol, followed by 70–150 mg/kg/hour intravenously in dextrose/saline (or orally) with the highest maintenance dose for drinkers (1 g ethanol = 1.2 mL) [4]. Ethanol solutions above 20% should preferably be given in a central line.

Haemodialysis is indicated for the critically-ill patient with a severe metabolic acidosis (base deficit >15–20 mmol/L), and/or visual disturbances. The methanol level per se is no indication for dialysis if fomepizole is the antidote used, but the treatment period will be prolonged for days without dialysis [6]. If ethanol is the antidote used, dialysis is recommended if the methanol level is above 20 mmol/L (60 mg/dL) [4].

Folinic acid (Leucovorin®) of 50mg (adult dose) should be given intravenously every 6 hours for 24 hours in order to enhance the endogenous formate metabolism.

Ethylene glycol

Diagnosis

Ethylene glycol in biological fluids can be determined by enzymatic methods or gas chromatography. If specific analysis is not available, the use of the anion and osmolal gaps may be helpful as for methanol poisoning. An ethylene glycol concentration of 1 g/L (16 mmol/L) increases the osmolality by (16/0.93) 17 mOsm/kg H_2O. Urine microscopy will often reveal needle-shaped calcium oxalate monohydrate or envelope-shaped dihydrate crystals. These findings may be absent or delayed, and a negative microscopy should therefore be repeated.

Assessment

The lethal dose of ethylene glycol is about 1–2 mL/kg. Ethylene glycol causes CNS-depression and inebriation (similar to ethanol), but its main toxicity is mediated through its metabolites from a combination of a severe metabolic acidosis caused by glycolic acid, and the precipitation of calcium oxalate monohydrate in various tissues (especially in the kidneys), with impaired end-organ function as a result.

Ethylene glycol poisoning is characterized by an initial CNS-depressant phase with inebriation progressing to coma. Following a short latent period of 4–12 hours, the signs and symptoms due to the metabolites start to appear. The increasing accumulation of glycolic acid leads to severe metabolic acidosis and an increasing hyperventilation.

Without adequate treatment, the patient will deteriorate rapidly and, in addition to CNS depression (cerebral oedema occurs), convulsions, oliguric renal failure, and respiratory problems usually develops. Pulmonary infiltrations may be observed radiologically, but these changes are thought to be non-infective in origin. In severe cases, ARDS may develop.

Management

If the patient is seen within 1 hour after ingestion, gastric aspiration and lavage should be considered. Activated charcoal is of no value.

The rapid correction of the acidosis by bicarbonate in these patients may provoke tetanic signs, especially when hypocalcaemia (result of precipitation of calcium oxalate) is already present, as discussed later. Fomepizole [7] or ethanol is given to inhibit ethylene glycol metabolism in the same dose as for methanol poisoning. Haemodialysis removes ethylene glycol and glycolate and helps in correcting the metabolic acidosis. If blood ethylene glycol values are not available, haemodialysis should be performed for 8 hours. Acute renal failure is a strong indication for haemodialysis because its origin is most probably the accumulation of calcium oxalate monohydrate in the proximal tubule cells [8], and not only prerenal failure. If treatment with fomepizole is initiated early before pronounced metabolic acidosis (BD >15 mM) and renal failure have developed, haemodialysis may not be necessary because the renal excretion of ethylene glycol is high (t/2 12–15 hours).

Tetany and seizures should be treated with calcium intravenously. However, calcium **should not be given** for hypocalcaemia per se, as this may increase precipitation of calcium oxalate crystals in the tissues. If calcium gluconate/chloride is not effective, convulsions should be treated conventionally.

It is important to acknowledge the fact that both coma (unless hypoxic brain damage), and the renal failure in ethylene glycol poisoning have a good long-term prognosis (dialysis may be necessary for weeks).

Diethylene glycol

Diethylene glycol is at least partially metabolized through ALDH and two major metabolites have been identified—2-hydroxyethoxyacetic acid (2-HEAA) and diglycolic acid (DGA). The former appears to be associated with acidosis and the latter

with cell toxicity [9]. Fomepizole may therefore be indicated, but there are no clear recommendations in the literature [10]. The clinical features include neurological and renal dysfunction, as well as a metabolic acidosis prior to multi-organ failure. Until further studies have been performed, we recommend diethylene glycol poisoning to be treated as ethylene glycol poisoning.

Higher alcohols

Higher alcohols (more CH_3-groups) are, in general, more lipid soluble than ethanol and usually have a larger CNS-depressing effect than ethanol. As their molecular weight increases dialysis becomes less effective and treatment is solely symptomatic.

CHAPTER 328

Management of carbon monoxide poisoning

Djillali Annane and B. Jérôme Aboab

Key points

- Carbon monoxide (CO), a colourless, odourless, and tasteless gas, is the main cause of poison-related death.
- CO causes tissue damage by oxygen deprivation and by promoting oxidative stress and systemic inflammation.
- Persistent neurological sequels and delayed neurological syndrome are the main complication of CO poisoning.
- The only specific treatment for CO poisoning is breathing 100% oxygen.
- Hyperbaric oxygen therapy should be limited to comatose patients and CO poisoning during pregnancy.

Definitions and epidemiology

Carbon monoxide (CO) poisoning could be defined as the clinical and biological consequences of increased tissue concentration as a result of acute or chronic exposure to CO. CO poisoning kills about 300 people per year in France and is the commonest cause of poison related deaths [1]. Its annual incidence is approximately 4500, and is probably underestimated. In the USA it is estimated there are about 50,000 CO victims annually, of whom about 5–7% will die [2].

Pathophysiology

CO density is very close to the density of air and it is therefore highly diffusible in the atmosphere. It has no colour, no odour, and no taste and, is thus indiscernible from air. CO is produced by incomplete combustion of carbon-containing products. Table 328.1 shows the most common sources of CO.

CO enters into the body exclusively via the lungs. It then goes rapidly into the circulation, where at least 80% of the gaseous molecules bind to haemoglobin to form carboxyhaemoglobin (COHb).Because haemoglobin affinity for CO is 210 times higher than its affinity for oxygen, oxygen is removed from haemoglobin. About 10–15% of CO binds to myoglobin, and about 5% to cytochromes and metalo-enzymes. CO is not metabolized and is cleared via the lungs. Its half-life at room air and sea-level atmosphere is about 4 hours.

There are two main mechanisms by which CO exerts its toxicity in subjects. First, CO induces profound tissue anoxia [3]. CO replaces oxygen on haemoglobin and other specific carriers blocking oxygen delivery to the tissues. CO further prevents oxygen release at the tissue level by shifting the oxygen–haemoglobin dissociation curve to the left. Moreover, CO substitutes for oxygen and binds to proteins of the mitochondrial chain preventing utilization of oxygen molecules that have already entered into the cells. Tissue anoxia with subsequent lactic acidosis is the hallmark of CO poisoning. More recently, tissues and systemic inflammatory response to CO has been recognized as a potential major cause for brain injury and organ dysfunction [4]. CO may directly activate neutrophils and, subsequently, the inflammatory cascade. More often, there is hypoxia-induced cell death, platelet aggregation, and neutrophil degranulation. The subsequent production of proteases, such as myeloperoxidase, and of radical oxygen species triggers lipid peroxydation, myelin degradation, and microglial activation.

Diagnosis

The diagnosis of CO poisoning is one of the most difficult in medicine except in very specific circumstances such as smoke inhalation, or suicide attempt by engine exhaust gas inhalation. Owing to the nature of tissue damage, i.e. anoxia and/or inflammation, the symptoms of CO poisoning are non-specific. Owing to the whole body tissue anoxia following CO intoxication, any of the body systems may be affected. As the brain is the most sensitive to hypoxia, neurological symptoms are the most frequent signs of CO intoxication and commonly include neuropsychological signs, headaches, seizures, fatigue, malaise, and altered mental status, transient loss of consciousness or coma [3,4]. Nausea, vomiting, and abdominal pain are also very common among a broad variety of clinical symptoms (Table 328.2). Rarely, CO poisoning may result in multi-organ failure syndrome. There are several aspects of the medical history that must draw the physician's attention and help him identify CO victims. First, several people may have been exposed to CO inhalation and will present together to the emergency room with similar dizziness or clinical features. Secondly, alleviation of symptoms at the time of presenting to the hospital is a clinical hallmark of CO poisoning. Indeed, when patients are extracted to the toxic atmosphere, CO is cleared via the lung with a half-life of 4 hours.

The diagnosis may be formally established by the detection of CO in room air, on the site of the accident, or by measuring exhaled CO concentrations or arterial COHb. The diagnosis of CO poisoning may be based on exhaled CO levels of 50 ppm or more, or on

arterial carboxyhaemoglobin levels of >10% or >5%, in smokers and non-smokers, respectively [5]. Carboxyhaemoglobin levels do not correlate with clinical symptoms [6]. Routine laboratory tests may show lactic acidosis, increased levels of creatine kinase, liver, or pancreas enzymes, and increased circulating neutrophils.

Prognosis

There are two main neurological complications to CO poisoning, i.e. persistent neurological sequels and delayed neurological syndrome [4]. Patients with persistent neurological sequels are CO victims that presented initially with neurological symptoms (as described previously), which will only partly regress. The delayed neurological syndrome consists of the onset of neurological symptoms (from neuropsychological signs to permanent vegetative state) after a symptom-free period, which may last from 2 weeks to 3–4 months. It is estimated that about half of CO victims may continue to present with neurological signs—mainly neuropsychological disorders—up to 1 year after CO exposure [4].

Risk factors for persistent or delayed neurological syndromes may include long exposure to CO, engine exhaust gas inhalation, dizziness before admission, headaches, or coma at time of admission, and arterial lactate levels [7]. However, COHb levels have no prognostic value [7].

Risk factors for death from CO poisoning include pre-existing cardiac diseases and CO related myocardial injury [2], need for mechanical ventilation and high lactate levels [8].

Treatment

Basis of therapy

Tissue oxygen deprivation being the hallmark of CO related damages, oxygen supplementation is the only specific treatment for CO victims. Fig. 328.1 provides a standard decision tree for patients' management. Immediate therapeutic measures should include removal of the patient from CO exposure and oxygen supplementation [3,4]. In spontaneously breathing patients with normal lungs, inhalation of 100% oxygen reduces the COHb half-life from 4 hours to about 50–60 minutes [3]. For an appropriate delivery of an inspired fraction of oxygen of 100%, a full-face mask is needed.

Supportive care may include mechanical ventilation, fluid replacement, vasopressor therapy, and more rarely renal replacement therapy depending on the number of CO-related organ failures. Although, CO poisoning may damage tissues by triggering an oxidative stress reaction and systemic inflammatory response, there is no evidence a pharmacological anti-inflammatory approach is of any benefit. There are no data to support the use of non-steroidal anti-inflammatory drugs, corticosteroids, or anti-oxidative drugs.

Role of hyperbaric oxygen therapy

Hyperbaric oxygen therapy (HBO) consists of placing the patient in a closed chamber to increase the atmospheric pressure in addition to providing 100% oxygen [3]. According to the atmospheric pressure, arterial partial oxygen pressure, arterial and tissue oxygen content will increase substantially. The increase in oxygen molecules in blood and tissues contributes to removal of CO from haemoglobin, myoglobin, and other proteins. For example, at a pressure of 2 absolute atmospheres and 100% oxygen, the half-life of COHb may decrease to about 20 minutes.

In CO-poisoned animals, HBO may [9] or may not [10] prevent brain damage.

There are nine controlled trials that have assessed the benefit of HBO in CO victims [5,11–18]. A recent systematic review and meta-analysis has included data from six of these trials; see Table 328.3) accounting for 1361 patients [19]. The main outcome for this meta-analysis was the proportion of patients presenting with neurological sequels. At 4–6 weeks, there were 202/691 (29%) and 219/644 (34%) of patients with neurological sequels in the HBO and normobaric oxygen therapy arms, respectively. The odds ratio of persistent neurological sequels was 0.78 (95% CI, 0.54–1.12). There was some heterogeneity across the trials (I^2 = 46%). There

Data from various sources (see references).

were major differences between trials with regard to the investigated populations (pure CO poisoning versus mixed population), to the practical modalities of HBO (different levels of pressure, different duration, and different number of dives), and to main outcome measures (complex neuropsychological testing versus more pragmatic evaluation). In practice, we recommend against the routine use of hyperbaric oxygen therapy in patients who did not lose consciousness and to perform one session of HBO in comatose patient (Fig. 328.1). Although there are no randomized trials evaluating HBO treatment in pregnant women or in infant, current guidelines recommend the use of HBO in these populations regardless of the clinical presentation. Indeed, it is thought that the toxicity of CO for the fetus and for young babies exceeds the potential toxicity of HBO.

CHAPTER 329

Management of corrosive poisoning

Ram E. Rajagopalan

Key points

- Ingestion of corrosive agents in adults has a higher potential for adverse events than accidental ingestion in children.
- Significant airway injury, and oesophageal and gastric perforation are early concerns.
- Endoscopic grading of the injury predicts the frequency of complications.
- No medical therapy reduces the rate of complications.
- Enteral nutrition can be continued in most patients, and endoscopy can guide the choice of oral or enteral routes.

Introduction

A corrosive is a substance that causes chemical damage to tissues by direct contact with them. Besides acids and alkalis, oxidizing, alkylating and dehydrating agents, phenols, halogens, and organic halides may be aetiological (Table 329.1). While some of these substances may have systemic effects as well, such effects are not a prerequisite to their toxicity on tissues. Although inhalational or cutaneous exposure to corrosives may also pose challenging clinical concerns, they will not be dealt with here.

Epidemiology

About 200,000 cases of corrosive ingestion are reported annually in the USA [1]. Caustic soda (sodium hydroxide), bleach (hypochlorite), household chemicals, including organic disinfectants (phenol) and acids are the commonest ingestants implicated. The majority of cases are accidental ingestions in children, which although declining in incidence in high-income countries, remain a significant concern in the developing world [2]. Fortunately, in most paediatric cases ingestions are of small volume, involve household chemicals that are of low concentration and seldom cause severe acute problems although long-term consequences related to strictures of the oesophagus are a serious concern in these children.

Although ingestion in adults constitutes a minority (<20%) of all corrosive ingestion, they are a greater cause for concern in the short term. These cases are invariably related to intentional consumption of large volumes of corrosive agents, which are usually of high concentration (industrial chemicals). As they are often co-ingested with alcohol or other toxins, initial management may be further complicated. It is estimated that 10% of all ingestions are severe enough to warrant medical treatment. Outcomes are best known only in patients with significant post-ingestion symptoms who require hospitalization [3]. Aspiration pneumonia (11%), respiratory failure (8%), and acute gastrointestinal haemorrhage (5%) are the three most common acute complications, with oesophageal strictures developing in nearly one-quarter of patients at around the second week after the ingestion. It is estimated that mortality in the short-term is ~10% in hospitalized adult patients in most parts of the world [4].

Mechanism of injury

The mechanism of tissue injury is dictated by the nature of the consumed corrosive. Alkali typically saponifies fat and solubilizes protein, resulting in liquefaction necrosis of affected tissue. Besides the generation of heat, collagen swelling, and thrombosis of the microvasculature, it results in a rapid progression of the injury that involves all layers of the digestive tract, especially at the sites that initially come in contact with the alkali, namely the oropharynx and oesophagus. Early oedema can significantly compromise the upper airway in these cases. The coagulative necrosis induced by acid ingestion appears more benign. Eschar formation may initially protect the underlying tissue from damage, but delayed loss of the eschar can cause significant bleeding or perforation of the gut. Although acid injuries are typically more superficial and have a tendency to spare the oesophagus, full thickness injury does occur and oesophageal lesions are seen in over one-half of all patients with acid ingestions. Ingestions of button batteries cause corrosive damage, mainly through electrolysis of tissue fluids and accumulation of hydroxide at the battery's negative pole [5]. Injury with hydrofluoric acid is initiated by the acidic (H^+) component, but after penetration of the tissues the dissociation of fluoride (F^-) ions perpetuates liquefactive necrosis and cellular dysfunction from the binding of Ca^{2+} and Mg^{2+}. The long-term sequels of corrosive ingestion are due to scar cicatrization and subsequent stricture formation in the affected segment of the alimentary tract.

In addition to the chemical properties of the ingestant, the extent of the injury can be influenced by a host of patient- and agent-specific factors [6]. Thus, solid particulate corrosive agents will cause localized deep burns in contrast to the diffuse involvement seen with liquids. The time of ingestion in relation to a meal is relevant as the food in the stomach could buffer the corrosive agent. Gastric transit times will influence the dwell time of the corrosive, and the severe gastric lesions created by acids is attributed to

Table 329.1 Common corrosive agents

Acids	Car battery fluid	Sulphuric acid
De-scalers	Hydrochloric acid	
Metal cleaners	Nitric acid	
Rust removers	Hydrofluoric acid	
Disinfectants	Phenol	
Alkali	Household cleaners	Ammonia-based
Disinfectants	Bleach (hypochlorite)	
Drain cleaners	Sodium hydroxide (caustic soda/lye)	
	Alkylating agents	Dimethyl sulphate
	Dehydrating agents	Phosphorus pentoxide, calcium oxide (quick lime), zinc chloride, elemental alkali metals
	Halogens	Elemental fluorine, chlorine, bromine, and iodine
	Organic halides	Acetyl chloride and benzyl chloroformate
	Oxidizers	Hydrogen peroxide

pyloric spasm and delayed gastric emptying caused by these agents. Although the volume of the ingestant and its concentration are obvious predictors of the extent of the damage produced by a corrosive, the importance of pH is debated. While the pH of the corrosive is relevant for strong acids and bases, it is often an inadequate correlate of the extent of tissue damage with weak agents. The titrable acid/alkali reserve (TAR; the amount of acid or alkali needed to neutralize the pH of a corrosive) has been proposed as an alternative measure, but also has been challenged in recent literature.

Clinical approach

Initial resuscitation

The initial management of the adult patient who has consumed a corrosive agent is primarily aimed at rapidly identifying life threats. Airway compromise is a significant concern, because supraglottic oedema can quickly ensue after the ingestion of corrosives. Any patient with significant injury to the oral or pharyngeal mucosa should be considered a risk. As the progression of the oedema is unpredictable, close observation and readiness for intubation of the airway is essential. In a patient with stridor, respiratory distress or depressed mentation, tracheal intubation is urgent. As oedema is likely to make the intubation difficult, the availability of fibre optic visualization can guarantee safety. The potential inability to intubate an oedematous airway after neuromuscular blockade should be considered when medications are chosen for induction of sedation and paralysis. Preparedness for the placement of a surgical airway can be lifesaving in difficult cases. Attempts at 'awake' nasotracheal intubations are very likely to be unsuccessful and have the potential to worsen the airway injury. In the patient without airway compromise, but with significant upper airway symptoms (drooling, dysphonia, hoarseness, and stridor) progression is unpredictable and close observation is essential. Most therapies attempting to minimize the oedema are extrapolated from the care of other forms of upper airway compromise (e.g. epiglottitis). Thus, the use of intravenous or aerosolized adrenaline, or of parenteral steroids has not been proven to reduce the rates of endotracheal intubation specifically in corrosive ingestion. Hypotension during the initial phases is usually related to hypovolaemia from haemorrhage, vomiting or third-space sequestration of fluids, and requires appropriate resuscitation with crystalloids.

Decontamination and dilution

Attempts to empty gastric contents by the induction of emesis or the placement of Ewald or nasogastric tubes are contraindicated in corrosive ingestion. Dilution or neutralization of the corrosive may generate heat and have no proven efficacy. Small volume dilution may be considered selectively very early (<30 minutes) after the ingestion of particulate corrosive agents. The risk of aspiration and gastrointestinal perforation must be considered in balance when attempting any of these procedures of unproven efficacy.

Primary clinical evaluation

After the initial stabilization, clinical, radiographic and endoscopic evaluations are performed mainly to identify the acute complications of corrosive ingestion (perforation and haemorrhage in the upper gastrointestinal tract), and to stratify patients by their risk of acute and long-term complications.

During the initial clinical examination, a complaint of chest or abdominal pain should raise suspicions of oesophageal and gastric perforation and ensuing mediastinitis and peritonitis. Haematemesis or malena may be seen with haemorrhage, which may be the initial presentation or occur at about 3 days after the ingestion after a disruption of eschar formed most typically after acid-induced injury. Subcutaneous emphysema and the Hamman's sign are characteristic of mediastinal air, while abdominal rigidity and rebound tenderness are seen with peritonitis. Radiographic confirmation of mediastinal leaks may be subtle ('continuous diaphragm sign') and small leaks from gastric perforation need not consistently manifest with subdiaphragmatic gas shadows. The use of water-soluble radiographic contrast may allow better identification of leaks. Immediate surgical intervention is warranted when a leak is identified.

Laboratory tests

Laboratory tests may not contribute significantly to identification or risk stratification. Though one small retrospective series [7] demonstrated a lower pH and larger base-deficit on the arterial blood gases of patients who developed surgical complications or who died, their value as independent markers is questionable. However, a WBC count >20,000 has been identified as an independent predictor of mortality after corrosive ingestion [8]. The existence of an anion gap or an osmolar gap could point in towards the existence of a co-ingestion. Hypocalcaemia is often profound in hydrofluoric acid ingestion.

Upper gastrointestinal endoscopy

The risk of early (perforation and haemorrhage) and late (cicatrization and obstruction) complications are logically proportional to the extent and depth of tissue damage. Direct evaluation of the magnitude of upper gastrointestinal injury by endoscopy is useful

in grading the severity and in triaging the patient with corrosive ingestion, besides facilitating appropriate decisions on nutritional support and in planning long-term care of the corrosive damage.

Patient selection

Patient selection for the performance of endoscopy is fairly logical. Asymptomatic patients who have no evidence of oral or airway damage do not need endoscopy. Likewise, on the other end of the spectrum, patients with identified perforation, mediastinitis or peritonitis will have no incremental value from an endoscopic evaluation as they are candidates for surgical management. Patients in whom symptoms may be inconsistent (children <6 years of age) or masked (unconscious patients) require endoscopy to grade the lesions. Endoscopy is also indicated for all symptomatic adult patients, those who have consumed large volumes of corrosives or who have ingested agents of high concentration.

Timing of the endoscopic study

There is some controversy about the timing of the endoscopic study. Very early evaluations, <6 hours after the ingestion, may not reveal the full extent of the corrosive injury. In the landmark study that developed the current grading of corrosive lesions [9], endoscopy was performed within 96 hours after the ingestion. As there are concerns that eschar destabilization, causing GI bleeding could occur by around the third day, the commonest practice is to perform the evaluation on day 1 or 2. Though it has been asserted that a relook endoscopy on day 5 allows better assessment of the extent of damage, no formal supportive evidence is available.

Grading

Corrosive lesions in the gastrointestinal tract are typically graded using the Zargar score [9]. Using this scoring system (Table 329.2) the authors demonstrated that both the mortality and complication rates were tightly correlated with the depth and extent of oesophageal and gastric injury. Patients with lesions classified as Grades 0, 1, and 2a had no long-term complications, while cicatrization occurred in 71% of higher grades. All deaths occurred with grade 3a/3b injury. A recent retrospective series of 273 adult corrosive ingestions, confirms the prognostic validity of the Zargar score [3]. In one model predicting mortality after corrosive ingestion, age, a white blood cell count of >20,000, ingestion of strong acid, the existence of an endoscopic 2b or 3a/3b lesions were independent predictors of death [8].

Table 329.2 Zargar Endoscopic Classification Scheme for corrosive mucosal injury

Grade	Definition
0	Normal mucosa
1	Hyperaemia of the mucosa
2A	Superficial ulcers, exudates, membranes, blisters, erosions, haemorrhages, and friability
2B	Grade 2A plus deep discrete or circumferential ulceration
3A	Small, scattered areas of necrosis
3B	Extensive necrosis

Reprinted from *Gastrointestinal Endoscopy*, **37**(2), Zargar SA et al., 'The role of fiberoptic endoscopy in the management of corrosive ingestion and modified endoscopic classification of burns', pp. 165–9. Copyright 1991, with permission from Elsevier.

Medications

There are no treatments of proven efficacy in reducing the progression or minimizing the complications of corrosive ingestion.

Corticosteroids

The use of corticosteroids to minimize complications is not supported by high quality evidence. In the only randomized control trial of systemic corticosteroids in this setting [10], no differences were noted in the development of oesophageal strictures or their progression in children with documented oesophageal injury who were initially given prednisolone parenterally (2 mg/kg), followed by oral prednisone for 3 weeks. Claims for the superiority of intralesional steroid injection are also not evidence-based.

Acid suppression

Though H2 blockers and proton pump inhibitors are traditionally used to attenuate the propagation of mucosal injury, only anecdotal support exists for their use in corrosive injuries.

Antibiotics

Antibiotics are indicated for established mediastinitis and peritonitis, but their use for prophylaxis is not based on reliable evidence.

Nutrition

Patients with grade 1 and 2a lesions on endoscopy can be initiated on oral feeds as soon as tolerated. The localized nature of grade 2b and 3a lesions can also permit nutrition via the enteral route, most often by the appropriate placement of a naso-enteral feeding tube. Nutritional support in grade 3b lesions can also be achieved enterally, but will require surgical placement of a feeding jejunostomy. Parenteral nutritional support is seldom required.

Referral for long-term nutritional support and management of oesophageal and gastric strictures should be appropriately handled at the time of discharge from the intensive care unit.

CHAPTER 330

Management of pesticide and agricultural chemical poisoning

Elspeth J. Hulse and Michael Eddleston

Key points

- Resuscitation, supportive care, and use of specific antidotes must precede decontamination.
- Aspiration of any pesticide and its solvents/surfactants can be lethal. Avoid through judicious management of the airway.
- Rapid use of atropine in patients with cholinergic features typical of organophosphorus (OP) or carbamate insecticide poisoning can be life-saving. Beware delayed recurrence of cholinergic features in patients in the intensive care unit.
- Airway obstruction and respiratory failure can occur on admission or after several days through paralysis caused by OP insecticides. Consider early intubation and ventilation for such patients.
- Supportive care is the mainstay of treatment for pesticide and agricultural chemical poisoning. In addition to atropine, other antidotes, such as methylthioninium chloride (methylene blue) and pralidoxime may be indicated for some pesticides.

Introduction

Agrochemicals are an extremely diverse group of chemicals, numbering in their thousands, with differing modes of toxicity and highly variable case fatality (from 0 to 43% in one large prospective case series) [1]. Pesticides cause at least 300,000 deaths every year, the majority following self-harm in rural Asia. The World Health Organization (WHO) now recognizes pesticide self-poisoning to be one of the most important means of suicide worldwide. Organophosphorus (OP) insecticides cause the greatest morbidity and mortality globally, although the most toxic OP insecticides are slowly being withdrawn from agricultural practice.

Most severe cases of poisoning occur after ingestion of concentrated agricultural liquid formulations. Highly toxic (WHO Class I) pesticides that have been diluted for use may cause occupational poisoning by inhalation or dermal exposure. Even the least toxic liquid pesticide may cause death, since they are co-formulated with solvents and surfactants that could cause severe chemical pneumonitis after aspiration. The effects of the pesticide or alcohol on consciousness may increase the risk of aspiration.

Diagnosis

Diagnosis of pesticide poisoning is largely clinical, combined with situational clues such as the smell of pesticides on patients' clothing. The large number of pesticides used in domestic and industrial agriculture makes identifying the particular pesticide involved difficult. In addition, patients will sometimes be exposed to more than one pesticide and co-ingest other toxins, e.g. alcohol.

Formal laboratory analysis of the pesticide using mass spectroscopy or chromatography is not available in a clinically useful time frame. However, a simple laboratory assay is available for paraquat in the urine that will confirm exposure. Cholinesterase assays may indicate OP or carbamate insecticide poisoning, but generally do not predict the course or outcome of poisoning.

Fortunately, case series with retrospective identification of the pesticide suggest that the history is often correct with the most clinically important pesticides producing clearly recognizable toxidromes (Table 330.1) [2–8]. Treatment is based on identifying the relevant toxidrome.

General management

Standard ICU management and investigations should be undertaken for all poisoned patients including routine blood tests, amylase, ABG, ECG and CXR. The pharmacokinetics and pharmacodynamics of pesticides once ingested can vary markedly depending on the combination of chemicals ingested, the pesticide's lipid solubility, enzyme reactivation, co-ingested toxicants (e.g. alcohol), extent of decontamination, and organ dysfunction.

Staff protection

Where possible, staff should wear standard universal precaution attire: gloves, gown, and eye protection. There is no evidence that nosocomial poisoning is common after agrochemical poisoning [9]. Patients should be cared for in well-ventilated rooms since the solvents may be highly volatile.

Airway, oxygen, and atropine

The airway and respiratory tract may have copious secretions that need suctioning and drying with atropine. Secretions are produced with many pesticides, but can be severe after OP and carbamate poisoning.

High flow oxygen should be administered as soon as possible. However, there is no good quality evidence to indicate that atropine should be withheld if oxygen is not available. Avoid oxygen in mild to moderate paraquat poisoning to reduce the production of superoxide radicals [7].

Swelling of the airway can be caused by aluminium phosphide and methyl bromide fumes. Some pesticides, particularly paraquat,

Table 330.1 Toxidromes for pesticide poisoning with management and complications

Toxidrome	Features	Pesticides	Pathophysiology	Antidotes and treatment	Complications
Cholinergic	**Muscarinic**: miosis, salivation, diarrhoea, vomiting, urination, bronchospasm, bronchorrhoea, bradycardia, hypotension **Nicotinic**: sweating, muscle weakness, fasiculations, flaccid paralysis (sometimes mydriasis, tachycardia, hypertension) **CNS**: coma, respiratory failure	◆ OP insecticides, e.g. dimethoate, parathion ◆ Carbamates, e.g. aldicarb	◆ Inhibition of AChE in blood, CNS, and NMJ causes excess cholinergic stimulation, pulmonary oedema, respiratory failure, and distributive shock ◆ Many patients need intubation and mechanical ventilation (40% in one study [2]); of these many will die (>50% in two studies [2,3])	◆ iv Atropine (or glycopyrrolate) and oximes (see general management) ◆ iv Benzodiazepenes	◆ NMJ dysfunction that necessitates mechanical ventilation, often for several weeks. May occur after the acute cholinergic syndrome settles, also called intermediate syndrome [4] ◆ OP-induced polyneuropathy
Seizures	Single or recurrent seizures in absence of other features	**Organochlorines**: e.g. endosulphan, lindane **Phenylpyrazoles**: e.g. fipronil **Methyl bromide**	Organochlorines and phenylpyrazoles inhibit GABA-A receptors resulting in neuronal hyperactivity	◆ Diazepam 10–20 mg iv, repeated as necessary. Do not use phenytoin as a second line agent, but if seizures persist use a barbiturate infusion [5] ◆ Check glucose levels and consider thiamine if appropriate	Hyperthermia, metabolic acidosis, rhabdomyolysis, hepatic toxicity
Methaemoglobinaemia	◆ Cyanosis ◆ Blood appears brown on inspection after phlebotomy	**Aromatic amines/nitros**: e.g. chloroaniline **Metals**: e.g. copper sulphate **Herbicides**: e.g. propanil, hydrazines **Oxadiazines**: e.g. indoxacarb	◆ Primary toxic effect is creation of metHb by compounds oxidizing iron in haemoglobin to metHb ◆ Secondary toxic effect is metHb causing systemic hypoxia due to reduced oxygen delivery	◆ Methylene blue 1% 1–2 mg/kg iv if symptomatic with metHb >20% or metHb >30% without symptoms ◆ Copper chelation therapy may be of some (unproven) benefit	◆ Intravascular haemolysis ◆ High metHb concentrations (>70-80%) may be fatal from cellular hypoxia, coma, and seizures ◆ Copper is corrosive and may cause GI haemorrhage
Nicotinic	Respiratory failure and coma in moderate-severe poisoning	**Neonicotinoid**: e.g. imidacloprid **Nicotine**	◆ Relatively selective nicotine agonist ◆ Neonicotinoids have high selectivity for insect receptors producing low human toxicity ◆ Nicotine is highly toxic to humans	◆ Supportive care ◆ Atropine for any muscarinic symptoms that occur	

(*continued*)

Table 330.1 Continued

Toxidrome	Features	Pesticides	Pathophysiology	Antidotes and treatment	Complications
Metabolic acidosis		**Acaricides**: e.g. fenpyroximate. **Triazenes**: e.g. atrazine.	Inhibition of the electron transport chain and/or oxidative phosphorylation results in poor oxygen utilization and lactic acidosis	◆ 8.4% sodium bicarbonate iv 50 mL or haemodialysis may improve acidosis. ◆ Acetylcysteine (antioxidant).	Coma, convulsions, dysrhythmias, hypotension
Coma (non-cholinergic)		**Avermectin acaricides**: e.g. abamectin. **Chloralose** (rodenticide) **Chlorophenoxy herbicides**: e.g. MCPA.	◆ Inhibitory and excitatory CNS effects via GABA receptors ◆ Chlorophenoxy poisoning may involve uncoupling of oxidative phosphorylation	◆ Supportive care for coma and hypotension. ◆ Chlorophenoxy poisoning may benefit from urinary alkalinization and haemodialysis [6]	◆ Respiratory failure, hypotension. ◆ Hyperthermia, rhabdomyolysis, hyperventilation.
Multi-organ failure		**Quaternary ammonium herbicides**: e.g. paraquat **Aluminium phosphide** (fumigant) **Glyphosphate surfactant**: e.g. Agri-dex	◆ Paraquat produces free radicals, which induce cellular toxicity and multi-organ failure ◆ Aluminium phosphide produces phosphine gas on contact with water in the stomach. Phosphine inhibits mitochondrial oxidative phosphorylation. ◆ Glyphosphate has an unknown mechanism.	◆ Avoid unnecessary oxygen therapy. Early charcoal haemoperfusion may benefit paraquat poisoning [7]. ◆ No proven efficacious therapy for aluminium phosphide poisoning—consider gastric lavage with 1:10,000 potassium permanganate and sodium bicarbonate 8.4%. Magnesium for cardiotoxicity [8]. ◆ Haemodialysis for glyphosphate poisoning.	◆ If patients survive early toxicity, death may occur from pulmonary alveolitis and fibrosis (from 1–2 weeks). ◆ Cardiotoxicity and shock in aluminiium phosphide poisoning ◆ Respiratory failure, cardiotoxicity, acidosis, hyperkalaemia in glyphosphate poisoning
Aspiration		All chemicals, plus hydrocarbon solvents, food particles, gastric contents	Chemical pneumonitis, which may progress to pneumonia and/or ARDS	◆ Avoidance of aspiration. ◆ Careful, timely airway management.	ARDS, pneumonia

CNS, central nervous system; NMJ, neuromuscular junction; AChE, acetylcholinesterase; metHb, methaemoglobinaemia; ARDS, acute respiratory distress syndrome.

Data from various sources (see references).

will injure the oropharynx and oesophagus, causing absolute dysphagia. Reflux of pesticide and solvent into the oropharynx around the endotracheal tube during long-term ventilation has caused strictures.

Atropine

- Early administration of atropine will reverse the muscarinic features of OP or carbamate poisoning. Characteristic features of cholinergic poisoning that should trigger atropine administration include pinpoint pupils and excess salivation and sweating [10]. Severely-poisoned patients will exhibit bradypnoea and gasping.
- After noting the pulse rate, blood pressure (BP), pupil size, and presence of pulmonary crackles, administer atropine 0.6 mg (for mild poisoning) or 3 mg (for severe poisoning) by rapid intravenous (iv) bolus. If there has been no improvement in observations after 5 minutes, administer double the previous dose of atropine.
- Continue to double the dose until the observations begin to show a clear improvement. Aim for adequate cardiorespiratory function: pulse rate >80 beats/min, systolic BP >80mmHg, and dry chest. Once nearly achieved, smaller doses of atropine can be used. Pupil dilatation may be delayed and should not be used to titrate atropine.
- Once the patient is stable ('atropinized'), set up an atropine infusion giving 10–20% of the dose used to stabilise the patient [10]. Titrate against signs of inadequate atropinization (reversal of cholinergic features) versus over-atropinization–tachycardia, agitation, confusion, hyperthermia, absent bowel sounds, and urinary retention. If the patient becomes atropine toxic, stop the infusion for 30–60 minutes, then restart at a lower rate.
- In one study, an average of 23 mg atropine (range 1–75 mg) was required to atropinize patients with moderate–severe OP poisoning [11]. A recent RCT showed that this approach to giving atropine benefitted patients [12].

Intubation and ventilation

Many poisoned patients will require non-invasive airway support. Severely-poisoned patients, in particular those with OP/carbamate poisoning, will often require mechanical ventilation (Table 330.1), sometimes for several weeks due to neuromuscular junction (NMJ) dysfunction. Intermittent mandatory ventilation (IMV) with continuous positive airways pressure (CPAP) maintains the patient's own respiratory pattern which can improve ventilator weaning and patient compliance [13]. Indications for intubation and ventilation are listed in Box 330.1.

Close observation of recently extubated and non-intubated patients is vitally important to detect:

- The onset of a repeat cholinergic crisis that requires further atropine.
- The onset of proximal muscle weakness (or intermediate syndrome) that may require intubation (or re-intubation) and ventilation.

Assessing whether a patient can lift their head off the bed against minimal force will pick up early signs. Tidal or minute volume should then be checked at least every 4 hours to determine whether respiratory paralysis is imminent [10].

Box 330.1 Indications for intubation and ventilation for pesticide poisonings

- Excessive secretions not controlled with atropine.
- Depressed consciousness GCS ≤ 13 [19].
- Vomiting with altered GCS.
- Uncontrolled seizures.
- Apnoea/hypoventilation:
  - Tidal volume < 5 mL/kg.
- Respiratory acidosis pH < 7.35.
- $PaCO_2$ > 50–55 mmHg (6.5 kPa).
- PaO_2 < 60 mmHg (8 kPa) on FiO_2 0.6.
- Exhaustion and cyanosis due to respiratory muscle paralysis.

GCS, Glasgow coma score.

Data from Eddleston M et al., 'Management of acute organophosphorus pesticide poisoning', *The Lancet*, 2008, **371**(9612), pp. 597–607.

Circulation

Severe pesticide poisoning can cause distributive and cardiogenic shock requiring invasive monitoring, iv fluids, vasopressors, and inotropes. Aim for an adequate blood pressure >80 mmHg with urine output >0.5 mL/kg/hour.

Drugs and antidotes for OP poisoning

- Oximes are drugs that reactivate inhibited acetylcholinesterase, reducing OP toxicity. However, a recent Cochrane review found no clear benefit from their use [14]. Administer pralidoxime 1–2 g (or obidoxime 250 mg) iv into a separate cannulae over 30 minutes to patients who require atropine in an ICU environment [15]. If there is improvement, administer further doses of pralidoxime every 6–8 hours, or obidoxime 750 mg/24 hours, for up to 48 hours.
- OP poisoned patients may have increased sensitivity to both non-depolarizing muscle relaxants (NDMRs) and depolarizing muscle relaxants (suxamethonium), and in these cases reduced doses of NDMRs for intubation should be used if required [16].

Decontamination

Topical decontamination of the patient involves removing and bagging their clothing in a well-ventilated area, and washing their body with soap and water.

Administration of multiple dose-activated charcoal (50 g every 4 hours for six doses) by the oral/nasogastric route has marginal proven benefit [17]. Patients who present early to hospital can have gastric lavage within 60 minutes of poisoning via an NG tube, except for corrosives such as paraquat [7] or copper sulphate, which increase the risk of oesophageal perforation.

Criteria for ICU admission

Many grading systems to determine the severity of OP poisoning and ICU requirement exist, but none have been prospectively validated in an independent cohort. In essence, if a patient

has consumed a large amount of pesticide, and has early respiratory signs and altered consciousness, they should be admitted to ICU [18]. In one large prospective study of mixed OP pesticide poisoning, a GCS≤ 13 gave a 37% case fatality rate for OP poisoning with an area under the receiver operator curve of 0.84 [19].

CHAPTER 331

Management of radiation poisoning

Francis Chin Kuok Choon and Phua Dong Haur

Key points

- Decontamination by removing clothes, washing of skin, and removal of debris can remove up to 90% of external contaminated radiation.
- Treatment of acute life-threatening injuries takes priority over treatment of radiation poisoning.
- Triage of severely-exposed patients can give an indication of dose and severity of radiation dose absorbed. Survival is related to dose absorbed.
- Early gastric lavage and specific antidotes for ingested radiation poisoning should be used with caution.
- Death is mainly due to infections and haemorrhage. Treatment of ARS is supportive with use of antibiotics, colony stimulating factors, blood products and stem cell transplants.

Definitions and principles in radiation poisoning

Exposure

This occurs when someone is near to a radioactive source and irradiated. Large acute doses to the whole body or to parts of the body can cause radiation injury or poisoning. There are specific acute radiation syndromes depending on the dose and body parts exposed. A person who is exposed may not be contaminated or continuously radiated after removal from the site/source of radioactivity.

Contamination

This occurs internally or externally when radioactive material is deposited on the clothes, skin, or open wound, ingested or inhaled. A person who is contaminated must be decontaminated as soon as possible, but without delaying critical care to the acute injuries. A contaminated person may continue to be irradiated by contaminants after removal from the site/source of radioactivity.

Radiation

Radiation can be detected by specialized equipment and this is the only way to confirm its presence. Physicists may be able to identify the nature of the radioactive source, if it is a pure source, from the signature of the compound. It may be alpha particles, beta sources, gamma photons, or neutrons.

Absorbed dose

This is the quantity of radiation energy absorbed. The unit of dose is Gray (Gy). An older unit is rad (radiation absorbed dose), 1Gy = 100rad. Dose rate is dose of radiation per unit time. Equivalent dose adjusts for different biological effects caused by the difference in potency of different types of radiation using a quality factor. Effective dose is quantity derived from International Commission of Radiological Protection (ICRP) and is a calculated dose after multiplying various organ weighting factors [1]. The unit of effective dose is Sievert (Sv), although an older unit (Roentgen equivalent man, rem) is still in use. So, because X-rays or gamma radiation has a quality factor = 1, absorbed dose in rads times quality factor yields rem:

$$100\,\text{rad} = 100\,\text{rem} = 100\,\text{cGy} = 1\,\text{Gy} = 1\,\text{Sv} \qquad \text{[eqn 1]}$$

Route of radiation poisoning

Sources of radiation poisoning and relevant isotopes are listed in Box 331.1. The route of poisoning can be internal poisoning by aerosol inhalation or ingestion of radioactive particulate matter, or by direct contamination on skin. Patients can also be exposed by accidental irradiation and not be continually exposed if no radioactive material is involved. Internal poisoning is particularly difficult to treat because it is difficult to detect and diagnose. Short-range acting radiation, such as alpha and beta radiation, is shielded by body and the greatest dose is absorbed by the body internally. Long-range acting gamma radiation is easier to detect using external detectors and less dose will be absorbed in the body.

Hospital response, decontamination, and protection of staff

Protection of staff relies on three principles of time, distance, and shielding. Reducing the time of exposure can be achieved with appropriate staff rostering and rotation. There is an annual legal limit for radiation workers and members of the public. For the UK and USA, the annual limit for radiation workers is 20 mSv and 50 mSv, respectively, and for both countries the limit for members of the general public is 1 mSv [2,3]. Pregnant women must avoid working in situations of potential exposure and radiation contaminated areas.

Box 331.1 Types of sources of poisoning

Radiation related to Nuclear Fuel Cycle

- **Mining and conversion**: U-235 and daughter products, Rn-222 and daughter products, and U-238 and daughter products.
- **Enrichment**: enriched U-235 and depleted U-238 waste.
- **Fuel fabrication**: U-235 and daughter products, Rn and daughter products, isotopes of plutonium.
- **Reactor cycle**: in addition radioactive gases (H, isotopes of xenon), solids (Rb, isotopes of strontium, isotopes of iodine, I, isotopes of Cs, neutron activation products Cr, Nitrogen, Co, Mg.
- **Nuclear waste**: U and daughter products, Rn and daughter products, isotopes of plutonium, fission by-products- Cs, I.

Sources related to medical diagnosis and therapy

Isotopes used in nuclear medicine diagnostic imaging and therapy (mTc, I), radiation oncology (Co-60, Cs-137, Ir-192, I-131, I-125, Ra-116, P-32, isotopes in biomedical research (I-125, P-32, H-3, S-35, C-14).

Sources of radiation in industry

Naturally-occurring radioisotopes H-3, C-14, Cl-36, Pb-210. Engineering, soil, pipe analysis, food irradiation, smoke detectors (Co-57,Fe57, Co-60, Kr-85, Br-82, Sr-90, Ce-144, Cs-137, Am-241).

Sources of radiation in the military

Components in various military equipment (H-3, Ni-63, Cs-137, Ra-226, Am-241, depleted U-235).

Radiation Sources in Nature

Rn-220 and daughter products, K-40, C-14, isotopes of uranium and daughter products. U-235,U-238, Th-232.

Decontamination should take place in an appropriate area of the emergency department and, ideally, only maximally-decontaminated patients should be transferred to the clean critical care or treatment area. Physicists with specialized detectors can advise if there is risk of exposure for the staff. Radioactive biological waste and effluent must be appropriately handled according to national regulatory guidelines. Patients with inhaled or ingested radioactive material usually do not pose a threat to staff because the radioactive source may have a short half-life or short effective radiation distance. Patients may need to be nursed and managed in specialized wards with radiation protection in place, especially if patients have been poisoned with a long-acting γ source and radiation can be detected outside the patient.

Increasing the distance reduces the radiation intensity significantly because of the inverse square law, which means that the radiation exposure is decreased four-fold when the distance from the source is doubled. Avoid handling radioactive sources directly with finger tips, especially during wound debridement. Use forceps or tongs and dispose of radioactive debris into appropriately shielded containers.

Depending on the radioactive sources (and on the recommendation of physicists), lead shielding may or may not be appropriate. Ingested beta sources require only simple paper gown and gloves to stop the short-acting beta radiation, even if it is excreted into blood, urine, sweat, and faeces. Generally, for ease of nursing or if lead gowns are in short supply, it may be more effective to tend to the needs of the patients quickly, and rely on reducing the time and increasing the distance, than to be encumbered by a lead gown.

Hospitals should activate their contingency radiation management protocols and alert the necessary national and international regulatory authorities, especially in mass casualty situations, seek appropriate advice from expert physicists and request the specialized equipment necessary to monitor and detect all the different types of radiation sources. Staff should be issued with personal radiation dose monitors if they are working in a designated radiation environment [4].

Psychological management of the patients, staff and members of public, including the worried well, is important. Counsellors and psychologists should be available to patients and the staff. Dissemination of appropriate information about the often inconsequential effects of minor exposure to radiation will allay fears and prevent mass panic, which may swamp the hospital system. It is important to differentiate true symptoms from psychogenic symptoms such as nausea, headaches, and episodic vomiting.

Triage

After decontamination down to a dose of twice background level, plus securing the airway, breathing, and circulation, the patient can be triaged. A full history of where and how long patients have been exposed in a particular place, a history of recurrent vomiting, or skin erythema may suggest a significant dose. Recognition of acute radiation syndrome (ARS) and differentiation from thermal injuries is important. Whole body dose monitoring with an appropriate monitoring device is helpful with contaminated patients, and doses around the nose and mouth may suggest ingestion or inhalation of a radioactive source [5]. Severity and type of symptoms is determined by the dose absorbed. Dose determination should be estimated with the Andrews lymphocyte nomogram (Fig. 331.1) for high risk patients.

Patients with psychogenic symptoms or <1 Gy whole body doses can be managed safely as outpatients with serial monitoring and will eventually recover. Those with 1–10 Gy whole body doses should be admitted for intensive treatment in a tertiary hospital environment equipped to handle bone marrow transplants.

Acute radiation syndrome

The severity of symptoms depends on the dose absorbed, and body area or system irradiated. Most common clinical situations involve radiation burns or an accidental exposure situation. If there is whole body irradiation, the symptoms and signs depend on the dose. ARS usually start with a prodromal stage of mild symptoms of nausea, vomiting, and skin erythema, followed by a delayed latent

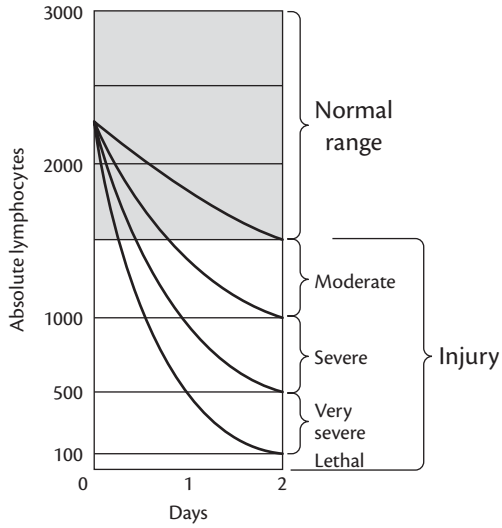

Fig. 331.1 Andrews lymphocyte nomogram.
Andrews GA et al., 'The Importance of Dosimetry to Medical Management of Persons Exposed to High Levels of Radiation'. In: *Personal Dosimetry for Radiation Accidents*. IAEA Vienna 1965. Reproduced courtesy of the IAEA.

stage, before manifesting as the full ARS symptoms [6]. Classically, ARS is a constellation of haemopoetic, gastrointestinal, and cardiovascular/central nervous system plus cutaneous radiation injury depending on the dose received. Those receiving whole body doses of 1–5 Gy may recover easily with appropriate medical management. Those with whole body doses of 6–10 Gy may survive with intensive management. Those patients with whole body doses of >10 Gy seldom survive [7].

Treatment of specific syndromes

Bone marrow

Haematopoietic syndrome occurs from exposure above 0.7–1.0 Gy and the prodromal stage is manifest by anorexia, nausea, and vomiting within a few hours up to 2 days after exposure. Stem cells in the bone marrow are acutely sensitive to radiation and start to die, although the patient can be manifestly well in the latent phase, which can last 1–2 weeks. The white cells fall first, followed by platelets and haemoglobin count. Patients will exhibit a manifest illness stage in 4–6 weeks with anorexia, fever, lethargy, and serial blood using Andrews Lymphocyte Nomogram (Fig. 331.1) can track the dose received and gauge the severity of the haematopoietic syndrome and subsequent improvement and recovery [8]. Blood in EDTA tubes for lymphocyte chromosome analysis can be sent to specialist laboratories for more precise dose absorbed estimation.

Management by haematologists experienced in stem cell transplants will increase survival. Death is primarily due to infection and haemorrhage. Consider appropriate GCSF/GMCSF and blood products infusion (Table 331.1), as well as antibiotic cover for symptomatic supportive care and barrier nursing to prevent infection [9]. Survival decreases with increasing dose and death may follow in a few weeks to months after exposure. Lethal whole body dose for an average individual is about 4 Sv. The lethal dose necessary to kill 50% of an exposed population in 60 days is about 2.5–5 Sv (250–500 rads).

Gastrointestinal

Symptoms are similar in the prodromal stage, with nausea, vomiting, and anorexia, in addition to abdominal pain, mild cramps, and diarrhoea, which may occur within a few hours up to 2 days after exposure. Doses causing gastrointestinal symptoms start from an acute dose of 6 Gy and above. Stem cells in the intestinal crypt base lining the gastrointestinal tract will die if the irradiated dose is more than 10 Gy in a single session. The patient may be well after the prodromal stage because mature gut cells are still alive and functioning. Manifest symptoms do not occur until 1–2 weeks after the death of the mature gut cells, which are not replaced by new cells generated by the stem cells. Patient will have severe cramps, watery diarrhoea with bloody mucous discharge, fever, dehydration, electrolyte imbalance, and death occurs within 2 weeks unless the patient is supported with total parenteral nutrition. Psychological counselling with a psychiatrist may be necessary for those with acutely toxic dose irradiation (>10 Gy) to the gut, while the patient is still in the acute to latent phase, because there is no curative treatment for symptoms that follow.

Cardiovascular/central nervous system

This syndrome occurs in patients with very high doses of exposure of 20–50 Gy and is characterized by nausea, vomiting, acute confusion, encephalopathy, cardiac arrhythmia, watery diarrhoea, abdominal cramps, and loss of consciousness [10]. Onset is rapid within minutes of exposure for these high doses and death occurs rapidly within a week of exposure. Typically, these high doses have only been seen in nuclear accidents, Chernobyl firefighters, and rescue workers in nuclear cleaning operations who are unwittingly

Table 331.1 Blood products and white cell stimulation

Agent	Dosage adults	Precautions
Epoetin alpha or pack red cells	150 U/kg/dose	◆ Sickle cell disease, ARDS ◆ Bone pain may result ◆ Discontinue if pulmonary infiltrates develop
GCSF or filgrastim	5 μg/kg/day till absolute neutrophil count >1000	
PEGylated G-CSF or pegfilgrastim	6 mg/day	
GM-CSF or sargamostin (leukine)	250 μg/m^2/day until absolute neutrophil count >1000	
Apheresis-derived platelets	Replacement of platelets	Maintain platelet at normal range

Table 331.2 Antidotes for internal contamination

Radionuclide	Medication	Mechanism
Iodine	KI (potassium iodide), Lugol's solution	Blocks thyroid deposition
Rare earths: plutonium(Pu), americium (Am), curium (Cu)	Zn-DTPA Ca-DTPA	Chelation and analogue blocking
Iron (Fe)	Deferasirox	
	Desferrioxamine	
Uranium	Bicarbonates	Alkalinization of urine, reducing chance of acute tubular necrosis
Caesium, thallium	Prussian Blue, (ferrihexacyano-ferrate (II))	Blocks absorption from GI tract and ion exchange resin
Tritium	Water	Isotopic dilution
Other fission isotopes without specific antidotes	Antacids	Minimize absorption
	Cathartic	Waste removal from body
	Gastric lavage/irrigation	Waste removal from body

exposed at such high doses. Fatality is inevitable and no effective cure is available.

Skin

Cutaneous radiation injury is acute injury to the skin. Skin damage can manifest within hours, days, or weeks after radiation exposure. Transient itching, tingling, erythema, and oedema may be seen within hours or days after exposure, and are usually followed by a latent period. The most common cause is accidental/overdose or skin after high dose concurrent chemoradiation. The skin may breakdown to blistering and desquamation up to 2 weeks to a few months after exposure. Occasionally, radiation recall syndrome when administering certain chemotherapy may trigger erythema in a previously irradiated site. Skin lesions may evolve and delayed occurrence of lesions is a differentiating factor from thermal burns. Cellulitis and severe wound breakdown may necessitate debridement and skin grafting. Minor injury may just be treated expectantly with wound care, emollient creams, and analgesia. Long-term sequelae of telangiectasia, chronic lymphoedema and fibrosis, and late ulcers may result [11].

Treatment of internal contamination

Internal contamination is by ingestion or inhalation, and is particularly suggested if the nose and mouth is contaminated, and there is a persistently high radiation survey reading, despite adequate repeated decontamination. Usually patients are well, unless a large amount of radioactive material has been inhaled or ingested. Consider the appropriate early administration of radionuclide-specific decorporation agents such as Prussian Blue, diethylenetriamine pentaacetate (DTPA) or bicarbonate shown in Table 331.2. If biological effluent such as blood, urine, and faecal samples are radioactive, consider getting whole body counts to assess dose and consult radiation experts [12].

Gastric lavage, antacids and cathartics may assist in clearing ingested contamination and usually only is effective if done within a few hours of ingestion.

Trauma

PART 16.1

Multiple trauma

CHAPTER 332

A systematic approach to the injured patient

Clay Cothren Burlew and Ernest E. Moore

Key points

- Systematic management of the seriously-injured patient consists of the primary survey with concurrent resuscitation, the secondary survey, diagnostic evaluation, and definitive care.
- The primary survey is concerned with the identification and simultaneous treatment of life-threatening injuries using a traditional airway, breathing, circulation approach with treatment prioritized to injuries that pose an immediate threat to life.
- As early decisions are time critical and affect survival, the initial resuscitation of seriously-injured patients should be carried out by a trained and practiced trauma team.
- Once life-threatening injuries have been treated and the patient stabilized, the secondary survey, a head-to-toe examination to identify all other injuries, should occur.
- The secondary survey is followed by diagnostic evaluation and definitive care.

Introduction

The initial management of the seriously-injured patient consists of the primary survey with concurrent resuscitation, the secondary survey, diagnostic evaluation, and definitive care; this approach is based upon the advanced trauma life support (ATLS) course of the American College of Surgeons [1]. The first step in management, the primary survey is to identify and treat conditions that constitute an immediate threat to life. The life-threatening injuries that must be identified and treated promptly include airway obstruction/injury, tension pneumothorax, open pneumothorax, flail chest with underlying pulmonary contusion, massive haemothorax, cardiac tamponade, bronchovenous air embolism, massive haemoperitoneum, unstable pelvic fractures, cervical spine injury resulting in neurogenic shock, and intracranial haemorrhage. The secondary survey entails a systematic evaluation for more occult, yet potentially limb- or life-threatening injuries. Data suggest that outcomes of multiply-injured patients can be improved if their initial management is performed by an efficiently functioning trauma team. While membership of the team may vary from hospital to hospital, each member of the team should have defined roles, so that all important tasks are accomplished in a simultaneous and coordinated manner. The team leader has overall responsibility and ensures each member attends to their tasks with the goal of identifying and treating life-threatening injuries as early as possible.

Primary survey

Airway

The primary survey encompasses the 'ABCDs' (airway, breathing, circulation, and disability) of resuscitation. Ensuring a patent airway, while immobilizing the cervical spine, is the first priority to avoid hypoxaemia or hypercarbia. Patients who are conscious, without tachypnoea, and have a normal voice are unlikely to need active airway intervention. Patients with penetrating injuries to the neck or complex maxillofacial trauma, however, may initially have a satisfactory airway that can become obstructed due to progression of soft-tissue swelling or expanding haematomas. Provision of a definitive airway (i.e. endotracheal intubation) is indicated in patients with apnoea, and/or an inability to protect their airway, impending airway compromise, and inability to maintain oxygenation. Orotracheal intubation is the preferred technique, even in the patient at risk for cervical spine injury, because it provides a large airway. Correct positioning of the tube should be verified with direct laryngoscopy, capnography, auscultation of bilateral breath sounds, and ultimately chest radiography. Failed intubation should be treated with a surgical airway (cricothyroidotomy) if bag and mask ventilation cannot maintain oxygenation.

Breathing

Once the airway is secured, adequate oxygenation and ventilation must be assured. All injured patients should receive supplemental oxygen and be monitored by pulse oximetry.

If there is a clinical diagnosis of a tension pneumothorax (hypotension with respiratory distress, tracheal deviation away from the affected side, or decreased breath sounds on the affected side), immediate decompression is warranted. While needle decompression with a 14-gauge venous catheter in the second intercostal space in the midclavicular line may be indicated in the field, tube thoracostomy should be performed in the emergency department (ED). An open pneumothorax (full-thickness loss of the chest wall, permitting free communication between the pleural space and the atmosphere) should be covered with an occlusive dressing taped on three sides to act as a flutter valve. Definitive treatment requires closure of the chest wall defect and tube thoracostomy remote from the wound. Flail chest occurs when three or more contiguous ribs are fractured in two locations, but the associated pulmonary dysfunction is largely due to the underlying pulmonary contusion, rather than loss of chest wall integrity. The patient's initial chest radiograph may underestimate the severity of the pulmonary contusion

as these often progress during the first 12 hours. Thus, patients with flail chest may require delayed intubation and mechanical ventilation.

Circulation

In evaluating the trauma patient's cardiovascular status, any episode of hypotension (defined as a systolic blood pressure (SysBP) less than 90 mmHg) is presumed to be due to haemorrhage until proven otherwise. External haemorrhage should be controlled with manual compression. For penetrating injuries of the neck, thoracic outlet, and groin, where bleeding is arising from deep within the wound, a gloved finger should be placed through the wound to control bleeding. Bleeding from scalp lacerations can be controlled with skin staples, Rainey clips, or a full-thickness, running nylon stitch. A massive haemothorax (defined as more than 1500 mL of blood) is evident on chest radiograph, but is best quantified by tube thoracostomy output. This volume is usually an indication for an emergency thoracotomy. Ultrasound of the pericardium (FAST exam), both hemithoraces, and abdomen is an integral component of the primary survey. When acute, the accumulation of less than 100 mL of blood in the pericardial space may cause cardiac tamponade (Fig. 332.1). Pericardiocentesis is successful in decompressing tamponade in approximately 80% of cases; the majority of failures are due to clotted blood within the pericardium in which case open surgery and clot evacuation may be required. Massive haemoperitoneum is identified by ultrasound, identifying free intraperitoneal fluid in Morison's pouch, the left upper quadrant, or the pelvis. Although exquisitely sensitive, it does not reliably determine the source of haemorrhage [2]; massive haemoperitoneum in a hypotensive patient warrants immediate laparotomy. Selected patients undergoing CPR upon arrival to the ED, or those suffering cardiac arrest after arrival, should undergo resuscitative thoracotomy based upon injury and duration of CPR (see Fig. 332.2 for criteria for resuscitative thoracotomy) [3,4].

Plain radiographs should be done to identify unstable pelvic fractures. Patients with a pelvic fracture and associated haemodynamic instability should undergo prompt stabilization with 'sheeting' of the pelvis, application of a commercial pelvic compression device, or placement of an external fixator. These devices reduce pelvic volume, which promotes tamponade of venous and cancellous bleeding, and prevents secondary haemorrhage from the shifting of bony elements. Options to control ongoing pelvic haemorrhage include embolization of bleeding vessels and pre-peritoneal pelvic packing (Fig. 332.3).

Disability

Neurological examination including Glasgow coma scale (GCS) score should be determined as soon as possible for all injured patients. Patients with a GCS <8 require immediate restoration of SysBP to >100 mmHg, normalization of $PaCO_2$, maintenance of oxygenation, and early neurosurgical consultation with consideration for intracranial pressure (ICP) monitoring. The presence of lateralizing findings (e.g. a unilateral dilated pupil unreactive to light, asymmetric movement of the extremities in response to noxious stimuli, or a unilateral Babinski sign) suggests an intracranial mass lesion, which may be amenable to surgical treatment. Once stabilized, such patients should undergo an urgent cranial CT scan.

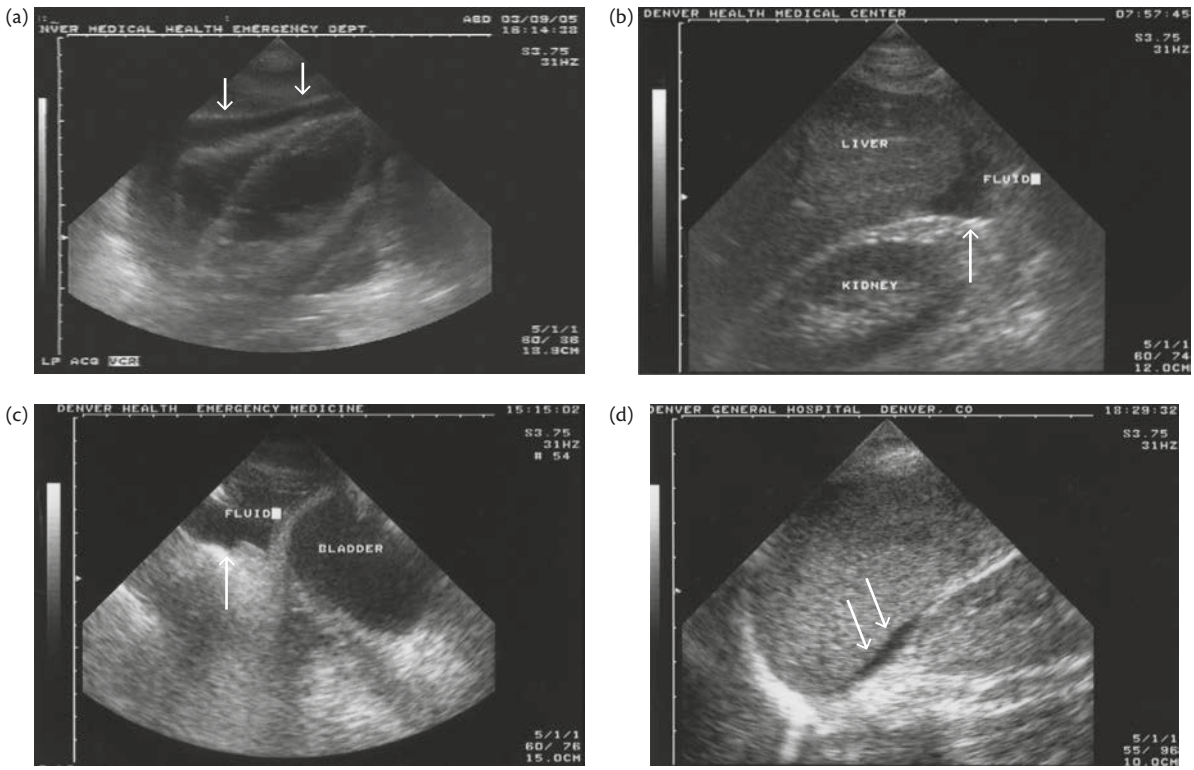

Fig. 332.1 Focused Abdominal Sonography for Trauma (FAST) examination can identify blood in (a) the pericardium, (b) right upper quadrant, (c) pelvic space, and (d) left upper quadrant.

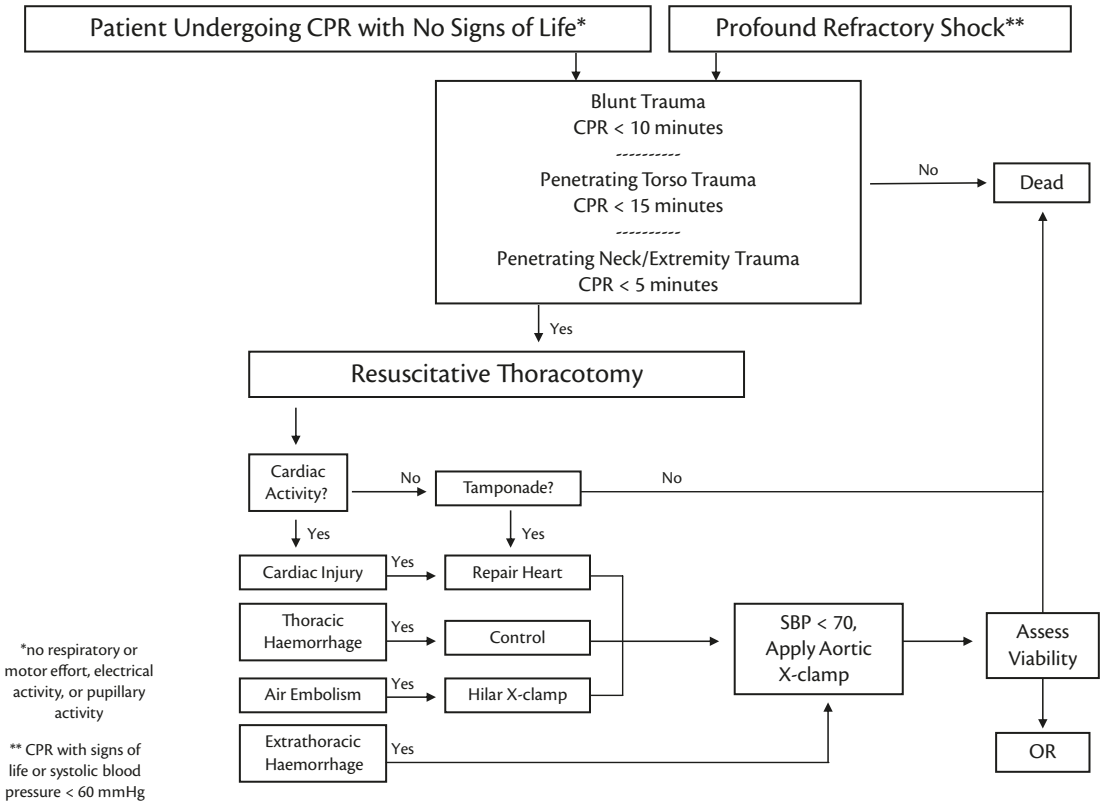

Fig. 332.2 Resuscitative thoracotomy is performed based upon injury, duration of cardiopulmonary resuscitation, and available resources.

Concurrent resuscitation

Intravenous (iv) access should be obtained with two 16-gauge peripheral catheters. If iv access is not easily obtained, an intraosseous needle should be placed. Blood should be drawn simultaneously for a bedside haemoglobin level and routine trauma laboratory tests. In the seriously-injured patient arriving in shock, an arterial blood gas, cross-matching for possible red blood cell (RBC) transfusion and coagulation tests should be obtained. In the hypotensive patient, secondary large bore cannulae should be obtained via the femoral or subclavian veins, or saphenous vein cutdown. Fluid resuscitation begins with a 2-L bolus of isotonic crystalloid in the adult. For patients with penetrating trauma, 'hypotensive resuscitation' to a SysBP of 90 mmHg should be considered to avoid increasing bleeding. In blunt injured patients with a potential head injury, however, the SysBP target should be >100 mmHg. Based on the initial response to fluid resuscitation, hypovolaemic patients can be separated into three broad categories—responders, transient responders, and non-responders. Individuals who are stable or have an appropriate response to their initial fluid therapy—'responders'—are unlikely to have significant ongoing haemorrhage and further evaluation for occult injuries can proceed. At the other end of the spectrum are patients classified as 'non-responders' who have persistent hypotension despite aggressive fluid resuscitation. A massive transfusion protocol should be activated immediately in these patients. Patients considered as 'transient responders' respond initially to volume loading, but deteriorate again.

Persistent haemodynamic instability may be due to haemorrhagic, cardiogenic, or neurogenic shock. Septic shock on presentation is extremely rare in trauma patients. Identification of haemorrhagic shock has been discussed previously. The differential diagnosis of cardiogenic shock in trauma patients is tension pneumothorax or pericardial tamponade, blunt cardiac injury, myocardial infarction, and bronchovenous air embolism. Although up to one-third of patients sustaining blunt chest trauma suffer blunt cardiac injury, this rarely results in haemodynamic embarrassment. Measurement of cardiac enzyme concentration is unhelpful as troponins lack specificity and do not predict significant arrhythmias [5]. β-Agonists may be initiated and echocardiography performed to exclude valvular or septal injuries, and evaluate wall motion abnormalities. Acute myocardial infarction may have preceded the patient's trauma; treatment for an evolving infarct, such as thrombolytic therapy or urgent coronary angioplasty, must be individualized according to the patient's injuries. Air embolism from an injured bronchus emptying into an adjacent vein can accumulate in the left ventricle and coronary arteries, impeding diastolic filling and disrupting coronary perfusion. Treatment is placement of the patient in Trendelenburg position, resuscitative thoracotomy, pulmonary hilar clamping, and aspiration of air from the apex of the left ventricle and aortic root, with coronary massage to remove air bubbles. Patients with neurogenic shock from high spinal cord injury are typified by hypotension with relative bradycardia due to physiological disruption of sympathetic outflow, and are often recognized due to paralysis, decreased rectal tone or priapism; treatment consists of volume loading and a vasopressor infusion.

Persistent hypotension during diagnostic evaluation should be treated with type O or type-specific blood transfusion. A massive transfusion protocol should be activated with empiric 1:2

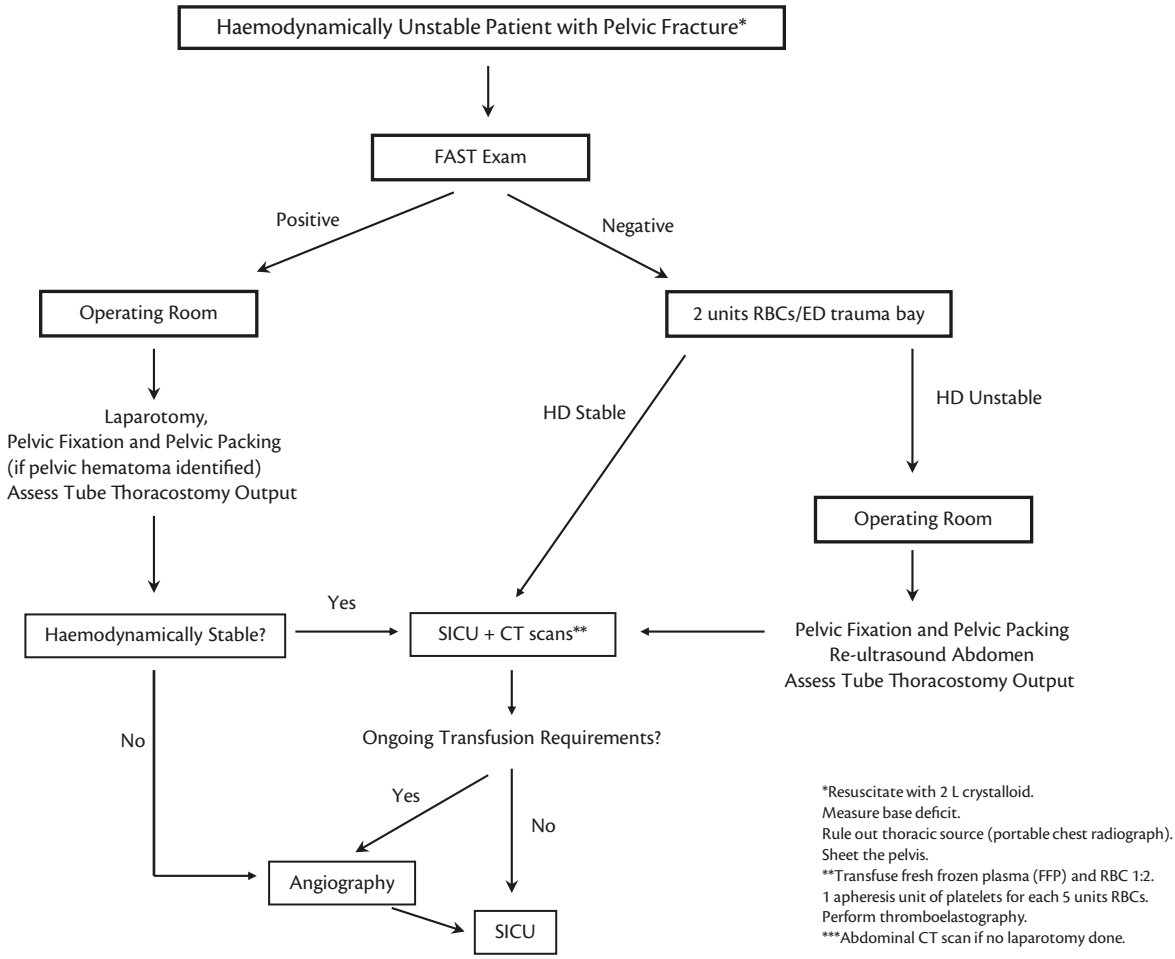

Fig. 332.3 Algorithm for the management of patients with a pelvic fracture and associated haemodynamic instability.

FFP:RBC ratio to address the acute coagulopathy of trauma. Thromboelastography (TEG) may assist in managing coagulopathy [6]. When accompanied by hypotension, the following are indications for urgent surgery:

- Penetrating chest trauma with greater than 1L chest tube output.
- Blunt chest trauma with greater than 1.5L chest tube output.
- Distended abdomen with peritoneal signs.
- Penetrating wounds entering the abdomen.

In patients without clear operative indications and persistent hypotension, one should systematically reassess the five potential sources of blood loss—scalp, chest, abdomen, pelvis, and extremities. Thoracoabdominal trauma should be evaluated with a combination of chest radiograph, FAST, and pelvic radiograph. If the FAST is negative and no other source of acute blood loss is obvious, diagnostic peritoneal aspirate (DPA) should be considered [7]. Fracture-related blood loss may be a major source of the patient's haemodynamic instability. For each rib fracture there is approximately 200 mL of blood loss, for tibial fractures 400 mL, femur fractures 800 mL, and pelvic fractures greater than 1000 mL. Although diagnostic imaging is important, transporting a hypotensive patient for CT or MRI scanning is hazardous, and should be delayed until the patient is stabilized.

Secondary survey

Once the immediate threats to life have been addressed, a thorough history is obtained and the patient is examined from head to toe in a systematic fashion. All seriously-injured patients should undergo digital rectal examination to evaluate for sphincter tone, presence of blood, and rectal perforation. Women with pelvic fractures should undergo vaginal examination to exclude an open fracture. Adjuncts to the physical exam include electrocardiogram (ECG) monitoring, nasogastric tube placement, in-dwelling urinary catheter placement, comprehensive ultrasound evaluation, laboratory measurements, and plain radiographs. A nasogastric tube (NGT) should be inserted in all intubated patients to decrease the risk of aspiration pneumonitis; the tube should be placed orally in patients with facial or base of skull fractures. NGT evaluation of stomach contents for blood may reveal occult gastroduodenal injury or the course of the NGT on chest film may indicate a diaphragm injury. Gross haematuria demands evaluation of the genitourinary system. In-dwelling urinary catheter placement should be deferred until urological evaluation in patients with signs of urethral injury; e.g. blood at the meatus, perineal, or scrotal haematomas, or a high-riding prostate.

Screening radiographs for patients with blunt trauma include chest and pelvic radiographs. Patients with gunshot wounds to the chest or abdomen, should have a chest and abdominal film, with

radiopaque markers at the wound sites, to determine trajectory of the bullet or location of retained fragments. Extremity radiographs are performed as indicated. In critically-injured patients cross-matching for transfusion, a full blood count (FBC), biochemistry, coagulation studies, lactate, and arterial blood gas (ABG) should be sent to the laboratory. Less severely-injured patients may only require an FBC and urinalysis, although the threshold for investigation should be lower in elderly patients.

Diagnostic evaluation

Depending upon mechanism, further diagnostic studies may be warranted during the initial evaluation. All patients with a significant closed-head injury (GCS <14) should have a CT scan of the head. For penetrating injuries, plain skull films may be helpful to determine the depth of injury. Patients at risk for carotid or vertebral artery injury (Fig. 332.4) should undergo multislice CT angiography because the injury may initially be asymptomatic. Similarly, a diligent evaluation for occult cervical spine injuries is mandatory to avoid the risk of subsequent spinal cord injury. In awake patients, the presence of posterior midline pain or tenderness should provoke a thorough radiological evaluation with CT scan in addition to a presumptive cervical collar. Additionally, intubated patients, patients with high energy mechanisms, distracting injuries, or another identified spine fracture should undergo imaging.

Penetrating injuries of the anterior neck that violate the platysma are potentially life-threatening because of the density of critical structures in this region. Management is structured according to level of injury (I, II, III); a selective non-operative approach is practiced in most centres [8,9]. Indications for immediate operative intervention for penetrating cervical injury include hard signs of injury, e.g. haemodynamic instability, active arterial haemorrhage, or airway distress. Most thoracic injuries can be evaluated by physical examination and chest radiograph, with a supplemental CT scan based upon initial findings and injury mechanism. Any patient that undergoes intervention—intubation, central line placement, tube thoracostomy—needs a repeat chest radiograph to document adequacy or complications of the procedure. Patients with a persistent pneumothorax or a large air leak following tube thoracostomy should undergo fibre-optic bronchoscopy to exclude a bronchial injury. Patients with haemothorax must have a chest radiograph documenting complete evacuation of the chest; a persistent haemothorax that is not drained by two chest tubes is termed a caked haemothorax and requires prompt thoracotomy.

Patients with a suspected thoracic aortic tear, suggested by widening of the mediastinum on initial AP chest radiograph, should undergo multislice CTA scan [10]. However, 7% of patients with an aortic injury will have a normal chest radiograph [11]. Thus, CT scanning is also performed based on the mechanism of injury—high-energy deceleration motor vehicle collision (MVC)

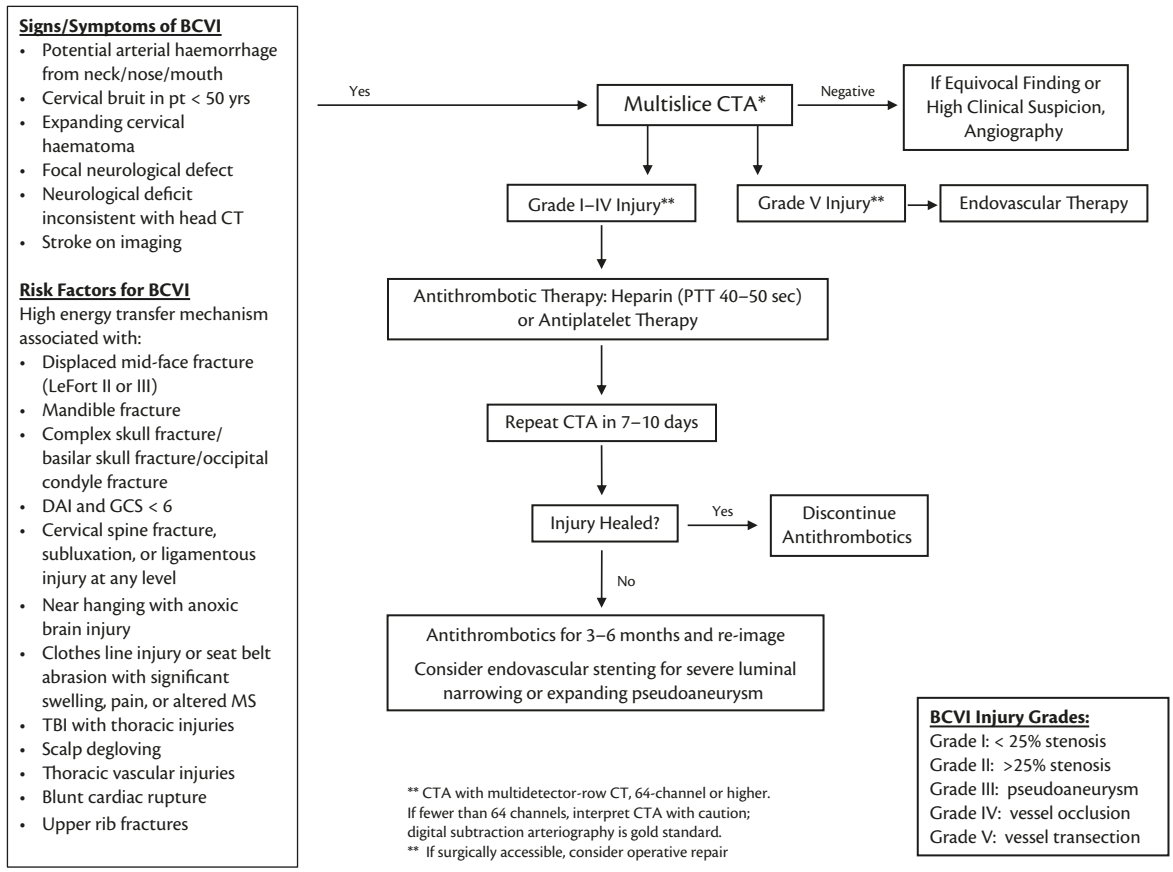

Fig. 332.4 Algorithm for blunt cerebrovascular injury screening and treatment.

BCVI Injury Grades: Reproduced from Biffl WL et al., 'Blunt carotid arterial injuries: implications of a new grading scale', *The Journal of Trauma and Acute Care Surgery*, **47**(5), pp. 845–53, copyright 1999, with permission from Wolters Kluwer.

with frontal or lateral impact, MVC with ejection, falls greater than 25 feet (7.5 m), or direct impact (horse kick to chest, collision with tree) [10]. For penetrating thoracic trauma, physical examination, plain PA, and lateral chest radiographs with metallic markings of wounds, pericardial ultrasound, and central venous pressure measurement will identify the majority of injuries. Haemodynamically-stable patients with transmediastinal gunshot wounds should undergo CT scanning to determine the path of the bullet; this identifies the vascular or visceral structures at risk for injury, and directs angiography or endoscopy as appropriate. If there is a suspicion of a subclavian artery injury, CT angiography should be performed.

Patients with anterior truncal gunshot wounds between the fourth intercostal space and the pubic symphysis, whose trajectory by radiograph or entrance/exit wound indicates peritoneal penetration should undergo operative exploration; over 90% of patients have significant internal injuries. Anterior abdominal stab wounds should be explored under local anaesthesia in the ED to determine if the fascia has been violated. If the tract does not violate the peritoneal cavity, the patient may be discharged from the ED. The optimal diagnostic approach for patients with fascial penetration, however, remains unclear. Options include serial examination, diagnostic peritoneal lavage (DPL), and CT scanning [12]. The most recent evidence supports serial examination and laboratory evaluation [13]. In haemodynamically-stable patients with penetrating trauma isolated to the right upper quadrant with trajectory confined to the liver by CT scan, non-operative observation may be considered [14–16]. Patients with penetrating trauma to the flank and back should undergo triple-contrast CT to detect retroperitoneal injuries of the colon, duodenum, and urinary tract [17]. Injury to the diaphragm should be evaluated in patients with stab wounds to the lower chest—diagnostic laparoscopy is the most accurate method to evaluate the diaphragm and allows for suture repair.

Patients with a 'positive FAST', following blunt abdominal trauma who do not have immediate indications for laparotomy, should undergo CT scan to identify and quantify their injuries [7]. The AAST injury grading scale (Table 332.1) is a useful guideline for non-operative management of solid organ injuries. Additional findings that should be noted on CT scan solid organ injury patients include contrast extravasation (i.e. a 'blush'), the amount of intra-abdominal haemorrhage, and presence of pseudo-aneurysms [18]. CT is also indicated for haemodynamically-stable patients who have an unreliable physical examination. Despite the increasing diagnostic accuracy of multislice CT scanners, CT still has limited accuracy for identification of intestinal injuries. Bowel injury is suggested by findings of thickened bowel, 'streaking' in the mesentery, free fluid without associated solid organ injury, or free intraperitoneal air [19]. Patients with free intra-abdominal fluid without solid organ injury need close monitoring for evolving signs of peritonitis; if patients have a significant TBI or cannot be examined serially, DPL should be performed to exclude bowel injury.

Plain radiographs permit early recognition of pelvic fractures, but ultimately CT scans determine the precise geometry. If the urinalysis contains RBCs, a CT cystogram is performed to rule out bladder rupture. On rare occasions, the iliofemoral arteries may be injured, and CT angiography is the preferred diagnostic tool. Hard signs of vascular injury (pulsatile haemorrhage, absent distal pulses, acute ischaemia) constitute indications for operative exploration. Extremity compartment syndromes should be suspected in patients with pain on active or passive motion of the muscles in the involved compartment. Paraesthesias with progression to paralysis can occur, but loss of pulses is a late sign. Compartment pressures can be measured with a hand-held Stryker device; fasciotomy is indicated in patients with a gradient <35 (gradient = diastolic pressure—compartment pressure).

Table 332.1 AAST Grading Scales for solid organ injuries

Liver injury grade	Subcapsular haematoma	Laceration
Grade I	<10% surface area	<1 cm in depth
Grade II	10–50% surface area	1–3 cm
Grade III	>50% or >10 cm	>3 cm
Grade IV	25–75% of a hepatic lobe	
Grade V	>75% of a hepatic lobe	
Grade VI	Hepatic avulsion	
Splenic injury grade		
Grade I	<10% surface area	<1 cm in depth
Grade II	10–50% surface area	1–3 cm
Grade III	>50% or >10 cm	>3 cm
Grade IV	>25% devascularization	Hilum
Grade V	Shattered spleen	
	Complete devascularization

CHAPTER 333

Pathophysiology and management of thoracic injury

Graciela Bauzá and Ayodeji Nubi

Key points

- A high proportion of polytrauma victims suffer thoracic injury, which is associated with mortality of with 25–50%.
- Initial management is guided by ATLS principles of **a**irway, **b**reathing, and **c**irculation.
- The focused assessment with sonography for trauma (FAST) exam plays a key role in the initial evaluation of thoracic trauma.
- Tube thoracostomy is often required for pneumothorax or haemothorax; generally, this is the only intervention required for thoracic trauma. Only 10–15% of thoracic injuries require operative intervention.
- Severe blunt chest trauma is often associated with other significant injuries.

Introduction

Thoracic trauma accounts for 25–50% of trauma-related deaths [1], as well as causing significant morbidity. Thoracic injury, blunt, or penetrating, involves injury to thoracic soft tissue and bony structures, in addition to injury of the lung parenchyma, tracheobronchial apparatus, heart, and great vessels or mediastinal structures. Death at the scene of injury occurs due to exsanguination from cardiac or great vessel disruption. Patients who die within hours of thoracic trauma usually have hypoxia from airway injury, tension pneumothorax, or haemorrhage. Late deaths result from sepsis, pulmonary complications, or missed injury.

Thoracic trauma is often associated with other significant body cavity injury (abdomen, pelvis, central nervous system). The majority of thoracic injuries do not require surgery, with only 10–15% requiring operative intervention [2].

Initial assessment

The initial evaluation of the patient with thoracic trauma follows the principles for any multiply-injured patient. Immediate priority is given to performing a rapid primary survey following standard advanced trauma life support (ATLS) protocols. Immediately life-threatening thoracic injuries include airway obstruction, tension pneumothorax, massive haemothorax, open pneumothorax, flail chest, and cardiac tamponade. (Table 333.1)

Following completion of the primary survey and stabilization of the patient, a detailed secondary survey is undertaken to identify other injuries. This involves a thorough physical examination and the use of diagnostic adjuncts. Thoracic injuries that should be sought include open wounds, rib fractures, flail segments, closed pneumothorax or haemothorax, and chest wall contusions. A plain chest X-ray (CXR) should be obtained to evaluate for rib fractures, pulmonary contusion, pneumothorax, haemothorax, and mediastinal or diaphragmatic abnormalities. The use of focused assessment with sonography for trauma (FAST) for the evaluation of haemopericardium has a sensitivity and specificity exceeding 96% [3]. Extended FAST (eFAST) exam for the diagnosis of pulmonary contusions and pneumothorax has also been reported [3]. Echocardiography and CT angiography are also useful. The latter should be performed in the stable patient, as a considerable number of patients will be found to have significant thoracic injuries on CT despite a normal CXR [4].

Table 333.1 Life-threatening thoracic injuries

Immediate	Potential
Airway obstruction	Traumatic aortic rupture
Tension pneumothorax	Major tracheobronchial injury
Cardiac tamponade	Blunt cardiac injury
Open pneumothorax	Diaphragmatic injury
Massive haemothorax	Oesophageal injury
Flail chest	Pulmonary contusion, rib fractures
Commotio cordis	

The use of other more invasive, but necessary interventions, such as **resuscitative thoracotomy** deserves brief mention. Its use should be highly selective for established indications, such as relief of cardiac tamponade, for open cardiac massage, hilar control of lung haemorrhage or descending aortic cross-clamping for control of distal bleeding. Survival rates following resuscitative thoracotomy for blunt trauma is approximate 1% [5,6] and, following penetrating injury, 15–60% (Table 333.2) [7,8].

Specific injuries

Chest wall

Rib fractures

These are common following blunt chest trauma, less common following penetrating injury. As many as 50% will not be apparent on CXR. They contribute significant morbidity and mortality

Table 333.2 Operative indications for thoracic injury

Injury	Intervention
Airway obstruction or major tracheobronchial disruption	ETT-endotracheal tube, surgical airway, thoracotomy for repair of tracheobronchial injury
Haemorrhage*	Thoracotomy for initial chest tube output of >1500 mL of blood or >250 mL/hour for 3–4 consecutive hours, or large retained haemothorax despite chest tubes
Cardiac or great vessel injury	Thoracotomy, sternotomy for repair of cardiac injuries, or endovascular repair of aortic injuries as indicated
Oesophageal perforation	Thoracotomy for repair of oesophageal injury

*Patient haemodynamics is primary indication.

in all patients, particularly in patients older than 65 years of age, where mortality is twice that of their younger counterparts; the incidence of pneumonia is also higher [6,9]. The pathophysiology of this stems from poor pulmonary toileting, secondary to severe pain and splinting with inadequate cough response. Rib fractures uncommonly require surgical treatment. Prompt analgesia from oral or parenteral non- steroidal anti-inflammatory medications (NSAIDs), paravertebral nerve blocks, epidural analgesia, or opioid-based patient-controlled analgesia (PCA) is generally effective.

Sternal fractures

The sternum is comprised of the manubrium and the sternum, articulating at the manubriosternal joint—this is the most frequent site of fracture. Management of the injury is guided by findings on initial imaging, such as CXR, electrocardiogram (ECG), and chest computed tomography (CT). When the fracture fragments are significantly displaced (>1–1.5 cm) manual reduction is often needed both for pain control and to avoid long-term malunion; rarely, operative fixation is required. Expectant management with healing is the natural history of this injury. Sternal precautions with regard to upper extremity use and weight bearing are observed for weeks until fracture is considered stable.

Flail chest

Flail chest is the paradoxical movement of a section of the chest wall resulting from the presence of two or more rib fractures in multiple places, usually associated with pulmonary contusion, pneumothorax, haemothorax, or tracheobronchial injury. Disruption of chest wall continuity leads to alteration of chest wall mechanics, resulting in inadequate tidal volume. Pain from fractured ribs plays a substantial role in inadequate chest expansion, decreased tidal volume, and producing inadequate coughing. Associated lung contusions and collapse result in pulmonary shunting and hypoxaemia. Patients with flail chest should be admitted to the intensive care unit (ICU) for close monitoring and pulmonary care. Incentive spirometry with close attention to pain control and gas exchange is crucial. Patients with mild flail can be managed conservatively with frequent reassessment for worsening of function. More severe cases may need tracheal intubation with mechanical ventilation. Analgesia is paramount. Options include epidural or paravertebral analgesia, or PCA.

Diaphragm

Blunt diaphragmatic rupture

This occurs after upper abdominal trauma results in increased intra-abdominal pressure causing a tear in the diaphragm. These injuries are often missed initially. Clinical signs are non-specific. Initial CXR may reveal a gastric bubble or nasogastric tube (NGT) within the left chest in cases of a large rupture. Delayed diagnosis is common as abdominal organs progressively herniate through the diaphragmatic defect.

Penetrating diaphragmatic lacerations

This should be suspected in all penetrating thoraco-abdominal trauma. Left thoraco-abdominal or flank wounds, below the nipple line, mandate exploration of the diaphragm via laparoscopic, thoracoscopic, or open approach. Right-sided diaphragmatic injuries are not always repaired because the liver may prevent the herniation of abdominal contents into the chest.

Lung

Pneumothorax

Pneumothorax results from injury to the lung or tracheobronchial tree. Diagnosis is usually by CXR. When large enough, it is suspected when auscultation of the chest reveals decreased breath sounds on the affected side. Tube thoracostomy is the treatment of choice (Fig. 333.1), which has the following stages:

- **Identify proper indication for chest tube**: wear protective devices.
- **Identify landmarks** (as seen in Fig. 333.1): 4th and 5th intercostal space anterior to mid-axillary line or the cross between axillary tail and infra-mammary fold; stay anterior to latissimus dorsi muscle
- Prepare and drape widely exposing axilla and ipsilateral nipple.
- Use local anaesthetic for non-emergent cases to anaesthetize skin, subcutaneous tissues, periosteum, and pleura.
- Make transverse incision, ~2 cm or as needed, just inferior to desired intercostal space. Carry incision down through subcutaneous tissues. If time allows, anaesthetize periosteum and pleura at this time.
- Use a large, curved Kelly clamp to puncture pleura above the rib to avoid neurovascular bundle, which rides along the inferior border of the rib. Keep control of your clamp to avoid lung injury, spread widely.
- Place index finger into thoracic cavity and sweep circumferentially to ensure no lung adhesions to chest wall. If adhesions are present, sweep gently; if unable to create space, abort procedure.

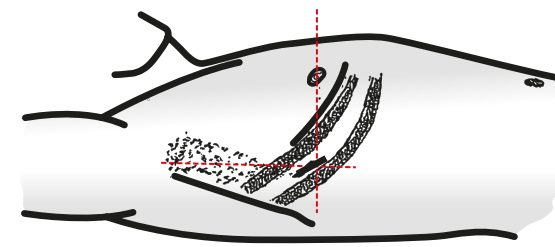

Fig. 333.1 Tube thoracostomy placement.

- **Place large bore chest tube (32 French) using clamp or finger**: guide chest tube posteriorly and apically. Stop when resistance is met. Ensure all chest tube holes are within the pleural space. (Clamp distal tube to avoid spillage prior to insertion.)
- **Confirm proper placement** by feeling tube inside thoracic cage with finger.
- **Connect tube to under water seal apparatus to 20 cm of water suction**: secure connection with tape or plastic tie.
- Secure chest tube to chest wall with heavy nylon, prolene, or silk suture.
- Obtain chest X-ray to confirm placement, resolution of pneumothorax, and evacuation of haemothorax.

Occult pneumothoraces (small pneumothorax seen on CT, but not CXR) may be observed with serial CXR regardless of the need for positive pressure ventilation [7,8,10]. Tension pneumothorax is not uncommon following trauma. Diagnosis should be clinical, not radiological; signs include absent breath sounds on the affected side, distended neck veins, hypotension, or tracheal deviation to the opposite side. Treatment is immediate needle decompression in the anterior second mid-clavicular interspace on the side with decreased breath sounds followed by chest tube insertion. Persistent air leaks from pneumothoraces should be investigated by video-assisted thoracoscopic surgery (VATS) [11,12,13,14].

Haemothorax

Haemothorax is the presence of blood in the pleural cavity, in isolation or in conjunction with a pneumothorax. When large enough, it produces similar symptoms and signs as a tension pneumothorax. Management involves the treatment of hypovolaemia and large bore tube thoracostomy (see Fig. 333.1), with the objective of complete evacuation. Initial output and ongoing drainage are carefully monitored and the need for thoracotomy (as previously discussed) is based on this. When blood is incompletely evacuated or presentation is late (>48 hours), it is defined as a retained haemothorax. For such patients, evacuation of haemothorax with early VATS, usually within 5 days of injury, is indicated to avoid infection, fibrothorax, and later need for thoracotomy. Fibrinolytic therapy for retained haemothorax may be used in patients where surgery carries high-risk.

Pleural empyema

Pleural empyema may occur due to trauma. Consequences include an adherent lung with poor mobility and compliance with or without a loculated seropurulent effusion. Causative factors include retained haemothorax or pneumonia with parapneumonic effusion. Presentation is usually that of sepsis, failure to thrive, or worsening respiratory failure. Diagnosis is best with CT. Temporizing management includes empiric antibiotics and image guided tube thoracostomy placement for drainage of collections. Decortication by open surgery or VATS is generally required [15].

Lung contusion/laceration

This is parenchymal bruising from either blunt or penetrating trauma and is the *sine qua non* of blast injury. The diagnosis is usually underappreciated on plain films and clearly delineated on CT, particularly as time progresses and following fluid resuscitation. The risk of developing ARDS (acute respiratory distress syndrome) [11], development of pneumonia are directly related to contusion size. Treatment depends on patient presentation and contusion size.

Tracheobronchial injury

The majority of blunt tracheobronchial injuries (>80%) occur within 2.5 cm of the carina [14,16,17]. Presentation depends on severity, mechanism, and location of the injury. Cervical tracheal injury is usually associated with injuries to adjacent structures—the oesophagus, vascular structures, or nerves. Symptoms include pain, swelling, stridor, subcutaneous emphysema, haemoptysis, or bleeding. When the injury is located within the thoracic cavity, the spectrum of presentation includes dyspnoea and tachypnoea, simple or tension pneumothorax, or a large air leak via chest tube with significant loss of tidal volume affecting oxygenation/ventilation. Other findings include pneumomediastinum, haemothorax, and bronchopleural fistula.

When the patient presents in respiratory distress, secure the airway by endotracheal intubation. This is optimally achieved by fibre optic bronchoscopic guidance. This method allows direct visualization of the airway, and identification of the site and extent of airway injury, avoidance of use of paralytics/sedatives in a patient with a potentially compromised airway, placement of the ETT distal to the injury, avoiding neck extension in a patient with possible cervical spine injuries. When patient presentation is more extreme, emergent cricothyroidotomy or tracheostomy may be required. Pneumothorax, if present is managed in standard fashion. When these persist or have a continuous air leak, a tracheobronchial injury with a bronchopleural fistula should be suspected.

Small disruptions of the trachea, main bronchi, and large bronchioles (<1/3rd of the circumference) can be managed conservatively. These may present late (weeks) post-injury as a persistent pneumonia secondary to scarring of the airway at the site of injury. Bronchopleural fistulas may be managed with advanced ventilator treatments such as high frequency oscillation ventilation. Prompt operative repair is usually needed for major airway disruption.

Mediastinum

Heart

Injury to the heart should be suspected with severe chest trauma marked by chest bruising, rib or sternal fractures, steering wheel deformity, or penetrating wounds in the cardiac box-from clavicles to costal margin and medial to the nipples.

Pericardial tamponade

75–100 mL of blood can produce pericardial tamponade in the acute setting, this occurs most commonly after penetrating trauma. Most patients with significant cardiac lacerations die before reaching the hospital. Those who arrive at the emergency room with cardiac tamponade often present in shock without evidence of significant blood loss or cardiac arrest after penetrating chest trauma. The signs of Beck's triad (i.e. jugular venous distention, hypotension, and muffled heart sounds) occur in only a third of patients. FAST is used to assess for fluid in the pericardial sac in both penetrating and blunt trauma [2,3]. Haemodynamically-stable patients with injury to the cardiac box or transmediastinal injury with high index of suspicion for cardiac laceration require evaluation with FAST to rule out pericardial fluid. A negative or equivocal FAST in this scenario may be confirmed by formal transthoracic echocardiography (TTE). Caution must be taken when a negative FAST exam exists

in combination with a haemothorax, as the pericardium may empty into the chest masking a cardiac injury. Finding pericardial fluid on FAST examination in a stable patient is usually treated with an operative subxiphoid pericardial window and sternotomy if blood is found in the pericardial sac. In patients in extremis, diagnosis is confirmed at emergency department thoracotomy. In the setting of trauma, needle pericardiocentesis is rarely used as an emergency manoeuvre for temporary relief of tamponade.

Blunt cardiac injury

Blunt cardiac injury after chest trauma can range from asymptomatic myocardial contusion to (rarely) acute heart failure. The right ventricle is most often affected. There is little consensus on diagnostic criteria and evaluation. Most commonly, cardiac injury presents as a dysrhythmia ranging from sinus tachycardia, premature atrial contractions, atrial fibrillation, to premature ventricular contractions. Initial assessment starts with an ECG. Patients who present as haemodynamically stable and in sinus rhythm rarely have acute complications from blunt cardiac injuries. These patients do not require further testing. Patients with known cardiac disease may be monitored for 24 hours, but risk remains low. ECG findings include arrhythmia, heart block, or ST changes. Recent evidence does not support troponin I levels as a screening tool. TTE is recommended in patients with unexplained haemodynamic instability to evaluate myocardial contractility. Invasive cardiac monitoring should be reserved for patients in whom blunt cardiac injury is suspected, those aged more than 60, haemodynamically unstable, polytrauma, have an abnormal ECG, and are undergoing a surgical procedure [18].

Commotio cordis

Commotio cordis is sudden death after a blunt chest trauma, often the result of a direct blow to the chest resulting in dysrhythmia without a structural abnormality. Management should follow guidelines for the management of cardiac arrest [19].

Great vessels

Blunt aortic injury

Blunt aortic injury results from rapid acceleration or deceleration mechanism such as motor vehicle crash or fall from a height. It is fatal in over 80% of cases. The injury itself consists of a tear in the wall of the aorta that is contained by the adventitia of the artery and the parietal pleura, most commonly at the ligamentum arteriosum, but can occur at any fixed point of the aorta. Prompt diagnosis and treatment based on high index of suspicion is paramount. Diagnosis is confirmed by spiral CT angiogram of the chest or conventional angiography. Although most patients do not have specific clinical signs, key symptoms include asymmetry in upper extremity blood pressure, wide pulse pressure, and chest or back pain. Initial CXR may reveal a widened mediastinum (>8 cm), tracheal deviation, an apical pleural cap, or left haemothorax. Transoesophageal echocardiography can make the diagnosis in patients who require immediate transport to the operating room for management of other injuries or for haemodynamically-unstable patients in the ICU who cannot be transported to CT (sensitivity 63%; specificity 84%). Although most aortic injuries are treated surgically, non-operative management is reserved for select patients in whom only intimal injury is identified. Management in those cases is similar to that of atraumatic type B aortic dissections. β-blockade and control of blood pressure to a goal systolic blood pressure of 100 mmHg may decrease risk of rupture, but should only be instituted after acute haemorrhage is controlled. Surgical repair techniques consist of endovascular aortic stent grafts; open repair is reserved for specific injuries where stenting is not a suitable option due to the location of injury or aortic size. Endovascular repair of blunt aortic injury has led to a significant decrease in overall mortality and procedure-related paraplegia.

Penetrating aortic and great vessel injury

Penetrating aortic and great vessel injury carries a high prehospital mortality rate. Those patients who present to hospital are generally *in extremis*, with pericardial tamponade or massive haemothorax, and require immediate surgical exploration.

Oesophagus

Injury to this posterior mediastinal structure is uncommon and usually occurs from penetrating trauma. Other mechanisms such as Boerhaave's injury (rupture of the oesophagus secondary to vomiting) or caustic injury affects the thoracic portion or parts of the oesophagus that are narrowed. Patients present with pain, fever, dyspnoea, or crepitus with subcutaneous emphysema. Diagnosis is often made intra-operatively at the time of thoracotomy or laparotomy for penetrating injury. Chest X-ray or CT scan may reveal mediastinal air or pleural effusion mandating further evaluation of the oesophagus and tracheobronchial tree. Combined careful upper endoscopy and oesophagography, first with gastrografin, then followed by a modified barium swallow, are adequate for evaluation of injury. Surgical management is the mainstay of therapy. Broad spectrum antibiotics, fluid resuscitation, and nutrition are essential supportive therapy.

Thoracic duct

Injury to the thoracic duct is uncommon from blunt or penetrating trauma; it is more commonly seen from iatrogenic trauma. Finding a cloudy/milky pleural effusion, which is rich in chylomicrons and triglycerides, confirms the diagnosis. The consequence is often malnutrition and immunological derangements. Treatment is initially conservative with diets high in medium chain triglycerides and an almost absolute reduction in the long and short chain versions. The use of total parenteral nutrition and octreotide may help. Surgical ligation of the thoracic duct is a last resort.

CHAPTER 334

Pathophysiology and management of abdominal injury

Steven B. Johnson

Key points

- Haemorrhage and sepsis are the main concerns following blunt and penetrating abdominal trauma, typically occurring early (<12 hours) and late (>5 days), respectively, following injury.
- Solid organ injuries are frequently managed non-operatively. Delayed haemorrhage may occur and angiographic embolization may be beneficial.
- Major hepatic injuries requiring operative intervention frequently require damage control surgery and haemostatic resuscitation.
- Damage control surgery requires close integration of operative and critical care management to aggressively correct physiological derangement characterized by metabolic acidosis, coagulopathy, and hypothermia.
- Abdominal compartment syndrome should be considered in patients manifesting remote organ dysfunction. Bladder pressure monitoring should be considered in patients following abdominal trauma especially in patients requiring large-volume fluid resuscitation.

Abdominal injury: pathophysiology and management

Abdominal organs are injured in approximately 25% of trauma patients. Susceptible to both penetrating and blunt trauma, these injuries present a spectrum from benign to the immediately life-threatening. Haemorrhage and sepsis are the main considerations following acute abdominal trauma, typically occurring early (<12 hours) and late (>5 days), respectively, after injury. Together with the thoracic cavity, retroperitoneum and pelvis, proximal lower extremities, and externally, the abdominal cavity is one of the five locations that can harbour sufficient acute blood loss following trauma to result in hypotension. Sepsis can result from missed or delayed diagnosis of bowel injury, ischaemic bowel injury, bowel perforation or anastomotic leak, abdominal abscess, or infected necrotic tissue.

The optimal critical care management of patients with abdominal trauma is dependent on the early and accurate identification and management of injuries, aggressive resuscitation and correction of physiological derangements, and early recognition and management of complications. Advances in damage control surgery, derived initially for management of abdominal injuries, but recently extended to other types of injuries, necessitates close alignment of operative and intensive care efforts to achieve optimal results.

Solid organ injury

Trauma to the solid organs of the abdomen include injuries to the spleen, liver, pancreas, and kidneys. Management of these injuries in major trauma centres is now more often non-operative, with or without angiographic embolization [1,2]. Non-operative management will be unsuccessful and necessitate operative intervention to control haemorrhage in 8% of hepatic and 7–19% of splenic injuries. The decision to perform non-operative management requires appropriate patient selection (Box 334.1), determination whether embolization would be beneficial, and close monitoring for haemorrhage. An abdominal and pelvic CT scan with intravenous contrast is essential in non-operative management, allowing the assessment of the extent of injury, presence of active contrast extravasation or pseudoaneurysms, extent of haemoperitoneum, and presence of associated injuries that may themselves require operative intervention. Embolization is helpful if active contrast extravasation or pseudoaneurysms are identified on abdominal CT scan [3]. Patients with significant solid organ injury, especially American Association for the Surgery of Trauma grade III–V hepatic injuries, may benefit from embolization. There is little role for embolization in injuries to the pancreas or for renal injuries with urinary contrast extravasation. Similarly, non-operative management of splenic injuries should be avoided in patients with significant portal hypertension or splenic pathology due to the increased risk of delayed haemorrhage.

Following the initial decision to perform operative or non-operative management of a solid organ injury, unique aspects are encountered for each organ. For splenic injuries, the predominant concern is delayed haemorrhage. The risk of delayed haemorrhage following non-operative management is related to the extent of injury, and presence of extravasation or pseudoaneurysms on CT scan. Prolonged bed rest, although commonly employed, does not alter the risk of delayed haemorrhage and patients can be ambulated on post-injury day 1 if other injuries do not preclude ambulation. Routine repeat CT scan to evaluate a splenic injury is not necessary and only indicated for evaluation of an unexplained decrease in haematocrit or increasing leukocytosis.

Box 334.1 Indications for non-operative management of solid organ injury

- **Haemodynamic stability**:
  - Absence of hypotension.
  - One episode of hypotension responsive to less than 2 L of fluid.
- **Minimal transfusions**: two or fewer units of packed red blood cells in first 12 hours.
- **Absence of other indications for laparotomy**:
  - Peritonitis.
  - Other organ injury requiring laparotomy.
- Non-operative management experience of personnel.
- Ability to perform close acute monitoring.
- Ability to provide close post-discharge follow-up.

Typical post-splenectomy related vaccinations are not necessary for patients managed non-operatively. The performance of partial splenic resections has become rare due to the increased use of embolization. Post-operative management of partial splenic resection patients is similar to non-operative management.

The critical care management of hepatic injuries is more complex [4]. For blunt hepatic trauma, the decision to perform operative intervention is based on significant haemodynamic instability and shock. This is typically associated with large blood loss and damage control surgery with perihepatic packing is frequently employed. The management frequently requires implementation of intensive care unit (ICU) damage control principles described later. The aggressive correction of the metabolic acidosis, coagulopathy, and hypothermia, while monitoring for ongoing blood loss are essential. These patients will require additional procedures to manage their injuries and expeditious physiological optimization is the goal. If they have not already undergone embolization prior to surgery, then consideration should be given to performing embolization prior to subsequent procedures. Major hepatic resections may be required, although this is discouraged during the initial procedure, as it may reduce hepatic function especially when associated with a marked hypoperfusion insult or portal triad in-flow occlusion clamping. Due to the associated hypoperfusion, the severity of acute hepatic dysfunction is typically more severe than observed with a similar resection performed on an elective basis. On rare occasions, total hepatectomy may be required, in which case hepatic support with an extracorporeal hepatic assist device for management of the anhepatic condition will be required, while awaiting emergent liver transplantation. In such patients, consideration should be given to intracranial pressure monitoring due to the risk of severe hepatic encephalopathy.

Penetrating hepatic trauma is more likely to require operative intervention because of concern for associated injuries. When compared with blunt trauma, these patients are more likely to undergo operative intervention without having haemodynamic instability and blood loss may be significantly less. Often, only simple hepatorrhaphy or omental packing of the hepatic injury is required and in the absence of hypoperfusion related to associated injuries or portal triad clamping, such injuries may cause minimal hepatic compromise. Alternatively, major penetrating hepatic trauma, especially those associated with high energy projectiles, can result in profound damage. The operative and critical care management is similar to those described for major operative blunt hepatic injuries.

The majority of hepatic injuries managed non-operatively are the result of blunt trauma, and therefore associated injuries, outside of the abdomen are common and may require priority. Early after injury, whether managed with or without embolization, the main risk of non-operative management of hepatic injuries is delayed haemorrhage. Hepatic injuries may also result in significant bile leakage that can result in a marked systematic inflammatory response in the early post-injury period. This response may be difficult to differentiate from that seen with a missed bowel injury. Repeat abdominal and pelvic CT scanning with intravenous contrast is warranted to assess for pneumoperitoneum suggestive of a bowel injury. Hepatobiliary scintigraphy scan can be helpful in determining if a bile leak is present [5]. If a large amount of fluid is observed on repeat CT scan, then paracentesis may be considered with evaluation for bile and microbial culture. Alternatively, patients with blunt hepatic trauma and a persistent marked systemic inflammatory response, and a large haemoperitoneum may undergo laparoscopic evacuation and perihepatic drain placement, typically between post-injury days 5 and 14. Traumatic bilomas that are contained can be treated with percutaneous drainage, but patients with persistent or uncontained bile leaks should undergo endoscopic retrograde cholangiography with common bile duct stent placement or transhepatic cholangiocatheter placement to minimize the bile leak.

Among hepatic trauma patients undergoing embolization, there is a risk of hepatic necrosis. This risk is increased with non-selective hepatic artery embolization or prolonged hypoperfusion. Major hepatic necrosis can be asymptomatic or cause a significant systemic hyperinflammatory response. Abdominal CT scan with intravenous contrast provides valuable information about the extent of hepatic necrosis and proximity to major intrahepatic structures. The most significant complication of major hepatic necrosis is secondary infection, which is not prevented by prophylactic antibiotics. Operative intervention should be considered for symptomatic or infected hepatic necrosis.

Pancreatic injuries can result from blunt or penetrating trauma. Nearly all penetrating pancreatic injuries are diagnosed at laparotomy. Failure to fully evaluate the lesser sac may result in delayed diagnosis of penetrating pancreatic injuries with subsequent marked hyperinflammatory response. Morbidity and mortality of penetrating pancreatic injuries is predominantly related to associated vascular injuries and delays in diagnosis. Blunt pancreatic injuries are more difficult to diagnosis and abdominal CT scan has a sensitivity of only 68% for detecting injury. Missed or delayed diagnosis of blunt pancreatic injuries can result in significant morbidity and mortality and serum amylase and lipase levels should be evaluated following blunt trauma especially in the presence of an unexplained hyperinflammatory condition. Pancreatic injuries are typically managed with peripancreatic drains, which may drain large amounts of fluid rich in pancreatic enzymes. These drains are a cornerstone of pancreatic injury management and should be left in place when draining significant amounts. Patients with persistent drainage may benefit from endoscopic retrograde pancreatography and pancreatic duct stent placement [6].

Hollow viscus injuries

Hollow viscus injuries are more common following penetrating, rather than blunt trauma. They may not be obvious in the first 24 hours, resulting in a delay in diagnosis, and increased morbidity and mortality [7]. Therefore, any patient with a penetrating abdominal injury that does not undergo a complete operative (open or laparscopic) evaluation must be considered at risk for a hollow viscus injury. Unless associated with a mesenteric injury, isolated hollow viscus injuries rarely cause exsanguination. More commonly, they result in abdominal sepsis, either because of delayed or missed bowel perforating injuries or leaks at enteric re-anastomosis sites. Major mesenteric vascular injuries or injuries associated with terminal mesenteric vessels can result in bowel ischaemia without perforation. Delay in return of bowel function, intolerance of enteral nutrition, new onset peritonitis, unexplained leukocytosis, or fever are indications for further evaluation. Abdomen and pelvis CT scan with intravenous and oral contrast are recommended in the absence of obvious surgical indications [8]. The addition of rectal contrast may be valuable to detect colonic perforations.

Damage control

The concept of damage control surgery recognizes that the time and procedures required to perform definitive operative repair may be detrimental when physiological derangements are excessive [9]. These physiological derangements are frequently referred to as the 'vicious bloody cycle of trauma' [10]. The criteria for initiation of damage control are listed in Box 334.2. When these conditions develop, continued operative efforts are detrimental and should be discouraged. Damage control encompasses three phases, each with specific goals and objectives. The initial phase is identification and temporarization. This occurs during the index procedure when damage control criteria are identified or anticipated to develop. During this phase, the procedure is truncated to only control haemorrhage and enteric contamination. This may include performing bowel resections without re-anastomosis, placement of temporary arterial shunts, and packing of major organ injuries. During this phase, haemostatic resuscitation should be initiated with transfusion of equal units of packed red blood cells, fresh plasma, and platelets, also known as 1:1:1 resuscitation [11]. Frequently, such patients are managed with an open abdomen and temporary non-fascial abdominal closure. Planned reoperation for definitive repairs will be required but only after physiological improvements. By definition, severe physiological derangements are present when these patients arrive in the intensive care unit.

Box 334.2 Intra-operative damage control criteria

- pH < 7.20.
- Non-mechanical bleeding related to coagulopathy (INR > 1.8, APTT > 50 seconds).
- Hypothermia (T < 34°C).
- Massive transfusion >10 units of packed red blood cells.

Data from Shapiro MB, et al., 'Damage Control: Collective Review', *Journal of Trauma*, 2000, **49**, pp. 969–78.

The second phase begins on arrival to the intensive care unit where continued aggressive resuscitation to stabilize and correct the physiological derangements are the goal. The continuation of haemostatic resuscitation should occur until correction of the coagulopathy as identified by standard laboratory parameters of coagulation or by thromboelastography (TEG). Not infrequently, these patients have hypofibrinogenaemia and benefit from administration of cryoprecipitate. Active rewarming is often necessary including the use of blood and fluid warming devices to minimize the adverse effects of hypothermia. Shock and the associated metabolic acidosis should be corrected with fluid administration. The administration of sodium bicarbonate or other alkalinizing agents should not occur unless the pH is less than 7.15. Rapid correction of shock induced lactic acidosis, even in the presence of a normal blood pressure, is associated with improved outcomes [12,13]. The goal of this phase is to aggressively restore physiological homeostasis in a timely manner in preparation for the patient returning to the operating room in 24–48 hours for definitive surgery.

The final phase occurs when the patient returns to the operating room for definitive management of their abdominal injuries. During this phase, bowel continuity is re-established or enterostomies performed, arterial reconstructions are completed, and packs removed. The physiological condition of the patient should be significantly improved as a result of ICU care in the second phase. This allows more extensive surgery to be performed without further compromise. On occasion the extent of injuries may result in recurrence of damage control criteria in which case phase 1 and 2 management, and goals should be reinstituted.

Abdominal compartment syndrome

Patients undergoing a trauma laparotomy with closure of the skin or fascia are at risk of developing increased intra-abdominal pressure due to resuscitation related oedema formation [14]. This increased pressure can be significant and result in compromise of remote organ function which is referred to as abdominal compartment syndrome. The presence of abdominal hypertension alone is not abdominal compartment syndrome, there must be associated organ dysfunction, most commonly oliguria, elevated peak and plateau airway pressures, and decreased cardiac output associated with bi-ventricular hypovolemia despite increased preload pressures. Increased intracranial pressures may also occur related to increased abdominal pressure. Patients undergoing large volume (>6 L in 24 hours) fluid resuscitation are at risk to develop abdominal compartment syndrome. Measurement of bladder pressures through an indwelling urinary catheter can be used as a surrogate measurement of intra-abdominal pressures [15]. Bladder pressures over 20 mmHg are suggestive of intra-abdominal hypertension. The management is emergency decompressive laparotomy which may be required at the bedside in the ICU. Successful decompression should rapidly reverse the physiological compromise that resulted from the abdominal hypertension. Absence of improvement is due to insufficient decompression or alternative causes of organ dysfunction. Reductions in intracranial pressure have been observed following decompressive laparotomy.

Open abdomen

In most patients undergoing damage control surgery or decompressive laparotomy, the abdominal wall fascia is left open and

a temporary abdominal closure dressing is applied. This allows preservation of the fascia and minimizes abdominal pressures by providing free expansion of oedematous abdominal contents. The open abdomen technique may be required for a prolonged period, but most trauma surgeons prefer to achieve abdominal closure within the first 7 days. Active fluid removal without causing hypovolaemia, either by diuresis or ultrafiltration, is beneficial in achieving abdominal wall closure. If the abdomen is not closed early then increased morbidity is observed especially the formation of enterocutaneous fistula and prolonged hypermetabolism [16].

Tertiary survey

All patients with blunt abdominal trauma admitted to the intensive care unit should undergo a tertiary survey to detect or exclude occult injuries that were not identified initially. This should occur within 24–48 hours of admission and involves a head to toe examination, and review of all radiological and laboratory studies. By doing a comprehensive tertiary survey, missed injuries can be reduced by 36% [17].

CHAPTER 335

Management of vascular injuries

Ramyar Gilani and Kenneth L. Mattox

Key points

- Prioritizing injuries and controlling the resulting sequelae are the predominant guiding principles in managing vascular injuries; the highest priority is saving the patient's life.
- Control of haemorrhage is life-saving and usually rapid, vascular reconstruction is often neither; definitive repair may need to be delayed while the patient is stabilized.
- Vascular trauma is almost invariably associated with injuries to other organ systems and many patients with vascular trauma are critically ill with limited physiological reserve.
- Endovascular repair may allow safe and efficacious intervention with less overall impact on the patient than open surgery.
- Vascular trauma may have a profound effect on the coagulation system; transfusion using a 1:1:1 ratio of packed red blood cells, fresh frozen plasma, and platelets is currently considered the best strategy.

Introduction

Despite significant advances in modern trauma care, management of vascular injuries continues to present a unique set of challenges involving all phases of patient care. Prioritizing injuries and controlling the resulting sequelae are the predominant guiding principles; paramount priority is given to saving a patient's life. Vascular trauma is almost invariably associated with injuries to other organ systems and with marked physiological derangements, and as a result many patients with vascular trauma are critically ill and while control of haemorrhage is life saving and usually rapid, vascular reconstruction is often neither. Complex vascular reconstructions in critically-wounded patients are often not practical.

Categorization of injuries can be made based on resulting life-threatening haemorrhage or distal ischaemia. Success with both entities is time dependent and, as a result, all that is technically feasible is not often in the patient's best interest. Vascular repairs for trauma should always adhere to principles derived from experience through elective and emergent procedures with continued evaluation of patient physiological envelope. When appropriate, imaging via computed tomographic angiography (CTA) or digital subtraction angiography (DSA), assists in expeditious diagnosis of vascular injuries, which then must undergo appropriate prioritization taking into account the patients overall clinical condition and the urgency of treating other injuries.

Recent advances in technology have expanded the application of intraluminal vascular solutions to vascular injuries. Endovascular techniques allow safe and efficacious interventions to occur with decreased overall impact to patients [1,2]. Finally, much recent focus has been placed upon vascular trauma and its profound impact on coagulation. Insults to this delicate framework due to various forms of traumatic injury severely disrupt the dynamic homeostatic environment of the vascular and haematological systems resulting in severe physiological derangements.

General principles

Injury assessment

Patient presentation with vascular injury can be quite variable even with similar injury patterns and this mandates flexibility in treatment algorithms. However, patterns of injury remain relatively finite in number and pattern recognition can assist with the categorization of injury severity. Penetrating trauma results in simple laceration, partial wall disruption or complete vessel transection. In addition, cavitation from high-velocity missiles can result in further injury that is not appreciable at initial inspection. Injury from blunt trauma leads to intimal flap, partial wall disruption, avulsion of branches, or complete vessel transection. Resulting haemorrhage indicates disruption of vessel wall architecture, whereas distal ischaemia indicates loss of lumen integrity.

Severity of haemorrhage and ischaemia must be noted early and their impact continuously and repeatedly assessed. A patient who is nearly exsanguinated from a stab wound to the brachial artery and arrives in the hospital unresponsive with a barely palpable pulse and a pH of 6.9 is clearly not a candidate for any type of vascular exploration. A patient with gunshot injuries to the liver, duodenum, colon, inferior vena cava, and right renal artery, even though appearing stable after initial control of haemorrhage and blood replacement, has in fact sustained a major insult. After an hour of surgery, transfusion of 10 units of blood, and a resulting temperature of 32°C, any attempt at renal revascularization may be lethal to this patient.

Exposure and vessel control

Initial control of haemorrhage is usually performed by applying direct manual pressure over the site of bleeding. Alternatively, tourniquets can be used for life-threatening extremity haemorrhage that cannot be controlled with manual pressure. Tourniquets should be removed as soon as possible. Adjunctive haemorrhage control techniques include the use of balloon catheters into a bleeding cavity providing external compression and tamponade [3]. Attempts at blind clamping without proper visualization should be avoided as they are often ineffective and result in injury to adjacent structures.

Fig. 335.1 Proximal balloon control of the subclavian artery, while performing endovascular repair.

Surgical haemorrhage control begins with proper exposure often beginning outside the zone of injury. For example, haemorrhage from a carotid artery may begin with a sternotomy and an injured common femoral artery may be approached first through a laparotomy. Injuries of the extremity and neck are exposed via axial incisions beginning beyond the injury. Within the chest, proper selection of incision provides access away from injury. Vessels within the abdomen are exposed via mobilization manoeuvres beyond zones of haematoma.

Although very effective, traditional surgical techniques can be suboptimal in situations such as transition zones, re-operative fields or for patients in extremis. Newer paradigms emphasize the principles of expeditious vessel control, while overcoming such challenges by shifting focus from the immediate area of injury towards a more familiar environment and utilizing the structural continuity of vessels to obtain access into proximity location and ultimately establishing flow control. Angiographic balloon control can be achieved expeditiously and without much technical difficulty (Fig. 335.1) [4]. Using standard over-the-wire techniques, a balloon catheter is guided into proper position proximal to the site of extravasation and inflated (Box 335.1). Once control is established, repair can be pursued either through a continued endovascular approach or in combination with open surgery.

Damage control

'Damage control resuscitation' refers to a surgical strategy intended to guide the management of a multiply-injured patient requiring collective interventions that would be exhaustive to physiology if performed without pause. With this approach, the traditional single definitive operation for trauma is replaced by staged operations, whereby a rapid operation is followed by a delayed more complex reconstruction after the patient's physiology has been stabilized [5,6]. The underlying premise is that prolonged operation in the severely-injured patient is further harmful to already deranged physiology. Prolonged operations and massive blood replacement result in a triad of hypothermia, acidosis, and coagulopathy that can be self-propagating and fatal [7].

Box 335.1 Approximate vessel sizes for balloon selection

- **Innominate**: 10–14 mm.
- **Carotid/subclavian/axillary**: 8–12 mm.
- **Common iliac**: 8–10 mm.
- **External iliac**: 6–8 mm.
- **Aortic bifurcation**: bilateral common iliac balloons, Fogarty balloons or aortic occlusion balloon (32, 40 mm; 46 mm).
- **Aorta**: 32, 40 mm; 46 mm.

Therefore, it is vital to distinguish between simple and complex vascular repair techniques. Simple repairs are rapid and include simple lateral repair, ligation, and temporary shunt insertion. The last two can also be viewed as vascular 'damage control' techniques. Complex repairs are more time-consuming and include patch angioplasty, end-to end anastomosis, and graft interposition [8]. Although simple repairs are feasible even under adverse physiological circumstances, complex repairs may not be. However, the decision not to restore vessel continuity may force the surgeon to accept tissue loss in order to save the patient's life. These are some of the most difficult decisions in trauma vascular surgery.

Repair techniques

Thrombectomy

Disruption to the vessel wall or lumen integrity leads to alterations in flow and resulting thrombosis. As a result, prior to re-establishment of flow, surgical thrombectomy is a necessary adjunct to remove any potential luminal thrombus. Once control is established, balloon catheters appropriate in size are passed proximally and distally until no further thrombus is yielded and preferably flow is appreciated.

Lateral repair

Technical keys to accomplishing a direct lateral repair of an injured vessel include debridement of the damaged wall and tension-free suture repair of the vessel wall preferably in a transverse fashion to avoid stenosis of the vessel lumen. Most would consider a mural defect of more than half the vessel circumference to be the upper limit of damage amenable to direct repair; but, in fact, as long as some of the posterior wall is present and the transverse orientation of the repair can be maintained, it is possible to re-approximate even large defects without tension. Additional dissection along the axis of the vessel may provide additional length for tension-free repair. In larger vessels such as the inferior vena cava (IVC) or aorta, simple lateral repair with some luminal narrowing is acceptable.

Ligation

Ligation is a valid technical option when the injured vessel is inaccessible, reconstruction is difficult, or more commonly the patient is too unstable to allow for other approaches. Ligation is quite well tolerated for arteries of distribution, such as the external carotid or internal iliac arteries. For arteries of conduction, such as the external iliac or superficial femoral arteries, ligation is often not

plausible and other forms of 'damage-control', such as shunting should be considered. Many injured veins can be ligated with the only resulting consequence being distal oedema to varying degrees [9]. However, ligation of certain veins such as the portal vein, superior mesenteric vein, suprarenal IVC, right renal vein and popliteal veins carries increased risk of end-organ damage that is not well defined.

Temporary shunting

The use of temporary vascular shunts is a simple and expeditious 'damage-control' option that has been extensively described by civilian and military surgeons [10,11]. It should be considered as a distal organ-preserving manoeuvre when more complex repair is not possible, this may be due to the patient's general condition or to surgeon capability. A commercially available carotid shunt, endotracheal suction catheter, or a piece of sterile nasogastric tube trimmed to the appropriate length can be inserted into both ends of a disrupted vessel and cinched in place with ties or Rummel tourniquets (Fig. 335.2). It is helpful to secure the shunt beyond side branches to avoid migration of the cinching apparatus. Also, appropriate thrombectomy should be performed prior to re-establishing flow. When the patient's condition allows and appropriate surgical expertise is available the patient can return to the operating room for shunt removal and definitive reconstruction.

Short-term (3–6 hours) shunt patency is very good when placed proximal to the elbow or knee and is maintained without systemic anticoagulation. Shunt dislodgement is an infrequent occurrence [12]. Indications for shunt placement are the following:

- Peripheral vascular injury requiring transfer from a remote facility to a trauma centre, where vascular reconstruction will be undertaken.
- Maintain perfusion, while addressing other life-threatening injuries.
- Perform skeletal alignment before vascular reconstruction.
- For 'damage control' in severely-injured patients who have exhausted their physiological reserves.

Primary end-to-end anastamosis

Primary end-to-end repairs of injured arteries are often performed in the setting of low energy penetrating wounds causing laceration to the vessel wall. Injuries from high-energy projectiles are often very difficult to approximate together in a tension-free anastomosis after adequate vessel debridement. The technical principles of vascular anastomosis apply equally well to direct end-to-end anastomosis and to graft interposition: arterial ends smaller than 1 cm in diameter should be bevelled, balloon thrombectomy should be performed distally and proximally, and both segments should be flushed with heparinized saline.

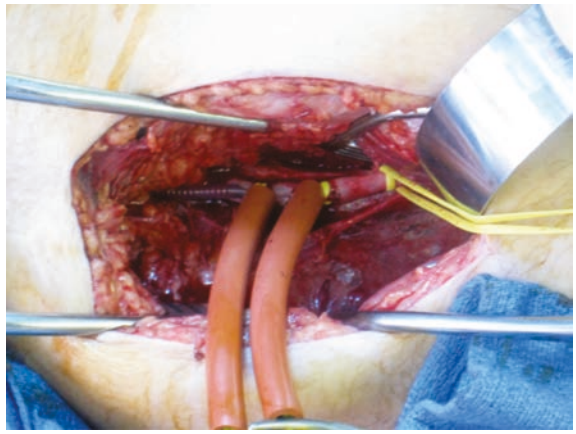

Fig. 335.2 Temporary shunt placed in the popliteal artery.

Interposition grafts

An interposition conduit is used for extensive vessel injury when simpler reconstructive options are inappropriate. Considerable discussion, debate, and research have focused on the use of synthetic versus autogenous grafts. Currently, for vessels of 5 mm or less in diameter, the use of a saphenous vein graft is the only practical option [13]. The use of prosthetic material in a contaminated field is also a subject of considerable debate. One option is to ligate the injured vessel and perform an extra-anatomic bypass around the contaminated area. The classic example is ligation of the iliac artery in an abdomen with gross faecal spillage and performance of a femoro-femoral bypass graft. In some instances, such as reconstruction of an injured abdominal aorta, it is virtually impossible to avoid reconstruction in an area of contamination.

A major advantage in the use of synthetic grafts is not requiring time for conduit harvest and preparation. A technical pitfall in graft selection for arterial trauma is inappropriate size selection. The arteries of young trauma victims are often surprisingly small, especially in the patient who is hypotensive and vasoconstricted. A conscious effort should therefore be made to select a slightly larger graft size than that thought to be appropriate.

Endovascular repair

Rather than clamp, sew, and tie, endovascular interventions can be thought of in terms of balloon, stent, and coil. The ability to obtain intraluminal vascular control especially in areas difficult to expose, such as subclavian arteries [14], or re-operative fields cannot be overestimated. Furthermore, once control has been established, intervention can continue with endovascular techniques or can be converted to an open procedure.

In contrast to balloons, stents are almost always intended for therapeutic intervention. They are designed as balloon-expandable or self-expanding and constructed as bare-metal or covered with graft material, and are available in any combination of those characteristics depending on intended use. Furthermore, stents are available in a wide array of sizes allowing for interventions in arteries ranging from coronary arteries to the aorta. Covered stents are intended to seal an area of injury or an arteriovenous fistula whereas bare-metal stents are designed to achieve luminal gain for intimal flap or dissection.

Surgical wisdom advices against 'cavalier' surgical methods for haemorrhage from arteries of distribution, such as hypogastric and profunda femoris arteries. Uncontrolled bleeding from these vessels can create a difficult dilemma requiring directed haemorrhage control without causing additional collateral damage. A solution lies in the use of angiographic coils. These coils are constructed with various materials all of which are designed to stagnate blood flow and result in thrombosis. They can be directly delivered to the site of injury, while minimizing damage and further thrombosis to adjacent structures and vessels.

Haemorrhage and coagulopathy

Trauma to the vascular system can cause significant disruption in the flow of blood leading to haemorrhage and thrombosis. Disruption of the vessel wall can lead to active haemorrhage, shock and a systemic inflammatory response. Damage to the layers of the vessel wall may cause cessation of blood flow, thrombosis, and impaired distal perfusion. Ongoing haemorrhage produces signs of haemorrhagic shock once 15% of blood volume is lost and loss beyond 40% is immediately life-threatening [15]. Haemorrhage control is paramount in vascular trauma not only because uncontrolled bleeding is eventually lethal, but it also places severe stress on physiological reserves and corrective manoeuvres such as surgery and anaesthesia can have additional negative effects.

Ongoing haemorrhage is accompanied by consumption of coagulation components, which can lead to a consumptive coagulopathy. Targeted blood component therapy should be initiated once large volume blood loss is anticipated. Use of thromboelastogram (TEG) has a role in trauma as results can be generated and acted upon rapidly [16]. However, waiting for laboratory evaluation of coagulation status should not delay blood component therapy. Transfusion using a 1:1:1 ratio of packed red blood cells (pRBCs), fresh frozen plasma (FFP) and platelets (PLTs) is currently considered the best strategy and is adjusted based on need [17].

With active ongoing haemorrhage and fluid resuscitation, hypothermia is almost inevitable, and exposure of large areas of skin may make correction of hypothermia quite difficult. The surrounding environment should facilitate maintenance of core body temperature. Active warming should be initiated early to prevent hypothermia from occurring. Keeping operative times to a minimum will also help to reduce heat loss and its consequences.

Ischaemia and the resulting acidosis from shock, thrombosis, and even vascular control have a definite impact on coagulation. Therefore, attempts should be made to minimize the impact of ischaemia and acidosis on coagulation. Haemodynamic status needs constant attention to optimize end organ perfusion through intravascular volume expansion or inotropic support. In the setting of thrombosis, rapid restoration of blood flow helps decrease ischaemic time and subsequent acidosis whereas cross-clamping for vascular control may worsen acidosis. Furthermore, in addition to causing ischaemia of other vital abdominal organs, supra-coeliac clamping causes hepatic ischaemia and may further worsen coagulopathy; consequently, clamp times must be kept to a minimum.

CHAPTER 336

Management of limb and pelvic injuries

Omar Sabri and Martin Bircher

Key points

- Pelvic injuries with disruption occur mainly due to motor vehicle accidents or falls from height.
- Less than 10% of pelvic injuries cause haemodynamic instability due to haemorrhage, where this occurs stabilization with a pelvic binder and correction of acidosis, coagulopathy, and hypothermia should be prioritized.
- Mechanical disturbance of the primary clot by log-rolling the patient or springing of the pelvis are strongly discouraged.
- Pelvic ring injuries are associated with significant concomitant injuries, including urinary, gastrointestinal, neurological, and reproductive organ injury.
- Limb trauma can be life or limb threatening; early identification, splinting, and resuscitation follow the same guidelines as for pelvic ring injuries.

Pelvic trauma

Anatomical considerations

The bony pelvis is made up of the two innominate bones and the sacrum. The two innominate bones are joined anteriorly at the symphysis pubis, while both innominate bones articulate with the sacrum posteriorly at the sacroiliac joints. The pelvis behaves as a ring with ligamentous structures joining the bony elements. The posterior ligamentous structures (sacroiliac ligaments) are some of the strongest in the body (Fig. 336.1).

The main functions of the pelvic ring are to transfer load between the spine and the lower limbs, protect internal organs and allow for muscle and vital organ attachment in order to facilitate their function. The ring has to therefore remain a stable structure to continue performing its functions.

Incidence and demographics

Pelvic fractures account for approximately 3% of all skeletal injury after blunt trauma [1], most result from motor vehicle crashes and falls from a height.

Significant disruption needs a deceleration force of at least 30 mph, which explains the high incidence of concomitant injuries in patients presenting with pelvic injuries [1].

The average age is 40 years old with a male predominance [2]. Pelvic fractures in the elderly are usually low energy and rarely result in instability. Less than 10% of pelvic fractures will result in haemodynamically instability from haemorrhage.

Pathophysiology

There are several classification systems available to describe the anatomical and biomechanical aspects of pelvic ring injuries. The most widely used and accepted is that of Young & Burgess [3] that relies on the description of the direction and magnitude of the energy sustained by the pelvis. Its categories are lateral compression, anteroposterior compression, vertical shear, and combined mechanical instability (Fig. 336.2). Each category is further subdivided into 1, 2, and 3 depending on pattern and the degree of displacement. In injuries where a mild amount of energy is absorbed, the pelvic ring tends to fail anteriorly first; symphysis pubis diastasis or pubic rami fractures of different configurations occur at the front. This is usually accompanied by some degree of strain to the sacrospinous and sacrotuberous ligaments.

With the continued application of force, the pelvic ring then fails posteriorly. This can occur at the sacroiliac joint, through a sacral fracture or through the posterior aspect of the iliac wing (crescent fracture). Sacral fractures can be difficult to identify on plain radiographs and the exact configuration is better appreciated on CT scans. The Denis Classification of vertical sacral fractures associated with a pelvic ring injury is widely used and accepted, and is a good predictor of neurological injury. It relies on the position of the vertical fracture line in relation to neural foramina:

- **Type I**: the fracture line runs lateral to the neural foramina. Nervous structures are generally are not affected.
- **Type II**: this type incorporates transforaminal fractures of the sacrum, frequently associated with lesions of sacral nerve roots (25% incidence).
- **Type III**: central fractures of the sacrum involve the sacral spinal canal and are therefore associated with 50% concomitant neurological injuries (Fig. 336.3).

Bleeding following a pelvic ring injury can be life threatening. The mechanism of injury has been directly linked to the amount of blood loss [4]. The majority of pelvic bleeding is venous arising mainly from the posterior presacral and paravesical venous plexus, and from bleeding cancellous surfaces. Such bleeding will quickly fill retroperitoneal space and the formation of a clot in that space is essential to stop further bleeding. In approximately 10% of cases with significant pelvic bleeding, an arterial injury will be the cause.

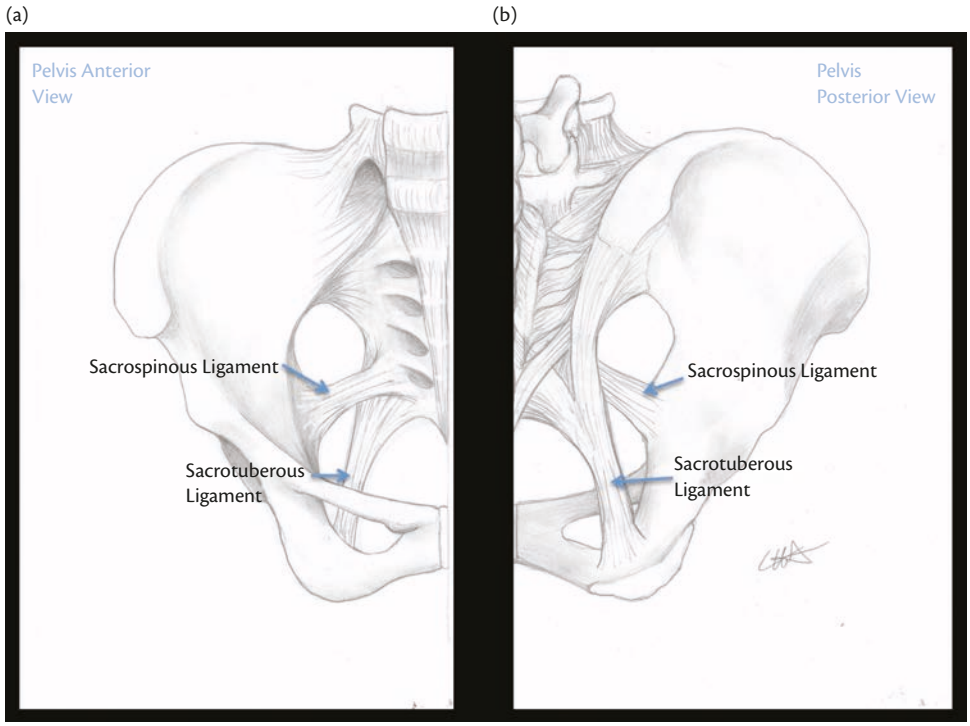

Fig. 336.1 (a) Anterior and (b) posterior views of the pelvis.
Reproduced with permission from Miss Laura Hamilton.

The bony pelvis also provides protection and soft tissue attachments for intrapelvic organs. The integrity of the pelvic floor is an important consideration and the direction of displacement can give an indication of associated soft tissue injury. Urogenital injuries are most common with anteroposterior compression and lateral compression injuries, while neurovascular injuries are more common in vertical sheer type injuries. More than 80% of patients with unstable pelvic fractures have additional musculoskeletal injuries.

Open fractures

Although a rare occurrence, open pelvic fractures are very serious injuries and carry a mortality of up to 50% [5]. The open nature of the fracture can be due to penetration of rectum or vagina, as well as through external wounds. Open injuries are frequently missed and often only discovered at time of surgery.

Management

Pre-hospital care

Having established that pelvic ring injuries are potentially life threatening and that a significant amount of energy is needed to create such injuries, the management of pelvic fractures begins at the scene. The mechanism of injury should be the first indicator of a possibility of a pelvic ring injury. Motor vehicle accidents and falls of greater than 2 m are the most common modes of injury. A pelvic binder should be applied at the scene in any major trauma patient especially if hypotensive. There is good evidence that the binder is effective in pelvic stabilization and can be life-saving irrespective of the injury pattern [6]. The binder needs to be applied correctly over the greater trochanters and inspected regularly for pressure necrosis should it be left on for more than 24 hours.

Haemorrhage control

The pelvis is next evaluated in the emergency department. Following Advance Trauma Life Support (ATLS) guidelines, pelvic injuries are addressed during the 'Circulation with Haemorrhage Control' part of the primary survey [7] . Springing or stressing the pelvis is now discouraged if an injury is suspected. It's both unreliable and risks disturbing the retroperitoneal clot. A pelvic X-ray used as an adjunct to the primary survey should be obtained early (Fig. 336.4).

If a pelvic ring injury is identified, resuscitation should continue with the pelvic binder *in situ*. Log rolling the patient is contraindicated if a pelvic ring injury is identified as this also risks disturbing a retroperitoneal clot. The best clot is the first clot and every effort should be made to preserve it. The retroperitoneal space can easily accommodate 2–2.5 L of blood.

Damage control resuscitation

The concept of damage control resuscitation (DCR), which started in the military, is now well accepted and is being adopted in civilian trauma centres. Initial resuscitation for severely-injured patients is based on a strategy of permissive hypotension and blood product resuscitation guided by patient's physiological response. In severely-injured trauma patient with ongoing major haemorrhage, there is improved outcome from early haemostatic resuscitation compared to large volume clear fluid resuscitation [8]. In the UK, NICE (National Institute for Care Excellence) recommends that crystalloid fluid therapy should only be administered to a trauma patient if there is an absent radial pulse. Boluses of 250 mL of crystalloid should be given, while the patient is transported to hospital without delay and the radial pulse intermittently checked. Haemostatic transfusion (also referred to as massive transfusion protocols) should be initiated early. Most transfusion protocols will contain plasma and platelets, as well as packed cells in an attempt to replenish clotting factors. Tranexamic acid has also been shown to be effective in reducing mortality as a result of significant bleeding [9]. It is most effective when administered as a 1 g bolus within the first 3 hours following the injury.

In approximately 90% of haemodynamically unstable patients with pelvic ring injuries, the previously outlined measures should be sufficient to control haemorrhage and stabilize the patient. In the remaining 10% of patients who continue to exsanguinate, more aggressive intervention is needed.

In a major trauma centre, a combination of surgical stabilization, pelvic packing and angiographic embolization can be used if general resuscitative measures do not control the bleeding. The management algorithm is dependent on available local resources. The use of cell-savers and other auto-transfusion devices has become standard practice during pelvic and acetabular surgery.

The lethal triad

The 'bloody vicious cycle' of coagulopathy, hypothermia, and acidosis should be corrected simultaneously to give the patient the best chance of survival. Surgical intervention to stabilize the pelvis has been shown to help control haemorrhage and avoid late complications. The timing of surgery is based on the patient's physiological state. A traffic light system of monitoring venous lactate, in conjunction with correcting acidosis, hypothermia and coagulopathy, has been shown to be effective in guiding management [10]. A venous lactate greater than 2.5 mmol/L is a STOP sign for surgical intervention, as the surgery will provide another physiological insult that a compromised patient may not tolerate. A venous lactate of less than 2 mmol/L is GO for surgical stabilization. If the venous lactate is between 2 and 2.5 mmol/L, then the trend is observed with descending pattern being favourable for surgery.

Dynamic assessment and observing of trends during resuscitation with regular communication between the decision-making clinicians has been demonstrated to improve overall safety and team effectiveness.

Urinary and bowel injury

The incidence of urethral lacerations and bladder ruptures in complex pelvic injuries appears to be 5–10%. The perineum should be inspected for any external signs of a urological injury. Blood at the external meatus is a sign of potential urethral or bladder injury. One catheterization attempt by an experienced practitioner should be performed along with a retrograde urethrogram. Early urological consultation should be sought if an injury is suspected

or catheterization fails. A suprapubic catheter or complete urinary diversion may have to be undertaken in severe cases.

Open injuries

In addition to inspection of the perineum, an open pelvic ring injury is not excluded until rectal and vaginal examinations have been performed. If this is not possible in the emergency department, it should be documented as 'outstanding' and eventually performed once the patient is stabilized or prior to surgery. Early administration of intravenous antibiotics with Gram-positive and -negative cover is now considered life saving in these injuries. If a rectal or bowel injury is suspected, a diverting colostomy with placement in the upper abdomen is advised.

Surgical stabilization and reconstruction

The aim of sophisticated reconstruction of the pelvis is the prevention of deformity. Deformity can occur as a result of fracture displacement at the time of injury or develop over time because of loading through unstable fractures or disrupted ligaments. Unequal leg length, rotational inequality of the legs and asymmetry of the ischial tuberosities resulting in a sitting deformity, are sequelae of malunited fractures of the pelvis.

Anterior ring

Injuries of the anterior part of the pelvic ring are best treated by open reduction and internal fixation. The type of fixation used will be determined by the pattern of injury the options available include plate fixation and column screws.

Anterior plating (Fig. 336.5) for a symphyseal diastasis normally only requires a Pfannenstiel-type incision and it is common to discover that the insertion of the rectus abdominis muscles has been avulsed from the anterior aspect of the pubis, making dissection relatively straightforward.

Where injury to the anterior part of the pelvic ring is complex and involves the pubic rami, additional access for longer plates may be required. Image-guided and/or navigated column screws (Fig. 336.6) may be used if the fracture is minimally displaced after closed reduction.

Pelvic external fixation is a good method of surgical pelvic stabilization. It can be used in the emergency setting or as definitive fixation. Several pin and bar configurations can be utilized, but the authors' preferred method is the use of two supra-acetabular pins and two iliac crest pins with either a low or a high bar configuration (Fig. 336.7a, b). If severe pelvic displacement is present, skeletal traction through a distal femoral pin can also be utilized in combination with the external fixator.

Posterior ring

Stabilization of the posterior structures of the pelvic ring can be achieved by a combination of closed or open reduction, percutaneous screw fixation or plate fixation.

Complications

Venous thromboembolism

Pelvic fractures are a risk factor for venous thromboembolism. Currently, the natural history of pelvic vein thrombosis is not known, but evidence suggests that more proximal clots are more likely to embolize. Pulmonary embolism is a potentially lethal complication in patients with pelvic and acetabular fractures, and has been reported as the most common fatal complication after operation or trauma to the lower extremities.

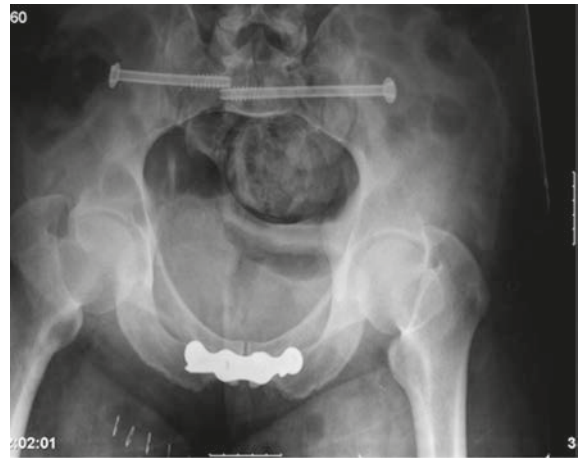

Fig. 336.5 Anterior plating + sacroiliac screw fixation.

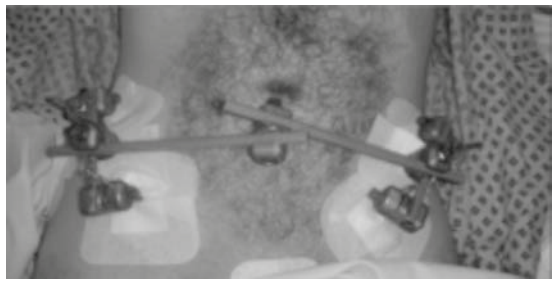
Patients should commence low-molecular-weight-heparin (LMWH) without delay. This strategy reduced the incidence of proximal deep vein thrombosis (DVT) to 10% in a cohort of 103 consecutive patients who were screened for this condition at 10–14 days after surgery [11]. The incidence of DVT was only 3% when LWMH was started within 24 hours of injury [11].

Authors current practice is to use LMWH, and compression stockings pre- and post-operatively until oral anticoagulation with warfarin reaches therapeutic levels. Patients are prescribed warfarin for 3 months.

An alternative is to place a vena cava filter, which is recommended in patients with a contraindication to anticoagulation (e.g. traumatic brain injury, patients managed non-operatively for splenic or liver laceration) or in patients with pelvic or acetabular fractures that warrant surgical management and are considered high risk for a thromboembolic event [12].

Fig. 336.6 Column screw fixation to anterior ring.

(a)



(b)

Fig 336.7 (a,b) Pelvic external fixator.

Functional outcome

There is a significant discrepancy in the reporting of functional outcomes after fractures of the pelvis. Different authors have reported many factors associated with worse functional outcome including open fracture [13], urological injury [14], neurological injury [15], fractures requiring open reduction and internal fixation [15,16], residual posterior displacement [16], injury pattern, and psychological problems [17].

Suzuki et al. [14] found that the Majeed score [18] Iowa pelvic score and Medical Outcomes Study Short Form 36-item Health Survey (SF-36) [19] are each altered after fracture of the pelvis and correlate closely with the presence of a neurological injury.

What is well recognized is that these are serious injuries and this group of patients will require prolonged physical, psychological and nutritional rehabilitation, as well as vocational support until return to the pre-injury level of function.

Limb trauma

Limb trauma can result in significant morbidity and mortality. Expeditious identification and treatment of limb injuries can avert potential complications, and improve outcome.

With any fracture of an extremity in a trauma patient, there must be an awareness of the possibility of a compartment syndrome or vascular injury that may result in limb ischaemia. Open fractures are also serious injuries that demand urgent attention.

Limb stabilization usually results in improvement in the patient's overall pulmonary status, hospital course, length of stay, and rehabilitation. Whether limb trauma is isolated or patient component of multitrauma, initial resuscitation should occur along the same principles outlined earlier in this chapter. Simple splinting and or longitudinal traction are usually sufficient until the patient has been adequately resuscitated. Fracture reduction and definitive stabilization is now usually performed on dedicated trauma operating lists during day light hours.

Open fractures

New guidelines have resulted in a move away from the historical rule of urgent debridement within 6 hours. Antibiotic administration within 3 hours, splintage and surgery on the next available operating list are now considered best treatment, especially when dealing with the tibia. Highly contaminated injuries and those with marine contamination need urgent washout and debridement. New Guidelines (BOAST 4) recommend definitive fracture stabilization within 24 hours and definitive soft tissue cover within 72 hours [20].

The use of tourniquets has been re-introduced by the military to control catastrophic limb haemorrhage with good effect. In cases where tourniquets cannot be applied, novel haemostatic agents, such as chitosan-coated gauze dressings can be directly applied to the bleeding surface. These work independently of the clotting cascade.

Compartment syndrome

Increase in the pressure within an osteofascial compartment following an injury can be limb threatening. This condition can occur with or without a fracture and with open or closed injuries. The most commonly affected patient group are males between 18–30 years of age. The tibia is the most commonly affected bone. The diagnosis is essentially clinical with 'disproportionate pain' being the main symptom and pain with passive stretching the main sign. Compartment monitoring is of use in the unconscious patient. Once diagnosed, urgent open complete decompression is the treatment.

CHAPTER 337

Assessment and management of fat embolism

Neil Soni

Key points

- Fat embolism is common, while fat embolism syndrome (FES) is rare.
- Theories as to mechanisms include the mechanistic and free fatty acids theories, but both probably require an additional inflammatory component.
- Gurds major and minor diagnostic criteria may be helpful as there is no definitive diagnostic test. Cerebral magnetic resonance imaging may be useful and increase the certainty of the diagnosis in neurological FES.
- Early fixation of long bone fractures may reduce likelihood of FES.
- There is no proven specific treatment; supportive treatment forms the mainstay of therapy.

Definition

Fat embolism is seen when fat globules enter the circulation and form potential emboli. This occurs relatively commonly, but is infrequently symptomatic. Fat embolism syndrome (FES) is when there is not only fat in the circulation, but the fat gives rise to an identifiable pattern of symptoms and signs. The syndrome is seen in a wide range of circumstances, and consists of a variable combination of respiratory failure with or without neurological disturbance and with a petechial rash.

Incidence

The incidence is difficult to define and is dependent on the diagnostic criteria used and the population studied. The incidence in clinical retrospective studies tends to be low, less than 1%, while prospective studies may report an incidence that is 10–20 times higher. In contrast post-mortem studies report a very high incidence of pulmonary fat embolism; 82% in patients dying after trauma and 63% in patients dying without trauma [1]. Cardiopulmonary resuscitation is associated with a high incidence of pulmonary fat embolism at post-mortem regardless of the underlying cause of death. The issue is, whether it is cause of death or an association.

In specific situations it is better defined. In patients with long bone fractures a rate of 0.7% has been reported. Patients with bilateral femoral fractures treated with reaming and nailing have an incidence of 4.1% with acute respiratory distress syndrome (ARDS) reported in 14.6% and death in 6.9%. Following elective orthopaedic surgery such as bilateral knee replacement, an incidence of 0.17% has been reported [2].

Pathophysiology

The mechanism underlying FES is unclear, although several theories have been advanced.

The mechanistic theory holds that fat embolism occurs when fat is forced into the circulation during trauma, or due to high pressure within the bone marrow or in fat tissues. Evidence for this is that emboli can be seen during and after various orthopaedic manoeuvres where high pressures are exerted in the marrow cavity. Interestingly, fat alone does not cause the syndrome in animal models and an inflammatory process is also important. The 'two hit concept' requires fat embolism and inflammation [3,4].

The free fatty acids theory suggests that trauma or surgery results in the release of lipases into the plasma, which destabilize circulating fats resulting in saponification and de-emulsification. This may be linked to or be an alternative to the concept that FES results from the histotoxic effects of free fatty acids, which in experimental models cause a vasculitis and inflammation with both inflammation and fibrosis developing within hours of fat embolism [5].

A key feature of the syndrome is that signs are seen on both the arterial and venous sides of the circulation, while fat is released only into the systemic venous system. Transit through a patent foramen ovale (PFO), present in up to 30% of the population, has always been suggested as important, but it is quite clear that it is not always present in those who develop the syndrome. As deformation of micelles that can traverse the pulmonary vessels has been shown in animal models it is clear there must be mechanisms or pathways, other than PFO for fat to pass from the systemic venous circulation to the systemic arterial circulation [6,7].

The haemodynamic changes associated with fat infusions have been characterized in animal studies. These include a rapid rise in pulmonary vascular resistance associated with a concomitant decrease in both cardiac output and blood pressure. This very transient effect leaves only a small incremental increase in pulmonary vascular resistance. Whether this is the same in clinical scenarios associated with FES is unknown [8].

Situations associated with FES

See Box 337.1 for situations associated with FES.

Box 337.1 FES is seen in a wide range of situations; the major ones are listed here

Bone marrow disruption

- Trauma especially long bones.
- Surgery involving marrow instrumentation. (Joint replacements, fracture fixation, scoliosis surgery.)
- Bone marrow harvest.
- Bone marrow transplantation.

Mechanical disruption of adipocytes

- Soft tissue injury: crush and blast injuries.
- Liposuction.
- Electrocautery.
- Liver failure: fatty liver.

Exogenous fat administration

- Parenteral nutrition.
- Propofol infusion.
- Lymphography.

Non-specific

- Burns.
- Extracorporeal circulation.
- Acute sickle cell crisis.
- Acute pancreatitis.
- Decompression sickness.
- Altitude sickness.

Box 337.2 Gurds modified diagnostic criteria—one major and four minor criteria needed for a positive diagnosis

Major criteria

- Petechial rash.
- Respiratory symptoms: tachypnoea, dyspnoea.
- Respiratory signs: bilateral inspiratory crepitations, haemoptysis, bilateral diffuse patchy shadowing on chest X-ray.
- Neurological signs: confusion, drowsiness, coma.

Minor criteria

- Tachycardia > 120 beat/min.
- Pyrexia > 39.4.
- Retinal changes: fat or petechiae.
- Renal changes: anuria or oliguria.
- Jaundice.

Laboratory

- Thrombocytopenia >50% decrease on admission value.
- Sudden decrease in haemoglobin level by >20% of admission value.
- High erythrocyte sedimentation rate >71 mm/h.
- Fat macroglobulaemia.

Clinical signs of FES

Fat emboli can be detected with Doppler ultrasound techniques, but the presence of fat emboli on ultrasound does not correlate well with the clinical syndrome. The clinical syndrome is a collection of signs not all of which will be necessarily present, and the severity of the syndrome can range from subclinical to catastrophic with an onset that may be slow and insidious through to fulminant. It is also a diagnosis of exclusion.

Presentation may occur intra-operatively or at time of injury, but more commonly the onset is over the 12–36 hours following injury or surgery. Increasing hypoxaemia is the most frequent sign and may be associated with neurological symptoms such as confusion, drowsiness, or coma. It may be accompanied by fever and a characteristic petechial rash, often in the axillae, but the rash may also be on the face or in the conjunctivae. These can all occur in relative isolation and post-operative confusion has been flagged as a potential sign of FES even when it occurs in isolation [9,10].

Diagnosis may be helped by using Gurds classification, or modifications thereof (Box 337.2). The classification discriminates between major signs or criteria, such as petechial rash, respiratory distress, and confusion, and a list of minor signs or criteria. Diagnosis requires one major and four minor criteria. While fat globules in the blood used to be a requirement, it is problematic because they can often be found with little or no suggestion of any clinical signs, and not just in high risk situations such as trauma or orthopaedics, but also in healthy volunteers. Therefore, they are not pathognemonic of FES [11].

Lindeque suggested an alternative approach, which is almost exclusively respiratory, and excludes the neurological and other presentations. It is unhelpful except as an indicator of a non-specific but severe respiratory presentation.

Pulmonary criteria for FES: lindeque

- A sustained PaO_2 of less than 8 kPa (FIO_2 0.21).
- A sustained $PaCO_2$ of more than 7.3 kPa or pH of less than 7.3.
- A sustained respiratory rate of more than 35 breaths/min even after adequate sedation.
- Increased work of breathing judged by dyspnoea, use of accessory muscles, tachycardia, and anxiety

Clinical features

Diagnosis of a syndrome requires an appropriate clinical context or predisposition, and the conditions listed in Box 337.1 provide those contexts. Most patients with FES (70%) have a significant respiratory component. It is important to realize that the patients in whom FES is likely, such as patients who have suffered trauma

or following orthopaedic surgery, may be expected to have some degree of hypoxaemia independent of the possible occurrence of FES. Of those with significant chest X-ray changes diagnosed as having FES, the degree of lung injury is very variable, but up to 44% may require mechanical ventilation [12].

The lung injury usually takes between 3 and 7 days to resolve, but this is highly variable as is the overall outcome.

The petechial rash, which is considered pathognemonic of FES is seen in only about 60% of cases. It is characteristic in the axilla, but may be seen elsewhere, including the forehead, the conjunctivae, and submucosa. One theory is that the distribution is due to fat droplets accumulating in the aortic arch, and showering through the carotid and subclavian vessels. The occurrence of petechiae is not directly associated with a decrease in the platelet count, which may remain over 50×10^9/L, but thrombocytopaenia may also be part of the syndrome. The mechanism of the rash is uncertain, but it may be due to vascular stasis, endothelial damage from free fatty acid or embolization.

The neurological features vary from mild confusion and disorientation to convulsions and coma, and almost anything between. The speed of onset is also highly variable with signs not necessarily present on admission to hospital following trauma or immediately post-operatively. There is no specific characteristic that is readily identified, but confusion in any patient at risk should have FES considered in the differential diagnosis. FES is particularly likely if the neurological abnormality is focal [13].

Outcome from cerebral fat embolism is often, but not always, good so accurate prognostication soon after presentation is difficult. It is increasingly likely that the improved sensitivity of cerebral MRI scanning may be helpful in showing either reversible vasogenic oedema or other evidence of damage. Cerebral MRI may assist in prognostication although that is not yet the case [14].

Investigations

FES is a syndrome so there are no definitive diagnostic tests, and it is the pattern that is important. Thrombocytopaenia (platelet count $<150 \times 10^9$/L) and anaemia are both common (37 and 67%, respectively). Hypocalcaemia and hypoalbuminaemia are non-specific features.

Fat globules may be identified in both blood and urine, but as they may be found in patients in the absence of FES, they are also not diagnostic. Serum lipase and phospholipase A2 both tend to increase in lung injury and are again non-specific. Monitoring pulmonary artery pressure with a pulmonary artery catheter was advocated for diagnosis of fat embolism, but pulmonary hypertension has many acute and chronic causes, and so this is no longer considered of benefit. Pulmonary artery fat sampling has also been reported, but its diagnostic value is not known. Bronchoalveolar lavage to find macrophages containing fat also lacks specificity.

The chest X-ray usually shows bilateral patchy oedema-like infiltrates and the term 'snow storm appearance' has been used in more severe cases. However, this is also a non-specific finding and not diagnostic.

Computed tomographic (CT) scanning of the lung is also unhelpful beyond showing non-specific markers of injury. CT of the brain is also non-specific, although an absence of correlation between the neurological picture and the cerebral CT findings should raise the possibility of FES. In severe, non-traumatic brain injury there may be cerebral oedema or high density spots, which in context may lend weight to a potential diagnosis of FES, but is not diagnostic.

Magnetic resonance imaging (MRI) is increasingly useful and is now the radiological investigation of choice with some characteristic findings, which are potentially, diagnostic. It may show a 'starfield' pattern (innumerable punctate areas of restricted diffusion). T2-weighted images are particularly useful showing small non-confluent hyperintense lesions in both white and gray matter, which are thought to indicative of micro-infarcts [15]. Vasogenic oedema is identified by areas of enhancement with gadolinium with background increases in the signal intensity of diffusion and T2-weighted images, and iso-intensity on apparent diffusion coefficient (ADC) mapping. These findings are relevant as they are reversible lesions that usually disappear by 21–30 days and often appear to correlate with clinical improvement [16].

Prevention of FES

This can be theoretically achieved by either changes in surgical management or by pharmacological intervention. With fractured long bones surgery techniques such as the use of external fixators, which reduce the risk of fat being pushed into the circulation should help. Early surgical fixation of long bone fractures compared with conservative management may reduce the risk of FES from 22% to 4.5%. There are high risk periods and evidence that fixation between days 2 and 5 should be avoided [4]. Avoidance of elective surgical techniques that generate high intramedullary pressures seems intuitively advisable, but is not definitely proven.

The role of pharmacological prophylaxis with corticosteroids remains unclear. One meta-analysis suggests that they might reduce the incidence and severity of FES following bone fractures, but these outcomes are subject to ascertainment bias and mortality, a more robust outcome, was not affected [17]. The conclusions are also limited by the poor quality of the trials included in the meta-analysis and based on current evidence corticosteroids should not be administered routinely.

Management of established FES

This is entirely supportive as there are no specific interventions proven to improve outcome. Animal studies suggest that FES may result or be exacerbated by a combination of fat emboli and then a secondary trigger by shock like states, the so called two hit hypothesis, resulting in an inflammatory reaction [3]. If this is the case, then early clinical stabilization, including early fixation of long bone fractures in patients well enough to tolerate surgery would make sense. Patients with FES may be clinically unstable so that although an MRI scan may help in diagnosis, transport to an MRI scanner may jeopardize immediate care without necessarily altering treatment. Corticosteroids are of unproven value in the treatment of established FES as are other treatments, such as dextrans and heparin, which have been used in the past.

Conclusion

First and foremost this is a clinical diagnosis based on appropriate clinical circumstances and the clinical features of the syndrome. As the clinical severity of FES is highly variable and the diagnosis is often unclear, it is difficult to define the impact of FES on clinical outcomes. Additionally, FES is rare so there are

few published series of any size with much of the data on outcome being extracted from case reports or small series. The high rate of fat embolism detected at post-mortem in patients dying within 1 hour of major trauma probably indicates an association with the severity of trauma and the poor outcome of patients who undergo CPR following trauma rather than indicating that FES is the cause of increased mortality. It is also clear that many patients with fat emboli do not develop the syndrome. However, severe pulmonary FES may be fatal and patients with severe neurological FES may be left with substantial deficits or die. MRI scanning may prove useful for prognostication but this requires further evaluation.

CHAPTER 338

Assessment and management of combat trauma

Sara J. Aberle and Donald H. Jenkins

Key points

- The practice of medicine in combat settings comes with additional challenges, including a potentially hostile environment, delayed patient evacuation, and limited resources.
- Data from recent combat continues to show haemorrhage as a primary cause of death, with most deaths occurring prior to hospital arrival and before injuries can be managed surgically.
- Life-saving interventions, such as tourniquet application and needle thoracostomies, decrease combat-related mortality if performed appropriately and in a timely fashion.
- The search for better outcomes is focused on improving prehospital management, including targeting remote damage control resuscitation.
- The usual order of management in civilian trauma hold true in the combat setting.

Introduction

General concepts

Combat trauma is a unique clinical entity that has important implications for those who are not well-versed in this area. Lessons learned from combat trauma can be highly relevant in both the military and civilian settings. Key areas that warrant exploration include the differences between combat casualties and civilian trauma patients, namely the environment in which they are treated, the mechanisms by which they are injured, and the methods used to provide their care. There are of course additional challenges of practicing medicine in the combat arena in what may be a hostile environment with prolonged patient evacuation times and limited resources.

Roles or levels of care

Medical care in the combat setting begins on the battlefield or at the site of injury and can extend as far back as the country of origin. The terms 'roles' or 'echelons', numbered one to five, are used to describe the capabilities and resources of various points of medical treatment along this spectrum. Once a patient is determined to need medical care that exceeds that role's capabilities, the care team works to evacuate the patient to a higher role or level of care [1].

Role 1 indicates care that is provided in the prehospital setting, to include that provided by soldiers and trained combat medics in the field. At this level, the primary goal is assess the patient, determine if a life-saving intervention is needed and either treat the patient and allow them to return to duty or evacuate the patient to a higher level of care. Role 2 teams or medical treatment facilities are generally mobile and have additional resources such as basic radiological (X-ray) and laboratory capabilities, limited in-patient facilities, and may have appropriate subspecialty expertise available. This level would also include forward surgical teams (FSTs), who are able to perform emergency surgery for life-saving stabilization. This allows the patient to be transported to a higher level of care when otherwise they would not have survived transportation.

The most extensive care patients can receive while still in the combat arena is that received at Role 3 medical treatment facilities. They may include combat support hospitals with in-patient bed capacities (usually ranging from the 80s to 200s). Examples of such medical treatment facilities include NATO alliance facilities, where the varied experiences and practice patterns of medical providers from different countries and training backgrounds come together to form a collective knowledge and skill base that can be shared and developed. Examples of this are advances in the use of tranexamic acid, tourniquets, and freeze-dried plasma, which are discussed later in the chapter.

A Role 4 facility has even greater care capacity as it is the first level at which care is provided outside the combat zone. An example of this is the facilities at Landstuhl Regional Medical Center near Landstuhl, Germany. Role 5 medical treatment facilities are located in the home countries of those injured and offer the most definitive care that the injured personnel requiring this extent of evacuation can receive. Included in these would be the Royal Centre for Defence Medicine in the United Kingdom (UK), one of the German Armed Forces Hospitals, such as those in Hamburg or Berlin, or Brooke Army Medical Center in the United States.

Medical provider functions

A health care provider deployed and serving in a combat zone or in any of the aforementioned levels of care can potentially perform a number of functions, including that of continuing their usual activities of practicing within their medical specialty, in day-to-day general practice, or ensuring soldier health and readiness. Closer to the front lines, health care personnel may serve directly as part of the trauma or forward surgical teams.

Mechanisms of combat injuries

Injuries sustained in combat can arise from a number of different mechanisms. While not exclusive to the military setting, certain

injuries are seen more commonly in those injured in combat. One such injury pattern is that seen from falling or landing after jumping or rappelling from a fixed- or rotary-winged aircraft. Landing injuries most often observed are fractures, sprains, and strains affecting primarily the lower extremities (especially the ankle), followed by the upper extremities and spine [2]. The risk of sustaining an injury is increased when jumps are made at night and in jumps made with the additional weight of protective and combat equipment used in operational jumps [2,3].

Blunt trauma is less common in combat injuries although it does occur. The causes of blunt combat trauma range from the landing injuries already discussed, to direct blows from an opposing soldier, motor vehicle accidents, or from tertiary blast injuries resulting from the explosive propulsion of the body into a hard surface. Standard spinal precautions and blunt trauma management strategies apply in these cases.

Penetrating injures are more common in combat trauma. Injuries from sharp or edged weapons, as well as small arms fire, are generally managed similarly in combat as they would be in the civilian setting. The many types of firearms can cause varying injuries and many of these wounds require operative management; this presents a key logistical consideration in combat trauma coordination. A core principle of managing gunshot wounds is the concept of 'trajectory determination equals injury identification', and establishing the trajectory of the projectile can help guide management planning. An easy and low-cost way to determine trajectory is taping paperclips near external wounds so that the entry and exit points can be pictured on radiographs or by CT imaging allowing the injuries in between to be surmised.

Some of the most significant injuries in modern combat are explosion-related blast injuries. In the recent years these have been seen primarily in injuries from improvised explosive devices (IEDs). These devices can be made in many ways, with various different substances; for instance, organic peroxides were used in the London Underground bombings in 2005. An important factor, while serving as a medical provider within a combat setting is that there is the potential to be affected by chemical, biological, or radiological warfare. As an example, an IED could be built with a propane component, as well as powdered chlorine, so that upon detonation there is both a combustive or fire element along with a chemical component. Methods like these pose a risk to the medical team, as well as the patient, and medical providers should be aware of these potential threats.

The fragmentation pieces associated with IEDs, or as a result of projectile debris that comes with a blast, serve as secondary blast injuries. The devastating effects of these flying fragments have been described as being similar to gunshot wounds [4,5], although some studies found a higher likelihood of surgical intervention from gunshot wounds compared to explosion-related injuries [4]. The biggest surprise to many combat providers is realizing just how many penetrating injuries casualties will suffer in one explosion.

There are two specific quaternary blast injuries of which medical providers in combat need to be aware, namely pulmonary embolism (PE) and traumatic brain injury (TBI). A recent study suggests the rate of PE in combat-wounded patients with extremity fractures and amputations is 4.7%, nearly twice the rate expected with civilian trauma [6]. This should raise the medical provider's concern for appropriate prophylaxis, including considering placement of a vena cava filter. Traumatic brain injury, which is now a common combat-related injury, increases the risk of affected persons developing psychiatric illness and sleep complaints, with both blast and blunt injuries having a high association with insomnia [7].

Studies from recent conflicts over a 10-year period have examined the injuries sustained in combat and reported that the majority of combat mortality (87.3%) occurs in premedical treatment facilities prior to reaching surgical intervention. Over three-quarters of the injuries were deemed to be 'non-survivable' with just under a quarter of the injuries thought to have been 'potentially survivable'. The vast majority of deaths occurring from potentially survivable injuries were due to haemorrhage; found most often to be truncal, with junctional and peripheral or extremity bleeding following thereafter. As most deaths occur in the prehospital setting, improvements in outcome will result from developing treatment strategies that target haemorrhage control, airway management, and efficient evacuation [8]. Another possible cause of preventable deaths are underperformance of life saving interventions (LSI's), the aforementioned uncontrolled major haemorrhage, and delayed evacuation before subsequent surgical intervention [9].

Management of combat injuries

The practice of Tactical Emergency Medicine Services (TEMS) and combat medicine has additional challenges. Taking these challenges into account, as well as the available data regarding the types of injuries and causes of death, many groups and individuals have worked to develop medical training specific to the combat setting and to optimize logistical systems to improve survival. Examples include battlefield advanced trauma life support (BATLS), battlefield advanced resuscitation techniques and skills (BARTS), combat lifesaver (CLS), and tactical combat casualty care (TCCC), which have been shown to be effective in decreasing mortality [10].

A major management theme taking prominence is 'damage control resuscitation'. Damage control resuscitation stresses haemorrhage control in the form of a permissive hypotension, with a goal of the return of a palpable pulse, a systolic blood pressure of greater than 80 mmHg, or a mean arterial pressure of 50 mmHg [11,12]. Haemostatic resuscitation seeks to administer blood products in a similar ratio to that of whole blood; namely by administering a 1:1:1 ratio of red blood cells (RBCs), fresh frozen plasma, and platelets [13]. Dried plasma is also being offered as a more versatile option than liquid plasma as it is easier to store and should be easier to employ in the combat environment. Studies of dried plasma are ongoing in Germany, France, and the United States [14].

The next logical step in addressing the majority of deaths occurring prior to arrival at medical treatment facilities is to extend these principles of damage control resuscitation to the pre-medical treatment facility setting [9]. This has been termed remote damage control resuscitation. Medical emergency response teams from the UK, as well as the Israeli Defence Force have reported success with similar approaches, extending use to other products like the antifibrinolytic, tranexamic acid [15]. Determining the patient's physiological trajectory in the resuscitation process will dictate plans to provide adequate transfusion of RBCs, plasma and platelets, along with pharmacological haemostatic adjuncts [16].

In addition to early transfusion, remote damage control resuscitation may also involve patient monitoring technologies or even telemedical technology to connect an on-scene pre-medical treatment facility with a medical provider capable of giving appropriate

instruction in instituting lifesaving interventions. While many soldiers are trained in BATLS, BARTS, CLS, or TCCC there are still a number of 'missed' LSIs where the delay or omission of the intervention is associated with increased mortality [9].

Actions considered as LSIs include appropriate tourniquet application, pressure dressings, or haemostatic agent application, needle or tube thoracentesis, obtaining intravenous or intraosseous access, and airway management. To execute these interventions, almost all soldiers in combat are issued with an Individual First Aid Kit, or 'IFAK'. These are now stocked with haemorrhage control methods, such as commercially-produced one-handed tourniquets that have shown to be more effective than improvised tourniquets, as well as haemostatic agents and pressure dressings such as Combat Gauze and Israeli bandages, respectively. Many IFAKs will also come with needles for chest decompression, and tools for obtaining vascular access. Medics in the premedical treatment facility setting may also have supraglottic airway devices, the training and tools to perform a surgical airway in the form of a cricothyroidotomy, and blood and procoagulant or antifibrinolytic products.

There are other changes and additions to tactical emergency medical services in the combat arena, many of which are being formally included in official tactical training. One such addition is the recommended use of ketamine for pain management prior to arrival at a medical treatment facility. The addition of tranexamic acid is also relatively new. Junctional haemorrhage causes 19.2% of lethal haemorrhage (5.7% more than peripheral haemorrhage) [8], and is not easily amenable to tourniquet application. Junctional haemorrhage in the inguinal region can be treated with tools like the combat ready clamp, in addition to haemostatic agents. Care should be taken if using the combat ready clamp, to place the clamp on the common iliac artery in the case of lower extremity junctional haemorrhage as opposed to the external iliac artery, to avoid ongoing bleeding from the collateral circulation [17]. Management of traumatic brain injury is also being initiated in the pre-medical treatment facilities setting, chiefly through efforts to limit secondary brain injury by minimizing hypotension and hypoxia with specific instructions to keep oxygen saturations above 90%.

The success of combat-related injury management has resulted in concepts being carried over to the civilian sector. An example of this is the Hartford Consensus, where leaders in the field issued a formal statement with recommendations for civilian organizations to improve survival during mass casualty shooting events. With concepts stemming from the combat zones of Iraq and Afghanistan, and TCCC training, recommendations were made in order to stress 'the importance of early and definitive hemorrhage control to maximize survival of the victims . . . '. They did so by proposing the acronym THREAT: **t**hreat suppression, **h**aemorrhage control, **r**apid **e**xtraction to safety, **a**ssessment by medical providers, and **t**ransport to definitive care [18]. Services in the UK have also taken steps towards haemorrhage control in the prehospital civilian setting by bringing blood products to the scene [19]. Additionally, various groups are working to develop competency-based training derived from military tactical medical teaching that can be applied in training those involved with tactical emergency medical services in the civilian sector.

One final principle of management for combat-related mechanisms and injuries is that 'common things are common', and best practice in the civilian setting is typically safe and effective in the combat-injured. The health care provider should recognize that the usual thought processes of civilian trauma management hold true for the management of those injured in combat. Treating patients with modern resuscitative and supportive techniques and to the same endpoints, is the hallmark of high-quality injury management regardless of the mechanism of injury or the location of the care facility [16].

PART 16.2

Ballistic trauma

CHAPTER 339

Pathophysiology of ballistic trauma

Michael C. Reade and Peter D. Thomas

Key points

- Explosions in air wound by four mechanisms: pressure waves (1°), accelerating projectiles (2°), the direct and indirect effects of a mass movement of gas (3°), and miscellaneous effects such as burns and asphyxiation (4°). Most casualties surviving to hospital care will not have significant primary blast injury.
- Energy transfer and the nature of the affected tissue are the two most important factors determining the effect of projectiles. Dichotomizing causative firearms into 'low' and 'high' velocity reflects only a small part of the relevant information.
- Military bullets must (by international law) be jacketed in a hard metal to reduce 'unnecessary suffering', while hunting bullets often have soft tips that maximize energy transfer to kill quickly. Fragmentation of projectiles does not prove they were not fully jacketed.
- The extent of devitalisation caused by projectiles is difficult to determine at early inspection, so serial debridement over a number of days is usually a better approach than early extensive resection of potentially viable tissue. Not all high-energy wounds require extensive debridement.
- Ballistic wounds are usually heavily contaminated with micro-organisms. Antibiotic prophylaxis is indicated as soon as possible after wounding, ideally within 3 hours.

Introduction

'Ballistics' is the study of projectiles. Explosions wound by various mechanisms, but in common medical use 'ballistic trauma' (inaccurately) refers to both blast and projectile effects. Intentionally used, weapons cause '**wounds**' not '**injuries**', a distinction important to soldiers as the repercussions of battle versus accidental aetiology are profound. Failing to understand the pathophysiology of ballistic trauma can result in treatment, such as unnecessary extensive debridement, which is worse than the injury itself.

Blast trauma

Mechanisms

Explosions release energy as a pressure wave, gas, and heat. **High explosive** (e.g. trinitrotoluene) produces a supersonic pressure wave; **less powerful explosives** (e.g. black powder) produce a subsonic wave. The first force felt by an affected body is the static pressure wave (Fig. 339.1). There is no mass movement of gas, rather pressure increases rapidly then falls to below baseline. The pressure wave can spread around walls, and is reflected from hard surfaces, increasing the force felt by bodies in enclosed spaces. The second force felt by a body in air is the mass movement of gases liberated by the exploding substance—the 'blast wind'. **'Enhanced' blast weapons** produce a lower but more prolonged overpressure that extends further than conventional high explosive. An example is the fuel-air missile, which disperses then ignites a cloud of vaporized fuel.

Primary blast injury is a common cause of death due to blast [1], but is uncommon in survivors. If the casualty is close enough to suffer a primary blast injury, other blast effects are usually fatal. Explosions commonly wound by other mechanisms listed in Table 339.1.

Pathophysiology of primary blast injury

The immediate response to primary blast to the chest is transient vagally-mediated hypotension, bradycardia, and apnoea. More significant are shear forces caused by alternating positive and negative pressure, greatest at the interfaces of tissues of different densities—ears, lungs, and gastrointestinal tract. Low peak overpressure may cause tympanic membrane haemorrhage without rupture, while higher pressures can almost obliterate the membrane and dislocate the auditory ossicles. At least half of blast-perforated tympanic membranes heal spontaneously. Persistent high-frequency hearing loss occurs in around 30% of patients, but in one series only 5% required a hearing aid [2].

Partly due to the importance of head orientation at the time of the explosion, rupture of the tympanic membrane is not an effective screening sign for significant blast injury elsewhere. In a recent series, half the patients with significant primary blast injury to other organs had intact tympanic membranes [3].

The pathophysiology of primary blast lung injury was a matter of speculation as late as the Second World War [4]. Noting experiences from the 1914–1918 war, three possibilities were considered:

- Blast wind overdistending the alveoli.
- Negative pressure following overpressure causing alveolar collapse.
- The pressure wave on the chest wall causing pulmonary contusion.

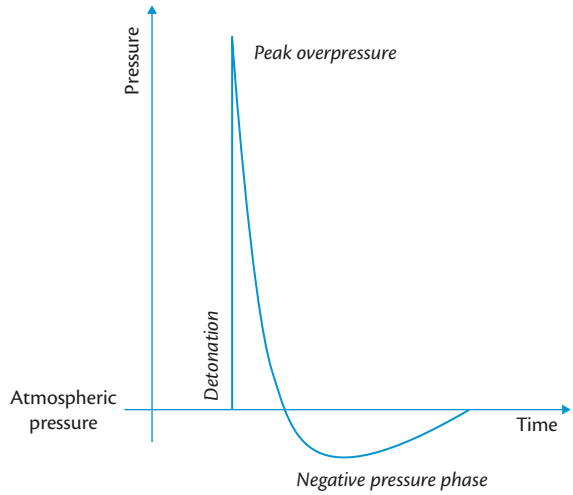

Fig. 339.1 The blast static pressure wave in air, described by the Friedlander equation.

Experiments showed the last of these was correct. The pressure wave shears the alveolar-capillary barrier, flooding alveoli with blood, fluid, and cellular debris. Hypoxaemia is usually apparent immediately, but can be delayed up to 72 hours. Arterial air emboli from alveolar-pulmonary venous communication cause most early deaths, and often result in neurological dysfunction and cardiac ischaemia in survivors. Pneumothorax, haemothorax, subcutaneous, and mediastinal emphysema are all possible (Fig. 339.2).

Table 339.1 Mechanisms of blast injury

Type of blast injury	Mechanism of injury	Wounds
Primary	Pressure wave	◆ Tympanic membrane rupture ◆ 'Blast lung' ◆ Rupture of hollow abdominal viscera ◆ Traumatic brain injury
Secondary	Penetrating trauma due to accelerated projectiles	Penetrating and blunt injury
Tertiary	Mass air movement ('blast wind'), injuring either directly or by interaction with the surroundings, e.g. collapse of buildings	◆ Blunt and penetrating injury ◆ Traumatic amputation* ◆ Traumatic brain injury ◆ Crush injury and entrapment
Quaternary	All other mechanisms, including burns, oxygen depletion, cyanide and carbon monoxide production, and inhaled dust	◆ Burns ◆ Inhalation of toxic gases ◆ Effects of ionizing radiation ◆ Asphyxiation

*Traumatic amputation is usually a combination of primary and tertiary effects. Primary blast trauma fractures long bones, the distal portion of which is then amputated by the blast wind. This explains why traumatic amputation due to blast is usually not through joints.

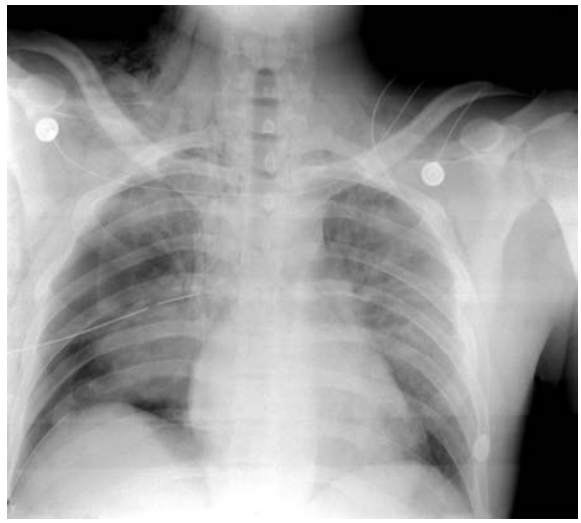

Fig. 339.2 Chest radiograph demonstrating bilateral opacity and pneumothorax due to blast injury.
Courtesy of the Australian Defence Force, Afghanistan, 2009.

Primary abdominal blast injury is uncommon, typically presenting late (after up to 14 days) with peritoneal irritation indicating visceral rupture. Multifocal bowel contusion, ischaemia, necrosis, and perforation may occur. The colon is the hollow viscus most commonly disrupted.

Blast waves can also cause traumatic brain injury (TBI). Intracranial haemorrhage or diffuse axonal injury can occur, but more common is mild traumatic brain injury, the pathological mechanism of which is unclear. Mild TBI shares many symptoms with post-traumatic stress disorder (PTSD), such as headache, insomnia, and mood changes, making diagnosis challenging [5]. Diffusion tensor MRI shows abnormalities in mild TBI, curiously poorly correlated with clinical signs [6].

Pathophysiology of secondary, tertiary, and quaternary blast injuries

Blast weapons can augment their effect by incorporating fragments. Fragments can be preformed projectiles (e.g. shrapnel and flechette), formed by casing fragmentation, or improvised using rocks, bolts, etc. Fragmentation multiplies many times the range and effect of smaller blast weapons such as grenades. Secondary blast injuries were more than three times more common than primary blast injuries during Operation Iraqi Freedom [7] and were the commonest cause of death. Survivors of blast fragmentation often have many low-velocity superficial wounds (Fig. 339.3). Around 10% will have eye injuries [8]. Urban explosions are particularly likely to cause secondary blast injury due to glass fragments energized from a bomb's surroundings.

Tertiary blast injuries mostly occur when the body is propelled against objects or crushed by structural collapse. This mechanism has the potential to kill the most victims. Quaternary injuries include respiratory compromise from inhaled pollutants (carbon monoxide, particulates, and toxic by-products of combustion such as cyanide) and airway burns, and external thermal burns from the superheated blast wind. Such effects are infrequently the major clinical problem in survivors.

Penetrating ballistic trauma

Wound ballistics

The most important considerations in wound ballistics are the amount of energy that is transferred from the projectile to the tissue, the function of that tissue, and its ability to tamponade haemorrhage. Energy transfer is determined by:

- **Kinetic energy (KE)**: mass and velocity.
- **Rotational energy**: usually negligible.
- **Projectile shape and impact angle**: determined by the distance travelled and any objects hit during flight. A bullet hitting side-on deposits more energy early than one hitting point-on.
- Projectile deformability.
- **Whether the projectile 'tumbles'** in tissue, determined by track length, shape, impact angle, and tissue density. Tumbling, a 180° rotation leaving the bullet lying base forward, occurs with all full metal jacketed bullets after a certain distance. A bullet exiting at the midpoint of this rotation will produce a large exit wound, but if rotation proceeds 180° the exit wound may be small. Exit wound size is therefore not an indicator of tissue damage.
- **Specific gravity of the tissue hit**: the higher the specific gravity (bone > muscle and liver > fat >> lung), the more energy transferred [9].

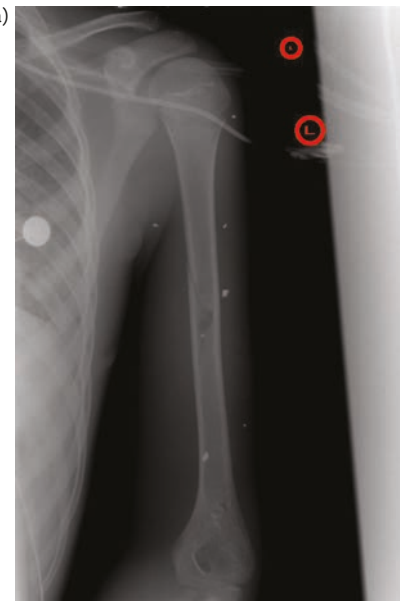
The terms 'high' and 'low' velocity firearms (demarcated at 1100–3000 ft/second) [10] are not as useful as 'power', incorporating mass, and even less useful than energy transfer. A high-powered rifle bullet will cause less tissue trauma if it misses bone and traverses a short muscle path than a 'low powered' pistol bullet that deposits all its kinetic energy after hitting bone. Notwithstanding, the kinetic energy of a rifle bullet is around 5–10 times that from a pistol. Hitting bone, a pistol bullet typically causes a simple fracture, while a rifle bullet causes extensive bone loss (Fig. 339.4).

Bullet deformability

Density preserves kinetic energy, so bullets are typically made of lead. Lead bullets melt at low velocities, necessitating 'jacketing' in a more resilient metal. Military bullets (according to Hague Convention of 1899) must have all but their base encased in hard metal (a 'full metal jacket'), which reduces bullet deformation in tissues and so causes less 'unnecessary suffering'. In contrast, hunting bullets are only partly jacketed, with a soft metal or polymer tip, increasing the chance of a quick, 'humane' kill. Police bullets can have a hollowed-out point, resulting in greater air drag and shorter range, but less probability of exiting the target and so harming bystanders.

Doctors are sometimes asked to comment on the type of bullet found in a patient. Even fully-jacketed bullets can deform and fragment. Indeed, many invariably will do so after a sufficient tissue

(a)



(b)

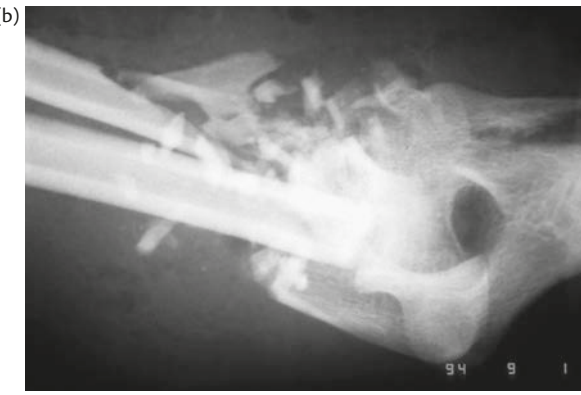


Fig. 339.4 Low and high energy transfer ballistic fractures. (a)The midshaft humeral fracture was the result of blast fragmentation, while (b) the fractures at the elbow were caused by a 7.62 mm high-energy AK47 bullet.

track. Finding no intact fully jacketed bullets does not allow this question to be answered.

Mechanisms of tissue damage

Bullets damage tissues by crushing/laceration, shock waves, and cavitation. Crushing and laceration are the principal mechanisms of injury due to 'low powered' firearms and blast fragmentation. Serious injury generally results only if vital structures are damaged. Tissue compression causes shock waves to propagate ahead of the bullet, which generally cause little damage but can rupture gas-filled organs [9] and possibly cause neurological injury. Cavitation results from tissue inertia imparted by a high-powered bullet. As tissues continue to move away from the bullet track, subatmospheric pressure sucks in debris. This 'temporary cavitation' produces an area of dead tissue around the wound track **up to** 30–40 times the bullet diameter (Fig. 339.5) [9,13]. Cavitation is dependent on the elasticity of the tissue, and damage is increased by shear forces if the cavity crosses a boundary between a mobile and immobile structure [11]. The much smaller residual permanent cavity is not a reliable indicator of the extent of devitalised tissue. Theoretical conceptualization of the size of the temporary cavity is rarely a useful guide to debridement [12]. The extent of tissue damage was traditionally identified using the 'four C's'—capillary bleeding, contractility, colour, and consistency. However, use of these criteria results in debridement of much potentially viable tissue, leading to recommendations for serial debridement only of clear necrosis [12].

While wound morphology varies with tissue type and energy deposited, the principal characteristics are shown in Fig. 339.6 [14]. Swelling of tissues affected by the temporary cavity can cause a compartment syndrome in limb wounds, particularly in the lower leg.

Retained fragments and lead poisoning

Bullets can become embedded in otherwise healthy tissue, where they do little damage. The exceptions are those that might erode vital structures such as major vessels, those that become a source of infection, and projectiles containing lead retained in joints (where they can cause arthropathy or systemic toxicity) or the subarachnoid space (potentially causing nerve damage or systemic toxicity).

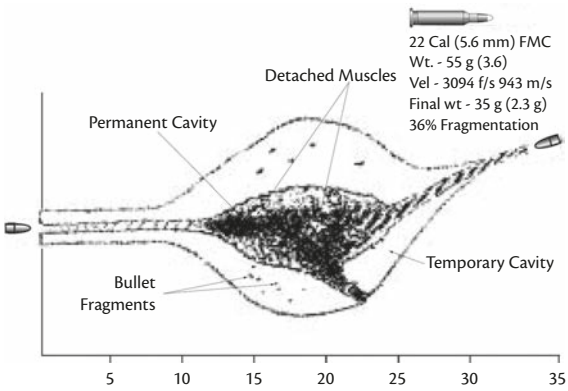

Fig. 339.5 Path of a M16 rifle bullet through tissue, showing bullet fragmentation, 180° tumbling, and permanent and temporary cavities. The exit wound may be no larger than the entrance wound.
Reproduced from *Emergency War Surgery*, Fourth United States Revision. Fort Sam Houston, Texas, USA. Borden Institute/Office of the Surgeon General; 2013.

Special cases

Landmines and improvised explosive devices

Buried or air-dropped landmines containing little metal are difficult to detect, so many omit fragmenting casings and wound mainly by blast, with penetrating injury only from local debris. Typically, such mines explode when stepped on, producing traumatic amputation through the midfoot or distal tibia. 'Bounding' landmines use two charges—one to propel a tethered canister upwards and a second, larger explosive to project fragments up to 100 m. The person stepping on them is usually killed, with bystanders suffering blast fragmentation.

Incendiaries (napalm, white phosphorous)

White phosphorus and napalm are incendiaries, and white phosphorus is also used to create smokescreens. However, both inflict severe wounds. Napalm is an adherent gel that produces full thickness burns involving muscle. A 10% burn typically causes rhabdomyolysis. White phosphorus ignites on air contact, so debridement requires keeping the wound moist. Systemically-absorbed white phosphorus causes hypocalcaemia and hyperphosphataemia.

Behind armour blunt trauma

Rifle bullets can be stopped by body armour but still kill by transmission of a force wave. The immediate effects of behind armour blunt trauma (BABT) are vagally-mediated apnoea and hypotension, accompanied by pulmonary and myocardial contusion, rib fractures, haemothorax, and pneumothorax. The commonest military bullet calibre, 5.56 mm, has negligible BABT potential, but larger calibres carry substantial risk. Body armour provides negligible protection against primary blast.

Infection in ballistic injury

Military wounds are particularly prone to infection. Typically, 3–6 different bacterial species are isolated from infected combat wounds, compared to single organisms in a civilian setting [15]. Bullets are not sterilized by firing, but this is clinically insignificant. Temporary cavitation sucks contaminated debris deep into devitalized tissue. The major infecting organisms are β-haemolytic streptococci and *Clostridia*, both effectively treated by penicillin. Contamination by soil is a particular feature of landmine wounds, and is associated with infection with other, more resistant organisms. Some modern military protocols recommend broader spectrum antibiotics, but the possible association of this strategy with invasive mould infection [16] is not yet understood.

Expected patterns of ballistic injury

Landmines caused over half the casualties in the Balkan wars, but less than 5% in the Vietnam War. IEDs have been the predominant weapon in the recent Afghanistan conflict. Mechanism affects

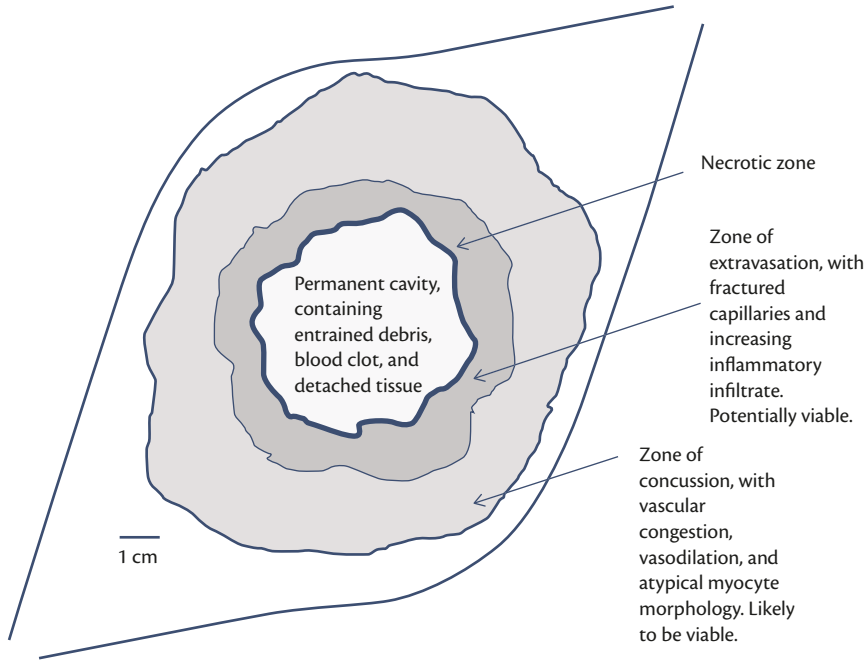

Fig. 339.6 Typical characteristics of a high-energy bullet wound cross-section in skeletal muscle.
Data from Garner J, 'Pathophysiology of ballistic wounding'. In: Smith J et al., (eds) *Oxford Desk Reference: Major Trauma*. Oxford: Oxford University Press; 2011. pp. 408–26.

case fatality rate—bullets (on average) kill 30–40%, artillery shells around 20%, and grenades around 10% of those wounded. The average lethality of combat wounds over the last century is around 25%, compared with more than 75% when weapons are used in a civilian context [17]. Civilian shootings tend to occur at close range to victims who cannot escape. Higher than expected case fatality raises the suspicion of executions, rather than battlefield deaths. Most patients killed by ballistic trauma die within 5 minutes of wounding, due to brain injury or exsanguination. Few have wounds amenable to treatment. Of potentially preventable deaths, 60% are due to limb haemorrhage, a third to tension pneumothorax, and 6% from airway obstruction [18].

Conclusion

Application of detailed epidemiological analysis to the 2001 wars in Iraq and Afghanistan has transformed military trauma care into a field based on data, with therapy guided by observational and trial evidence. Previous wars left legacies as diverse as penicillin, blood banking, and plastic surgery; the epidemiological approach to ballistic trauma will be that of early twenty-first century conflict.

CHAPTER 340

Assessment and management of ballistic trauma

Timothy Hooper and David Lockey

Key points

- Prehospital care of trauma patients should include immediate life-saving interventions and rapid transfer to an appropriate hospital.
- Careful clinical assessment and CT scanning guides initial management.
- Life-saving interventions should not be delayed by unnecessary investigations.
- Treat the wound and not the weapon.
- Damage control resuscitation and surgery should be considered in unstable and critically unwell patients.

Introduction

Ballistic trauma refers to the wounds sustained from the discharge of arms or munitions, most commonly firearms, as a result of armed conflicts, crime, hunting, or attempted suicide.

Access to firearms varies substantially by country. The USA has an estimated 270 million civilian firearms (88.8 per 100 population) compared with 25 million in Germany (30.3 per 100 population), 3.4 million in England and Wales (6.2 per 100 population), and 3.05 million in Australia (15 per 100 population) [1]. Although strong associations between firearm availability and homicide rates have been demonstrated [2], other factors, particularly socioeconomic are influential. This is evident in Honduras, which has the world's highest homicide rate (68 deaths per 100,000 population) despite only having 6.2 firearms per 100 population [3].

Nearly seventy per cent of homicides in the USA result from firearm use (approximately 11000 firearm-related homicides in 2013) [4]. Of the 526 homicides in England and Wales during the year 2013/14 only 29 (6%) resulted from the use of firearms [5].

Ballistic injury severity depends on multiple factors including:

- Bullet type (mass, shape, deformation, and fragmentation tendency).
- Velocity.
- Whether it has passed through objects prior to entering the body (clothing, body armour).
- Tissue type penetrated.
- Energy transfer; dependent on the bullet's path through the body, mass, velocity, and yaw (deviation of the long axis from its line of flight).

Tissue damage is caused by two mechanisms. First, the direct crushing effect of the bullet as it passes through tissues (permanent cavity) and, secondly, the displacement of surrounding tissue by the pressure wave (temporary cavity). The type of tissue through which the bullet passes also influences the degree of damage caused. Elastic tissues, such as skeletal muscle and lung, suffer little damage from temporary cavitation whereas inelastic tissues, such as liver and spleen, can sustain significant disruption [6]. Of note, shotgun injuries result in mortality rates nearly twice that of other firearms due to the destructive nature of the shot, especially at short range.

Although knowledge of ballistic science can help medical staff understand the wounds sustained, information from the patient or bystanders about the weapon used and the situation surrounding wounding is often unreliable. Furthermore, entry and exit wound characteristics, although important, do not necessarily give insight into the degree of underlying tissue damage. Management of ballistic trauma patients therefore needs a considered, objective approach with careful assessment, appropriate imaging, and directed treatment of the wounds found, rather than those suspected—Dr Douglas Lindsey's quote from 1980 of 'treating the wound, not the weapon' [7] still holds true.

Prehospital care

Only time-critical life-saving interventions, most often related to the control of bleeding, should be carried out at the scene of the injury. Most patients with penetrating trauma should to be transported to an appropriate hospital as rapidly as possible.

Triage, treatment, and transport form the framework of effective prehospital care and this is particularly important where there are multiple casualties. Triage to prioritize the most severely-injured and treatment of individual patients using ATLS™ (Advanced Trauma Life Support) principles should be carried out prior to and during transport.

Emergency department

The emergency department (ED) may receive little warning of the arrival of a gunshot victim, particularly when the patient is conveyed to hospital by private transport. On arrival in the ED the patient should have a rapid primary survey performed using an 'airway, breathing, circulation' approach to reveal any injuries that need immediate intervention.

Clothing should be removed to fully expose the patient and evaluate wounds, while aiming to maintain body temperature.

To preserve forensic evidence bullets or fragments should be collected and wound characteristics carefully documented. Particular attention should be paid to the axilla, perineum, and scalp, as wounds can be missed in these areas. Cutting through bullet holes in clothing should be avoided. While entry wounds (Fig. 340.1a.) are normally round to oval in shape with a punched out clean appearance, exit wounds vary considerably (Fig. 340.1b.). Although generally larger and more irregular than entry wounds, due to deformation and yawing of the bullet in the body, they may be of similar size if little energy has been lost along the bullet's path. Occasionally, entry wounds may be larger if the bullet has deformed or fragmented prior to impact with the body [8]. To this end, documenting wounds as 'entry' and 'exit' should be avoided.

Emergency interventions are common to other trauma patients:

- Injuries to head and neck may need urgent intubation to protect and secure the airway.
- Insertion of one or more chest drains may be indicated to treat pneumothoraces or haemothoraces.
- Haemorrhagic shock can be associated with injuries to any body region, but particularly the abdomen and chest, and may need significant blood product transfusion to correct hypovolaemia [9].

Tetanus prophylaxis should be administered using tetanus toxoid if the patient does not have adequate protection with the addition of human tetanus immunoglobulin in patients not previously immunized or with uncertain immunization history [8].

The belief that bullets are sterilized by the heat of firing is false [10]. However, there is ongoing debate about the use of prophylactic antibiotics for ballistic injuries. Approximately 2% of minor gunshot wounds become infected and this is not necessarily reduced by prophylactic antibiotics. Prophylaxis should be considered if there are multiple injuries, gross wound contamination, significant tissue devitalization, large wounds or a delay in treatment [11].

Broad-spectrum intravenous antibiotics are indicated for penetrating abdominal, cranial, and thoracic injuries, and injuries where there is significant tissue damage (including shotgun wounds) [12,13]. Duration of antibiotic treatment varies according to injury. A single pre-operative dose may be adequate for

Fig. 340.1. High velocity entry (a), and exit (b) wounds. The entry wound is a neat punched out oval with surrounding bruising, while the multiple exit wounds are due to bullet fragmentation, which can be seen on the chest X-ray (c), and bony fragments from the underlying fractured scapula, as seen on the CT reconstruction (d).

penetrating abdominal injuries without hollow viscus damage. High-velocity, shotgun, and intra-articular gunshot fractures may be adequately treated by 2 days of an intravenous first generation cephalosporin, with the addition of penicillin if grossly contaminated, and gentamicin in the presence of significant tissue damage [12]. Many protocols advocate up to 2 weeks of broad spectrum antibiotics where there is gross contamination of the wound (e.g. from bowel contents or soiled clothing), although there is little evidence of benefit beyond 24 hours [13].

Investigations

Bullets and fragments may be identified with plain radiography (Fig. 340.1c.). Both anteroposterior and lateral radiographs help localize fragments and skin wound markers can be useful to estimate the trajectory of projectiles. Other injuries, such as pneumothoraces, haemothoraces, and fractures can also be identified.

Performing an extended focused assessment with sonography for trauma (eFAST) examination allows rapid, bedside evaluation of the lungs, pericardium and peritoneum. In the presence of penetrating abdominal trauma, a positive FAST is highly predictive of intraperitoneal injury (sensitivity 46% and specificity 94% in one study) [14] and occult pneumothoraces are more likely to be detected with ultrasound than with chest X-ray alone [15].

Computed tomography (CT) is considered to be the gold standard for imaging projectiles, including those that are not radio-opaque (Fig. 340.1d.). Imaging can define the bullet tract, injuries sustained, and extent of tissue damage, helping to guide further management. CT angiography can provide additional information about vascular injuries. Modern helical scanners are fast, but some unstable patients may require transfer to the operating theatre for surgery without imaging.

Surgery

The decision to operate and nature of surgery is determined by the patient's suspected injuries, physiological condition, and the surgical expertise available [8,9]. Bullet and fragment removal and debridement of wound tracts in penetrating head and spinal injuries is becoming less common. However, dural leaks should be closed to prevent secondary infections and insertion of intracranial pressure monitors can aid intensive care management. Thoracic injuries can usually be treated by the insertion of pleural drains, while thoracotomies are reserved for patients with cardiac tamponade, high output from existing pleural drains, or cardiovascular instability. Diaphragmatic injury occurs in approximately 50% of patients, and the co-existence of thoracic and abdominal injuries is reported to be between 6 and 42%. Abdominal injuries may be treated conservatively if imaging suggests there is no intra-abdominal pathology. However, an exploratory laparotomy is usually required for patients who are haemodynamically unstable, have peritonitis or have bowel evisceration. Laparoscopy is an alternative approach, although a proportion will proceed to laparotomy.

Management of soft tissue injury depends on the degree of tissue damage and contamination. Wounds with minimal tissue damage, frequently caused by low-velocity hand guns with low-energy transfer may only require superficial debridement, irrigation, and be left open to heal by secondary intention. Wounds with extensive tissue damage (from high-velocity bullets or close range shotgun wounds) need aggressive and repeated surgery, typically every 48–72 hours, to assess need for further debridement of devitalized tissue (Fig. 340.2). The degree of debridement needs careful consideration as studies have suggested that overzealous debridement of potentially healthy tissue can cause greater disability to the patient than the initial gunshot wound [16].

Fractures caused by low-energy gunshot injuries have similar characteristics to closed fractures and can often be managed in the same way. Some will be amenable to non-operative management, while others will require operative intervention, especially if unstable. By contrast, high-energy gunshot fractures are frequently severely comminuted with devitalized fragments and extensive surrounding tissue damage. Due to the risk of infection and compartment syndrome, external fixation, often with fasciotomies, is commonly required.

Damage control resuscitation

Damage control resuscitation (DCR) is a systematic approach to major trauma that aims to minimize blood loss, maximize tissue oxygenation and optimize outcome from point-of-wounding to definitive treatment. Damage control surgery is part of this and consists of an initial time-limited operation to save life, a period of haemostatic resuscitation on the intensive care unit (ICU), then further definitive surgery. Patients with ballistic injury may benefit from this approach.

During DCR, haemostatic resuscitation seeks to address the lethal triad of hypothermia, acidosis, and coagulopathy while tolerating a short period of moderate hypotension until surgical control is achieved. This approach is different to standard resuscitation methods that are suitable for the 90% of trauma patients who are not shocked or coagulopathic on admission to hospital [17].

Recent trauma transfusion strategies have developed to mimic the delivery of whole blood using packed red blood cells, and high ratios of plasma and platelets [18]. The early use of empirical blood component therapy is likely to become standard practice in shocked trauma patients although the optimal ratio of blood products is still unclear. The use of laboratory tests and point-of-care dynamic clot assessment (thromboelastometry) to target appropriate administration of blood products and other factors, especially fibrinogen, is also gaining favour.

Fig. 340.2 Second-look surgery after initial debridement and washout of a high velocity gunshot wound through soft tissues of the shoulder.

Intensive care

Indications for admission to intensive care are standard and include the need for on-going organ support, cardiovascular instability and injuries that require close observation or have the potential for rapid deterioration.

The ICU management of patients with ballistic trauma is generally supportive and common to that of other trauma patients. Particular attention should be paid to cardiovascular status, coagulation, nutrition, thromboprophylaxis, infection, and the management of specific injuries.

Antibiotic therapy should be driven by wound cultures and local microbiology protocols. Infective organisms are likely to be from skin commensals, clothing, and other contaminants. Clostridial infections may occur, potentially causing severe myonecrosis (*C. perfringens*) and rarely botulism (*C. botulinum*). These have been more commonly associated with older or homemade shotgun ammunition, where animal fibres and other substances are used as wadding [8]. Botulism should be considered in at-risk patients with an unexplained bulbar palsy and descending motor weakness.

Patients often require surgery for wound inspection, further debridement, and definitive surgery on multiple occasions. Communication with the multidisciplinary team, including transfusion services, is vital for effective planning. Compartment syndrome should be considered and actively excluded in all limb injuries where there are comminuted fractures and tissue damage, even if fascitomies have been performed.

Lead and copper poisoning can occur due to retained bullet fragments. Although lead fragments in soft tissue usually become encapsulated with fibrous tissue and cause few problems, those in intra-articular, disc space and bursal locations can cause systematic effects [19]. This usually takes years to develop, but can occasionally be rapid. Treatment is based on chelating agents and fragment removal. Lead, copper, and nickel can also cause local inflammation and necrosis, leading to arthritis if joints are involved.

Rehabilitation

Gunshot wounds may require protracted hospital stays and extensive reconstructive surgery. Chronic pain, permanent disability, and post-traumatic stress disorder are common, especially where injuries affect the brain, spinal cord, or peripheral nerves. The psychological and social impact of these injuries should not be underestimated, and rehabilitation may be harder with the demographic skew of patients from lower socioeconomic groups. Timely and comprehensive rehabilitation makes successful functional recovery and social reintegration more likely [20].

PART 16.3

Traumatic brain injury

CHAPTER 341

Epidemiology and pathophysiology of traumatic brain injury

Imoigele Aisiku and Claudia S. Robertson

Key points

- Traumatic brain injury (TBI) is a devastating injury that causes a huge burden of disease around the world; approximately 1.6 million people suffer a TBI in the USA each year.
- TBI is a bimodal disease that affects young adults (15–34), the elderly (>75), and males more than females.
- Mechanism of injury, age, gender, and initial severity of injury are the most significant predictors of mortality.
- Harm from TBI arises from direct damage to the brain at the time of the initial injury (primary injury), which places the brain at risk of further harm from secondary injury.
- Secondary injury may occur due to intracranial hypertension, hypotension, hypoxia, reduced cerebral perfusion, and inflammation.

Introduction

Current estimates suggest that traumatic brain injury (TBI) will surpass many diseases as the major cause of death and disability by the year 2020. The burden of disease due to TBI is evident throughout the world, and is especially prominent in low and middle income countries. Latin America and Sub Saharan Africa have a particularly high incidence of TBI—varying from 150–200 per 100,000 respectively [1,2]. Detailed data on the incidence and impact of TBI are available for the USA, where someone sustains a traumatic brain injury every 15 seconds resulting in 1,500,000 new cases of brain injury each year. Of these patients, over 260,000 (17%) will be hospitalized, of who more than 50,000 will die, and 80,000 will survive with permanent disability [3]. The risk of brain injury is highest among adolescents, young adults, and those older than 75 years, and the risk for males is twice that for females. An estimated 5.3 million persons, slightly more than 2% of the United States populations, currently live with disabilities resulting from traumatic brain injury. The immediate medical costs for these patients are estimated to be $48.3 billion annually, with hospitalization accounting for $31.7 billion, and fatal injuries costing $16.6 billion each year [4,5]. Survivors with functional disabilities, such as changes in language, thinking, emotion, and behaviour are also major contributors to the costs of TBI.

Classification of traumatic brain injury

TBI begins with high-energy acceleration or deceleration of the brain within the cranium or with a penetrating injury to the brain. Classically, TBI has been divided into two different periods, representing primary and secondary injury. The demarcation between these two periods is somewhat arbitrary as primary and secondary injury represents more a continuum of injury. TBI can also be classified by severity with the most commonly used severity grading scale being the Glasgow Coma Score (GCS) Scale. The GCS which stratifies TBI as mild, moderate or severe Scale. TBI can also be classified by type of radiographic injury as focal or diffuse (Figs 341.1 and 341.2) [6,7]. Focal injuries tend to occur at the site of impact, with focal neurological deficits referable to those areas. The orbitofrontal and anterior temporal lobes are characteristic sites of injury. Diffuse injuries are a combination of linear translational and rotational forces, which when combined produce angular acceleration or deceleration injuries resulting in straining, shearing, and compression of brain tissue. The effects of these injuries are maximal on axonal projections and small blood vessels within and around the brain stem, the parasagittal white matter of the cerebrum, the corpus callosum, and the gray–white matter junctions in the ventral and anterior frontal and temporal lobes [8]. These injuries are

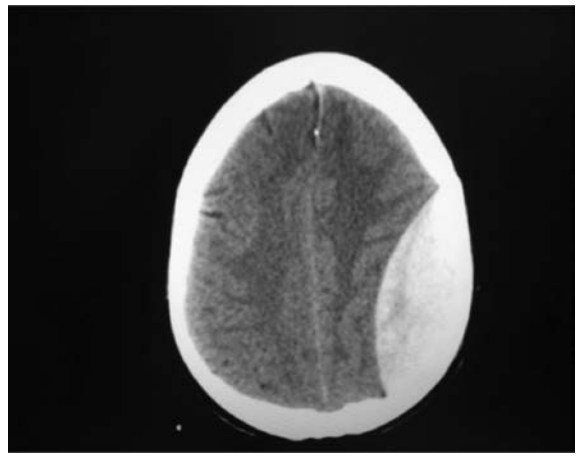

Fig. 341.1 Focal lesion (epidural haematoma).

Fig. 341.2 Diffuse lesion.

often referred to as diffuse axonal injuries or multifocal injuries [9]. Diffuse axonal injury is the predominant mechanism of injury in 40–50% of traumatic brain injuries and often believed to be a component in most presentations of non-penetrating injury [9].

Risk factors for poor outcome

Various risk factors are associated with poor outcome following TBI. These include mechanism of injury (penetrating versus blunt), age, gender, genetic factors, and the occurrence of secondary insults, such as hypotension and hypoxia. Physical findings with prognostic significance include the Glasgow Coma Score (GCS) and pupillary reactions to light. Approximately 20–30% of patients who present with a GCS of 8 or less have bilaterally fixed and dilated pupils; 70–90% of these patients will have a poor outcome. The GCS has been a widely used tool for over 40 years and has been well validated for its prognostic utility (Table 341.1). The GCS, however, does not provide any information on the type of intracranial injury and the need for surgical versus medical management. CT findings provide additional information. While various grading systems have been developed, the Marshall classification is arguably the most often used or quoted [10]. (Table 341.2)

Pathophysiology

Cellular pathophysiology

Pathophysiological processes initiated by TBI are complex, and can be divided into those due to the primary and secondary injuries. The primary injury is a direct result of the original insult. Depending on the severity of the insult, the primary injury can result in immediate physical damage to neuronal and glial cells, glial endfeet, axonal and dendritic projections, and synapses, as well as to the cells making up the cerebral vasculature. This damage can result in focal or multifocal contusions, diffuse axonal injury, and/or haematoma formation [11]. Primary pathologies develop extremely rapidly and are not therefore amenable to therapeutic interventions other than prevention. In addition to causing immediate physical damage to the brain, the primary injury sets in motion molecular, cellular, genomic, and metabolic alterations that result in secondary injury. Secondary injury includes physical disruption of cell membranes and infrastructure, disturbances of ionic homeostasis secondary to increased membrane permeability and a cascade of neurotoxic events mediated by intracellular calcium. Secondary brain injury occurs minutes, hours, or days after the primary injury as a result of pathophysiological events, also called secondary insults [12]. These secondary pathological processes may be of intracranial or systemic origin. Intracranial secondary insults include intracranial hypertension or elevated intracranial pressure (ICP), cerebral oedema (fluid-mediated swelling), and cerebral ischaemia. Systemic events include systemic arterial hypotension, hypoxaemia and hyperthermia. In severe TBI, secondary events include changes in cerebral blood flow, local and systemic inflammation, alterations in oxygen delivery and metabolism, and both ischaemic and apoptotic death of neural cells [13]. Intravascular coagulation is common in severe TBI and in addition to causing local ischaemia may also lead to a systemic consumptive coagulopathy [14]. A majority of secondary insults contribute to ischaemia and are associated with poorer outcome [15,16]. Secondary insults occur frequently, despite current intensive care management [17], and their effect may be particularly detrimental when adaptive responses that normally act to maintain cerebral perfusion are impaired. Since secondary insults evolve over time they are at least potentially preventable [18]. A large percentage of patients suffering from severe TBI (GCS < 8) manifest elevated ICP and decreased cerebral blood flow (CBF) that are significantly associated with increased morbidity and mortality.

Intracranial pressure and cerebral autoregulation

Elevated ICP is a key secondary event that is associated with increased morbidity and mortality. One of the primary considerations of clinicians caring for patients with TBI is controlling elevated ICP. A sustained increase in ICP to greater than 20 mmHg has been linked to increased morbidity and mortality, whereas monitoring and treatment of elevated ICP have been associated

Table 341.1 Glasgow Coma Scale

	Score					
	1	2	3	4	5	6
Eye opening	No response	To painful stimuli	On spoken command	Spontaneous		
Motor responses	No response	Extensor posturing	Abnormal flexion	Normal flexion	Localizing response	Obeys commands
Verbal responses	No response	Incomprehensible speech	Inappropriate speech	Confused conversation	Orientated

Table 341.2 Marshall classification

Category	Description
Diffuse injury I (no visible pathology)	No visible intracranial pathology seen on CT scan
Diffuse injury II	Cisterns are present with midline shift 0–5 mm and/or lesion densities present. No high- or mixed-density lesion >25 mL, may include bone fragments and foreign bodies
Diffuse injury III	Cisterns compressed or absent with mid-line shift 0–5 mm. No high- or mixed-density lesion >25 mL
Diffuse injury IV	Mid-line shift >5 mm. No high- or mixed-density lesion >25 mL
Evacuated mass lesion	Any lesion surgically evacuated
Non-evacuated mass lesion	High- or mixed-density lesion > 25 mL, not surgically evacuated

with improved outcomes [19]. Elevated ICP can lead to further brain damage by causing tissue herniation and cerebral hypoperfusion. If severe, hypoperfusion can reduce blood flow to the extent that it is insufficient to meet the tissue's metabolic needs, it will then cause ischaemia, additional brain damage, and ultimately death.

Cerebral autoregulation

Cerebral autoregulation is an adaptive mechanism that maintains a relatively constant blood flow to the brain despite changes in systemic arterial blood pressure. Therefore, cerebral autoregulation is one of the major mechanisms responsible for brain protection when cerebral perfusion pressure (CPP) is unstable. Cerebral autoregulation is impaired in up to 90% of patients following severe TBI and may be one of the mechanisms rendering the brain more vulnerable to potentially preventable secondary ischaemic injury. Autoregulation is often impaired from early following TBI and may remain impaired for 3 weeks or longer after the original injury.

Pro-inflammatory and cellular injury biomarkers

Inflammatory responses to TBI, both local and systemic, are complex. Invading cells from the blood (e.g. leukocytes, monocytes, macrophages) and/or activated resident cells (e.g. microglia) release a number of inflammatory molecules and free radicals that can contribute to brain oedema and worsen neurological outcome. Increased serum and/or CSF concentrations of pro- and anti-inflammatory cytokines, chemokines, and acute phase reactant proteins have been observed following TBI. The role of inflammation in determining the progression of TBI-associated pathologies has been the focus of numerous studies. More recently, the expressions of these factors has been appreciated as potential markers of injury, and studies are ongoing to test if their levels correlate with outcome or can serve as surrogate markers of treatment efficacy. For example, glial fibrillary acidic protein (GFAP) is a monomeric intermediate filament protein expressed by astrocytes. It is a brain-specific protein that is released after TBI. Increases in serum GFAP levels after TBI have been shown to be predictive of elevated ICP, reduced mean arterial pressure (MAP), low CPP, poor Glasgow Outcome Scores (GOS), and increased mortality.

Cerebral oxygenation

Maintaining adequate cerebral oxygenation is considered a key objective in optimizing recovery after TBI. There currently exist three methods for monitoring cerebral oxygenation. Brain tissue oxygenation ($PbtO_2$) monitoring, jugular venous saturation ($SjvO_2$) monitoring, and near infrared spectroscopy. Brain tissue oxygenation is the most widely used. $PbtO_2$ can be monitored continuously and requires the placement of an intracranial catheter. Some controversy exists as to whether placement in damaged versus undamaged regions of the brain is the optimal placement. Brain hypoxia as measured by $PbtO_2$ of less than 10 mmHg for more than 15 minutes is an independent predictor of worse outcome and mortality. Although $PbtO_2$ less10 mmHg is associated with poor outcomes, most clinical practice parameters target $PbtO_2$ 15–20 mmHg for treatment goals. A meta-analysis of four studies comparing an ICP/CPP-based algorithm to a combined $PbtO_2$/ICP/CPP algorithm suggested improved outcomes in the $PbtO_2$ treatment group. Jugular venous saturation monitoring has been in use for over 20 years and values of less than 55% suggest increased oxygen extraction relative to perfusion indicating brain ischaemia. Increased $SjvO_2$ values most likely reflect hyperaemic states. The value of $SjvO_2$ monitoring in the absence of an ICP monitor and CPP measurements is limited. Currently, there is significant controversy over the ideal patient and situation in which to use cerebral oxygenation monitors, but these tools provide insight to the mechanisms of secondary injury in TBI and additional information to aid clinical decision making.

Conclusion

TBI remains a major cause of death and disability around the world. It affects many people with significant productive years ahead of them and results in major economic burdens. The pathophysiology is complex and the varying degrees of secondary insults make the care of patients with TBI particularly challenging. Hopefully improved diagnostic and neuroprotective mechanisms will lead to improvements in mortality and neurocognitive outcomes. The principal goal of neurological critical care is to intervene in time to prevent, detect and treat secondary injury mechanisms described previously [13].

CHAPTER 342

Assessment of traumatic brain injury

Peter J. D. Andrews and Jonathan K. J. Rhodes

Key points

- Traumatic brain injury is a common clinical problem and the resulting burden of disease is expected to increase substantially, particularly in the developing countries, in the next 10 years.
- Early assessment is based on a careful history, clinical assessment, and neurological imaging—usually a CT scan of the brain.
- An immediate CT scan of brain should be obtained in any adult patient at risk of harbouring intracranial pathology.
- In adult patients who have a Glasgow Coma Scale score below 15 and indications for a brain CT scan, the scan should include the cervical spine by scanning from the base of skull to T4.
- Establishing a reliable prognosis early after injury is notoriously difficult, but recent predictive models are readily accessible to clinicians via a web-based calculator to aid early clinical decision making and to allow better informed discussions with patients' families.

Introduction

Traumatic brain injury (TBI) is a major cause of death and disability throughout the world. The epidemiology of traumatic brain injury (TBI) is difficult to describe accurately due to inconsistencies in the definition and classification of the condition, but it is estimated that the annual incidence in the United States is been between 180 and 250 per 100,000 population per year [1]. TBI is the cause of one-third to one-half of all trauma deaths, and the leading cause of disability in people under 40, severely disabling 15–20 people per 100,000 population per year [2]. Injuries are projected to account for 20% of the worldwide burden of death and disability by 2020 [3].

Research into new therapies for TBI has been disappointing. More than 23 multicentre clinical trials have been conducted since 1985, none of which has produced an effective treatment for TBI. Clinical trials into TBI provide significant challenges; trauma is a neglected research topic worldwide, consent in unconscious patients requires careful ethical consideration, and traumatic brain injuries have very heterogeneous mechanisms and pathologies [4].

Assessment of traumatic brain injury

The heterogeneity of traumatic brain injury (TBI) is considered one of the principal barriers to finding effective treatments. Considerable international research effort has gone into outlining the steps needed to develop a reliable, efficient and convincing classification system for TBI that could be used to link specific patterns of brain and neurovascular injury with appropriate therapeutic interventions.

Currently, the Glasgow Coma Scale (GCS-Table 342.1) is the primary criterion for the clinical classification of patients with TBI. It has high inter-observer reliability and generally good clinimetric and prognostic capabilities [5]. The GCS is obtained by eliciting the best response in three domains—eye opening, verbal response, and motor response. The score ranges from 3 to 15 with lower scores indicating more severe injury or deeper coma. Mild injury is defined as GCS score 15–13, moderate by GCS score 12–9 and severe by GCS score <9. A meta-analysis found that decreased GCS was a strong predictor of intracranial injury in adults with a minor head injury (relative risk, 5.58) [6].

While the GCS is extremely useful in the clinical management and prognosis of TBI, it does not provide specific information about the pathophysiology and mechanisms that are responsible for neurological deficits, and might be targeted by available and novel interventions. Due to the limitations of the GCS the development of a new, multidimensional classification system for use in clinical trials of patients with TBI has been proposed, although no such system is yet agreed and this remains a vision for the future.

Prehospital assessment

A large number of variables have been identified as elevating risk of deterioration or adverse outcomes after TBI (Box 342.1).

Prehospital assessment includes not only the probable severity of injury assessed using the GCS score and the mechanism of injury, but also the likelihood of adverse outcome from modifiable factors, such as hypotension, hypercarbia, and hypoxaemia.

Assessment in the emergency department

A detailed review of all aspects of assessment of patients with TBI in the emergency department (ED) is not within the scope of this chapter. Evidence-based guidelines approve the principles of advanced trauma life support (ATLS), the systematic,

Table 342.1 The Glasgow Coma scale (derived by adding the score for the best response in each of the three categories eye opening, verbal response, and motor response)

Response	Best response recorded	Score
Best eye opening response	**Select one option:**	1
	◆ Does not open eyes	2
	◆ To painful stimuli	3
	◆ In response to voice	4
	◆ Spontaneously	
Best verbal response	◆ Makes no sounds	1
	◆ Incomprehensible sounds	2
	◆ Utters inappropriate words	3
	◆ Confused, disorientated	4
	◆ Orientated, converses normally	5
Best motor response	◆ Makes no movements	1
	◆ Extension to painful stimuli	2
	◆ Abnormal flexion to painful stimuli	3
	◆ Flexion/withdrawal to painful stimuli	4
	◆ Localizes painful stimuli	5
	◆ Obeys commands	6

internationally accepted approach for assessment and resuscitation of trauma patients developed by the American College of Surgeons Committee on Trauma.

On arrival in the ED a patient with a TBI should have their GCS reassessed if possible, patients who have a symptomatic TBI or who cannot be assessed clinically are likely to need a CT scan once stabilized. In the past, the approach to management of TBI was often observation and repeated examination, and only taking urgent action following the detection of neurological deterioration, this approach has been superseded by pre-emptive investigation to detect lesions before they lead to neurological deterioration. The main focus of ED assessment should be assessing the risk of clinically important brain injuries, injuries to the cervical spine, and the need for imaging. Attention should also be paid to co-existing injuries and to other concerns (for example, non-accidental injury and a possible non-traumatic aetiology, such as intracerebral haemorrhage). Early imaging, rather than admission and observation for neurological deterioration, reduces the time to detection for life-threatening complications and is associated with better outcomes.

- Previous cranial neurosurgery.

Imaging

The current primary investigation for the detection of acute clinically important brain injuries is CT imaging of the brain. This is based on level one evidence and is considered to be a grade A recommendation in many evidence-based guidelines.

For safety, logistic and resource reasons, magnetic resonance imaging (MRI) scanning is not currently indicated as the primary investigation in patients who have sustained a traumatic brain injury, although it is recognized that additional information of importance to the patient's prognosis can often be detected by MRI. Importantly, MRI is contraindicated in both head and cervical spine investigations, unless there is absolute certainty that the patient does not have an incompatible device, implant, or foreign body, the exclusion of which often necessitates a CT scan of head/brain.

Four studies have sought to develop 'decision rules' for selecting patients for CT imaging by identifying patients at a high risk for traumatic brain injury (usually intracerebral haemorrhage or haemorrhagic contusion). The Canadian CT-rules and the 'New Orleans' criteria are considered the most clinically relevant [7,8]. Two versions of the Canadian rules are available, a 5-point version designed

Box 342.2 Risk factors that indicate CT scanning of the head be requested immediately

- GCS less than 13 on initial assessment in the ED.
- GCS less than 15 at 2 hours after the injury on assessment in the ED.
- Suspected open or depressed skull fracture.
- Any sign of basal skull fracture (haemotympanum, 'panda' eyes, cerebrospinal fluid leakage from the ear or nose, Battle's sign).
- Post-traumatic seizure.
- Focal neurological deficit.
- More than one episode of vomiting.
- Amnesia for events more than 30 minutes before impact.
- CT should also be requested immediately in patients with any of the following risk factors, provided they have experienced some loss of consciousness or amnesia since the injury:
  - Age 65 years or older.
  - Coagulopathy (history of bleeding, clotting disorder, current treatment with warfarin).
  - Dangerous mechanism of injury (a pedestrian or cyclist struck by a motor vehicle, an occupant ejected from a motor vehicle or a fall from a height of greater than 1 m or five stairs).

to detect 'need for neurological intervention', and a seven point version designed to detect 'clinically important brain injury'. The latter outcome is more clinically relevant and is therefore recommended. However, it is acknowledged that the 5-point rule has some benefit in determining the urgency with which CT imaging should be obtained.

The Canadian derivation sample was much larger than the New Orleans sample with 3121 and 520 patients, respectively, and 909 patients in the New Orleans validation phase. Marion Smits et al., have published an external validation of the Canadian CT Head Rule (CCHR) and the New Orleans Criteria (NOC) for CT scanning of patients with minor head injury [9]. The authors report that the results of adapted rules that did not consider loss of consciousness as a prognostic factor, and showed that both the NOC and the CCHR had 100% sensitivity for identifying patients who underwent neurosurgical intervention after minor head injury. This was true for both the original decision rules (when applied to the patient population that these rules were designed for) and for the adapted rules applied to Smits' entire study population. Sensitivity for traumatic lesions detected by CT scanning or for clinically important lesions, however, was not 100% for both rules. The NOC decision rule had high sensitivity for traumatic brain CT lesions, but the CCHR did not. The difference in sensitivities for traumatic brain CT findings between the two decision rules seems to be mainly due to the more strict use of the risk factor of external injury in the CCHR.

Current guidelines recommend adult patients who have sustained a traumatic brain injury and present with any one of the risk factors listed in Box 342.2 should have a CT scan of the brain without delay [9].

Radiological classification of TBI

Cranial CT scans provide information on the presence of mass lesions, such as intracranial haematomata (Fig. 342.1a, b) and contusions, diffuse brain swelling, and distortion of normal intracranial architecture, such as shift of midline structures. Cranial CT scans in patients with TBI are often classified or graded using the Marshall classification (Box 342.3).

Prognosis

Establishing a reliable prognosis early after traumatic brain injury is notoriously difficult. Prognostic models are statistical models that

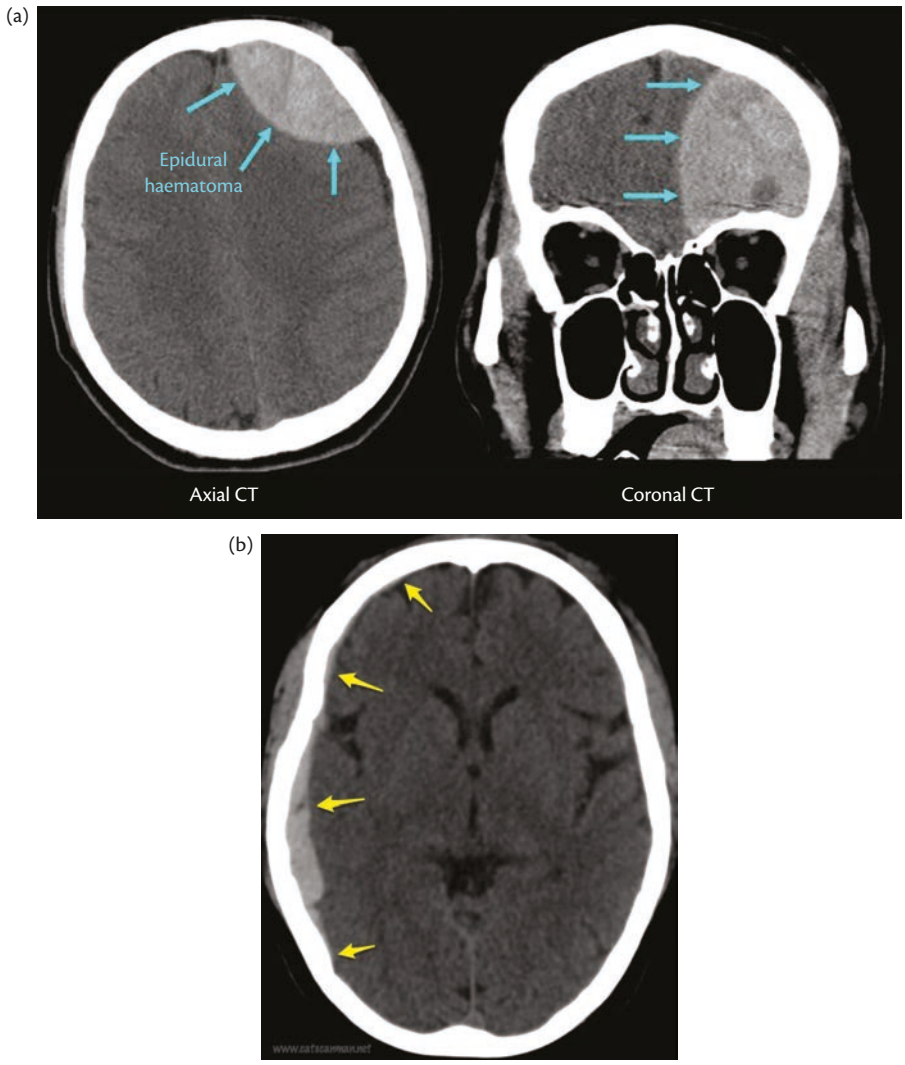

Fig. 342.1 (a) Extradural haematoma detected by CT scanning. (b) Subdural haematoma detected by CT scanning.

Box 342.3 Marshall classification

Ct abnormalities in brain trauma

- **Diffuse injury I (no visible pathology):** no visible intracranial pathology seen on CT scan.
- **Diffuse injury II:** cisterns are present with midline shift of 0–5 mm and/or lesions densities present; no high or mixed density lesion >25 cm^3 may include bone fragments and foreign bodies.
- **Diffuse injury III (swelling):** cisterns compressed or absent with midline shift of 0–5 mm; no high or mixed density lesion >25 cm^3.
- **Diffuse injury IV (shift):** midline shift >5 mm; no high or mixed density lesion >25 cm^3.

Evacuated mass lesion

Any lesion surgically evacuated.

Non-evacuated mass lesion

High or mixed density lesion >25 cm^3; not surgically evacuated.

combine data from patients to predict clinical outcome. Such models based on data collected soon after presentation could, in theory, be used to aid early clinical decision-making and to allow better informed discussions with patients' families. They could also assist in clinical audit by allowing adjustment for case mix.

However, while many prognostic models have been developed, none are widely used. A recent systematic review of prognostic models in TBI found that they were developed from small samples of patients, had poor methodology (for example, in over half of the models loss to follow-up was not reported), were rarely externally validated, and were not clinically practical [4].

Prognostic models based on admission variables are essential to support early clinical decision-making, and to facilitate reliable comparison of outcomes between different patient series and variation in results over time. Furthermore, prognostic models have an important role in randomized controlled trials (RCTs), for stratification and statistical analyses that explicitly consider prognostic information, such as covariate adjustment.

In recent years there have been two milestones that helped forward research into TBI: the formation of the IMPACT (International Mission on Prognosis and Analysis of Clinical Trials in traumatic brain injury) database [10], and the CRASH (corticosteroid randomization after significant head injury) trial [11]. The IMPACT database combined patient data from eight randomized controlled clinical trials and three observational studies to give a patient population of over 9000. The CRASH trial was a RCT of the effect of early steroid administration on outcome after TBI. The CRASH trial enrolled 10,008 patients and is the largest clinical trial ever conducted in patients with TBI [12,13].

As well as being the largest prognostic models developed for TBI, there are other key differences from previous models—the new models were externally validated, included patient data from low and middle income countries, and are accessible to clinicians and public via a web-based calculator [14,15]. While the predictors of age, motor score, and pupillary reactivity have been included in many prognostic models for TBI, Steyerberg and colleagues' model, and the model produced by the CRASH collaborators are the largest and most robustly validated that have been developed so far [12,13].

Caution must be advised in applying population-based estimates of outcome to individual patients. While both of these prognostic

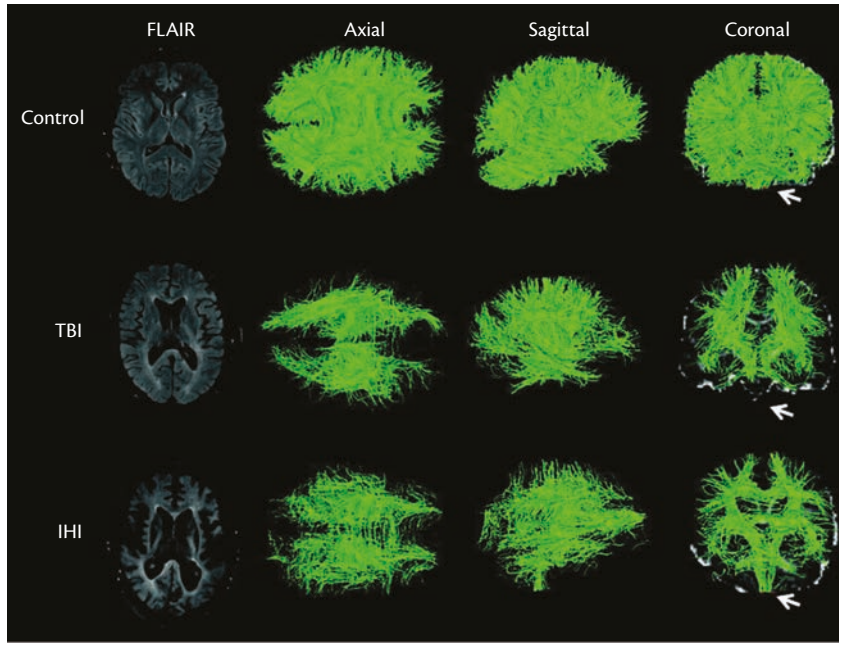

Fig. 342.2 Diffusion tensor imaging after trauma or ischaemic hypoxic injury (IHI).

models have been externally validated, they have essentially been validated against the populations of each other. All of the patients from CRASH and most of the patients from IMPACT were enrolled in clinical trials. Work is needed to establish the accuracy of these models prospectively in patients **not** enrolled in clinical trials. The CRASH data set are more heterogeneous than many of the phase III neuroprotection studies because inclusion GCS included moderate and severe injury, and included a high number of patients from low and middle income countries. Steyerberg and colleagues models seemed less accurate at predicting outcome following TBI in low and middle income countries.

These models may provide useful additional information in regard to clinical decision making and the counselling of patients' relatives, but it must be remembered that their outcomes apply to populations, and so great caution is needed if applying them to individual patients. These models are potentially of great use in clinical audit, allowing comparison between different hospitals and changes in management over time, with adjustment for case mix. The models should also allow better trial design and analysis: many patients with TBI previously included in clinical trials have expected outcomes that are so good or bad that no intervention could be expected to alter the outcome [16]. Future clinical trials could focus on those patients with a more uncertain prognosis.

Advanced imaging and prognosis

Diffuse axonal injury (DAI) is the predominant mechanism of the injury in 40–50% of patients with TBI who require hospitalization and is probably a factor in most cases that result from high-speed motor vehicle collisions. DAI is a consequence of acceleration and deceleration forces that can shear axons and produce microscopic changes in the brain. Diffusion tensor imaging (DTI, MR sequence) permits quantification of white matter integrity and TBI frequently involves white matter injury. Therefore, DTI represents an appealing method of demonstrating white matter pathology attributable to TBI (Fig. 342.2). Diffuse axonal injury is a multifocal injury that primarily affects the parasagittal white matter, corpus callosum, and brainstem. Recent studies have shown that DTI tractography-based quantification may be useful for detecting DAI and predicting outcome [17]. However, in mild TBI, this methodology has some limitations as alterations in white matter integrity are not specific to TBI, and their presence does not necessarily confirm a diagnosis of TBI.

CHAPTER 343

Management of traumatic brain injury

Alistair A. Gibson and Peter J. D. Andrews

Key points

- Traumatic brain injury is a leading cause of death and disability worldwide.
- Admission to a centre offering specialist neurological critical care and management of extracranial injuries improves outcome.
- Initial management priorities address the 'ABCs'—airway with cervical spine control, breathing, and circulation. Neurological assessment using the Glasgow Coma Score and pupillary reaction should be repeated regularly to detect deterioration.
- Intracranial haematomas causing mass effect should be surgically evacuated without delay.
- Specific TBI management focuses on avoiding secondary cerebral insults by avoiding hypotension and hypoxia, controlling ICP, and maintaining cerebral perfusion pressure.

Introduction

Traumatic brain injury (TBI) is a leading cause of death and disability worldwide. It carries a significant social and economic burden and affects patients indiscriminately; young male adults are at particular risk. In the United States of America TBI kills approximately 52,000 people annually [1]. TBI is associated with a mortality rate of up to 33% [1] and up to half of those adults admitted to hospital with TBI will suffer from long-term psychological or physical disability [2].

Neurological damage occurs through two mechanisms:

- **Primary injury**: direct injury to brain tissue and neuronal cells as a result of blunt or penetrating trauma, which causes shearing and compression of surrounding structures. The extent of injury depends on the nature of the impact.
- **Secondary injury I**: as a result of raised intracranial pressure (ICP) and other 'secondary insults'; reduced brain perfusion and ischaemia result in failure of oxygen delivery to the primarily injured area of brain. This can occur within minutes, but can take days to manifest itself.
- **Secondary injury II**: the primary injury initiates many secondary process that are believed to be injurious. These include energy failure, mitochondrial dysfunction, free radical formation, inflammation, and excitotoxicity. It is believe these processes are worsened by secondary insults.

Primary injury is irreversible and as a result the management of TBI has focused on preventing or reducing the impact of the secondary injury processes [3]. Prevention and/or recognition and treatment of these secondary insults has resulted in improved outcomes including reduced mortality and improved functional capacity [4].

TBI can be classified as mild, moderate, or severe based on the Glasgow Coma Scale scores (GCSs) (13–15, 9–12, and 3–8, respectively). This chapter will focus on the management of patients with severe TBI as these patients require assessment and management in a critical care unit, and have better outcomes if managed in a specialist centre.

Prehospital management

Initial assessment of TBI patients should follow standard National guidelines and local protocols with the aim being to follow an Airway with cervical spine control, Breathing and Circulation approach. Patients with TBI are often multiply injured and those injuries that are immediately life threatening should be treated first. Assessment of the brain injury is not straightforward as the patient may be confused, combative, or intoxicated. Management priorities for first responders are prevention of hypoxaemia and hypotension both of which are associated with worse outcome [5–7] . Hypotension (systolic blood pressure (SysBP) <90 mmHg) should be treated with isotonic intravenous (iv) fluid (if iv access can be established) and hypoxia should be treated with appropriate oxygen therapy titrated to maintain SpO_2 above 90%. GCS should be monitored as it provides a standardized and reliable method for evaluating a change in a patient's neurological status and is refined by assessment of focal signs including the pupillary response to light.

Prehospital endotracheal intubation may help prevent cerebral hypoxia and control intracranial pressure by preventing hypercarbia. Tracheal intubation can prevent airway obstruction and aspiration of gastric contents when protective airway reflexes are absent. However, tracheal intubation can also be harmful. If performed in difficult settings, and by unskilled staff, failure, and resulting hypoxaemia are possible. Intubation on scene may increase the risk of early onset pneumonia and hyperventilation during the prehospital period can aggravate cerebral ischaemia and secondary brain injury with associated increased mortality. It is therefore controversial whether patients with severe TBI benefit from prehospital intubation and mechanical ventilation, and no firm guidance can be given. The benefit and harm of prehospital intubation almost certainly depend on additional factors including organization of

emergency medical services, competency of staff, risk of procedure failure, and expected transport times. If such factors are well known in a given clinical situation, they should be used to inform the decision-making at the accident scene.

Management in the emergency department

Emergency department (ED) management should aim to avoid secondary insults by avoiding hypoxia and hypotension. Ongoing assessment of neurological status, including GCS and pupillary reaction should continue.

UK National Institute for Health and Clinical Excellence (NICE) guidelines for the management of TBI state that care in the ED should concentrate on airway, breathing, and circulation before assessing other injuries. In patients with a GCS of less than 9 an appropriately-trained clinician should provide airway management and assist with resuscitation. Those patients who have not been intubated in the prehospital setting may benefit from a secure airway to avoid hypoxaemia, ensure normocarbia, and to facilitate subsequent investigation/imaging. Sedation and analgesia should be given with care, and titrated to effect with attention to maintaining cardiovascular and respiratory stability.

In patients with clinical signs of severe TBI (Box 343.1) a CT scan of brain and cervical spine should be carried out following stabilization, ideally this should occur within 1 hour of the initial CT request. Plain radiographs are no longer indicated for investigation of TBI, although they may have a role in the investigation of paediatric non-accidental injury.

Referral to tertiary centre

Transfer to a specialist neuroscience centre reduces mortality for patients suffering from TBI [8]. All patients with TBI and survivable injuries should be treated in a facility that provides 24-hour neurological intensive care.

Referral to specialist neuroscience services should take place when [2,7]:

- CT scan in a non-specialist hospital shows a recent intracranial lesion.
- A patient fulfils the criteria for CT scanning but facilities are unavailable.
- Patient has clinical features that suggest that specialist neuroscience assessment, monitoring, or management are appropriate, irrespective of the result of any CT scan.

Features suggesting that specialist neuroscience assessment, monitoring, or management are appropriate include [2,7]:

- Persisting coma after initial resuscitation.
- Confusion which persists for more than 4 hours.
- Deterioration in level of consciousness after admission.
- Focal neurological signs.
- Seizure without full recovery.
- Compound depressed skull fracture.
- Definite or suspected penetrating injury.
- Cerebrospinal (CSF) leak or other sign of a basal skull fracture.

Transfer

It is common for patients with TBI to require transfer from the admitting hospital to specialist centres. This can either be by ambulance or an aeromedical transfer depending on the distances and urgency of transfer. Critically-ill patients are at risk of marked physiological instability which in turn can result in secondary insults and consequently worsen outcomes [2,7,9]. Transfer of patients with TBI should not be undertaken prior to effective resuscitation, management of life threatening extracranial injuries and establishment of high level of critical care monitoring [9]. Transfer of patients with multiple injuries should be to a centre with the expertise to manage both the TBI and all associated injuries [9].

Organization of services for patients with TBI varies greatly around the world. In the UK, NICE recommend that all patients meeting the criteria should be intubated, and ventilated for transfer and adequate ventilation (PaO_2 > 13 kPa and $PaCO_2$ 4.5–5.0 kPa) achieved.

Box 343.1 Criteria for immediate cranial CT scan in adults

- GCS less than 13 on initial assessment in the ED.
- GCS less than 15 at 2 hours after the injury on assessment in the ED.
- Suspected open or depressed skull fracture.
- Any sign of basal skull fracture.
- Post-traumatic seizure.
- Focal neurological deficit.
- More than one episode of vomiting.
- Amnesia for events more than 30 minutes before impact.

Box 343.2 Indications for immediate intubation and ventilation

- **Coma:** GCS less than 8.
- Loss of protective laryngeal reflexes.
- Ventilatory insufficiency as judged by blood gases: hypoxaemia (PaO_2 < 13 kPa on oxygen) or hypercarbia ($PaCO_2$ > 6 kPa).
- Spontaneous hyperventilation causing $PaCO_2$ < 4 kPa.
- Irregular respirations.

Box 343.3 Indications for intubation and ventilation prior to patient transfer

- Significantly deteriorating conscious level (one or more points on the GCS motor score) even if not coma.
- Unstable fractures of the facial skeleton.
- Copious bleeding into mouth.
- Seizures.

- **Coma**: GCS less than 8.
- Loss of protective laryngeal reflexes.
- **Ventilatory insufficiency as judged by blood gases**: hypoxaemia (PaO_2 <13 kPa on oxygen) or hypercarbia ($PaCO_2$ >6 kPa).
- Spontaneous hyperventilation causing $PaCO_2$ <4 kPa.
- Irregular respirations.
- **Significantly deteriorating conscious level:** one or more points on the GCS motor score, even if not coma.
- Unstable fractures of the facial skeleton.
- Copious bleeding into mouth.
- Seizures.

During transfer of the patient, management should focus on maintaining mean arterial pressure (MAP) greater than 80 mmHg, ensuring adequate oxygenation and preventing intracranial hypertension.

Management of secondary insults

Secondary insults (Table 343.1.) are largely amenable to intervention and aggressive treatment can result in improved outcomes. The aims for the management of secondary injury are to:

- Reduce ICP.
- Maintain cerebral perfusion pressure (CPP).
- Maintain adequate oxygenation.

Management of intracranial causes of secondary injury may require neurosurgical intervention.

Neurosurgery

An intracranial haematoma is present in 25–40% of patients with severe TBI and in up to 12% patients with moderate TBI [10]. Without effective and prompt (generally <4 hours) [10] surgical intervention severe morbidity can arise that may ultimately result in death or permanent neurological injury. Decompressive craniectomy is performed in some centres as a treatment for refractory intracranial hypertension. However, a recent study reported that very early decompressive craniectomy in patients with diffuse TBI [11] may result in worse outcome at 6 months after the injury.

Table 343.1 Causes of secondary injury

Intracranial	Systemic
Cerebral oedema	Hypotension (SysBP < 90 mmHg)
Haematoma	Hypoxaemia (SpO_2 < 90%)
Hydrocephalus	Hypocapnia ($PaCO_2$ < 4 kpa)
Seizures	Hypercapnia ($PaCO_2$ > 6 kpa)
Infection	Hypertension (MAP >110 mmHg)
Metabolic disturbance	Anaemia (Hb < 10 g/dL)
	Hyperglycaemia (blood sugar >10 mmol/L)
	Hyponatraemia
	Hyperthermia (Temp > 37.5°C)
	Acid base disturbance (acidaemia or alkalaemia)

Ongoing trials will hopefully further clarify the role of later decompressive craniectomy used to treat more refractory intracranial hypertension.

General critical care

High quality critical care is fundamental to achieving the best possible outcomes as patients with TBI are at risk of multiple complications.

In common with all critical care patients' supportive care should be undertaken as outlined here:

- Turning the patient regularly.
- Providing eye care, mouth care, and skin hygiene.
- Bowel regimen to ensure nutritional goals are met (and avoid constipation).
- Physiotherapy.

Sedation, analgesia, and paralysis

Opiates are essential to provide good analgesia and to achieve synchrony with mechanical ventilation, and combined with a judicious sedation regimen will obtund airway reflexes preventing patient coughing and associated rises in ICP. Opioids are commonly provided by continuous iv infusion and combined with sedatives by infusion. Commonly used sedatives are benzodiazepines and propofol. Younger patients often require large doses of sedatives for extended periods. Patients should not be administered neuromuscular blocking drugs unless required for the management of raised ICP. The use of neuromuscular blocking drugs is associated with critical illness neuropathy and an increased risk of developing ventilator associated pneumonia (VAP).

Lung protective ventilation

In an attempt to reduce the occurrence of the acute respiratory distress syndrome (ARDS) in patients with TBI a lung protective ventilation strategy using low tidal volumes and moderate PEEP should be adopted with the goal to maintain oxygenation (PaO_2

>13 kPa) and normocapnia ($PaCO_2$ 4.5–5.0 kPa). The theoretical deleterious effects of PEEP causing increased intrathoracic pressure and impeding cerebral venous drainage, are only seen when PEEP is above 15 cmH_2O; it is therefore safe and encouraged to apply PEEP in patients with TBI.

Venous thromboembolism

Patients with TBI are at increased risk of developing venous thromboembolism [3]. Mechanical thromboprophylaxis using graduated compression stockings and sequential compression devices are recommended unless contraindicated. Unless contraindicated, low molecular weight heparin (LMWH) should be prescribed as pharmacological thromboprophylaxis within 72 hours of injury. Care should be taken when prescribing LMWH as it increases the risk of haematoma expansion in the patient with existing intracranial haemorrhage.

Nutrition

Patients with TBI are in a hyper-metabolic state and early initiation of enteral feeding is recommended. Enteral feeding maintains normal gastrointestinal function and as a result preserves the immunological gut barrier [12]. Brain trauma foundation guidelines recommend that full calorific replacement should be achieved by day 7 post-injury [3].

Glycaemic control

Studies have highlighted that hyperglycaemia is associated with worse neurological outcome following TBI [13], but hypoglycaemia is also potentially harmful; a target blood glucose of 6–10mmol/L is recommended.

Ventilator-associated pneumonia

Patients suffering from TBI are at increased risk of VAP because they are often ventilated for prolonged periods, are administered neuromuscular blocking drugs and may have associated chest trauma. The incidence of VAP increases with TBI severity [3].

Raised intracranial pressure

Patients suffering severe TBI and at risk for intracranial hypertension should have an intracranial pressure (ICP) monitor inserted. ICP cannot be reliably predicted by CT scan alone. ICP data are useful in predicting outcome and guiding therapy, and there is an improvement in outcomes in those patients who respond to ICP lowering therapies when ICP increases above 20 mmHg [3]. ICP monitoring is addressed in a separate chapter of this book.

Increased ICP can be treated with medical or surgical interventions. First line interventions include:

- Ensure the patients head is in a neutral midline position to promote venous drainage.
- Tilt bed to 30 degrees, head up.
- Endotracheal tubes are taped and not tied to avoid obstructing cerebral venous drainage.
- Ventilate to normocapnia ($PaCO_2$ 4.5–5 kPa).
- Maintain adequately oxygenation (PaO_2 >13 kPa).
- Maintain normothermia.
- Ensure euvolaemia.
- Ensure adequate sedation +/– paralysis with neuromuscular blocking drugs.

If the first line manoeuvres above do not correct the intracranial hypertension then second line procedures should be considered.

Cerebrospinal fluid drainage

External ventricular drain (EVD) is considered first line treatment in many centres.

Osmolar therapy

In clinical practice there are currently two options—mannitol and hypertonic saline. Mannitol is given in a dose of 0.25–1 g/kg with intermittent boluses appearing to be more effective than continuous infusion. Hypertonic saline may have advantages over mannitol as it does not have the secondary effect of causing hypovolaemia and thus reducing CPP. Hypertonic saline increases intravascular volume and may improve haemodynamic variables.

Acute hyperventilation

Acute hyperventilation should only be considered for a short duration emergency treatment, such as imminent coning. Prolonged hyperventilation may exacerbate the secondary ischaemic injury [3].

Therapeutic hypothermia

The publicly available data suggest there may be a role for cooling of patients with raised intracranial pressure after TBI. Currently, there are two ongoing trials testing prophylactic hypothermia (POLAR-RCT) and titrated hypothermia to reduce ICP (Eurotherm3235Trial). The Eurotherm3235 trial was stopped early because of the concern for patient safety. The results show when hypothermia is used to reduce ICP after TBI, as a second line therapy, it is associated with a higher mortality and poorer recovery [15].

Anticonvulsant therapy

Seizure prophylaxis should be administered to patients at high risk of early post-traumatic seizures for 7 days. Traditionally, phenytoin has been the drug of first choice with an initial loading dose of 15–20 mg/kg and then titrated to plasma phenytoin levels.

Barbiturate coma

Barbituate coma reduces cerebral blood flow (CBF), cerebral metabolic rate, and ICP. Barbiturates should only be considered in patients with refractory raised ICP and who are haemodynamically stable. Extreme caution should be exhibited if therapeutic hypothermia is already initiated. Therapeutic hypothermia markedly alters the pharmacokinetics of barbiturates.

Maintaining CPP

Cerebral perfusion pressure is calculated by subtracting ICP from MAP and should be targeted between 60 and 70 mmHg. Thus, CPP can be maintained either by reducing ICP or increasing MAP. Targeting a CPP above 70 mmHg is associated with an increased risk of ARDS, probably due to the administration of large volumes of resuscitation fluids to maintain MAP.

Hypotension (SysBP <90 mmHg) is common after TBI and worsens patient outcomes [6]. The most common cause of hypotension in patients with TBI is hypovolaemia, either secondary to

The Impact calculator is based on the prediction models for TBI, published by Steyerberg EW, Mushkudiani N, Perel P, Butcher I, Lu J, et al. (2008) Predicting Outcome after Traumatic Brain Injury: Development and International Validation of Prognostic Scores Based on Admission Characteristics. *PLoS Medicine*, **5**(8), e165. doi:10.1371/journal.pmed.0050165.

haemorrhage or due to polyuria as a result of diabetes insipidus. Other less common causes of hypotension include direct myocardial injury due to trauma or vasodilatation secondary to spinal cord injury. Fluid resuscitation with isotonic crystalloid solutions, or in the presence of haemoglobin <100 g/L packed red blood cells, to restore euvolaemia is the first line therapy for hypotension. Vasopressors should be administered if euvolaemia fails to correct hypotension, and are then titrated to achieve the desired CPP or MAP.

Corticosteroids

The CRASH study [14] demonstrated that high dose corticosteroids are associated with an increased risk of death and corticosteroids are considered to be contraindicated in patients with TBI.

Prognosis

TBI is a heterogeneous disease and this causes uncertainty when predicting outcome for individual patients. Two prognostic models have been developed, which are encompassed in the CRASH and IMPACT prognostic calculators. The IMPACT model was developed using a dataset that comprised patients with moderate and severe TBI and predicts mortality and unfavourable outcome (death, vegetative state or severe disability). The IMPACT model incorporates three calculators—the core, core + CT, and lab models (Box 343.4). The two CRASH calculators (the basic and the CT models) were created using a larger dataset, but included mild, moderate, and severe TBI, mainly from low–middle income countries (Box 343.5). The CRASH models predict mortality at 2 weeks and unfavourable outcome at 6 months. The calculators are shown in Box 343.5 and can be accessed online at: http://www.tbi-impact.org/?p=impact/calc

PART 16.4

Spinal cord injury

CHAPTER 344

Assessment and immediate management of spinal cord injury

Simon Finfer and Oliver Flower

Key points

- Spinal cord injury is a devastating injury that predominantly affects previously healthy young men.
- Level of injury and completeness should be assessed and described using the American Spinal Injury Association (ASIA) Impairment Scale.
- Spinal cord injury is often a component of multisystem trauma and immediate management should be prioritize life-threatening injuries.
- Respiratory system complications are common and 75% of patients with injuries at C5 or higher will require tracheal intubation and mechanical ventilation.
- High thoracic and cervical injuries can result in bradycardia and hypotension typical of neurogenic shock, maintaining arterial pressure through normovolaemia and vasopressors may help optimize outcome.

Introduction

Spinal cord injury is a potentially devastating injury that may occur in isolation, but more commonly occurs in the setting of multiple injuries. Depending on the level of the injury and its completeness, patients may be left with paraplegia or tetraplegia with an obvious profound impact for the patient and their family. Acute management is largely supportive and aimed at avoiding preventable secondary injury. Early identification of the injury and appropriate management may result in improved outcome, which is important to reduce disability and thus to reduce the individual, societal, and health care system costs of long-term management.

Epidemiology

Spinal fractures occur in approximately 5% of trauma patients, with 20% of these having an associated spinal cord injury. One-third of affected patients will suffer tetraplegia and half will have complete cord lesions. Motor vehicle accidents, falls and sports injuries are the common causes; 70–80% of patients are male with the 15–35-year-old age group most commonly affected. In developed countries cervical spine injuries account for more than 50% of injuries. In developing countries the proportion and prevalence of cervical injury is lower, possibly due to lower prehospital survival.

Diagnosis

The diagnosis of isolated spinal cord injury may be obvious, for example, and isolated cervical cord injury due to diving into shallow water or suffered as a sporting injury. In such patients, the loss of motor and sensory function below the level of injury combined with diaphragmatic breathing with or without pain at the site of injury makes the diagnosis clinically obvious. However, the majority of spinal cord injuries occur in patient who have suffered multiple injuries and, in such patients, spinal cord injury may not be readily apparent. This is particularly true if the patient has a depressed level of consciousness or sedated to tolerate mechanical ventilation. In conscious patients, the injury may be apparent on physical examination, but the diagnosis may be unclear due to the distracting pain and immobility due to other injuries. Any patient suffering significant trauma should be managed as if they have a spinal injury until it is has been actively excluded. Injuries to the thoracic and lumbar spine result from massive force and abnormality is almost invariably present on plain X-rays. Cervical spinal cord injury can occur in the presence of normal cervical spine X-ray, particularly in children, and this has resulted in considerable controversy over the degree of investigation needed to 'clear' the cervical spine. Obtaining adequate anteroposterior, lateral and odontoid views by plain radiology can be very difficult in the acute setting and plain X-rays have a sensitivity of around 50% for identifying patients with cervical spine injury. In comparison, computed tomography (CT) has a sensitivity of around 98% [1]. In developed countries most multiply-injured patients will undergo CT scanning of the cervical spine, thorax, and abdomen. Injury to the thoracolumbar spine can be excluded by CT with a high degree of confidence even in unconscious patients. Opinion differs on whether a normal CT scan is sufficient to exclude a cervical spinal cord injury in patients who cannot cooperate with examination or who have significant distracting injuries. A normal multidetector row CT scan has a sensitivity of detecting cervical spine injury, including ligamentous injury, of close to 100% [2]. Where doubt exists a magnetic resonance imaging scan (MRI) should be performed. MRI is more sensitive than CT and can delineate soft tissue, as well as bony injury. Example images are given in Fig. 344.1.

Spinal cord injury should be excluded as soon as possible to avoid unnecessary restriction on patient positioning and movement, which may result in avoidable morbidity.

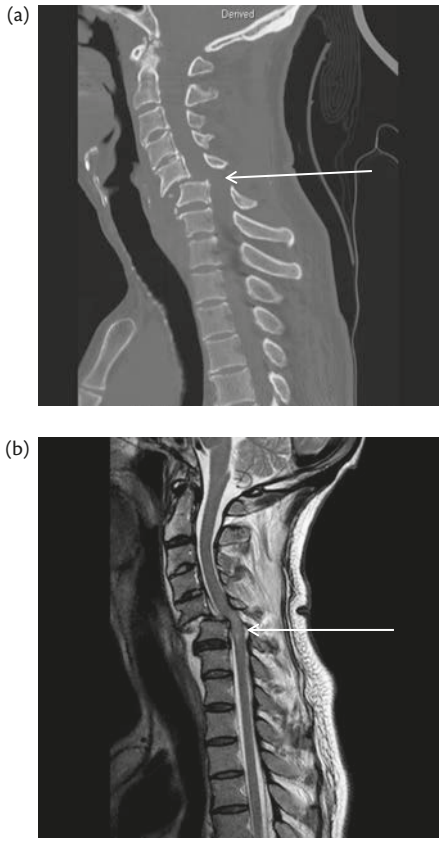

Fig. 344.1 (a) Sagittal CT image showing anteriolisthesis of C5 on C6 (arrow) secondary to bilateral facet joint dislocation (arrow). (b) T2-weighted MRI image of same injury with signal change in the spinal cord (arrow) and disruption of anterior and posterior longitudinal ligaments.

Assessment

Assessment of a patient with a spinal cord injury involves determining the neurological level of injury, and whether the spinal cord injury is complete or incomplete. The neurological level of injury is the most caudal (lowest) spinal cord segment with normal motor and sensory function bilaterally. This level can be quite difficult to determine as the lowest level of motor and sensory function may not appear to be the same, and may also differ from one side to the other. As a result, it is best to describe lowest left- and right-sided motor and sensory levels separately. Complete spinal cord injury is indicated by absence of both motor and sensory function in the lowest sacral segments, which is indicated by the absence of anal tone or sensation. The American Spinal Injury Association (ASIA) impairment scale is a validated instrument for diagnosing and classifying spinal cord injury. A neurological examination incorporating bilateral sensory and motor examination, including digital rectal examination, is performed to determine a single neurological level of injury, the completeness of injury, and the ASIA grade (Fig. 344.2).

Management

Initial assessment

The initial assessment of a patient with a spinal cord injury is no different from any other patient who has suffered trauma and should be a systematic assessment focusing first on the detection and treatment of immediately life-threatening conditions (the primary survey) attending to first life-threatening airway, breathing, cardiovascular, and neurological injuries. A high cervical spinal cord injury (above C5) may result in life-threatening respiratory failure necessitating urgent tracheal intubation and positive pressure ventilation to sustain life. In the presence of pre-existing lung disease or acute lung or chest wall injury lower levels of spinal cord injury may also produce life-threatening respiratory failure. Patients with spinal cord injury have better outcomes if managed in specialist centres; after initial resuscitation, early transfer to one of these centres should be a high priority [3].

Management of the unstable spine

While spinal cord injury can occur in patients with a stable bony spine, the majority of injuries occur in conjunction with spinal fractures and dislocations that are unstable. To prevent further cord injury the initial management is to immobilize cervical spine in a semi-rigid collar and to maintain the whole spine in alignment until the exact anatomy of the injury is delineated through imaging. Immobilizing the spine and maintaining it in alignment may complicate the management of other injuries, particularly chest injuries and adds significantly to nursing work load as the patient must be log rolled or lifted for pressure area, and other nursing care. To protect the thoracolumbar spine the patient has to remain in the supine position with the spine in the anatomical position, although the whole bed can be placed in a reverse Trendelenberg position if the patient is haemodynamically stable. This positioning can compromise weaning from mechanical ventilation and may increase the risk of nosocomial and ventilator-associated pneumonia. For these reasons, the spine should be surgically stabilized as soon as the patient is fit for operation.

Cardiovascular management

Sympathetic innervation of the heart is from the upper thoracic segments via the cervical ganglions, and the peripheral vasculature vasomotor tone is controlled by segmental sympathetic innervation. Thus, spinal cord injury above these levels can result in hypotension due to bradycardia and loss of vasomotor tone, where this compromises tissue perfusion it constitutes neurogenic shock. Cardiac parasympathetic innervation is via the vagus nerve and so is unaffected by spinal cord injury. In patients with multiple injuries, hypovolaemia from blood loss and cardiogenic shock from direct cardiac injury may co-exist, and must be excluded or treated. Hypotension may theoretically cause secondary injury to the spinal cord through impaired perfusion and a number of authors have reported better than expected outcomes in patients treated with protocols that include maintaining mean arterial pressure (MAP) at 85 mmHg or greater for the first 7 days after injury [4,5]. These findings have not been confirmed in randomized trials, but it seems reasonable to maintain arterial pressure at or above 85 mmHg with vasopressors and normovolaemia if this can be achieved without compromising other aspects of patient care.

Respiratory management

Even in the absence of direct chest trauma the respiratory system is the system most often compromised following spinal cord injury and respiratory dysfunction is the commonest cause of morbidity following spinal cord injury. The risk of respiratory failure and the

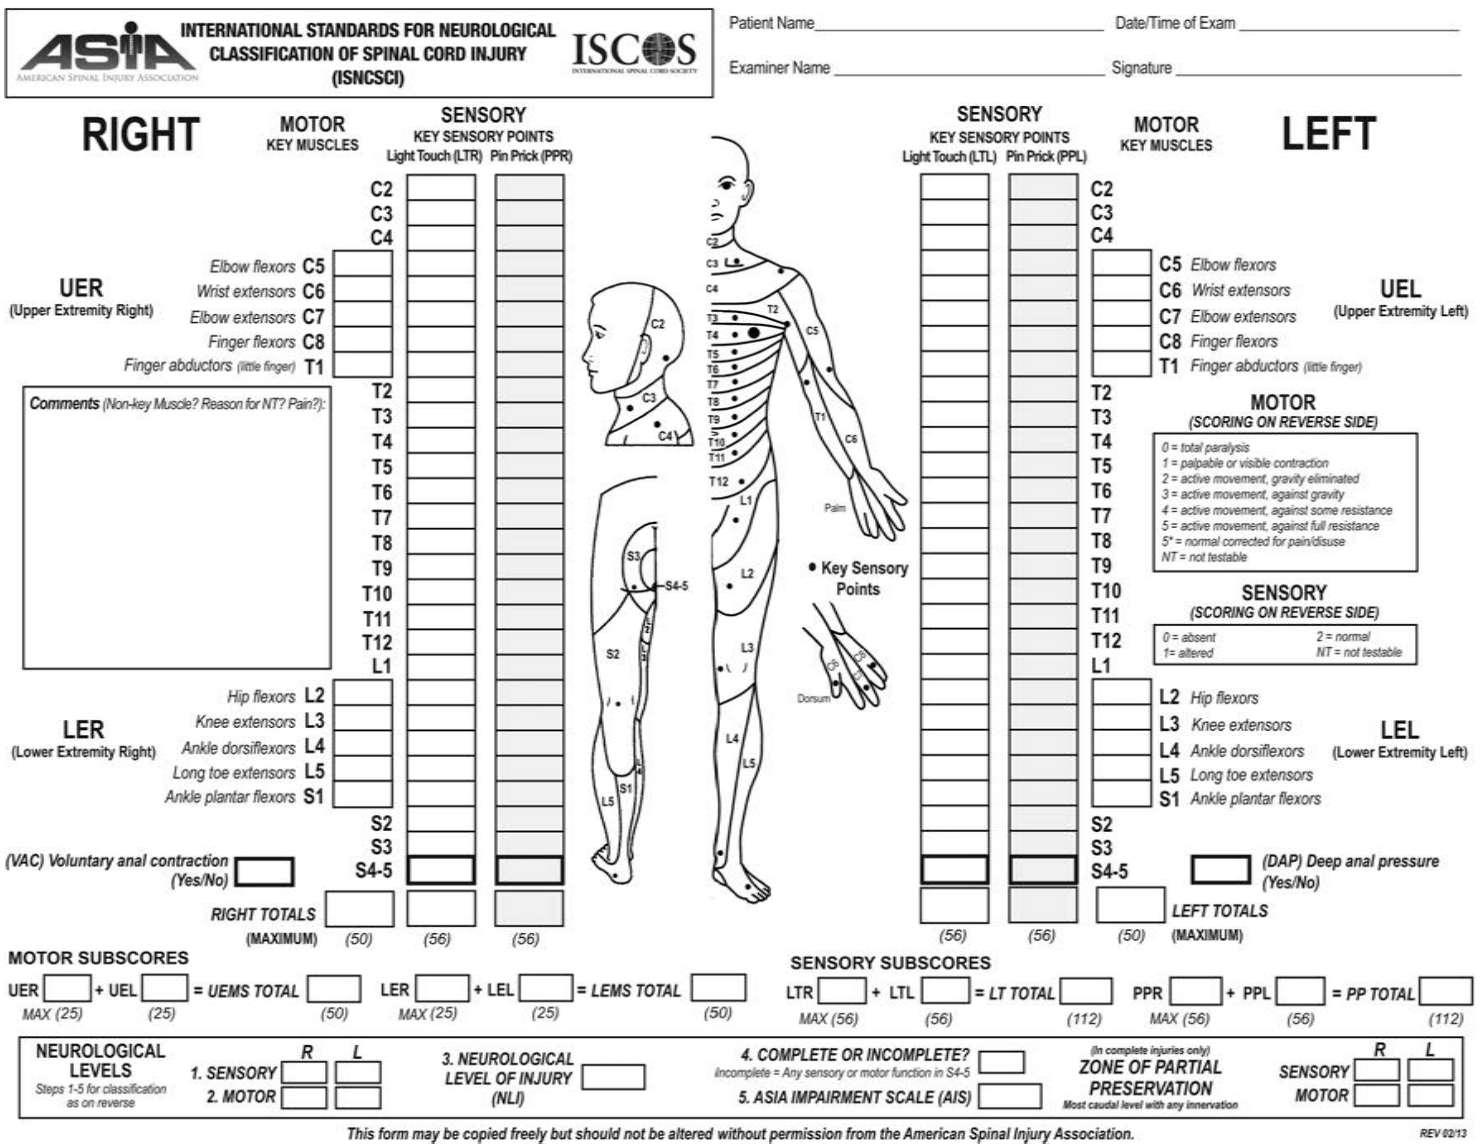

Fig. 344.2 American Spinal Injury Association: International Standards for Neurological Classification of Spinal Cord Injury, (ISNCSCI).

need for tracheal intubation increases the higher the injury with around 75% of patients with cervical spinal cord injury being treated with tracheal intubation and mechanical ventilation. Where respiratory function is compromised, but initially adequate, monitoring vital capacity can detect further deterioration and predict the need for mechanical ventilation. Once vital capacity is less than 15 mL/kg body weight, most patients will require mechanical ventilation.

Tracheal intubation

Tracheal intubation may be required urgently because of respiratory failure, decreased level of consciousness with airway compromise or to facilitate the treatment of other life-threatening injuries. Less urgent intubation may be needed for deteriorating respiratory function and secretion clearance. Following trauma, any patient at risk of, or with confirmed, cervical spinal cord injury must haven their neck immobilized during tracheal intubation. The best intubation technique will depend on the availability of equipment and expertise and also on the acuity of the situation. Where time, equipment, and expertise are available, awake fibre optic intubation minimizes the risk of moving the neck. In more urgent situation direct laryngoscopy with manual inline immobilization should be employed. Whilst manual inline immobilization does not eliminate all spinal movement it is likely to be the best option for truly urgent intubation. Video laryngoscopy is now increasingly available and has been shown to improve visualization of the glottis and reduce intubation difficulty in patients with cervical immobilization

Initial management of ventilation

In the acute stage ventilation strategy may be dictated by other injuries, such as traumatic brain injury or acute lung injury. In the absence of such concerns, the ventilation strategy should be tailored to patient comfort and optimizing condition for weaning from mechanical ventilation. In contrast to other conditions, patients with high cervical spinal cord injury appear to tolerate and to be more comfortable when ventilated with large tidal volumes. Tidal volumes in excess of 10 mL/kg ameliorate air hunger and prevent atelectasis. In one uncontrolled study, patients ventilated with tidal volumes in excess of 20 mL/kg suffered fewer respiratory complications and were weaned faster from mechanical ventilation than similar patients ventilated with lower tidal volumes [6]. If high tidal volume ventilation is used dead space tubing must be inserted into the ventilator circuit to prevent profound hypocarbia.

Tracheostomy

The proportion of patients needing tracheostomy after cervical spinal cord injury varies between 20 and 60%, but almost all patients with a complete injury above C5 will require tracheostomy. Tracheostomy may also be required for other injuries, such as severe traumatic brain injury or prolonged weaning after acute lung injury. Where indicated, early tracheostomy will provide better patient comfort and aid weaning from mechanical ventilation. Percutaneous tracheostomy can be performed safely by experienced operators and with care it can be performed even if an unstable cervical spine is being managed conservatively. If an anterior approach to surgical fixation of an unstable cervical spine is planned, percutaneous tracheostomy may have to be delayed, but can be performed safely at a later date. Surgical tracheostomy is an alternate option if expertise in percutaneous tracheostomy is lacking.

Venous thromboembolism

In the absence of prophylaxis venous thromboembolism (VTE) is a near universal complication of spinal cord injury and VTE may be responsible for one in 10 deaths occurring in the first year following spinal cord injury. With prophylaxis, the rate of VTE may be reduced to around 5% with accompanying reductions in resultant morbidity and mortality [7]. Currently, low molecular weight heparin (LMWH) is the preferred pharmacological agent for prophylaxis, and this can be combined with mechanical prophylaxis in the form of anti-embolism stockings and mechanical calf compression. When heparin is contraindicated mechanical prophylaxis can be used alone. Prophylaxis with LMWH should be started as soon as possible, immediately on admission to the ICU if possible and preferably always within 72 hours [8].

Gastrointestinal function and feeding

Acute gastric dilatation, paralytic ileus, constipation, and faecal retention are common complications following spinal cord injury. Optimum bowel management includes ensuring adequate level of hydration, appropriate diet, and a regular regimen of laxatives and daily suppositories. Despite these measures, manual evacuation may be required on a regular basis. Muscle wasting through disuse atrophy is inevitable following spinal cord injury, and cannot be prevented by feeding or overfeeding. The optimal energy and protein intake will vary from patient to patient and normal calculations have to be modified to avoid over feeding. Depending on the level of injury, patients with SCI have resting energy requirement of 50–90% of that estimated using standard calculations, such as the Harris–Benedict equation [9]. Although feeding by the enteral route may initially be difficult to establish, as with other forms of critical illness it is far preferable to parenteral feeding.

Psychosocial issues

Spinal cord injury, particularly high cervical spinal cord injury, is a devastating injury that often affects previously healthy young men. The initial reaction is often one of fear and uncertainty about the future, which may subsequently change to anger and/or depression. In the acute phase there may be uncertainty about the extent and completeness of the injury, and if any doubt exists, definitive statements about the certainty of permanent disability are best avoided. Initially, management is focused on physical issues and communication may be limited due to tracheal intubation and the use of analgesic and sedative agents. Over subsequent days acute physical issues will resolve and psychological issues may come to the fore. Management of these issues require no less skill and experience than managing the physical problems of spinal cord injury. It is often beneficial to nominate a core group of nurses to provide continuity of care and seek the involvement of a psychiatrist experienced in supporting patients with spinal cord injury.

Outlook

Death during the acute phase of spinal cord injury is rare except when due to the presence of other unsurvivable injuries. Patients with thoracic or lumbar injuries may only need short term peri-operative treatment in an intensive care unit. Patients with high cervical spinal cord injury may remain ventilator dependent for weeks or months or indefinitely. Although some patients who remain ventilator-dependent due to a high cervical spinal cord

injury may choose to discontinue ventilation, rather than survive with severe physical disability, discussions, and decisions regarding discontinuing ventilation are conducted once the acute physical problems have been resolved. Overall hospital mortality after spinal cord injury is around 10% with elderly patients and those with co-morbid conditions being at greatest risk of death.

CHAPTER 345

Ongoing management of the tetraplegic patient in the ICU

Oliver Flower and Raymond Raper

Key points

- Manage traumatic spinal cord injury in a specialist centre.
- Consider the nuances specific to the respiratory care of cervical spinal cord injury.
- Consider early percutaneous tracheostomy.
- Commence venous thromboembolic prophylaxis as soon as possible.
- Involve the patient in discussions regarding long-term ventilation.

Introduction

Traumatic tetraplegia is a devastating injury with major functional and psychosocial implications. Patients who have suffered a traumatic cervical spinal cord injury (CSCI) present unique critical care challenges. Following the initial assessment and management, certain issues are common in the ongoing management of patients during their acute presentation. Survivors of traumatic tetraplegia are at lifelong risk from complications of their neurological deficit and management-related complications of unrelated illnesses. Patients are best managed in centres with specialist medical, nursing, and allied health expertise [1]. The language used when discussing CSCI is important and is clarified in Box 345.1.

Acute CSCI

The management of patients with CSCI must be individualized. Nevertheless, management is best approached in a systematic fashion.

Neurological

A detailed neurological examination should be performed as early as feasible during the admission. The American Spinal Injury Association (ASIA) impairment scale is the most validated instrument for diagnosing and classifying spinal cord injury (SCI). It is currently the only standardized neurological examination available that allows prognostication and has sufficient inter-rater reliability for local and international data collection and comparison. Key findings from examination include a single neurological level of injury (NLOI) and completeness of injury, which specifically refers to whether there is absence of motor or sensory function in the S4/5 region (sacral sparing), highlighting the importance of an adequate sacral and rectal examination for the ASIA impairment scale form. Another important finding is whether there is presence of reflexes such as the bulbocavernosus reflex. This suggests spinal shock is resolving and heralds the potential for complications such as autonomic dysreflexia [2].

Following resolution of spinal shock, muscle spasticity almost invariably occurs and is a consequence of loss of spinal inhibitory signals modifying reflex arcs. Initial treatment consists of enteral baclofen as a muscle relaxant. Some patients require very high oral doses or, in refractory cases, intrathecal administration via an implanted baclofen pump. An alternative agent is tizanidine.

Neuropathic pain is common and can be devastating. Involvement of specialists with expertise in acute pain management is appropriate, although over-focus on the pain can be counterproductive. Useful medications include carbamazepine, gabapentin, and pregabalin, as well as nortriptyline and amitriptyline as part of conventional multimodal analgesia.

Box 345.1 The language of spinal cord injury (SCI)

- **Tetraplegia**: Greek nomenclature, preferred to quadriplegia, which is a mixture of Latin and Greek. Motor and/or sensory deficits affecting upper and lower limbs due to cervical SCI.
- **Paraplegia:** motor and/or sensory deficits affecting only lower limbs due to SCI below the cervical levels.
- **Neurological level of injury (NLOI):** the most caudal (lowest) cord segment with normal motor and sensory function bilaterally. This is distinct from the skeletal level or radiological level of injury.
- **Complete SCI:** absence of motor and sensory function in the lowest sacral segments (i.e. no anal tone or sensation).
- **Zone of partial preservation:** with incomplete SCI, this refers to the spinal segments that have any motor or sensory function below the NLOI.
- **Spinal shock:** the period of flaccid paresis and areflexia following a spinal injury, lasting from 48 hours to weeks, ending with return of reflexes, such as the bulbocavernosus reflex.
- **Neurogenic shock:** a form of distributive (cardiovascular) shock following SCI due to loss of sympathetic tone in peripheral vasculature.

Data from: American Spinal Injury Association: International Standards for Neurological Classification of Spinal Cord Injury, revised 2013; Atlanta, GA. Reprinted 2013; and Ditunno JF et al., 'Spinal shock revisited: a four-phase model', *Spinal cord*, 2004, 42, 7, pp. 383–395. Epub 2004/03/24

Respiratory

Respiratory complications are the leading cause of morbidity and mortality in the short and long term following CSCI. Mechanical ventilation (MV) is required initially in 74% of patients with CSCI. Risk factors for requiring MV in the first week include NLOI at C5 or above, complete SCI, excessive respiratory secretions and pneumonia. MV may be required for days to weeks and approximately 7% of tetraplegic patients remain ventilator dependent on discharge from hospital [3]. The process of liberating these patients from the ventilator requires patience, a long-term plan, and a coordinated team approach involving medical, nursing, and physiotherapy staff [4].

In the acute phase, the mode and settings of MV should be dictated by associated conditions. Brain protection for any associated traumatic brain injury or lung protection for acute lung injury (aspiration pneumonitis, acute respiratory distress syndrome, pulmonary contusion, or infection) will determine the early pattern of ventilator support. Once this phase has past, ventilatory capacity can be evaluated and a regimen aiming for progressive ventilatory weaning, if possible, can be initiated

Specific strategies to assist respiratory function in ventilated patients with acute CSCI are listed in Table 345.1. Following complete CSCI, the intercostal and abdominal muscles are paralysed, and if the NLOI is C5 or above, the diaphragm will also be affected. Unopposed parasympathetic activity results in bronchospasm in susceptible individuals and thick, excessive pulmonary secretions. These should be addressed pharmacologically with bronchodilators and mechanically with humidification, frequent endotracheal suctioning and bronchoscopy as required. The pattern of muscle loss affects expiratory muscles more than inspiratory so expiratory reserve volume is reduced, while residual volume is increased. Assisted coughing and insufflation/exsufflation devices facilitate sputum clearance. Low levels of PEEP help restore functional residual capacity (FRC) and there is some evidence that high tidal volume ventilation facilitates sputum clearance, reduces atelectasis, and shortens the requisite duration of mechanical ventilation. It certainly ameliorates the commonly experienced air hunger, but may necessitate the use of respiratory circuit dead space to prevent hypocarbia. This confounds the addition of active humidification. Forced vital capacity (FVC) is paradoxically improved in the supine position in tetraplegic patients because the weight of the abdominal contents positions the diaphragm higher in the chest, essentially preloading this principal respiratory muscle. This effect can be simulated with an abdominal binder, which is an essential aid as patients move from the supine to the sitting position.

Tracheostomy is required in approximately 60% of patients with CSCI; NLOI and completeness of neurological deficit being the most important predictors of need for tracheostomy. Patients who have a complete injury above C5 invariably require a tracheostomy and individual factors influence the need when the injury is lower or incomplete. An FVC <11.9 mL/kg, requirement for tracheal suctioning more than hourly and a PaO_2/FIO_2 ratio <189 mmHg have been found to predict the need for tracheostomy [5]. A tracheostomy before day 7 can reduce intensive care unit (ICU) length of stay and duration of mechanical ventilation, with the added bonus of facilitated communication and reduced sedation requirements. A percutaneous, dilatational approach performed in ICU is safe and does not increase the rate of surgical wound infection, even after anterior cervical fixation.

Table 345.1 Strategies employed in the respiratory care of tetraplegic patients

Strategy	Rationale
Baseline spirometry measurements	For monitoring and respiratory prognostication. Vital capacity <11.9 mL/kg is predictive of needing prolonged support and tracheostomy
Regular use of bronchodilators	Sympathetic denervation leads to parasympathetic over-activity causing bronchospasm
Use of an humidified circuit	Sympathetic denervation leads to parasympathetic over-activity causing thick tenacious secretions, risking mucous plugging
Keep flat or head down when self-ventilating	With loss of abdominal muscular tone, the upright position causes the abdominal viscera and diaphragm to be drawn so far down that ventilation is difficult. When supine, the viscera push the diaphragm up to position that permits more effective ventilation
Use of abdominal binder	This pushes the abdominal viscera upwards and puts the diaphragm in a more mechanically advantageous position for ventilation
Low positive end-expiratory pressure (PEEP)	High PEEP may push the diaphragm down into a position of mechanical disadvantage, impairing gas exchange
High tidal volume	In the absence of PEEP, higher tidal volumes may prevent atelectasis and segmental collapse. Air hunger is common and may be relieved with higher tidal volumes
Use of dead space in ventilator circuit	High tidal volumes may lead to hypocapnoea unless dead space is introduced into the ventilator tubing
Inspiratory muscle training (IMT)	IMT improves physiological variables and may help to expedite liberation from the ventilator
Low threshold to perform bronchoscopy	Thick tenacious secretions frequently causing plugging of large airways. Sudden desaturation should prompt consideration of therapeutic bronchoscopy
Early tracheostomy	Often necessary for prolonged ventilation; reduces sedation requirements, facilitates weaning from the ventilator, allows ongoing tracheal toilet, improves communication and speech

Data from: American Spinal Injury Association: *International Standards for Neurological Classification of Spinal Cord Injury*, revised 2013; Atlanta, GA. Reprinted 2013; and Ditunno JF et al., 'Spinal shock revisited: a four-phase model', *Spinal Cord*, 2004, **42**(7), pp. 383–95. Epub 2004/03/24.

Many different permutations of progressive ventilator-free breathing (VFB) strategies are used when trying to wean the patient from the ventilator. The key components of these are a clear and documented, consistent approach over weeks to months and avoidance of fatigue by ensuring brief and well-monitored periods of spontaneous breathing. These periods can be progressively extended as tolerated, with adequate rest periods in between. Setbacks such as infections or lobar collapse from mucous plugging may delay the weaning process. Even after successful weaning and decannulation of the tracheostomy, there may be an ongoing requirement for nocturnal non-invasive ventilation, as there is a high prevalence of obstructive sleep apnoea and nocturnal hypoventilation in this population.

There is some evidence supporting the use of inspiratory muscle training devices as part of the weaning process. Once patients are able to tolerate short periods of VFB, regimens using these devices appear safe and provide achievable goals at a time when patients have control of little else.

Respiratory physiotherapy has an important role in preventing infections and expediting the weaning process. Techniques employed include regular turning, deep breathing exercises, incentive spirometry, assisted coughing (with insufflation/exsufflation devices and assisted 'quad' coughing) and mobilization out of bed with an abdominal binder.

Cardiovascular

In the first few days following CSCI, neurogenic shock is common, due to a combination of distributive shock from loss of sympathetic vascular tone and bradycardia from loss of sympathetic innervation to the heart with unopposed cardiac vagal stimulation. There is weak evidence that a mean arterial pressure (MAP) >85 mmHg should be maintained for up to 7 days following injury [6], theoretically improving cord perfusion pressure and preventing secondary spinal cord injury. After initial fluid resuscitation vasopressors, such as noradrenaline are commonly required to meet these targets. Chronic, relative hypotension is expected following CSCI. Anticholinergics like atropine may be required for patients who experience severe bradycardia associated with certain stimuli, such as tracheal suctioning. Rarely, chronotropic infusions (e.g. isoprenaline) or even cardiac pacing may be required for severe bradycardia.

Venous thromboembolism (VTE) is highly prevalent following CSCI. The use of low molecular weight heparin or unfractionated heparin in combination with mechanical measures, such as anti-embolism stockings and sequential calf compression, is recommended for thromboprophylaxis. Low molecular weight heparin (specifically enoxaparin) may be superior to unfractionated heparin with mechanical measures in decreasing the incidence of pulmonary embolism, and have a lower rate of bleeding complications [7]. Adequate VTE prophylaxis is easier if all planned spinal surgical procedures are undertaken as soon as practicable.

Renal

In the initial phase following injury, the bladder is hypotonic and effective drainage is essential to avoid over-distension and injury. Following resolution of spinal shock, bladder spasticity often occurs with detrusor muscle hyperreflexia. To prevent a contracted, low-volume bladder, an anticholinergic agent, such as oxybutynin, tolterodine, or solifenacin should be prescribed. These may be started once the bowels have been opened (as they may worsen constipation). A suprapubic catheter is usually indicated and usually easier to arrange, while the patient is still in the ICU. Bone mineral loss is common following CSCI. This may result in hypercalcaemia, and frequently causes hypercalciuria placing patients at significant risk of developing calcium oxalate nephrolithiasis. A baseline CT of the renal tract can be useful and renal calculi, and urinary tract infections should always be considered as precipitants of autonomic dysreflexia.

Gastrointestinal

Neurogenic bowel is colonic dysfunction resulting from lack of central nervous control. The upper motor neuron bowel syndrome seen following CSCI is characterized by increased colonic wall and anal tone, with loss of external anal sphincter control. This results in constipation and faecal retention. Stool evacuation may be induced by a reflex activity caused by a rectal stimulus, such as an irritant suppository or digital stimulation. These are key components of multifaceted bowel management programmes that also include adequate fluid intake, diet, pharmacology, and occasionally surgery or electrical stimulation. Daily suppositories are commonly required, with polyethylene glycol-based suppositories having advantages over hydrogenated vegetable oil-based bisacodyl suppositories. There is less evidence supporting oral laxatives or additional dietary fibre. Ideally, opioids and other constipating medications should be avoided [8].

Unopposed parasympathetic activity results in hyperacidity. Gastric pH is difficult to control with antihistamines, so a proton pump inhibitor may be indicated for ulcer prophylaxis.

Skin

The development of cutaneous pressure sores is the commonest complication following SCI. They are a source of considerable morbidity and are associated with increased hospital length of stay, life-threatening infections, chronic refractory osteomyelitis, and autonomic dysreflexia. Skin healing in denervated skin is significantly delayed so prevention is vital. Risk factors for pressure ulceration include the degree of immobility, initial hypotension, malnutrition, and prolonged use of spinal boards and hard collars. Preventive measures must be employed, including early use of a pneumatic pressure-relieving mattress, 2-hourly postural change, and a high degree of vigilance for early signs of pressure ulcers [9]. Device-related (especially collar) ulceration can be painful as it tends to affect innervated skin. Occipital ulceration can be particularly devastating and can delay mobilization and respiratory weaning.

Early rehabilitation

Physiotherapy to increase range of movement, particularly in shoulders and hands, may prevent contractures that may significantly affect functional status at a later time. Adhesive capsulitis of the shoulders and deforming hand contractures may be prevented by passive movement exercises and splinting devices. Early mobilization once spinal stability has been achieved is also important for reducing complications such as pressure sores and VTE, as well as addressing the accelerated deconditioning that follows CSCI.

Psychosocial

The psychological and social impact of tetraplegia is immense. The functional loss is huge, and employment and family implications are obvious. An initial grieving response is common and this will be manifest in various ways depending on premorbid characteristics. Situational depression may occur, but antidepressants may not be helpful. It is important for staff to appreciate and communicate that many quadriplegic patients are able to achieve satisfactory levels of function, and are able to enjoy highly meaningful lives and relationships. It is essential not to prejudge patient responses, no matter what views they may have expressed prior to the injury. It is also important not to be overly nihilistic. Psychosocial support should include establishing early effective communication and engendering an environment of trust by open, candid, and

receptive communication. Focusing on what is possible, rather than on what is not possible is recommended. Support from others who have achieved a meaningful life in spite of tetraplegia may be helpful. A psychologist or psychiatrist with experience of assisting patients following SCI should be available.

Ventilator-dependent tetraplegic patients sometimes request to have ventilation discontinued and to be allowed to die. This can create considerable difficulties for staff and families. In principle, mechanical ventilation is a medical treatment and competent patients are legally able to decline medical treatment even if this results in their death. This is the principle of autonomy. The concern, of course, is that the decision may not be stable—it may be impacted by a short-term emotional response to the injury and may change over time if survival is enforced till a different frame of mind is achieved. Some surety is provided if the patient's decision is consistent over time and consistent with any premorbid views. Nevertheless, the right not to be treated in these circumstances is established in law [10] and forcing a patient to undergo unwanted treatment in the hope of a change of mind is not reasonable. Some patients who have died after elective discontinuation of treatment have donated organs for transplantation after death based on their own consent process.

Acute issues in chronic tetraplegia

With improved survival following CSCI, patients with longstanding tetraplegia are now more frequently requiring critical care admissions for a variety of reasons, with different issues to those following initial presentation.

Autonomic dysreflexia

Whilst common, autonomic dysreflexia (AD) is a potential medical emergency that may require intensive blood pressure monitoring and control to avoid a hypertensive intracerebral haemorrhage or myocardial ischaemia. It may occur in any patient with a cord lesion above T6 after spinal shock has resolved. AD is the result of uncontrolled sympathetic discharge in response to noxious stimuli resulting in hypertension, bradycardia, headache, and diaphoresis. Common precipitants are listed in Box 345.2. General management includes primarily detecting and treating the precipitant, sitting the patient up (to induce the orthostatic hypotensive response), loosening clothing, and treatment with anti-hypertensives. One regimen is to give sublingual or transdermal glyceryl trinitrate initially, followed by immediate release nifedipine if this proves insufficient, before intravenous agents, such as sodium nitroprusside or glyceryl trinitrate infusions are required. Some patients may develop chronic, severe AD requiring multiple classes of antihypertensive medications. It must be remembered that in the setting of chronic hypotension, systolic blood pressure of >150 mmHg can be life threatening [11].

Box 345.2 Potential precipitants of autonomic dysreflexia

- Bladder distension.
- Urinary tract infection.
- Renal calculi.
- Faecal impaction.
- Decubitus ulcers with or without infection.
- Foot disease including ingrown toenails.
- Surgical procedures.

Respiratory failure

Because of variably limited reserve, tetraplegic patients commonly develop respiratory dysfunction. This may be precipitated by acute problems, such as pneumonia or pulmonary embolism, but may also present more insidiously due to chronic hypoventilation and recurrent respiratory problems leading to pulmonary hypertension and right heart failure.

Peri-operative care

Because of their limited cardiorespiratory reserve, patients with longstanding tetraplegia may require higher dependency or ICU care following surgery. AD may also complicate surgery, particularly surgery of the bladder or bowel.

Sepsis

Sepsis is another frequent complication in chronic tetraplegia, which may require ICU admission. Common sources include pneumonia, urinary tract infections, and infected pressure areas (often with underlying osteomyelitis). Septic shock may present late as hypotension is masked by chronically low blood pressure. Acute kidney injury may be missed initially as the serum creatinine is commonly low due to low muscle mass and may triple yet still be within the normal reference range. High prevalence of colonisation with multiresistant organisms also complicates treatment of sepsis and should be taken into account when choosing antibiotics.

Complications of intrathecal infusion devices

Continuous intrathecal baclofen infusions from subcutaneously implanted pumps are occasionally used to treat disabling spasticity refractory to conventional measures. If the pump stops working or runs out of drug, baclofen withdrawal syndrome may ensue, with severe spasticity, seizures, hyperthermia, rhabdomyolysis, multi-organ failure and death [12]. This may also occur with the abrupt discontinuation of regular enteral baclofen, which should be avoided or if unavoidable baclofen should be replaced with benzodiazepines. Excessive baclofen administration, which may occur if the pump is changed and a bolus accidentally given, may result in profound coma. Intrathecal devices may also become infected with potentially severe infection of the central nervous system.

PART 16.5

Burns

CHAPTER 346

Pathophysiology and assessment of burns

John A. M. Paro and Geoffrey C. Gurtner

Key points

- Burn injury represents a complex clinical entity with significant morbidity and remains the second leading cause of trauma-related death.
- Thermal insult results in coagulative necrosis of the skin, and the depth or degree of injury is classified according to which skin layers are involved.
- Large burns can initiate a massive hypermetabolic response with systemic effects affecting multiple organ systems.
- Accurate assessment of total body surface area involved in burn injury is critical for prognosis and resuscitation.
- Physical diagnosis remains the gold standard for assessment of burn depth, although other objective measures show promise.

Introduction

Great progress has been made over past decades in the care of burn patients. Burn injuries range in severity from minor to life threatening, and an expanding knowledge of the pathophysiology of burns has led to improved management of a complex clinical entity. This chapter will focus specifically on the local and systemic effects of thermal injury and discuss initial assessment of the burn victim.

Epidemiology

It is estimated that well over one million people in the United States experience some form of burn injury each year. The vast majority of these injuries can be successfully treated on an outpatient basis, resulting in little to no significant morbidity. Some 50,000 burned patients annually, however, require hospitalization in some capacity. Ultimately, 5000 people will die from their injury, making it second only to motor vehicle accidents in the cause of trauma-related deaths [1].

Burn rates remain considerably higher than this in the developing world. Nearly 200,000 deaths, mostly in low-income countries, are attributed to burns [2]. In Western nations, access to care as well as considerable prevention efforts are responsible for a declining incidence and severity of injury [3]. In the UK, the Birmingham Burns Centre has been systematically tracking outcomes for over 75 years, and has helped quantify some of the dramatic improvements in mortality. Since their initial report in 1949, mortality has been halved for patients with comparable burn size and age [4] (Table 346.1).

Burn aetiology

Burns can be classified into five primary causes based on the source of thermal energy transfer. Flame or fire burns are the most common, and account for the majority of reported injuries. Scald injuries result from contact with hot liquids and represent about one-third of known cases. Contact injury with hot or cold surfaces results in nearly 10% of injuries. Burns from noxious chemicals and by the conduction of electricity result in 4% and 3% of injuries, respectively [3]. This distribution is similar in developing countries, with nearly 90% of burns occurring in the home [2].

Pathophysiology

Local changes

Thermal injury to the skin results in coagulative necrosis of the epidermis and the contents below. The extent of destruction is influenced by both the temperature and duration of exposure—skin will absorb the majority of this damage. From superficial to deep, skin includes the following layers:

- **Epidermis**: provides a vapour and bacterial barrier.
- **Dermis**: important for flexibility, strength, and home to hair follicles, nerves, and vasculature.
- **Subcutaneous fat**.
- **Deeper structures**.

Burns are classified according to the extent of damage caused by the thermal insult. First degree burns are those limited to the epidermis, for example, a sunburn. First degree burns heal relatively quickly, without scarring. Second degree burns are further categorized into superficial and deep, based on dermal involvement. An injury involving minimal dermis is also referred to as a superficial partial thickness burn. These injuries take roughly 1–2 weeks to heal, and can result loss of pigment in the affected area. Deep partial thickness burns include more extensive injury to the dermal layer. They require 2–5 weeks to heal spontaneously and can result in substantial scarring and contracture [5].

Third degree burns include injury to epidermis, dermis, and the subcutaneous fat. This is also referred to as full thickness. If the damage extends to underlying tissue, such as muscle, tendon, or bone, this is considered to be a fourth degree burn.

Histologically, the transfer of heat leading to skin injury is classically divided into three zones. The ‘zone of coagulation’ refers to the area of cutaneous necrosis that is irrevocably damaged. This is

Table 346.1 Mortality (all ages) grouped by burn size

%Total body surface area burn	Mortality rate
0.1–9.9	0.6
10–19.9	2.8
20–29.9	8.8
30–39.9	16.4
40–49.9	25.5
50–59.9	36.4
60–69.9	43.3
70–79.9	57.7
80–89.9	74.3
90+	82.8

surrounded by a 'zone of stasis,' characterized by decreased tissue perfusion and a less severe thermal insult. The viability of this tissue depends on both the body's own local immunochemical response to injury, as well as the timely response of the treating physicians. Finally, a 'zone of hyperaemia' lies peripheral to and below the zone of stasis, and is characterized by vasodilation from a variety of inflammatory mediators released by neighbouring tissue. This zone has minimal injury and should not be victim to further damage.

Systemic changes

It is easy to focus mainly on the local damage and physical findings following a burn injury. Much more is at stake, however, than the local cutaneous damage—a major burn injury will initiate a massive systemic response capable of complete homeostatic disruption. The inflammatory mediators that give rise to the local effects described above can also produce substantial vasodilation in the periphery, leading to increased capillary permeability and multifocal oedema. The systemic inflammatory response provides a substantial contribution to burn-related death.

Hypermetabolism

The hypermetabolic response to a severe burn can last for months following injury. The release of inflammatory hormones leads to a long-standing increase in cardiac output, basal metabolic rate, and oxygen consumption. Clinical manifestations include tachycardia, tachypnoea, and fever. Often, the metabolic rate may be more than double baseline resting energy expenditure [6].

Other hormones released during this phase include catecholamines and cortisol. These have significant effects on mobilization of the body's energy stores and can lead to significant catabolism. Glucose availability is increased through hepatic gluconeogenesis, which is supported by peripheral lipolysis and proteolysis. Early nutrition is essential following significant burn injury to reduce the deleterious effects of this catabolic state. Lean muscle can decrease markedly. Continued lipolysis in an effort to provide more substrates can lead to the development of fatty liver [7]. This metabolic effect has been known to last for as long as 1-year following injury. Ultimately, the body reverts to an anabolic state in an effort to slowly rebuild fat and protein stores.

Immune system effects

Severely-burned patients are at significant risk of infectious complications, both due to prolonged hospital stays, as well as a marked reduction in immune function. Animal models have confirmed an increased susceptibility to infection based on burn size. This appears to be related to altered polymorphonuclear cell surface receptors causing impaired leukocyte adherence, as well as a separate mechanism resulting in a globally decreased bactericidal activity [8].

Differentiating between the systemic effects of a thermal injury and an overt infection can be difficult given the hyperglycaemia, tachycardia, fever, and leukocytosis that often accompany significant burns. Surgical site infection, cellulitis, and pneumonia are all common in patients hospitalized with burns.

Other organ systems

Initial decreased perfusion to the gut can lead to early atrophy of intestinal villi, which disrupts the mucosa, impacts digestion and nutrient absorption, and has profound effects on intestinal permeability. Ultimately, absorption of glucose and amino acids is impaired. Additionally, there is increased translocation of microbes such as *Candida* [9].

Transient oliguria and temporary increases in creatinine concentration occur frequently in the resuscitative stage of post-burn care. This may be related to low flow states seen in the first 24–48 hours following injury and the incidence of transient renal dysfunction varies from 15 to 40% depending on the definition used. There is increasing evidence that early acute kidney injury is a strong predictor of severe renal dysfunction and increased mortality [10].

Assessment

Initial evaluation of a burned patient should be the same as for any victim of trauma. Multiple systems may be affected, and the first priority is to recognize and treat any life-threatening injuries.

Primary survey

It is important to quickly ascertain the stability of the burn victim's airway. Smoke and heated air will cause both direct and indirect damage to a patient's upper airway, and respiratory tract oedema may lead to critical airway obstruction and hypoxaemia. Physical clues of potential airway compromise include singed facial or nasal hair, tachypnoea, expectoration of carbonaceous sputum, and inspiratory or expiratory wheeze. Airway swelling can progress rapidly, and requires constant reassessment throughout the early hospital course. The physician should have a relatively low threshold to secure a definitive airway through tracheal intubation, as upper respiratory swelling will often worsen with fluid resuscitation.

A patent airway alone does not ensure adequate ventilation as deep burns of the chest wall can constrain thoracic mobility thereby limiting ventilation. Monitoring carbon dioxide through capnography is a useful adjunct.

Early haemodynamic assessment is essential, but may be difficult due to the presence of charred extremities and invasive systemic arterial pressure monitoring is often needed. Heart rate can be used as a marker of overall circulation, but is typically elevated in burn injury. Patients with burns must also be fully assessed for other traumatic injuries including spinal injury. Finally, it is critical to

provide full exposure of the patient, typically by cutting and removing all clothing.

Secondary survey

After any potentially life-threatening conditions have been identified and treated, a more thorough head-to-toe physical examination is performed. While all potential sources of traumatic injury must be assessed, the extent and depth of cutaneous damage must be assessed and documented as it has significant impact on both the prognosis and management of burn patients.

Determining extent of injury

The most common method for assessing burn size is the 'rule of nines,' dividing the total body surface area (TBSA) into sections of 9%. Each upper extremity, as well as the head and neck, are 9%. Eighteen per cent is assigned to the chest/abdomen, to the back, and to each lower extremity. The remaining 1% is designated for the genitals and perineum (Fig. 346.1).

A similar method that has been described, especially helpful for smaller and oddly-shaped burns, is to define the area of a patient's full hand (palm and fingers) as 1% TBSA and use this as a mapping template. Some data suggest that an even more accurate assessment involves using only the patient's palm as an estimate of 0.5% body area [11].

Both of the above methods are very useful, particularly in the preliminary evaluation for triage and initiation of resuscitation. They have their limitations and tend to be considerably less accurate in children, who have a different distribution of body surface area (Table 346.2). The rule of nines technique also tends to overestimate burn size [12]. We recommend that, once the patient is stabilized, a more exact measurement of burn size be established using such methods as the Lund–Browder chart or Berkow Formula (Table 346.2).

Determining depth of injury

First degree burns are confined to the epidermis. These are the least serious types of injury, quickest to heal, and perhaps the easiest to diagnose. They blanch when touched, are erythematous and painful, and appear to be like sunburn. Full thickness or third degree burns are dry, insensate, and leathery to the touch.

Differentiating between the two types of second degree burns is more challenging. Superficial partial thickness burns are erythematous and painful as well, and can also blanch to the touch. There is often blistering overlying this type of wound. Sensation is intact, and a pinprick will be felt as sharp. Deep partial thickness burns may demonstrate pallor or mottling, and will not blanch as easily. Sensation remains intact, but diminished—a pinprick may be felt only as pressure (Table 346.3)

These differences are subtle—some studies suggest that experienced burn surgeons are able to accurately classify second degree burns 60–75% of the time [5]. While careful examination by the responsible physician remains the gold standard for burn size and

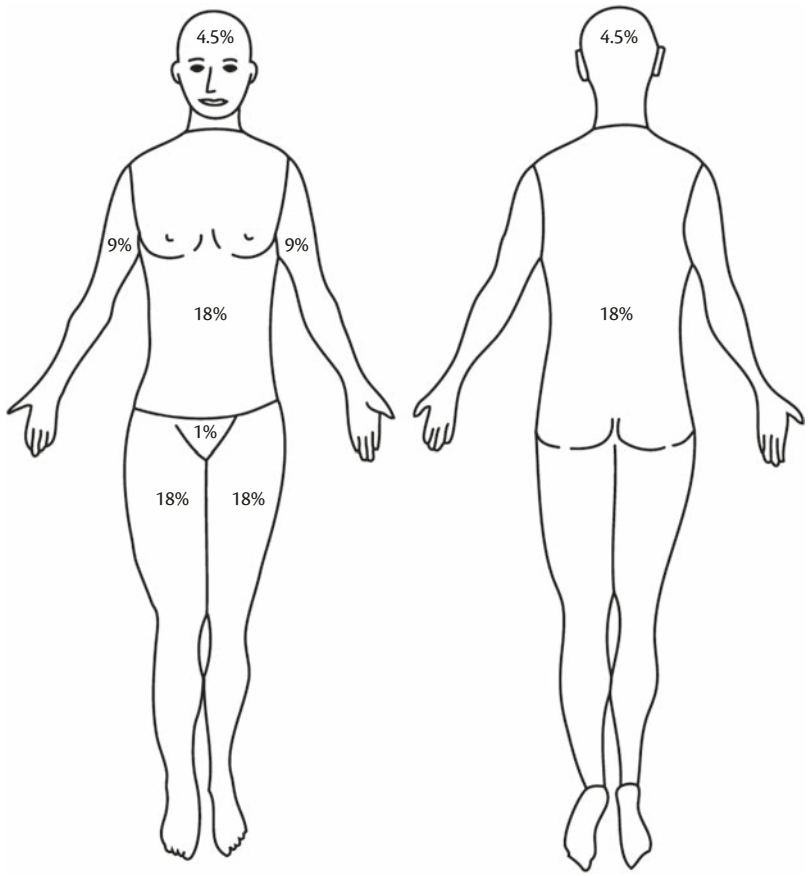

Fig. 346.1 'Rule of nines' chart for estimating body surface area burned in adults.

Each upper arm	4	4	4	4	4	4
Each lower arm	3	3	3	3	3	3
Each hand	2.5	2.5	2.5	2.5	2.5	2.5
Each thigh	5.5	6.5	8	8.5	9	9.5
Each leg	5	5	5.5	6	6.5	7
Each foot	3.5	3.5	3.5	3.5	3.5	3.5

This table is adapted from *Sabiston Textbook of Surgery*, Townsend et al., Copyright Elsevier 2007. Data from 'A method of estimating the extensiveness of lesions (burns and scalds) based on surface area proportions', Berkow SG, *Archives of Surgery*, 1924, **8**(1), pp. 138–48. doi:10.1001/archsurg.1924.01120040149006.

depth evaluation, other adjuvant technologies have been piloted and studied. These techniques include histological examination of biopsy specimens, video angiography, vital dyes, video microscopy, and the use of laser Doppler [13,14].

Burn units

Burns units are specialized centres that provide collaborative and team-based approaches to burn care. Patients with substantial burns, burns requiring specialized surgical care, or who have other injuries or significant co-morbidities who should be referred to a burn unit include those with:

Table 346.3 Properties of different burns, according to depth of injury

Burn depth	Skin layers involved	Physical exam	Healing
First degree	Only epidermis	Blanching, painful, and erythematous	Typically within 1 week
Second degree/ superficial partial thickness	Involves minimal portions of dermis	Blanching, painful, and erythematous, with blistering	Epithelialize from retained epidermal structures in 1–2 weeks
Second degree/ deep partial thickness	Injury extends into reticular dermis	Non-blanching, pale and mottled, retains some pain sensation	Heal in 2–5 weeks, with severe scarring
Third degree	All dermis, into subcutaneous fat	Insensate, hard, and leathery	Can only heal from wound edges

- Partial thickness burns greater than 10% total body surface area (TBSA).
- Burns that involve the face, hands, feet, genitalia, perineum, or major joints.
- Third degree burns in any age group.
- Electrical burns, including lightning injury.
- Chemical burns.
- Inhalation injury.
- Burn injury in patients with complex pre-existing medical disorders.
- Any patient with burns and concomitant trauma (such as fractures) in which the burn injury poses the greatest risk of morbidity or mortality.
- Children with burns, who are in a hospital without dedicated paediatric support.
- Burns in patients who require special social, emotional, or rehabilitative intervention.

Conclusion

Burns give rise to complex local and systemic physiological effects, an understanding of those effects, and the ability to accurately quantify the extent of injury, is critical in the understanding and management of patients with burns. These principles provide the foundation for resuscitation and management.

CHAPTER 347

Management of burns in the ICU

Shahriar Shahrokhi and Marc G. Jeschke

Key points

- Burn critical care is an essential component of modern burn care and significantly improves survival.
- Adequate resuscitation is essential for organ preservation.
- Immediate recognition, as well as early and adequate treatment of inhalation injury decreases detrimental pulmonary sequelae.
- Burn care needs to recognize time patterns for burn patients—prehospital, early, and late management.
- Attenuation of hypermetabolism improves post-burn outcomes.

Introduction

There is no greater trauma than a major burn injury, which can be classified according to different burn causes and different depths. More than 500,000 burn injuries occur annually in the United States per year [1]. Although most of these burn injuries are minor, approximately 40,000–60,000 patients require admission to a hospital or major burn centre for appropriate treatment. The devastating consequences of burns have been recognized by the medical community, and significant resources and research have been dedicated, to improving outcomes [2]. Specialized burn centres and advances in treatment, based on improved understanding of resuscitation, protocolized and specialized critical care, enhanced wound coverage, more appropriate infection control, improved treatment of inhalation injury, and better support of the hypermetabolic response to injury have improved the clinical outcome of this unique patient population over the past years [2,3]. However, a severe burn remains a devastating injury affecting nearly every organ system, and leading to significant morbidity and mortality [2–5]. The management and care of burn patients is complex, entailing many members of various specialties.

Survival of the burn patient depends on:

- **Prehospital care**: adequate and timely response, and treatment, resuscitation, and transport.
- **Initial hospital phase**: admission to a burn centre, escharatomies and fasciotomies, treatment of inhlation injury, and critical care to maintain organ perfusion and function.
- **Later hospital phase**: wound care including burn surgery, infection control, attenuation of hypermetabolism, and maintenance of organ function.

Three critical components have been shown to contribute to increased post-burn morbidity and mortality, and are typical hallmarks of critical care responses:

- Burn shock and resuscitation.
- Inhalation injury.
- Burn hypermetabolism.

Burn shock and resuscitation

The initial management and therapeutic goal is prevention of organ failure, which begins with adequate resuscitation [6]. Burn shock was recognized early on as a predominantly hypovolaemic state, but is now known to be a complex process that includes components of hypovolaemic, distributive, and cardiogenic shock, and which fluid resuscitation alone cannot correct. After thermal injury, inflammatory mediators are released from the burned skin. These include histamine, serotonin, bradykinin, nitric oxide, lipid peroxides, prostaglandins, derived oxygen and nitric oxide free radicals, thromboxane, cytokines (interleukins and tumour necrosis factor (TNF)), and platelet aggregating factors [1,6]. This inflammatory response is proportional to the injury, and the systemic effects of these mediators will become obvious with burns exceeding 20–25% TBSA [7]. The systemic response includes local vasoconstriction, systemic vasodilatation, and massive capillary leak, with subsequent hypovolaemia and haemoconcentration that peaks approximately 12 hours post-burn. Without adequate resuscitation, multi-organ failure and death results [8].

Maintenance of organ perfusion during burn shock depends first on restoration of intravascular volume. The most commonly used algorithm for fluid resuscitation is the Parkland formula, which calculates a total volume of crystalloid to be given over the first 24 hours as 2–4 mL/kg patient weight/% (total body surface area (TBSA) burnt, with half of this amount to be given in the first 8 hours after the burn and the remaining half in the next 16 hours. Thus, as a guideline, a patient weighing 80 kg with 50% TBSA burn would require 2–4 × 80 × 50 mL = 8000–16,000 mL of crystalloid resuscitation in the first 24 hours after the burn [6,8,9]. As recommended by the American Burn Association (ABA), the resuscitation formula is only to be used as a guideline for resuscitation in burn shock. The Parkland formula is deficient in calculating the fluid requirements for resuscitation of patients with large burns, deeper burns, inhalation injury, delays in resuscitation, alcohol or drug use, as well as those with electrical injury leading to inadequate/inappropriate resuscitation.

The endpoints for fluid resuscitation have traditionally been a urine output of 0.5 mL/kg/hour, and a mean arterial pressure (MAP) of >65 mmHg. These endpoints are based on physiological rationale and tradition as there have been no large scale trials of different resuscitation endpoints in patients with severe burns. Currently, there are insufficient data to make evidence-based recommendations regarding the best resuscitation endpoints for patients with severe burns, and survey data suggest that urine output remains the most commonly used endpoint. Even using traditional endpoints for resuscitation, patients with severe burns may receive far greater volumes of crystalloid than predicted by the Parkland formula. Inherent complications of fluid resuscitation in the presence of capillary leak include pulmonary oedema, pleural effusions, pericardial effusions, abdominal compartment syndrome, extremity compartment syndrome, and conversion of burns to deeper wounds. In addition increasing fluid administration in burn patients are associated with increased risk of developing ARDS, pneumonia, bloodstream infections, multi-organ failure, and death [10]. Given the risk of abdominal compartment syndrome with large burns, intra-abdominal pressure monitoring should be considered in patients with burns involving more than 30% TBSA [11].

The role of colloid resuscitation in patients with severe burns is the subject of a long running debate [6,10,11]. Several small studies suggest that colloid resuscitation can result in the administration of less fluid, a less positive fluid balance, and decrease the incidence of intra-abdominal hypertension. Hydroxyethyl starch (HES) is not well studied in burn patients, but smaller studies indicated that HES is associated with increased adverse events. Based on these results and on results from larger trials in the critical care literature the use of HES in burns is not recommended [12]. There are some promising approaches to fluid resuscitation, which involve the modulation of inflammation with the use of antioxidants (specifically ascorbic acid in high doses). In 2000 Tanaka demonstrated in a small open-labelled non-randomized trial that the use of high dose ascorbic acid can lower fluid requirements during resuscitation and decreases the total ventilator days [13]. More recently Kremer et al. demonstrated that administration of high dose ascorbic acid reduces the microvascular barrier dysfunction in vivo [14]. These studies indicate a potential benefit for the resuscitation of burn patients, but one has exercise caution with the use of high vitamin C. This should not be standard, rather a subjective adjunct for burn patients and conducting large multicentre clinical trials to determine whether this should be a standard treatment is highly recommended.

The goals of resuscitation are to stabilize and restore haemodynamic status as soon as possible, and ensure tissue perfusion and oxygenation. To achieve this aim, the clinician can utilize various tools, including a combination of fluids (crystalloids and colloids after 8–12 hours), which aim to restore the intravascular volume, and inotropic and vasopressor agents. Fluids alone may not restore adequate tissue perfusion in all patients. During the initial phase post-burn massive burns may be associated with cardiogenic shock characterized by low cardiac output. The management of initial cardiogenic shock may require a combination of dobutamine and noradrenaline, in doses titrated to target (cardiac index ≥2.5–3 L/min/m^2, mean arterial pressure >60 mmHg) once intravascular volume has been restored as evidenced clinically, as well as by use of non-invasive cardiac output monitors (PiCCO, etc.). A cautious restrictive attitude towards fluids and tight clinical supervision is essential in ensuring optimal outcome. The initial resuscitation should aim to maintain organ perfusion—urinary output 0.5 mL/hour, lack of tachycardia, maintenance of MAP ≥60 mmHg, normal lactate and base excess levels will generally reflect this global condition [1,6,10].

A novel approach for burn patients has been the use of thermodilution catheters to determine cardiac function, systemic vascular resistance, and lung water [15]. The use of these catheters may enable focused and algorithm-driven therapy, which may improve the resuscitation phase, but as of now there are only few small studies published that do not allow major conclusions. However, these systems show promising results to optimize resuscitation.

Inhalation injury

Inhalation injury affects 15–30% of burn patients and is a significant additive variable in burn injury increasing morbidity (ventilator dependence, increased length of hospitalization, etc.) and mortality [3,4,16]. The ideal mode of ventilation for treatment of inhalation injury is yet to be agreed and remains controversial.

The diagnosis ranges from history and physical findings, to examination by bronchoscopy and measurements of serum markers [8,17]. However, there is general agreement that thermal injury associated with being in an enclosed space, loss of consciousness, and severe head and neck burns can have associated inhalation injury. The grading can be established by bronchoscopy, but its relationship to possible mortality, length of ventilatory requirement, and need for tracheostomy remains unclear [8].

A common grading system of inhalation injury developed by Gamelli et al., derived from findings at initial bronchoscopy, is based on the presence of: airway oedema, inflammation, mucosal necrosis, presence of soot and charring in the airway, tissue sloughing or carbonaceous material in the airway [18]. The treatment of inhalation injury should start by immediately securing the airway by endotracheal intubation if early evidence of upper airway oedema is present as airway oedema progresses rapidly in the first 6 hours, and delivering 100% oxygen until adequate oxygenation can be established by monitoring pulse oximetry and arterial blood gases.

Inhalation injury is often associated with inhalation of toxins such as carbon monoxide (CO), and cyanide (CN). The treatment for CO toxicity remains administration of 100% oxygen. The role of hyperbaric oxygen remains controversial, although both physiological data and some randomized-trial data suggest a potential benefit, in particular in terms of reduction of cognitive sequelae [19].

CN toxicity associated with inhalation injury remains a diagnostic dilemma as markers for CN toxicity (elevated blood lactate, elevated base deficit, or metabolic acidosis) can also represent under-resuscitation, associated trauma, CO poisoning or hypoxia. Regardless, aggressive resuscitation and administration of 100% oxygen remains the mainstay of treatment. Controversy remains as to the need for specific antidotes in cyanide poisoning. The use of hydroxocobalamin (a standard of prehospital care in some European centres) has not been as widely accepted in North America. There's minimal evidence for the role of CN antidotes in smoke inhalation injury and, therefore, aggressive supportive therapy aimed at allowing for the hepatic clearance of cyanide without specific antidotes should be the first line of treatment.

Other treatment modalities (β_2-agonist, nebulized heparin, and nitric oxide) have been proposed for inhalation injury. β_2-agonist resulted in improved lung physiology by reducing pulmonary oedema and lung vascular permeability to protein in animal models; however, there's lack of evidence for its use in humans.

Following inhalation injury, casts composed of mucus secretions, airway epithelial cells, inflammatory cells, and fibrin may form within the airway and can cause airway obstruction. In order to improve pulmonary toilet it is essential to prevent and be able to dissolve fibrin deposition. The role of nebulized heparin therapy has been studied in animal models and single-centre trials that demonstrate potential role in inhalation injury, particularly when combined with other anti-inflammatory agents and antithrombin.

Studies in animal models have consistently shown a reduction in pulmonary hypertension associated with inhalation injury with the administration of inhaled nitric oxide. There are limited studies in humans, which have demonstrated an improvement of PaO_2/FIO_2 ratio with the NO. With the current level of evidence the role of NO is unclear in inhalation injury and should only be considered in those who have failed traditional ventilation strategies.

Therefore the treatment guidelines for inhalation injury call for nebulized heparin, acetyl cysteine, adrenaline, and lung protective ventilation.

Post-burn hypermetabolism

The complex metabolic response to burn is extremely profound and one of the central determinants for post-burn survival. Recently, it was shown that this response persists for years [2,4,5]. There's a pronounced increase in catecholamine secretion with a resultant 140–180% increase in the resting metabolic rate, which induces prolonged tachycardia, fever, muscle protein catabolism, and hepatic dysfunction [2,4,5]. This continued hypermetabolic state results in a decrease in lean body mass, compromise of the immune system with resultant increase risk of infection/sepsis, delayed wound healing and prolonged recovery period [2,4,5].

Over the last decade or two various therapies have been studied with the goal to alleviate this catabolic and hypermetabolic state. To-date no single therapy exists to block hypermetabolism, but various therapeutic approaches have been implemented for burn patients [20]:

- Raise ambient temperature.
- Nutrition.
- Early excision and grafting.
- Exercise.
- Adequate organ support.
- Anabolic and/or anticatabolic agents.

Of the systemic therapies the use of anticatabolic β-blocker (propanolol) and anabolic agents such as growth hormone, oxandrolone, insulin, insulin-like growth factor-1, glucagon-like peptide ketoconazole, or the combination of various agents have demonstrated beneficial effects (all reviewed in [20]). Each of the agents have advantages and disadvantages. Currently, three agents should be considered for therapeutic intervention—propranolol will decrease the catecholamine induced post-burn stress, oxandrolone is anabolic and can increase strength and endurance, and finally, insulin is an anabolic hormone regulating post-burn insulin resistance and hyperglycaemia. To summarize, there is no magic bullet to treat hypermetabolism, but it is believed that survival of burn patients depends on the attenuation of the hypermetabolic response using adequate nutrition, early excision and grafting [2], increased ambient temperature, exercise, and administration of anabolic and anti-catabolic agents, such as oxandrolone, insulin, and propranolol [20].

Conclusion

The management of the critically-ill thermally-injured patient can be very complex. The treatments modalities can remain, at times, controversial as there is a lack of high-level evidence. There have been many advances in the field of the critical care of the thermally-injured patient, which would benefit from large-scale multicentre trials. This brief chapter highlights few of the important nuances in the care of these patients and places emphasis on the need for intricate support for the all organ systems in order to improve morbidity and mortality.

Physical disorders

PART 17.1

Drowning

CHAPTER 348

Pathophysiology and management of drowning

Jerome H. Modell and Sean Kiley

Key points

- Drowning is a process beginning with airway submergence under a fluid medium and progressing to aspiration and ultimately death in the absence of intervention.
- Aspiration of both fresh and salt water cause pulmonary oedema, decreased compliance, intrapulmonary shunting, and severe hypoxia.
- Devastating neurological injury resulting from prolonged cerebral hypoxia is proportional to the duration of submersion and delay in effective resuscitation and oxygenation.
- Victims presenting to the emergency department awake and alert, or even stuporous, are likely to have a good neurological outcome with follow-up intensive care. Those presenting comatose are much more likely to have severe neurological deficits.
- Key to survival are timely rescue from the water, immediate initiation of aggressive supportive care regarding airway, cardiovascular, and pulmonary function, and optimization of tissue oxygenation.

Epidemiology

Over the past 50 years, knowledge of the pathophysiology of drowning has expanded greatly [1] and improvement in critical care of drowning victims, emergency medical services, pool safety standards, and lifeguard training have been instrumental in reducing the death rate from drowning in the United States from 3.87 deaths per 100,000 population in 1970 to 1.35 deaths per 100,000 population in 2009 [2]. Factors that contribute to drowning include leaving unattended children at water sites, alcohol or other drug abuse, limited swimming ability, exhaustion, trauma, risky behaviour, deliberate prolonged submersion, exacerbation of existing medical problems (e.g. seizure disorder, cardiac disease, or syncope), and suicide.

Omissions in safety precautions, such as inadequate pool fencing, faulty pool design resulting in victims becoming trapped below the surface of the water, poor pool maintenance causing cloudy water that obscures submerged bodies, lifeguards distracted by socializing and doing administrative chores when on duty, and lifeguards who do not recognize a person in trouble, or have not been properly trained in rescue and resuscitation techniques, all contribute to drowning.

To drown implies death, yet many victims are resuscitated and recover. The terms 'near-drowning', 'drowning without aspiration' or 'dry drowning', 'active and passive, or silent drowning' have been abandoned. The new definitions for 'drowning' and 'the drowning process' were published in 2003 [3].

The drowning process

The drowning process begins when the victim's airway lies below the surface of the liquid, at which time the victim voluntarily holds his or her breath. This is usually followed by an involuntary period of laryngospasm secondary to liquid in the oropharynx or larynx. During this time, the victim is unable to breathe gas, and becomes hypercarbic, hypoxaemic, and acidotic. Respiratory movements become very active, but there is no exchange of air because of the obstruction at the level of the larynx. As the victim's arterial oxygen tension drops further, laryngospasm abates, and the victim actively inhales liquid. Changes occur in the lungs, body fluids, blood–gas tensions, acid–base balance, and electrolyte concentrations, which are dependent on the composition and volume of the liquid aspirated and duration of submersion. Surfactant washout, pulmonary hypertension, and shunting also contribute to development of hypoxaemia [3].

Pathophysiology

The submerged victim holds his or her breath, and/or is in laryngospasm, for approximately 1½–2 minutes before the oxygen in blood perfusing the brain decreases to the extent that laryngospasm can no longer be sustained and ventilation occurs. Consciousness is lost at about the same time due to cerebral hypoxia. If rescued promptly and permitted to breathe air, the individual will not undergo the remainder of the drowning process. If water is aspirated a far more complex occurrence results. Experimentally, it has been shown that cardiac arrest due to hypoxia occurs by 3–4½ minutes [1].

If the victim is rescued, and ventilation and circulation are re-established, acute lung injury usually follows the drowning incident. Studies have shown 2.2–44 mL/kg of water instilled into the trachea of anaesthetized dogs resulted in immediate decrease in the partial pressure of oxygen in arterial blood (PaO_2) that persisted for many hours or even days [4,5]. Likewise, human drowning victims often demonstrate prolonged hypoxia post-event [6].

Rapid hypothermia results from drowning in cold water, which prolongs the length of time they may be submerged and still recover [7].

However, significant hypothermia also can lead to delay in myocardial conduction, dysrhythmias, and cardiac arrest.

Aspiration of water

Once it was thought that approximately 10–15% of human drowning victims died without aspirating liquid. Lunetta et al. in 2004 [8], questioned whether drowning without aspiration actually occurs. They reviewed the autopsies of 578 persons presumed to have drowned, and found evidence of water in the lungs of 98.6% of the victims studied [8]. They concluded drowning requires the aspiration of water. If the heart stops before the individual's airway becomes submerged, water does not passively seep into the lungs. Persons found dead in water without evidence of aspiration at autopsy, probably died of some other cause, such as a homicide or lethal cardiac arrhythmia [8].

Sea water is hypertonic and draws capillary fluid into the lung by osmotic pressure, leading to intra-alveolar oedema [9]. Fresh water aspiration alters the surface tension properties of pulmonary surfactant, rendering the alveoli permeable to fluid and also to collapse [10]. Fresh water is also absorbed into the circulation creating rapid haemodilution [4]. This results in a temporary increase in systemic blood volume, cellular swelling, and haemolysis [4].

Pulmonary oedema occurs with either type of water and decreases compliance, and increases intrapulmonary shunting. The aetiology of this process is fluid-filled, but perfused alveoli when seawater is aspirated and alveolar collapse due to surfactant instability when fresh water is aspirated [11].

Pathological changes caused by drowning are usually reversible if the person is rescued and treated promptly with aggressive pulmonary support, including the use of positive end-expiratory pressure (PEEP) or continuous positive airway pressure (CPAP) [11]. Acute respiratory distress syndrome (ARDS) and pneumonia increase mortality associated with drowning. If pneumonia is diagnosed, antibiotic treatment should be broad and include coverage for the ecology of organisms in the body of water in which the drowning incident occurred.

Changes in blood volume and serum electrolytes

Differences in tonicity of the aspirated medium produce different effects on intravascular volume. When a large volume of hypotonic fluid is aspirated, it is absorbed quickly and intravascular volume increases in proportion to the volume aspirated [4]. Fluid shifts and redistribution may ultimately result in hypovolaemia. Conversely, aspiration of hypertonic fluid causes immediate shifting of fluid from the intravascular space to the alveoli rapidly creating hypovolaemia [5].

Electrolyte changes during drowning are directly associated with the intravascular volume changes [4,5]. Clinically significant volume or electrolyte abnormalities in survivors are unlikely because they rarely aspirate sufficient volumes of liquid to cause such changes [6].

Cardiovascular effects

If freshwater is aspirated, the resultant hypotonicity of the plasma in the presence of hypoxemia causes red blood cell lysis with release of haemoglobin and potassium. Rarely, serum potassium increases and serum sodium decreases are sufficient to lead to ventricular fibrillation [12]. Arrhythmias related to hypoxia are relieved when oxygenation is re-established [1].

Choi et al. [13] reported that 8.5% of drowned victims had genetic mutations compatible with long QT syndrome. However, Lunetta et al. [14] found QT syndrome founder mutations in *KCNQ1* (*KVLQT1*) and *KCNH2* (*HERG*) genes in only one of 165 consecutive drowning victims. He concluded that long QT-induced arrhythmias resulting in drownings are rare [14].

Neurological effects

Mental status upon arrival at the hospital provides insight regarding long-term neurological effects related to cerebral hypoxia. If the victim is awake and orientated, virtually 100% survive without neurological deficits [15,16]. If they present stuporous, but capable of arousal and have purposeful responsiveness to pain, there is a 90% likelihood that there will not be long-term neurological effects [15,16]. If drowning victims present in coma, the outcomes are worse. Conn et al. [15] found 57% of comatose drowning victims had persistent severe neurological deficits or died and Modell et al. [16] found 44% had severe hypoxic brain damage or died.

The degree of neurological injury is proportional to the duration of submersion and delay in providing effective resuscitation. If effective resuscitation starts within 3 minutes of the onset of submersion, survivability is excellent. However, irreversible cell death usually occurs after about 5 minutes of submersion or inadequate oxygen delivery. There are reports of prolonged cold water immersion in which victims survive neurologically intact [7]. These usually relate to children because they have a large exposed surface area, and cool rapidly thus benefiting from hypothermic protection from hypoxia. The extent of neurological injury is difficult to detect early on, even with imaging. The patient's response to therapy over time is the only true prognosticator.

Shallow water blackout

Craig, et al. [17] studied the breath-holding breaking point in human volunteers and found breath-holding could be prolonged one-and-a-half times longer if it was preceded by hyperventilation. However, during simulated underwater swimming after hyperventilation breath-holding time was reduced to baseline. He concluded although exercise, such as swimming, increased metabolically-produced carbon dioxide, the arterial carbon dioxide tension was decreased in their volunteers because storage was depleted during hyperventilation and the urge to breathe was delayed. With exercise after hyperventilation, arterial oxygen tension decreased to levels incompatible with maintaining consciousness before the level of partial pressure of carbon dioxide in alveolar blood ($PaCO_2$) became unbearable. The victim then begins to breathe under water due to a hypoxic drive, aspirates water, and drowns. This has been termed 'shallow water blackout'.

Treatment

On scene

Treatment for drowning victims begins with immediate rescue from the water. Rescue breathing and support of circulation should begin promptly. Despite anecdotal claims of the use of the Heimlich manoeuvre to treat drowning victims, the Institute of Medicine recommends against the Heimlich manoeuvre because of

its questionable value and it delays initiation of cardiopulmonary resuscitation [18].

Basic life support (BLS) should be instituted immediately and should be followed by advanced cardiac life support (ACLS) as soon as possible. No matter what the patient's appearance after retrieval and resuscitation, transport to the hospital should be immediate, with prompt initiation of oxygen therapy and monitoring with a minimum of pulse oximetry, blood pressure, and ECG. If the patient remains apnoeic and/or in cardiac arrest, ACLS should be continued.

Hospital treatment

Initial treatment should focus on optimizing oxygen delivery to tissues. Oxygen supplementation may be adequate in patients who maintain adequate spontaneous ventilation and circulation. CPAP is effective in recruiting alveoli and reducing intrapulmonary shunt in patients having difficulty maintaining adequate oxygen saturation [12]. Endotracheal intubation and mechanical ventilatory support is required for all comatose patients and those having difficulty maintaining adequate oxygen saturation. Arterial blood gas values must be obtained as soon possible to assess for hypoxia, hypoventilation, and acid–base disturbances. Sodium bicarbonate administration may be necessary to treat profound metabolic acidosis that occurs from anaerobic metabolism.

Severe hypothermia is common and rewarming should be initiated via passive and active external methods, including humidified warm inspiratory gases. Conduction, convection, and radiant warming also may be necessary. Recent data suggests therapeutic hypothermia post-arrest may lead to better outcomes. Walpoth and Daanen recommend rewarming to only 32–34°C for 12–24 hours post-drowning [19].

Haemodynamic monitoring is required when there is concern with fluid balance. Arterial catheters facilitate obtaining serial arterial blood gases. CPAP and/or PEEP should be optimized to improve ventilation/perfusion ratios and to permit F_IO_2 to remain as low as possible to avoid oxygen toxicity. Prophylactic broad spectrum antibiotics are only indicated when the drowning medium is known to be contaminated [1].

Seizures should be treated if present. Studies have been conducted to evaluate the empiric use of mannitol, hyperventilation, barbiturates, and neuromuscular blockade for aggressive cerebral resuscitation [15]. However, outcome benefit has not been demonstrated [16,20]. While intracranial pressure (ICP) monitoring may be used to direct therapy to keep ICP below 20 mmHg, optimizing cerebral perfusion pressure, increased ICP probably reflects damage done at the time of drowning.

PART 17.2

Electrocution

CHAPTER 349

Pathophysiology and management of electrocution

Jeffrey S. Neiger and Richard G. Trohman

Key points

- Electrocution is a common source of morbidity and mortality, primarily affecting children in the home and young adults via occupational exposure.
- A familiarity with the basic principles of electrical physics helps one understand the typical injuries suffered following electrical shock.
- Exposure to electrical shock can affect a variety of organ systems, including the skin, cardiovascular system, and nervous system.
- Patients who survive initial cardiopulmonary arrest often have a favourable prognosis, and their injuries should be treated aggressively in a specialized burn or trauma unit.
- Because the full degree of injury is not always initially apparent, determination of prognosis can be difficult in electrical shock victims.

Introduction

Electrocution occurs relatively frequently and has a high mortality [1]. Approximately 1000 people die from electrical exposure in the USA annually [1]. Most electrocution victims are children under the age of 6 years who suffer electrical injury in the home and young adults exposed to electricity as a consequence of their occupation, such as miners and construction workers [1]. Patients surviving the initial insult of electric shock account for approximately 3% of the annual admissions to specialized burn units [1].

Physics

There are two methods by which electric power is delivered, alternating current (AC) and direct current (DC). In AC, the form in which electric power is delivered to businesses and residences, the direction of electron flow reverses rapidly in a cyclic fashion. For example, in the USA, standard household current of 110 V flows at 60 cycles per second (60 Hertz (Hz)). In Europe, the power system operates at 220–240 V and a frequency of 50 Hz. Batteries, high tension power lines, and lightning deliver electrical power via DC. In such situations, current flows constantly in one direction across a potential gradient [1].

The primary determinant of damage caused by electrical injury is the amount of current flowing through the body. Additional factors include voltage, resistance, type of current, current pathway, and duration of contact with the electrical source [2]. Joule's law determines the amount of thermal energy delivered, which leads to tissue damage, is a function of the current squared, time, and resistance [1].

Higher resistance tissues, such as skin, bone, and fat, tend to increase in temperature and coagulate. Nerves and blood vessels, which have low resistance, conduct electricity readily. Dry skin has a higher resistance than moist skin, and may suffer extensive superficial tissue damage from electricity, while limiting conduction of harmful current to deeper structures [3]. Moist skin serves as a better current conductor, resulting in less superficial thermal injury, but more extensive damage to internal organs.

Mechanism of injury

In patients exposed to electrical shock, voltage is typically the only variable that is known with certainty [1]. Electrical shocks of 1000 V or more are classified as high voltage and result in more severe injury per time of exposure, while shocks less than 1000 V are considered low voltage. Typical household electricity has 110–230 V, high-tension power lines have over 100,000 V, and lightning strikes can produce 10 million V or more [3].

Electrocution causes injury via four mechanisms:

- Direct effects of current on body tissue, leading to asystole, ventricular fibrillation (VF), or apnoea.
- Blunt mechanical injury from lightning strikes, resulting in muscle contraction or falling.
- Conversion of electrical energy to thermal energy, resulting in burns, protein denaturation and coagulation.
- Electroporation, defined as the creation of pores in cell membranes by means of electrical current, leading to cell death without significant heating [1]. Electroporation occurs with high strength electrical fields (defined as volts per meter).

Contact with DC results in a single muscle contraction, often throwing the person receiving the shock away from the electrical source. When an individual touches an AC electrical source with their hand, repetitive tetanic muscle contraction can cause the hand to grip the source tighter (because of stronger flexor than extensor tone), leading to longer electrical exposure time and greater injury. For this reason, AC is the more frequent cause of electrocution. The amount of AC needed to cause injury varies with the current's

frequency. Skeletal muscle becomes tetanic at lower frequencies, ranging from 15 to 150 Hz [1]. Household electricity (60 Hz) is especially arrhythmogenic, and may lead to the development of fatal ventricular tachyarrhythmias [1].

Typical injuries

Skin

Skin exposed to electrical shock results in four different types of burns: electrothermal burns, arc burns, flame burns, and lightning injuries [1]. Electrothermal burns result in a classic injury pattern, with skin entrance and exit wounds. Skin wounds due to electrical exposure are typically classified by the depth of injury as partial- or full-thickness, or burns involving deeper subcutaneous tissue. High-voltage injuries commonly produce greater damage to deeper tissues, largely sparing the skin surface. Therefore, estimating the area of surface burns as a guide for therapy may lead to critical errors because an apparently 'minor' superficial injury may be associated with massive coagulation necrosis of deeper tissue [4].

An electrical arc is a current spark that travels via (typically) non-conductive matter such as air, across a gap between electrically charged surfaces. It occurs when two surfaces approach each other, before the halves actually touch, or when the surfaces separate from each other by breaking the current path in the circuit. Arcing can generate temperatures of 3000°C to 20,000°C and crosses 2–3 cm for every 10,000 V [5]. Arc injury occurs when the victim becomes part of the arc itself, and leads to characteristic 'crocodile skin' burns in the portions of the body that come in contact with the arc (Fig. 349.1) [6]. These multiple burnt, punched-out lesions of varying depth are a result of the arc 'dancing' across the body surface.

Respiratory

Respiratory arrest following electrical shock may result from inhibition of the central nervous system respiratory centre, prolonged paralysis or tetanic contraction of respiratory muscles, or combined cardiorespiratory arrest secondary to ventricular arrhythmias. If respiratory arrest is not treated promptly by ventilation, secondary hypoxic VF may occur [1]. Parenchymal damage to the lung is rarely seen in patients who suffer electrical injury. However, fatal air embolism may complicate electrical injury to the deep tissues of the neck.

Cardiovascular

Electrical shock may induce arrhythmias and conduction abnormalities, as well as myocardial injury due to direct electricity exposure and/or secondary injury due to induced ischemia [1].

Arrhythmias

Low-voltage AC more commonly results in sudden cardiac death due to ventricular fibrillation. In contrast, DC or high-voltage AC shocks are more likely to result in asystole [3]. Experimental studies show AC to be more hazardous than DC applied at the same voltage. Interestingly, with exposure to between 50 and 500 V, the incidence of VF was inversely proportional to voltage, while ventricular tachycardia (VT) and atrial fibrillation (AF) were directly proportional [7]. Potentially fatal arrhythmias are more likely to be caused by horizontal current flow (hand to hand), whereas vertical current (head to foot) usually leads to myocardial tissue damage [1,3]. Most arrhythmias occur shortly after the electrical shock, but delayed ventricular arrhythmias can been seen up to 12 hours following exposure [8]. Subsequent arrhythmias are relatively common (10–46%) among survivors, with sinus tachycardia and premature ventricular complexes being most frequent [1,9]. However, VT and AF have also been reported [1]. Patients who survive electric shock often display non-specific ST-T wave that typically resolve spontaneously [3,10]. Those without initial ECG changes are at a lower risk for subsequent life-threatening arrhythmias [11]. Electrocution injury has also been reported to result in typical Brugada pattern ECG changes, with ST elevations in the right precordial leads (V1–V3) and a right bundle branch block pattern [12]. These changes resolved spontaneously and are of unknown significance regarding the long-term risk of malignant arrhythmias [12].

Conduction abnormalities

Sinus bradycardia and high-degree atrioventricular (AV) block have been reported following electrical shock. AC current injury seems to have a predilection for the sinoatrial (SA) and AV nodes [13]. Some of these conduction abnormalities may persist as long-term sequelae of electrical injury and should be monitored closely in survivors of electrical shock.

Myocardial injury

Myocardial damage may occur after exposure to high or low voltage current. Injury is caused directly by electrothermal injury and electroporation, or secondarily by contusion following lightning strike. Other mechanisms described include coronary spasm leading to ischaemia and hypotensive arrhythmias causing secondary hypoperfusion. Diagnosing myocardial injury can be difficult due to the diffuse nature of myocardial necrosis. Typical symptoms and specific ECG changes are not usually present, myocardial perfusion scans are normal, creatine kinase–MB elevations are of uncertain significance, and troponins have not been well-studied in this setting [1].

Musculoskeletal

Bony tissue has the highest electrical resistance and experiences the most severe electrothermal injuries, including periosteal burns, destruction of bone matrix, and osteonecrosis [3,14]. Fractures and large joint dislocations may be caused by forceful tetanic contractions or falls [14]. Electrothermal injury may lead to rhabdomyolysis and compartment syndrome [15]. The extent of muscle tissue

damage can be assessed by serum creatine kinase level, which generally correlates well with the amount of burned surface area and may be useful as a decision aid for surgical decompression [1].

Neurologic

Electrical shock can result in damage to the central and peripheral nervous system. Loss of consciousness, generalized weakness, autonomic dysfunction, respiratory depression and memory disturbances are frequent manifestations [1]. **Keraunoparalysis** is a specific form of reversible, transient paralysis with associated sensory disturbances and peripheral vasoconstriction seen in some victims of lightning injury [16]. It is important to note that such patients may have fixed and dilated pupils (due to reversible autonomic dysfunction), which should not prompt termination of resuscitation efforts or withdrawal of care. Central nervous system complications also include hypoxic encephalopathy, intracerebral haemorrhage, and cerebral infarction. Although sensorineural hearing loss has been reported, hypoacusis is usually due to rupture of the eardrums, a common consequence of lightning strikes.

Renal

Acute renal failure resulting from rhabdomyolysis and myoglobinuria is a common cause of death following electrocution. Rapid fluid resuscitation to correct hypovolaemia and acidosis can significantly reduce the incidence of acute renal failure in these patients.

Special circumstances

Lightning

Lightning strike is unique because it causes cardiac and respiratory arrest, resulting in 25–30% mortality [17]. Lightning delivers a large amount of DC electricity (up to hundreds of millions of volts and 200 amperes) during a very short period (milliseconds) [1]. Thus, the energy delivered may be less than with other high-voltage electrical injuries because of the short exposure time. Patients rarely sustain extensive tissue destruction or large cutaneous burns.

Lightning strikes have been subdivided into three distinct categories, each with different cardiac effects (Table 349.1) [18].

Although rarely seen, Lichtenberg figures are pathognomonic skin manifestations in persons struck by lightning (Fig. 349.2) [19]. Lichtenberg figures are typically formed by rapid dispersion of charge from the surface of poorly conducting tissues. They are transient in nature and do not cause apparent damage to the epidermis or underlying tissues.

Fig. 349.2 Lichtenberg figures typically formed by rapid dispersion of charge from the surface of poorly conducting tissues.

Patients with implantable cardiac devices

Isolated reports exist of patients exposed to high-voltage electricity or lightning strike, who were saved from potentially fatal VF by a successful ICD shock [18]. Conversely, the electromagnetic interference caused by electrical exposure may lead to bradycardia or asystole from inhibition of ventricular pacing, or result in inappropriate shocks leading to induction of ventricular arrhythmias. It is important to perform a thorough device interrogation in all patients with pacemakers or ICDs who suffer electrical injury, in order to help clarify the role of the device in treating any resulting arrhythmias, and to ensure proper function of the device and leads following such exposure.

Management

Cardiopulmonary resuscitation

Victims of electric shock should undergo intensive cardiopulmonary resuscitation (CPR) and therapeutic hypothermia. Cardiac arrhythmias and prolonged respiratory arrest may be the only

Table 349.1 Cardiac effects from various types of lightning strikes

Direct strike (Current passes through person from head/upper body to feet)	Side flash (Person in proximity to, but not in contact with object through which current discharges)	Ground strike/step voltage (Lightning strikes ground and dissipates irregularly)
◆ Immediate cardiac arrest due to asystole or hypoxia-induced ventricular fibrillation ◆ Severe biventricular failure/pericardial effusion ◆ Myocardial injury common (75%) ◆ QT prolongation/ST elevation	◆ Sinus tachycardia, ventricular fibrillation ◆ Myocardial injury common (66%) ◆ Non-specific ST-T wave changes	◆ Sinus tachycardia, ventricular fibrillation ◆ Myocardial injury uncommon (12%) ◆ Non-specific ST-T wave changes

clinical problem, especially in patients struck by lightning. In addition, patients who suffer exposure to electrical shock are commonly young, and have few or no comorbid conditions. They may survive prolonged CPR with minimal or no sequelae, especially with appropriate initiation of therapeutic hypothermia protocols. It is important to remember that keraunoparalysis leading to autonomic dysfunction may masquerade as irreversible neurological injury in patients who have been electrocuted.

Prognosis

It is difficult to predict the outcome of patients admitted to the intensive care unit for electrical shock because the full extent of their injuries may not be apparent. Most patients are young and otherwise healthy so a favourable prognosis is likely. Fatal arrhythmias generally occur immediately following the electrical shock. Thus, death in patients who survive to intensive care unit admission following electrical injury is, for the most part, not a result of cardiovascular damage. Most patients surviving cardiopulmonary arrest resume spontaneous breathing within 1 hour. Ventilatory support for patients who have experienced electrical shock should be continued for a reasonable time until cerebral function can be fully assessed [1].

Prediction of neurological outcome following resuscitation from electrical shock is usually based on the presence or absence of findings compatible with anoxic encephalopathy. Recent advancements in post-resuscitation care, especially implementation of therapeutic hypothermia protocols, have significantly increased the proportion of patients who survive with preserved neurological function [20]. Furthermore, commonly accepted guidelines for outcome prediction in hypoxic–ischaemic coma, may not initially apply to patients who survive electrocution. Brainstem reflexes and motor responses may be absent because of keraunoparalysis. Therefore, in patients resuscitated following an electrical shock, prognosis should be assessed very cautiously and may only be reliable several days post-event, when the direct effects of electrical shock are no longer present [1].

The extent and depth of burn injuries affects prognosis [1]. Deeper and more extensive burns may require emergent wound exploration, debridement, and fasciotomy. Rehabilitation of burn victims is also a fundamental component of management. The rehabilitation phase begins when wound coverage is near completion (wounds may require autologous skin grafting) and represents an extension of acute-phase therapy, which includes pain management, wound coverage, positioning, and exercises. Hypertrophic scars are also a concern in patients with electrical burns. Young age, prolonged healing times, deep initial wounds, and pigmented skin are factors that increase the risk for hypertrophic scars [1].

PART 17.3

Altitude- and depth-related disorders

CHAPTER 350

Pathophysiology and management of altitude-related disorders

Daniel S. Martin and Michael P. W. Grocott

Key points

- Acute high-altitude related illnesses include acute mountain sickness (AMS), high altitude pulmonary oedema (HAPE) and high altitude cerebral (o)edema (HACE).
- AMS is common and generally a benign self-limiting condition if managed with rest, no ascent, and symptomatic treatment. Descent is indicated in severe cases.
- HACO and HAPO are rare, but serious conditions that should be considered medical emergencies. Management involves urgent descent, supplemental oxygen (cylinder, concentrator or portable hyperbaric chamber) if available, and specific treatment with dexamethasone (HACO) or nifedipine (HAPO).
- Slow, controlled ascent (adequate acclimatization) is the best prophylaxis against the acute high-altitude related illnesses. Acetazolamide is effective prophylaxis against AMS.
- Other conditions of relevance at altitude include retinal haemorrhage, neurovascular disorders (including transient ischaemic attacks and cerebrovascular accidents), thrombosis, high altitude cough, disordered sleep, cold injury, and sunburn.

Introduction

Ascent to high altitude results in a progressive fall in the partial pressure of oxygen in air as the barometric pressure declines (fraction of inspired oxygen concentration (F_IO_2) remains constant at 0.21). This reduction in oxygen availability has a profound effect on oxygen transport within the body and triggers an adaptive response known as acclimatization. Increases in heart rate (and therefore cardiac output), minute volume, and haemoglobin concentration result in normalization of oxygen delivery, but this process can take days to weeks. The speed and success of acclimatization varies widely, as a consequence of which, some individuals develop acute high altitude-related illness [1]:

- Acute mountain sickness (AMS).
- High altitude pulmonary oedema (HAPO).
- High altitude cerebral oedema (HACO).

There is no clear definition of 'high' altitude and individual responses vary widely. The development of altitude-related illnesses is related to both the absolute elevation and the rate of ascent. Most people begin to notice changes in their physiology (e.g. increased breathlessness on exertion) above approximately 2500 m. Permanent habitation does not commonly occur above 5000 m and this may be because humans are unable to adapt to this degree of hypoxia in the long-term. Altitudes above 8000 m have been referred to as the 'death zone', particularly on Mount Everest (8848 m), and most climbers require supplementary oxygen to function effectively at such great altitudes.

Acute mountain sickness (AMS)

AMS is commonly encountered on ascent to high altitude with 50–60% of those ascending above 4000 m reporting symptoms of AMS. The symptoms are usually self-limiting, but can progress to the more serious high-altitude clinical syndromes if ignored. The symptoms of AMS include:

- Headache.
- Lack of appetite.
- Poor sleep.
- Lethargy.
- Fatigue.

The severity of AMS can range from a mild symptom disturbance to severe debilitation. AMS tends to develop 6–12 hours after arrival at a new altitude. The Lake Louise self-assessment scoring system can be used to assess the presence and progression of AMS and is based upon assigning a score of 0 (no), 1 (mild), 2 (moderate) or 3 (severe) to the symptom domains outlined in the previous list [2]. A score of three or more with the presence of a headache indicates AMS. Headache is considered universal in AMS, and if not present, other possible diagnosis should be considered.

There are a number of factors that increase the likelihood of AMS:

- Rapid ascent to altitude.
- Excessive exercise at altitude.
- Concomitant systematic illness (cold, chest infection, diarrhoea. and vomiting).

- Dehydration.
- Excessive alcohol.
- Previous AMS.

The pathophysiology of AMS is not fully understood. Whether it represents a mild form of HACO or is a discrete entity of its own is a matter of debate. A phenomenon called high-altitude headache has also been proposed, which is defined as headache with no other symptoms of AMS.

Treatment for AMS is to stop the ascent, rest, and monitor the symptoms. If the symptoms resolve over 24–48 hours, it should be safe to continue ascending slowly. If symptoms do not resolve (or worsen) over this time, the individual should descend. If descent is impossible, the administration of supplemental oxygen can be beneficial until descent is feasible. AMS can be treated pharmacologically, primarily with acetazolamide at a dose of 250 mg bd. This carbonic anhydrase inhibitor induces a diuresis with bicarbonate loss, resulting in a metabolic acidosis that is compensated for by hyperventilation, improving partial alveolar pressure of oxygen (P_AO_2) and acclimatization. The side effects of acetazolamide can be troublesome, including paraesthesia of the hands and feet, an unpleasant taste in the mouth, and the need for frequent nighttime urination. It is also a sulfonamide-containing drug, so should be avoided in those with a known sulfonamide allergy. The steroid dexamethasone (4 mg qds) is also effective, but due to the adverse effect profile of steroids, this is usually considered a second-line treatment.

High altitude cerebral oedema (HACO)

As its name suggests, HACO [3] is thought to result from cerebral oedema, which leads to elevated intracranial pressure and, if untreated, death may result from herniation of the brain stem through the foramen magnum. AMS often, but not always, precedes HACO. The prevalence of HACO is far lower than AMS and is probably in the region of 1–2% of those ascending over 4500 m. Clinically, HACO is diagnosed by the presence of any signs that may be related to the central nervous system in an individual at high altitude. Recognized signs of HACO include:

- Ataxia.
- Confusion.
- Drowsiness.
- Behavioural changes.
- Hallucinations.
- Reduced level of consciousness.
- Coma.

Any individual presenting with any of the signs of HACO (with or without a headache) at altitude should be presumed to have HACO until proved otherwise. However, it is important to differentiate the symptoms and signs of HACO from hypothermia, hypoglycaemia, and alcohol intoxication.

There are a number of candidate causal mechanisms explaining the development of HACO including:

- Vasogenic oedema formation.
- Cytotoxic oedema formation.
- Venous congestion.
- The 'tight fit hypothesis'.

Treatment of HACO should start immediately and a descent of at least 500–1000 m should be arranged urgently. Oxygen should be administrated if available or a portable altitude chamber (see Fig. 350.1) can be used if oxygen or immediate descent is not possible. Dexamethasone should be administrated at a dose of 8 mg stat, then 4 mg qds. This may be given po, but should be given parenterally if the individual is unable to swallow or has a decreased conscious level. If able to swallow, acetazolamide should also be

Fig. 350.1 A portable altitude chamber being used at high altitude to achieve 'simulated descent' by increasing the pressure within the bag and thereby increasing the partial pressure of oxygen.
Published with permission of Xtreme Everest.

administrated as per AMS. In severe cases, where the level of consciousness has declined significantly, supportive measures may be required, such as intubation and mechanical ventilation. This can be challenging in a wilderness environment unless the medical team has specifically planned for such an event.

Once evacuated it is important to rule out any other neurological diagnoses, such as a cerebrovascular event, and this is usually achieved by computed tomography (CT) scan. Some individuals continue to complain of altered neurology after descent; they should be closely monitored and followed-up appropriately to exclude alternative causes of cerebral deterioration, including cerebral ischaemia or haemorrhage.

High altitude pulmonary oedema (HAPO)

HAPO [4] is a non-cardiogenic pulmonary oedema that tends to affect people 24–48 hours after arriving at a new altitude. Its prevalence is approximately 2% of those ascending over 4000 m. HAPO tends to be preceded by AMS, but this is not always the case. Symptoms include:

- Persistent cough.
- Excessive shortness of breath (especially after exercise) in comparison with others.
- Chest pain.
- Profound fatigue.

On examination, severe hypoxaemia and widespread chest crepitations are common. Chest X-ray reveals a patchy pattern of pulmonary infiltrates. Some individuals are more susceptible to HAPO than others, and will tend to develop it each time they reach a specific altitude; they are termed 'HAPO susceptible'.

A rise in pulmonary artery pressure occurs when anyone ascends to high altitude. However, those individuals affected by HAPO tend to have a considerably higher pulmonary artery pressure than those who are unaffected. The pathogenesis of HAPO can be explained by a combination of factors:

- Blunted hypoxic ventilatory response.
- Exaggerated and heterogeneous hypoxic pulmonary vasoconstriction.
- Impaired clearance of alveolar fluid.

As with HACO, the treatment of HAPO requires immediate descent to a lower altitude. Exertion should be avoided as this may worsen hypoxaemia. If possible the patient should be carried to a lower altitude. Oxygen is of particular benefit in HAPO as it leads to a rapid reduction in pulmonary artery pressure. A portable altitude chamber can be used if oxygen is unavailable. Nifedipine is the most effective treatment for HAPO, and should be administrated orally at a dose of 10 mg tds. Recently, dexamethasone and sildenafil have also been shown to be effective in the treatment of HAPO. Sildenafil (50 mg tds) should not be administrated with nifedipine as it risks promoting systemic hypotension. Inhaled nitric oxide has also been shown to be effective in treating HAPO and may be useful in an intensive care unit, but is rarely available in the wilderness environment.

Once evacuated, the casualty should be investigated to rule out alternative pathologies, such as pneumonia or pulmonary embolism (PE). Chest X-ray and CT scan will be useful in the first instance and if PE cannot be excluded, a CT pulmonary angiogram should be considered.

Prevention of high altitude illnesses

The most effective way to avoid any of the high altitude illnesses is to ensure a slow ascent to high altitude. Recommendations suggest that individuals travelling above 3000 m should not increase the sleeping elevation by more than 500 m per day and should include a rest day (i.e. no ascent to higher sleeping elevation) every 3–4 days [5]. Metaanalysis and systematic reviews have shown that prophylactic use of acetazolamide in doses between 125 mg and 1 g per day (most commonly 125 or 250 mg bd) reduces the symptoms of AMS during ascent. Dexamethasone is also effective as a prophylactic pharmacological agent, but its use for this purpose should be discouraged due to side effects and its usefulness as a treatment in life-threatening illness. Ginko biloba, a herbal medication, has been shown in some studies to be effective in the prophylaxis of AMS, but there is also data published with conflicting outcomes.

Other pathologies related to high altitude

There are a number of other conditions that can occur at high altitude:

- **Retinal haemorrhage:** reported to occur in 0–79% of those trekking to 5000 m [6]. Usually asymptomatic, but can lead to visual field defects if they involve the macula.
- **Neurological disorders**: transient ischaemic attacks (TIAs), cerebrovascular accidents (CVAs), nerve palsies, and a variety of other neurological conditions have all been reported at high altitude, some with perhaps a greater incidence compared with at sea level.
- **Thrombosis:** the increase in haematocrit that occurs as part of acclimatization may explain the increase in thrombotic events such as deep vein thrombosis (DVT) and PE that have been reported at high altitude.
- **High altitude cough**: this could be multifactorial and related to the effect of reduced humidity at altitude on the respiratory tract mucosa.
- **Disordered sleep**: this is due to periodic breathing that occurs at night. The imbalance between oxygen and carbon dioxide levels controlling ventilation leads to periods of hyperventilation, followed by apnoea and waking.
- **Cold injury**: adiabatic cooling means the temperature falls linearly as altitude is gained. Hypothermia, freezing, and non-freezing cold injury are therefore common at high altitude, but should be preventable.
- **Sunburn**: increased ultraviolet light penetration and the reflective capacity of snow and ice means that skin is easily burnt at high altitude.

CHAPTER 351

Pathophysiology and management of depth-related disorders

Peter Radermacher and Claus-Martin Muth

Key points

- Decompression illness comprises decompression sickness resulting from tissue inert gas super-saturation and pulmonary barotrauma due alveolar or airway over-distension.
- Since decompression illness may mimic any other emergency pathology, any emergency coinciding with decompression is 'due to' decompression.
- There are no data on pharmacological treatment, although aspirin is widely used.
- Specific treatment consists of pure O_2 breathing under supra-atmospheric pressures.
- Early treatment initiation is mandatory.

Introduction

Decompression illness (DCI) comprises medical disorders resulting from a decrease in ambient pressure (i.e. decompression). The common characteristic is tissue damage by excess gas during and after decompression. DCI often presents with severe neurological symptoms requiring both intensive care and hyperbaric oxygen therapy (HBO) [1–3]. Although there is a consensus on DCI treatment, there are no randomized control trials supporting current treatment guidelines according to evidence-based-medicine standards [3–5].

Mechanisms of decompression illness

According to Boyle's law, the volume of an enclosed gas will increase as ambient pressure decreases. When expanding intrapulmonary gas, which was inhaled under higher pressure, is not adequately exhaled during decompression, airway over-distension can cause pulmonary barotrauma. Depending on the site of tissue rupture, gas may track along the perivascular sheaths and cause mediastinal emphysema or pneumothorax. Gas may also pass into the pulmonary vasculature with subsequent arterial gas embolism into the cerebral or (rarely) the coronary circulation. According to Henry's law, body tissues saturate with N_2 (or any other inert gas used, e.g. He) at elevated ambient pressure, because of the proportional relationship between the amount of physically-dissolved gas in a liquid and the partial pressure of that gas above the liquid. During decompression, the decrease in ambient pressure may exceed the elimination rate of N_2, resulting in tissue super-saturation and, ultimately, gas bubble formation. Normally, the venous system transports these bubbles to the lungs, where they are eliminated. **Decompression sickness** (DCS) arises when gas bubbles cause mechanical tissue compression or venous embolization. Finally, paradoxical gas embolism may occur through transpulmonary passage of venous gas bubbles or via extra- or, to a lesser extent, intrapulmonary right-to-left shunts. A patent foramen ovale (PFO) is the most common pathway in divers [6].

Pathology

Gas bubbles can cause vascular obstruction or tissue compression due to an expanding volume, resulting in tissue ischaemia and oedema. Increased diffusion distances impeding gas elimination will aggravate the damage. This depends largely on the kinetics of the gas contained within the bubble, and the size and location of the embolus. Interactions between the blood–gas interface and the endothelium will result in further tissue damage, mediated by activation of complement, platelets, and neutrophils. These secondary effects trigger an inflammatory cascade, ultimately causing endothelial damage with capillary leakage, fluid loss from the intravascular space, and haemoconcentration.

Clinical manifestations and presentation

The large majority of DCI occurs during scuba diving. During a rapid ascent with large pressure changes, arterial gas embolism from pulmonary barotrauma is a frequent complication accounting for more than one-third of all recreational scuba-diving fatalities [2]. Severe DCS is most common after long, deep scuba-dives, but may occur after any decompression when there is a significant venous gas load, especially in the presence of right-to-left shunts [7]. Post-diving altitude exposure during long distance commercial flights or by driving across mountains imposes an additional DCS risk [8]. DCS presents with a large variety symptoms, ranging from skin itching and vague constitutional symptoms to shock and cardiopulmonary arrest. The central nervous nitrogen saturation and elimination kinetics and its limited ischaemia

tolerance favour the development of neurological symptoms. Sensory symptoms including numbness, tingling, paraesthesiae, and abnormal sensation are more common than severe neurological symptoms, that typically develop progressively, beginning with mild paraesthesia, followed by regional numbness, weakness and, occasionally, paresis of the affected limbs [1]. Symptoms usually occur within hours after decompression, but may also present immediately. Respiratory DCS presenting with coughing, chest pain, dyspnoea, and haemoptysis may occur when a high venous gas load overwhelms the pulmonary bubble filter, inner ear DCS presents as vertigo, tinnitus, and hearing loss [9]. In contrast to DCS, arterial gas embolism typically presents as a stroke-like syndrome with unilateral neurological symptoms, depending on the affected areas of the brain. Cognitive symptoms and unconsciousness are most frequently observed, seizures, focal motor deficits, visual disturbance, and sensory changes are also common [10]. Bubbles may, however, occlude any artery including the coronary or skeletal muscle vasculature. Spinal cord lesions with sensory or motor paraplegia are more likely to result from DCS. Arterial gas embolism and DCS can be discriminated according to the onset of symptoms, with gas embolism predominantly developing within a few minutes after or even during decompression. Nevertheless, symptoms of arterial gas embolism may be indistinguishable from DCS or even non-diving-related disorders. Finally, severe neurological DCS may be superimposed on gas embolism.

Diagnostic evaluation

The term DCI allows assigning a diagnosis without differentiating between arterial gas embolism and DCS. This is particularly helpful since outcome of severe DCI largely depends on time to treatment. Definitive therapy should not be delayed, especially as no specific tests are available [11]. History and physical examination, including neurological examination, are mandatory for the initial assessment. The temporal relation of the patient's complaints to decompression, including information on time to onset of symptoms, is crucial. Laboratory investigations are useful to evaluate haemoconcentration and dehydration, serum creatine kinase activity was reported as a marker of the severity of arterial gas embolism. A chest X-ray allows evaluating the presence of a pneumothorax, the drainage of which is mandatory prior to recompression [12].

Treatment of DCI

For ethical reasons, no controlled prospective studies in humans are available comparing treatment with '**no treatment**' [4,5]. Therefore, assessment of effective treatment for DCI must rely on empirical evidence and data from animal studies. Immediacy of treatment is crucial and comprises rapid gas elimination and the correction of hypoxia, which is best achieved by hyperbaric oxygen therapy [1,3,12]. An algorithm for treatment is shown in Fig. 351.1.

Initial treatment

Animal studies and diving accident statistics indicate that early normobaric hyperoxia with inspiratory O_2 concentrations close to 100% improves clinical outcome, because it prevents further inert gas uptake and increases the diffusion gradient of inert gas from the bubble into the tissue. Therefore, 100 % O_2 should be administered via a tightly fitting face mask, either from a demand-valve regulator or by a closed-circuit apparatus. In addition, fluid resuscitation is useful to counteract haemoconcentration and dehydration [13]—divers are prone to dehydration because of fluid loss through respiration and increased diuresis during the scuba dive resulting from the immersion-induced increase in intrathoracic blood volume. Intravascular accumulation of gas bubbles and subsequent endothelial damage with capillary leakage will aggravate dehydration. Depending on the patient's level of consciousness, mild DCI may be managed by oral fluids; otherwise, intravenous administration is recommended [10,12]. Adequate fluid resuscitation will allow continued inert gas washout from tissues due to maintenance of microvascular flow.

Patients with DCI should be kept supine, unless a head-down position is required for circulatory support. Thermal control of the patient is necessary as **hyperthermia** worsens neurological outcome, while **hypothermia** impairs tissue nitrogen elimination due to peripheral vasconstriction. Frequently, patients require transport from remote locations. Since altitude exposure precipitates a recurrence of symptoms due to additional N_2 release and bubble growth under reduced pressure, transport should take place in airplanes maintaining sea level cabin pressure. Ground or helicopter transportation at a flight level as low as considered '**safe**' by the pilot are preferable, with hyperbaric oxygen therapy given at the nearest location possible.

Definitive treatment

Recompression will reduce excess intracorporeal gas and increase the driving force for its return into solution. However, recompression per se causes only limited bubble shrinkage, especially as gas emboli do not maintain a spherical shape when trapped in vessels. Hyperbaric oxygen therapy accelerates gas elimination, both by raising the ambient pressure and creating systemic hyperoxia. Hyperbaric oxygen therapy requires patient placement in an environment pressurized at two to three times sea-level atmospheric pressure, while breathing 100% O_2. This usually results in an arterial PO_2 up to 2000 mmHg (267 kPa) and an amount of O_2 physically dissolved in the blood of approximately 60 mL/L. The improved outcome of DCI after hyperbaric oxygen treatment results from its physiological effects, i.e. an increased diffusion gradient for O_2 into the gas bubble and for N_2 out of the bubble, improved tissue O_2 delivery, hyperoxic vasoconstriction, and inhibition of $ß_2$-integrin-dependent neutrophil adherence.

There are no randomized studies in humans comparing recompression breathing air with hyperbaric oxygen therapy. In experimental animals, however, bubble shrinkage was faster during recompression breathing O_2. Clinical experience suggests that recovery from DCI is inversely related to the time to initiation of hyperbaric oxygen therapy [11]. Most improvement occurs when treatment is started within minutes, although improvement was still observed when treatment began hours later. Repetitive recompression treatments should be considered as long as there is clinical improvement, but the more hyperbaric treatments are needed to relieve symptoms, the less likely they are to be effective.

Several empirically derived hyperbaric oxygen treatment schedules are in use, which differ with respect to maximal pressure, duration, and the breathing gas mixture [14]. The most common treatment algorithm ('**U.S. Navy treatment Table 6**'; see http://www.eubs.org/documents/DHM%20vol42%20no3%20suppl%20deep%20tables.pdf) comprises cycles of 100 % O_2 breathing at

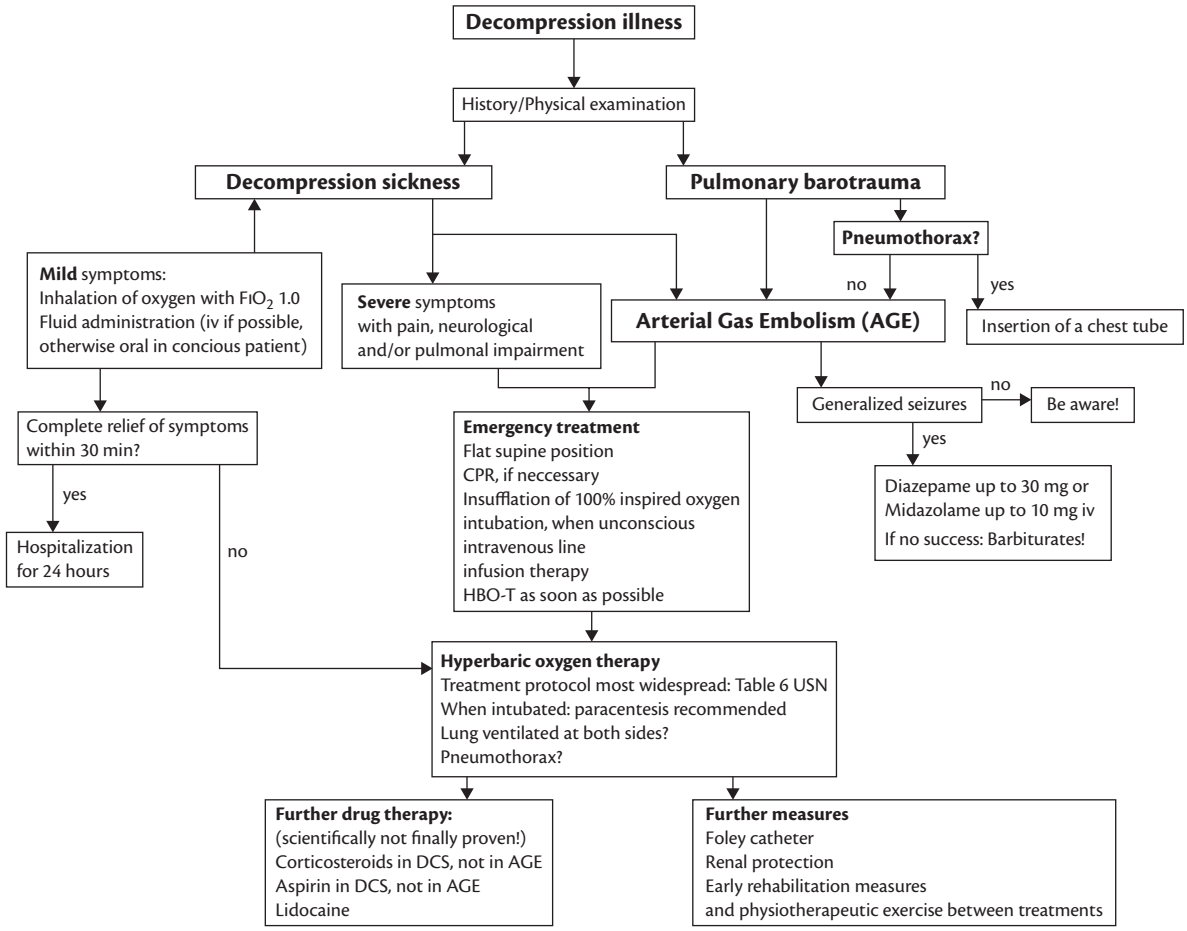

Fig. 351.1 Flow chart for management of DCI.

With kind permission from Springer Science + Business Media: *Intensive Care Medicine*, 'Evaluation and management of decompression illness-an intensivist's perspective', **29**, 2003, pp. 2128–36, Tetzlaff et al., Figure 2, copyright 2003 European Society of Intensive Care Medicine.

18 m sea water (0.28 MPa) and 9 m sea water (0.19 MPa) with a total recompression time of approximately 4 hours 45 minutes [1]. There is an ongoing discussion on the best recompression regimen, and various other treatment algorithms are discussed, e.g. recompression to 50 m seawater, while breathing O_2-enriched gas mixtures using N_2 ('nitrox') or He ('heliox') as carrier gas has been recommended for arterial gas embolism and severe cases of DCS [14]. However, no clear advantage has been shown.

Adjunctive measures

There are scarce data on the efficacy of pharmacologic interventions [4,5]. Nevertheless, **aspirin** is frequently used due to its analgesic, anti-inflammatory and anti-platelet aggregating properties [15]. **Anticoagulants** have been advocated to counteract haemoconcentration and coagulopathy. Low-dose heparin or low-molecular-weight heparin may be given in patients with leg weakness due to DCI as a prophylaxis against deep vein thrombosis [12]. **Corticosteroids** have been recommended for arterial gas embolism to counteract brain oedema. However, cerebral arterial gas embolism provokes cytotoxic brain oedema, which, in general, is unresponsive to corticosteroids. Again, no study date is available. The non-steroidal anti-inflammatory drug **tenoxicam** reduced the number of recompressions required [4], but further studies are needed. Recent ovine and porcine studies showed that intravenous **perfluorocarbon** emulsions reduced both morbidity and mortality. This approach is still highly experimental, and any recommendation must be cautioned. Finally, **lidocaine** improved neuronal recovery in feline air embolism. Mechanisms are not completely understood, but may largely be attributed to a reduction in intracranial pressure and improved cerebral blood flow. Clinical data are confined to one single trial showing cerebral protection in cardiac surgery, with bolus lidocaine administration (1.5 mg/kg) and maintaining a therapeutic concentration thereafter.

Intensive care in the hyperbaric environment

Certain issues must be considered for the management of critically-ill patients in a hyperbaric chamber. Limited access due to narrow space, noise, decreased ambient lighting and altered sound transmission impair clinical observation [12,16]. For ECG and invasive blood pressure monitoring electrical connections are necessary across the chamber wall to the outside physiological monitor [12,16]. While transcutaneous pulse oximetry is of only

limited value due to hyperoxia, transcutaneous PO_2 sensors may provide information on adequate tissue oxygenation. Intravenous lines should be placed prior to hyperbaric oxygen treatment since the hyperbaric chamber environment complicates insertions. Any untreated pneumothorax contraindicates hyperbaric exposure, since it will result in a life-threatening tension pneumothorax during decompression due to gas expansion [12,16]. Therefore, a chest tube must be inserted, and the appropriate instruments must be readily available inside the chamber. During hyperbaric therapy chest tubes should be removed from vacuum drainage and a Heimlich valve inserted [16].

Cardiopulmonary resuscitation during hyperbaric therapy imposes significant risks both for patients and medical staff, especially when cardiac defibrillation is needed: First, there is a significant risk of catastrophic fire due to the elevated PO_2 of the pressurized chamber atmosphere. Secondly, the medical staff are exposed to increased tissue N_2 uptake. It is therefore strongly recommended to avoid electric defibrillation inside the chamber and slowly decompress with the attendants breathing 100 % O_2 from 9 m sea water until reaching surface pressure [12,16].

For fluid administration by gravity, plastic containers should be used instead of glass bottles. Massive gas embolism can result during decompression and, hence, all fluid containers must be vented. The use of flow-controlled automatic infusion pumps is possible, when the device is equipped with a battery as a power supply for minimized risk of fire inside the chamber. Nevertheless, there are substantial variations in performance and accuracy of infusion pumps under hyperbaric conditions [17].

Patients should be sedated and, if indicated, intubated before therapy starts and the chamber pressurized. Total intravenous anaesthesia is the method of choice. Air has to be evacuated from the endotracheal cuff prior to hyperbaric exposure, and the cuff must be filled with an equivalent amount of liquid (e.g. distilled water) to achieve an appropriate seal [12,16]. The endotracheal tube must be tightly secured and stabilized in place with documentation of its depth and auscultation of bilateral breath sounds. Unintended tube displacement may cause bronchial obstruction and subsequent over-inflation of the unvented part of the lung with consecutive barotrauma and/or a sudden drop in blood pressure due to decreased venous return [12,16].

Intubated patients will need myringotomy or, in case of repeated hyperbaric treatments, tympanostomy, as they are unable to actively equilibrate their middle ear by the Valsalva manoeuvre. Patients with a nasal endotrachial tube can suffer from barotrauma of the sinuses during compression [16].

Ventilated patients will frequently require deep sedation or even muscle relaxation because of limited options in terms of ventilation mode. A pressure-controlled ventilatory mode is preferable when controlled ventilation is used to avoid over-estimation of tidal volume and minute ventilation (most ventilators use mass-flow measurements). A higher level of inspiratory pressure support is often needed to compensate for increased work of breathing resulting from the compression-related rise in gas density [16,18–20].

PART 17.4

Temperature related disorders

CHAPTER 352

Pathophysiology and management of fever

Gabriele Bassi and Roberto Fumagalli

Key points

- Temperature control and fever played a cornerstone role in mammal evolution.
- Fever is a beneficial host response to infection and may play a potential protective role during sepsis in critically-ill patients.
- High fever may be detrimental during non-septic conditions, especially in neurological patients.
- Definitive evidence on the efficacy and safety of pharmacological and mechanical antipyretic methods in critically-ill patients is lacking.
- Bedside assessment of every case is required when dealing with fever control in critically-ill patients so as to prevent the routine use of antipyretics.

Physiology of core temperature

Understanding and assessing physiological core temperature

Most of the energy intake of the human body is used to maintain a constant body core temperature of 37° C [1]. Core temperature, in humans, is strictly regulated within a few tenths of 1°C. It is interesting that almost all mammals have a similar average temperature and even poikilothermic ('cool blooded') species maintain the same core temperature by applying behavioural adaptations to environmental thermal changes [2]. These observations led to the concept that thermic homeostasis plays a pivotal role in all biochemical processes and human evolution [3].

Normal body temperature should generally be considered as 37°C [4]. However, there is almost 1°C circadian oscillation around 37°C with a nadir in the early morning and a zenith in the late afternoon. This physiological daily variation is much higher than the few tenths of a degree centigrade threshold, which as general rule, triggers compensatory mechanisms in response to environmental or clinical conditions [3].

Core body temperature is most accurately measured by an intravascular thermistor, using the pulmonary artery catheter as a gold standard. Urinary bladder catheter thermistor, oesophageal probe, rectal probe are nearly equally accurate while infrared ear thermometry is generally accepted, although not so precise. Temporal artery and axillary thermometers are, on the other hand, less reliable [4].

Regulation of core temperature: general considerations

Following a thermodynamic view, body temperature is the result of the constant thermic exchange between core and surrounding environment through conduction, radiant heating, and evaporation [1]. Since a behavioural response in critically-ill patients is not usually possible, the relative contribution of each single mechanism should be taken into account when trying to control core temperature. Similarly, knowledge of autonomic responses to thermic disturbance may help clinicians to optimize fever control or therapeutic hypothermia. The main autonomic responses against heat are perspiration and pre-capillary vasodilatation. The former enhances heat loss by evaporation, while the latter drives the opening of arteriovenous shunts leading to the dissipation of heat from the core to the environment [2]. The main autonomic responses against cold are, on the contrary, vasoconstriction and shivering. The first preserves core heat accumulation, while the second is a last resort reflex, which induces a production of heat by rapid muscle contractions. The vasoactive response is highly metabolically efficient, since it protects core temperature from environmental changes without requiring fluid loss, as in perspiration, or high oxygen consumption as in shivering. The role of the vasoactive response may be lost when dealing with major burns, where skin arteriovenous shunts may be lost.

Our thermal physiology is 'asymmetrical' [5]. Normal core temperature is closer to the upper (protein denaturation point) than the lower (freezing of water) limit of tolerance. Despite the asymmetry, thermoregulatory defence (vasodilatation and vasoconstriction) is triggered by the same inter-threshold range of ≈0.2°C [2]. This strict regulation has been traditionally described as the result of a complex integration of peripheral thermosensor signals with the central thermosensitive neurons of the pre-optic anterior hypothalamus. The hypothalamus triggers the autonomic and behavioural responses when the core temperature exceeds the actual inter-threshold range [1].

Among drugs generally used in critically-ill patients propofol linearly reduces shivering and the vasoconstriction threshold with a dose-dependent correlation while midazolam reduces the set point of 'hypothalamic thermistor' with no effects on amplitude of the inter-threshold of compensatory mechanism activation [2]. An interesting point is that muscle paralysis obviously precludes shivering, but does not reduce fever nor does it prevent vasoactive autonomic defence to core temperature changes [6]. Finally, when

dealing with deliberate cooling (e.g. therapeutic hypothermia), clinicians may consider the role played by skin warming receptors in the autonomic response. Since skin thermosensors contribute more than 20% of the effective thermoregulation, shivering may be prevented by warming hands, face or even the whole skin surface [2].

Role of fever in ICU

Physiology of fever

According to the physiological thermoregulatory mechanism, fever has been described as a 'complex, coordinated autonomic, neuroendocrine, and behavioural controlled response, orchestrated largely by the hypothalamus, which is adaptive and used by nearly all vertebrates as part of the acute-phase reaction to immune challenge' [7]. It differs from uncontrolled conditions such as heat stroke and malignant hyperthermia in that fever is a stereotypical response induced by a rapid modification of the threshold of the core hypothalamic thermistor. Infection, trauma, and tissue injury may cause the release of endogenous pyrogens (IL6, IL1, TNF-α) [8] from macrophages. It has been assumed that these pyrogens break through the blood–brain barrier via an active carrier or a leak at the hypothalamic level and induce the synthesis of prostaglandin E_2 from the organum vasculosum of the laminae terminalis [1–3,5,8]. Prostaglandin E_2 slows down the priming of warm sensitive neurons in the pre-optic nucleus resetting the thermistor threshold and triggering a heat-preserving autonomic response. The mechanism is appropriately regulated by a feedback of biochemical pathways that enhance the level of endogenous antipyretics (arginine vasopressin, glucocorticoids, α-melanocyte-stimulating hormone) preventing excessive core temperature increase and thus restoring a normal thermistor threshold [3].

The febrile response evolved hundreds of millions of years ago and has played a pivotal role in mammal evolution [3]. Fever, as far as physiological body temperature regulation is concerned, has always covered a major biological role as demonstrated by evidence that even cool-blooded animals move to a hotter environment in order to increase core body temperature after experimental bacterial inoculation. From a biochemical point of view, fever induces production of heat shock proteins leading to an important modulation of the inflammatory response during septic shock. Heat shock proteins, in fact, downregulate the activity of the pro-inflammatory nuclear transcriptor NF-κB, which has been reported to be linked to mortality in septic shock [8].

Fever and outcome

Experimental studies have shown reduced bacterial growth, stronger resistance to virus infection, and an overall association with survival within a physiological rise in body temperature [8,9].

A recent review summarizes the results of the main papers on the role of fever and temperature abnormalities in critically-ill patients. A final conclusion was not reached on the association between fever and outcome [10]. Aetiology of fever (infective versus non-infective), specific populations (neurological, trauma, and mixed) and the use of different methods to control fever (drugs versus cooling) represent confounding factors.

Neurological critically-ill patients

During brain injury, fever may increase neuronal excitotoxicity, accelerated free radical production and produce profound alterations in the blood-brain barrier [11]. An increasing body of evidence supports the negative impact of fever on morbidity and mortality during the acute phase of ischaemic brain injury, intra-cerebral haemorrhage, and cardiac arrest. ICU length of stay is prolonged in brain injury and subarachnoid haemorrhage with a linear correlation with temperature [12]. Thus, fever control in neurological critically-ill patients would be generally advised, at least in the acute phase.

High fever

Two of the larger case studies on the association between fever and mortality [13,14] in non-neurological non-selected ICU populations demonstrated that high fever (≥39.3°C and ≥39.5°C) was independently associated with increased intensive care unit mortality. Conversely, fever below 39.3°C had no impact on survival in both studies. These results were not confirmed by a recent survey on two very large, independent, multicentre, geographically distinct and representative databases [15]. A protective role on hospital mortality of high peak fever (39–39.4°C) in the first 24 hours after admission was shown. However, the advantage of fever was restricted to the subgroup of patients with infection, while higher peak temperatures were associated with an increased risk of in-hospital mortality in patients with a non-infection diagnosis. The results of the three studies are difficult to compare since neurological patients were not excluded in the last one and patients with fever related to infection were not isolated in the first two. Nevertheless, there is widespread acceptance that high peak fever, unrelated to infection, may have a different physiological role compared with rising temperature during the sepsis process.

Hypothermia

In spite of conflicting results on the role of fever in most, if not all, experimental and clinical studies, the occurrence of hypothermia is related to increased ICU and hospital mortality [8–12,14,15]. The adjusted odds ratios for in-hospital mortality increased from 1.3 to 3 and 2.8 in the infection and non-infection group, respectively, for temperature drop from 36.4°C to less than 36°C [15]. Since it has been estimated the incidence of hypothermia on ICU admission is 10% for mild hypothermia (35.0K35.9°C), 5% for moderate hypothermia (32–35.9°C) and 1% for severe hypothermia (<32°C), ICU personnel must prevent excessive heat loss and maintain strict temperature monitoring [16].

Clinical management of fever in ICU

Definition and epidemiology of fever in ICU

The American College of Critical Care Medicine and the Infectious Diseases Society of America stated body temperature of 38.3°C in immunocompetent patients admitted to ICU should warrant further investigation to determine whether infection is present [4]. This led to a wide discussion on the epidemiology of high body temperature in ICU. Frequency of fever changed from 9.3% [15] to 70% [12] according to different thresholds, case mix and sites of measurement. Infection related admissions in the same studies ranged from 10.8% [15] to 50% [12], while fever (defined as temperature ≥38.5°C) was recorded in 16.9% of patients among the infection group and 9.3% in the non-infection group [15]. Fever in ICU is quite common and, perhaps, one of the most used criteria for infection assessment in critically-ill patients. Since the prognostic value of fever may differ in infection and non-infection populations, clinicians should take into account a wide spectrum of non-infective clinical conditions, which could

be associated with a rise in body temperature. Non-infectious aetiologies of fever may include pulmonary embolism, drug and transfusion reactions, pancreatitis, endocrine disturbance, myocardial infarction, trauma, and cerebrovascular injuries.

Decision making for fever control

Kluger concluded the function of fever wouldn't have persisted for millions of years if it had not been adaptive [3]. Despite this teleological consideration, clinical studies have demonstrated a significant reduction in oxygen consumption (from a mean of 359.0 ± 65.0 to 295.1 ± 57.3 mL O_2/min) and cardiac output (from a mean of 8.4 ± 3.2 to 6.5 ± 1.8 L/min) once temperature decreased from 39.4 to 37°C [17]. Furthermore, fever control may improve comfort, reduce heart rate, pulmonary shunt, and vasoactive drug requirement. Thus, a rationale for fever suppression exists when dealing with oxygen delivery dependent conditions, were improved supply-demand balance may reduce tissue hypoxic injury. On the other hand, short-term prompt beneficial effects of fever control may give way to potential long-term adverse impact on ICU and hospital outcome, particularly in septic patients. Controversy on the need for fever suppression in the critically ill still remains open and warrants further investigation.

As in other open issues in critical care, the decision-making strategy in the context of fever management must be supported by individual case assessment. The following general rules are proposed.

Excluding septic fever

Outcome in septic shock has been widely demonstrated to be associated with few time- dependent interventions (e.g. early targeted shock resuscitation and early antibiotic therapy). In this context fever or, more generally, temperature abnormalities, should trigger appropriate, prompt, and cost effective investigations as stated in published guidelines. Fever, as a clinical sign after antibiotic therapy, may direct clinical judgment and may represent a natural host defence reaction [3].

Balancing fever control

Antipyretic therapy may be justified when the metabolic cost exceeds the potential physiological benefits. This could be the case in non-septic fever where high temperature has been associated with increased mortality [15]. Nevertheless, even patients with septic shock may benefit from fever control by external cooling [18]. Neurological and paediatric patients may require special consideration, especially if fever is particularly high. Rationale for temperature control in this population is well documented [11].

Options for antipyretic strategy

Although several drugs have proved to be effective in fever suppression, a definitive recommendation on a first line pharmacological strategy is still lacking. A recent systematic review and meta-analysis concluded there was not enough evidence to estimate the effect of pharmacological antipyresis on mortality in critically-ill patients [19]. Low-dose infusion of diclofenac proved to be more effective, haemodynamically better tolerated with a lower impact on hepatic function than bolus administration in neurosurgical patients [12]. Despite acetaminophen being widely used in more than 65% of critically-ill patients, further investigations are advocate to assess safety and association with mortality. Finally, non-pharmacological methods must be considered. Contrasting, but promising results were observed using external cooling. Henker demonstrated minimal effects in temperature control with cooling blankets in comparison with acetaminophen [20], while Schortgen concluded that external cooling was effective in fever control in septic shock, with a beneficial impact on mortality potentially due to a vasoactive sparing effect [18].

CHAPTER 353

Pathophysiology and management of hyperthermia

Abderrezak Bouchama

Key points

- Hyperthermia is a state of elevated core temperature above 40°C secondary to failure of thermoregulation.
- Hyperthermia is a cardinal feature in heatstroke, malignant hyperthermia, and neuroleptic malignant syndrome.
- High temperature induces direct cellular death and tissue damage as a function of the degree of hyperthermia and its duration.
- Rapid cooling is the primary therapeutic goal in hyperthermia, particularly when it is associated with central nervous system alteration and/or haemodynamic instability.
- Pharmacological cooling with dantrolene sodium is crucial in the treatment of malignant hyperthermia.

Introduction

Hyperthermia is a failure of thermoregulation due to excess heat gain that overwhelms the heat dissipating mechanisms [1,2]. Whereas in fever, the body core temperature seldom exceeds 40°C, the body core temperature in hyperthermia can rise rapidly above 40°C and reach a temperature as high as 47°C (1,3,4). Hyperthermia has many causes, but it is the hallmark of heatstroke, malignant hyperthermia, and neuroleptic malignant syndrome (Box 353.1) (1,3–6). Hyperthermia requires immediate cooling, because heat per se is cytotoxic, and the severity of tissue damage is related to the degree of hyperthermia and its duration [1].

Normothermia, fever and hyperthermia

In humans, the hypothalamus regulates body temperature within the narrow range of approximately 36.6°C ± 0.38°C [2]. Thermal control is achieved through communication between thermoreceptors in the skin and body core, and thermosensitive neurons in the pre-optic/anterior hypothalamus. The peripheral receptors transmit temperature information through direct neural connections or via blood to the hypothalamus, which adjusts the heat loss or gain accordingly. When a temperature increase is perceived, the hypothalamus initiates three mechanisms of temperature regulation:

- Cutaneous vasodilatation.
- Increased sweating.
- Decreased heat production.

The hypothalamic set-point remains normal and the body attempts to dissipate excessive heat. In contrast, during fever the temperature set point is raised through release of prostaglandins, largely PGE_2, into the anterior hypothalamus by circulating pyrogenic cytokines, such as TNFα and IL-1β [2]. In this case, the mechanisms for raising the body temperature are activated, including vasoconstriction and shivering, until the blood and core temperature are elevated to match the hypothalamic set point. Hyperthermia occurs when the production of heat exceeds its dissipation, or there is impairment in heat dissipating mechanisms (Box 353.1).

Pathophysiology

The clinical and metabolic alterations in hyperthermia include change in mental status, haemodynamic instability, disseminated intravascular coagulation, rhabdomyolysis, and lactic acidosis that can culminate in multiple organ system failure and, if left untreated, death [1,3,5]. These alterations result from an interplay between the pathophysiological changes initiated by the underlying condition together with those associated with hyperthermia (Box 353.1). Heat induces direct cytotoxicity, ischaemia-reperfusion injury, and an uncontrolled activation of inflammation and coagulation.

Heat cytotoxicity

Both in vitro and in vivo studies demonstrate high temperature causes direct damage to most cellular structures and their function resulting in cell death by necrosis [1,7,8]. Similarly, excessive heat induces apoptotic cell death, particularly of the lymphoid organs [7,8]. The extent of cell death and tissue damage is proportional to the degree of hyperthermia and its duration.

Ischaemia-reperfusion injury

Hyperthermia presents a major strain to the cardiovascular system [9]. When hyperthermia is sensed, cutaneous blood flow increases markedly, consuming up to 70% of the cardiac output, so that heat is transported from the core in order to be dissipated at the skin surface. This active cutaneous vasodilatation mediated by the hypothalamus results in a marked increase in cardiac output together with splanchnic vasoconstriction to maintain blood pressure. In experimental models for hyperthermia, splanchnic hypoperfusion results in ischaemia of the gastrointestinal organs followed by reperfusion injury during the sudden splanchnic vasodilatation that precedes the onset of hemodynamic collapse and hyperthermia [10].

Box 353.1 Causes of hyperthermia

Principal conditions

- Heatstroke.
- Malignant hyperthermia.
- Neuroleptic malignant syndrome.

Drugs affecting thermoregulation

- **Recreational drugs**: amphetamine, metamphetamine, cocaine, and monoamine oxidase inhibitors.
- **Anticholinergic medications**: anti-depressants, antihistamines, antipsychotics and antiparkinsonics.
- **Serotonergic medications*:** tricyclic antidepressant, monoamine oxidase inhibitors, serotonine and norepinephrine reuptake inhibitors, selective serotonin reuptake inhibitors.

Diseases affecting thermoregulation

- Thyrotoxicosis.
- Phaeochromocytoma.
- Status epilepticus.
- Cerebrovascular accidents.

*Other medications with serotonergic activity used in intensive care unit include linezolid, fentanyl, meperidine, tramadol, metoclopromide, and valproate.

Activation of inflammation and coagulation

Heat activates host innate immunity and heat shock responses to protect against tissue injury and promote repair and healing [1]. There is clinical and experimental evidence to suggest excessive inflammation and coagulation activation may contribute to organ dysfunction/damage. Widespread haemorrhage and thrombosis, margination, and transmural migration of leukocytes, and endothelial cell activation and/or injury in vascular beds of most organs of the body are prominent features in human and experimental animal studies of heatstroke [7].

Principal hyperthermic conditions

Heatstroke

Heatstroke is a life-threatening illness characterized by hyperthermia associated with central nervous system abnormalities, such as stupor, confusion, or coma following exposure to a high ambient temperature (non-exertional or classic heatstroke) or strenuous physical exercise (exertional heatstroke) [1]. Although prevalent in hot climates, classic heatstroke occurs sporadically in epidemic form in temperate zones during heat waves. The heat wave that affected Europe in the summer of 2003 led to an unprecedented 70,000 excess deaths, of which one-third was attributed to heatstroke [11].

Clinical findings

Hyperthermia and neurological alteration are the hallmark of heatstroke. The rectal temperature is greater than 42°C in most cases. The neurological abnormalities include delirium and restlessness, deep coma, and seizures. Tachycardia and tachypnoea are common and are accompanied by distributive shock in a third of the cases. Cardiogenic shock-like syndrome in hyperthermia is rare. Hypoxemia without overt lung injury is common, but can progress to full blown acute respiratory distress syndrome.

Biochemical findings

A mixed respiratory alkalosis and metabolic acidosis predominate in patients with classic heatstroke. Hypophosphataemia and hyperglycaemia are the most frequent abnormalities. Creatine kinase is moderately elevated with no overt rhabdomyolysis. Exertional heatstroke is characterized by severe lactic acidosis, hyperphosphataemia, hypocalcaemia, and renal failure. Twenty-four hours after cooling of the body to normal temperature, a third of patients with hyperthermia may progress to one or more organ failures. Mortality and permanent brain damage in classic heatstroke survivors can reach up to 60 and 30%, respectively.

Malignant hyperthermia

Malignant hyperthermia is a complication encountered during anaesthesia for patients suffering from inherited autosomal dominant muscle disorders [3,4]. The incidence of malignant hyperthermia is 1:50,000 adults undergoing anaesthesia, and 1:15,000 children because of the frequency of congenital myopathies. Early diagnosis and treatment with dantrolene sodium and cooling reduce the mortality from 70% to less than 10% [3,4].

Clinical findings

An abnormally high cytosolic calcium concentration in skeletal muscle triggered by inhalational anaesthetic agents (halothane, sevoflurane, desflurane, isoflurane, and enflurane) or depolarizing muscle relaxants (succinylcholine) cause most of the cases of malignant hyperthermia in humans. This alteration in the regulation of intracellular calcium has been linked in some susceptible families to a series of mutations in the ryanodine receptor-calcium release channel gene, but not in others suggesting that malignant hyperthermia is a heterogeneous genetic disorder [4].

The clinical manifestations are seen within 30 minutes of anaesthesia in most of the cases. The earliest event is a rise in end-tidal CO_2 as a result of increased skeletal muscle metabolism. Muscle fasciculation and increased tone are detected early in the masseters and pterygoid muscles after administration of a paralysing agent. Tachycardia is another early sign, and is associated with labile blood pressure and ventricular arrhythmias. If the patient is not treated, hyperthermia, and severe lactic and respiratory acidosis occur within minutes, leading to widespread tissue damage and death.

Biochemical findings

Laboratory data include lactic and respiratory acidosis, hypoxaemia, hyperglycaemia, and overt rhabdomyolysis with hyperkalaemia and hypercalcaemia.

Neuroleptic malignant syndrome

Neuroleptic malignant syndrome is a rare and potentially fatal idiosyncratic reaction to neuroleptic and psychotropic medications, characterized by the development of hyperthermia, muscular rigidity, altered levels of consciousness and autonomic dysfunction [5]. The incidence and mortality of neuroleptic malignant syndrome are difficult to estimate because there is no universally accepted

definition. The risk is estimated to range from 0.1 to 3.2% and the mortality ranges from 10 to 30% [5].

Clinical findings

Neuroleptic malignant syndrome typically develops within 1–3 days of starting a course of neuroleptic drug treatment. Although, all types of dopamine receptor antagonists used in the treatment of psychosis have been implicated, the butyrophenone haloperidol accounts for half of the reported cases [5].The syndrome is characterized by four classical signs—hyperthermia, rigidity, autonomic instability, and altered level of consciousness. The rectal temperature is usually less than 40°C, although temperatures higher than 41°C have been reported and there is profuse sweating.

Biochemical findings

Laboratory data are not diagnostic; however, elevation of serum creatine kinase levels several hundred-fold is considered confirmatory of neuroleptic malignant syndrome. Elevation of creatine kinase is associated with myoglobinuria and may result in renal failure. Leukocytosis with left shift, and haemoconcentration, has also been recorded. Brain imaging and CSF studies are usually normal, and this helps to rule out other diagnoses, such as infection and brain structural diseases [5].

Treatment of hyperthermia

General approaches

Hyperthermia is a true medical emergency with rapid (hours) progression to multiple organ system failure and death. The primary therapeutic goal is to reduce body temperature as quickly as possible, particularly when hyperthermia is associated with central nervous system alteration and/or haemodynamic instability using cooling methods (Box 353.2). Support of airway, breathing, and circulation should be initiated concomitantly with cooling because mental status alteration with inability to protect the airway, circulatory, and respiratory failure are early complications of hyperthermia. Identification of the cause of hyperthermia is crucial since the therapeutic approach depends, in large part, on the aetiology. The second therapeutic objective is to treat the late or post-cooling complications of hyperthermia.

Cooling methods

Cooling comprises three simultaneous steps including:

- Cessation of the causative mechanism of hyperthermia, namely moving patient with heatstroke from hot environment to a cooler place and discontinuation of the offending medications (anaesthetic agents or neuroleptic drugs) that triggered malignant hyperthermia or neuroleptic malignant syndrome, respectively.
- Initiation of physical cooling.
- If indicated, the use of pharmacological treatment to accelerate cooling (Box 353.2)(1,3,5,12).

Physical cooling

Rapid dissipation of heat is accomplished by increasing the temperature gradient (conduction), water vapour pressure (evaporation), and velocity of air (convection) between the skin and the surrounding air [1]. Several external or internal techniques have been devised based on these principles (Box 353.2) [13,14].

Box 353.2 Methods of cooling

Surface cooling

Techniques based on conductive cooling*

- Ice pack applied to head, neck, and groin.
- Cold water or air circulating cooling blankets.
- Water circulating gel-coated energy transfer pads.†
- Immersion in cold water.

Techniques based on evaporative and convective cooling

- Fanning undressed patient at room temperature (20–22°C).
- Wetting of the body surface during continuous fanning.

Internal cooling

Techniques based on conductive and convective cooling

- Infusion of normal saline or ringer lactate solution at 4°C.†
- Cooling catheters using ice-cold fluids circulating in a closed circuit.†
- Extracorporeal circulation cooling system.†
- Iced gastric and peritoneal lavage.‡

Pharmacologic cooling§

- Dantrolene sodium.
- Dopamine agonists (bromocriptine and amantadine).
- Antipyretics (acetaminophen, aspirin, and non-steroidal anti-inflammatory drugs).

*Conductive cooling lower the skin temperature <30°C, triggering cutaneous vasoconstriction and shivering. Keeping skin temperature around 33°C with concomitant spray of tepid water or hot air, and/or vigorous massaging of the skin is recommended.

†New generation of cooling methods used for the induction of hypothermia post-cardiac arrest. Their efficacy has not been tested in hyperthermic conditions.

‡Cooling techniques investigated essentially in animals.

§Dantrolene is administered intravenously at a dose of 2.5 mg/kg and repeated at 5-min intervals until temperature, heart rate, and muscle rigidity are controlled or a maximum total iv dosage of 10 mg/kg is reached. Dopamine agonists are advised in neuroleptic malignant syndrome, but their efficacy has not been established by controlled trials. Antipyretics have no role in hyperthermic conditions.

Systematic reviews assessing the optimal cooling method in heatstroke identified the lack of solid evidence as most of the studies were observational case series [13,14]. Nonetheless, they suggest immersion in iced water is effective in young people suffering from exertional heatstroke. In classic heatstroke, evaporative- and conductive-based cooling techniques were found to be equivalent. There is also no evidence of a specific endpoint temperature at which to halt cooling. A rectal temperature of less than 39°C appears to be safe in terms of mortality in heatstroke, but associated long-term morbidity, particularly neurological, has not yet been established. At present, there are no data available on the optimal

cooling methods in malignant hyperthermia or neuroleptic malignant syndrome.

Pharmacological cooling

Dantrolene sodium, a hydantoin derivative, is the primary pharmaceutical agent for prevention and treatment of malignant hyperthermia. Dantrolene binds to ryanodine receptors and reduces the release of Ca^{2+} from the sarcoplasmic reticulum, thereby reversing skeletal muscle rigidity and increased metabolism [3,4]. Dantrolene is administered intravenously at a dose of 2.5 mg/kg, and repeated every 5 minutes until temperature, heart rate, and muscle rigidity are controlled or until a maximum total intravenous (iv) dosage of 10 mg/kg is reached.

No pharmacological treatment has been found to be beneficial in heatstroke, including dantrolene sodium and antipyretics [1,15]. The administration of dantrolene sodium and dopamine agonists, such as bromocriptine and amantadine, have been advocated in neuroleptic malignant syndrome to reduce muscle rigidity and to restore central dopaminergic activity, respectively, but their efficacy has not been established by controlled trials [12].

Treatment of complications

Non-specific resuscitative measures similar to those used in other critical care conditions may be needed in hyperthermia to support its late complications. These include management of liver failure, rhabdomyolysis, acute kidney injury, disseminated intravascular coagulation, and acute respiratory distress syndrome

CHAPTER 354

Pathophysiology and management of hypothermia

Colin Ferguson

Key points

- Accidental hypothermia is uncommon, but may present in any age group in any season of the year.
- Profound hypothermia results in circulatory arrest.
- The threshold for ventricular fibrillation is lowered at about 30°C.
- Treatment relies on maintaining a circulation and rewarming by any means available.
- A local preplanned multidisciplinary protocol is key to good outcomes.

Introduction

Accidental hypothermia is defined as a core temperature of <35°C. It is an uncommon condition presenting with varying severity, either alone or secondary to some other illness. Although precise figures for incidence and outcome are not available, the approximate incidence quoted is 0.3/100,000 per year in the USA and 0.13/100,000 in France. As a result of the low incidence, evidence-based treatment protocols and pathways based on cohorts of patients do not exist. Since the severely cold patient may be in cardiac arrest, areflexic, and in coma, decision making regarding treatment, its initiation and continuation, may be difficult. An agreed local protocol to inform local practice when encountering these rare patients is essential.

Traditionally hypothermia is classified into mild (33–35°C), moderate (28–33°C) and severe (<28°C), but these are not distinct clinical syndromes. A more recent classification into stages I–IV based on level of consciousness, shivering and vital signs has emerged from alpine medicine [1] and a treatment algorithm based on it has been published recently [2].

Pathophysiology of hypothermia

Physiological changes in the various systems are shown in Table 354.1. In the central nervous system, cooling initially affects higher functions and may lead the patient to not take action to prevent continuing heat loss. Behaviour becomes more bizarre as temperature falls, pupils dilate, and reflexes are depressed until, in severe hypothermia, the patient is in coma with absent eye and peripheral reflexes. In the circulation initial tachycardia and hypertension ('cold stress') are replaced, as the patient cools, with gradually worsening hypotension and bradycardia, prolongation of the cardiac cycle, atrial and re-entry arrhythmias, and eventually, ventricular fibrillation and asystole. The threshold for ventricular fibrillation is reduced at about 30°C, which is an important temperature to note since resuscitation of the pulseless patient requiring CPR is self-evidently more hazardous. The 'J' or Osborn wave, a characteristic ST segment deformation on the ECG, occurs at 32–33°C, but is not pathognomic and occurs in other conditions, such as subarachnoid haemorrhage and hypercalcaemia. In the respiratory system there is initial tachypnoea progressing, as the patient cools, to hypoventilation and apnoea with pulmonary oedema. Importantly, airway reflexes are depressed during moderate hypothermia exposing the patient to the risks of aspiration and its consequences; securing the airway should be considered early in treatment. In the kidneys there is initial cold diuresis owing to reduced tubular resorption, and later oliguria and anuria.

Box 354.1 shows a range of other pathophysiogical changes, many due to reduced enzyme action, in hypothermic patients. Coagulopathy is prominent and platelet function is depressed, but conventional tests of clotting are not helpful since they are carried out at normothermia in the laboratory. All membrane pumps slow such that the barriers between body compartments become porous with consequences for fluid management. Changes in protein binding, liver metabolism, and excretion make drug effects unpredictable. Loss of fluid from the circulation increases blood viscosity and metabolic acidosis develops with a shift in the oxygen dissociation curve. A raised serum amylase is common and may accompany frank pancreatitis presenting during treatment of the hypothermia. Wischnewsky ulcers (multiple haemorrhagic lesions) are seen in the gastric mucosa.

Clinical features and causes

The clinical presentation of hypothermia may be primary, where the cold injury is the major pathology, or secondary, where patients develop hypothermia incidental to another illness (Box 354.2). This is particularly important in trauma patients. A study from an Australian Major Trauma Centre showed hypothermia increased the risk of death threefold in these patients [3] and Gentilello [4] showed that aggressive warming using a femoral arteriovenous shunt in trauma patients with a mean Injury Severity Score of 37 and temperature of 33.2°C reduced mortality and length of hospital stay. Of more general interest, fluid requirements in the warmed group were almost halved in the first 24 hours, from 15 to 8 L.

Table 354.1 Physical signs in hypothermia

	Central nervous	Cardiovascular	Respiratory
Mild (33–35°C)	◆ Apathy ◆ Dysarthria ◆ Ataxia ◆ Impaired judgement ◆ Amnesia (34°C)	◆ Tachycardia + hypertension ◆ Bradycardia + hypotension ◆ Prolonged cardiac cycle ◆ Prolonged QT interval	Tachypnoea
Moderate (28–33°C)	◆ Reduced consciousness ◆ Bizarre behaviour ◆ Hallucinations ◆ Dilated pupils ◆ Hyporeflexia	◆ Atrial arrhythmias ◆ J wave (32–33°C) ◆ VF threshold reduced <30°C	◆ Hypoventilation ◆ Loss of airway reflexes
Severe (<28°C)	◆ Coma ◆ Absent eye reflexes ◆ Peripheral areflexia	◆ Re-entry arrhythmias ◆ VF ◆ Asystole	◆ Congestion ◆ Oedema ◆ Apnoea

Box 354.1 Other changes

- Coagulopathy.
- Reduced platelet function.
- Reduced liver metabolism.
- Reduced Na/K pumps.
- Hyperglycaemia.
- Increased viscosity.
- Acidosis.
- Left shift dissociation carve.
- Hyperamylasaemia.
- Pancreatitis.
- Wischnewsky ulcers.

Box 354.2 Clinical setting, primary or secondary

- **Recreational**: especially hills or water.
- Trauma.
- Drugs, alcohol, self-poisoning.
- **Urban**: old, poor.
- Cerebrovascular accidents.
- Spinal cord transection.
- Hypothalamic disease.

The adage that the patient is 'not dead until they are warm and dead' has emerged from reports of patients with profound hypothermia, in cardiac arrest and areflexic in deep coma, making uncomplicated recoveries after resuscitation and rewarming. It is certainly not possible to prognosticate on the basis of temperature alone and consideration of such cases is informative. Gilbert [5] reported the case of a 29-year-old woman whose lowest temperature was recorded as 13.7°C. She fell while skiing in Norway and was rescued by air by a team that were able to provide advanced life support from physicians from the moment of rescue. She received CPR for three-and-a-half hours, was rewarmed on cardiopulmonary bypass (CPB) and spent some weeks in the ICU, including a period of ECMO, but at the time of the publication was returning to work as a physician. Stoneham [6] reported a 30-year-old man rescued by road ambulance without a specialist crew. His lowest recorded temperature was 23.0°C and he received CPR for four-and-a-half hours. He was rewarmed with warmed gases, warmed fluids, and a heating blanket, and left the hospital 5 days after admission, apparently unharmed. The lowest recorded temperature is 9°C [7], in a patient in whom hypothermia was induced as an adjunct to the treatment of ovarian cancer. The patient was anaesthetized and cooled to the point of asystole, then rewarmed. She was unharmed by the treatment and survived a few weeks before dying from effects of malignant ureteral obstruction

Other prognostic indicators have been suggested, such as hyperkalaemia, but none have been established as generally applicable. Faced with the hypothermic patient in cardiac arrest, the reasonable response is to initiate resuscitation, exclude lethal injury and rewarm. Although some methods of rewarming (e.g. CPB and ECMO) are not generally available, the cases previously mentioned illustrate that, if perfusion is maintained and heat supplied to the patient, a successful outcome is possible with a variety of methods. Many patients will be hypothermic without serious circulatory compromise, especially in secondary hypothermia.

Rewarming methods

Rewarming methods (Box 354.3) are classified as passive or active and the latter subdivided into external, core, and extracorporeal. Rates of warming in degrees per hour for different methods are not helpful since the rate of rewarming has not been shown to affect outcome. The aim of treatment is a live patient not a rate of temperature change. Passive external warming consists of placing the patient in a warm environment with blankets and a hat, and is suitable for the

Box 354.3 Rewarming methods

- Passive external.
- Active external.
- Forced air.
- Warm water.
- Core infusions.
- Humidification.
- Cavity lavage.
- Extra corporeal.
- Haemofiltration.
- CPB.
- ECMO.

mildest cases. Active warming should be considered for patients with a temperature of 32°C or less, in that it transfers heat more rapidly; patients in this temperature range may be approaching the VF threshold, especially if they continue to cool. Resuscitation without a stable circulation is much more difficult. Active external warming is most easily achieved with forced air blankets. They are generally available in many designs and have been shown to be effective. Commercial devices designed for therapeutic hypothermia may have a warming function (e.g. Arctic Sun™). Immersion in warm water is simple for small children and has been used successfully in adults. Active core warming may be achieved by the use of warmed infusion fluids, although this will not provide a great deal of heat, and by lavage of various body cavities. Gastric, colonic, mediastinal, pleural, bladder, and peritoneal lavage have all been used, and the choice depends on local familiarity. Peritoneal lavage has the advantage of warming the liver directly and also the heart through the diaphragm. Humidified gas in ventilated patients may also be used with temperatures of up to 60°C described, although not all humidifiers have this facility. Extracorporeal methods include continuous veno-venous haemodiafiltration, cardioplumonary bypass and extracorporeal membrane oxygenation. While continuous veno-venous haemodiafiltration is commonly available and has been used successfully, CPB is the technique with the most experience, having been in use since the late 1960s. Reported mortality varies from 22 to 75%, but survivors have a good neurological outcome [8]. There may be problems with access via the femoral route and bleeding if heparinization is needed, although heparin-bonded circuits may circumvent this. Extracorporeal membrane oxygenation (ECMO) has entered the field in the last few years. It has the advantage of being portable and better outcomes have been reported after its use [9]. Although reported experience is limited, as familiarity with the technique increases its place will be established and, in specialist hands, it offers the possibility of definitive treatment from the moment of rescue.

Most hospitals lack the ability to perform ECMO and CPB so the establishment of referral networks and liaison with rescue services within regions, similar to trauma networks, is needed to ensure optimal availability of these extracorporeal techniques to appropriate patients. All hospitals need a local pre-planned multidisciplinary protocol to use what facilities they have to treat patients with hypothermia and consider transfer possibilities. Even where CPB is available prior consensus is required in patient selection and the process to be followed. An evidence base may be developed by the use of a registry between hospitals, either nationally or internationally.

Assessment and resuscitation

Assessment of the hypothermic patient includes evaluation of haemodynamic stability and other injuries to exclude lethal injuries, in particular in the patient in cardiac arrest. Resuscitation and rewarming should then commence according to the local protocol that has been devised to optimize the facilities and teams available in the hospital. Since the ventricular fibrillation threshold is reduced at about 30°C and cardiac arrest will complicate management and worsen outcome, it would seem sensible to get the patient warmer than this as soon as possible. Passive external warming may be adequate above 32°C, but at this temperature, active warming should be used. Below 30°C internal warming should be considered, the aim being to rewarm the patient as quickly as possible without complications.

Resuscitation consists of oxygenation and intubation and ventilation if needed. There is no evidence that malignant arrhythmia is a risk in the well-oxygenated patient during intubation. Chest compressions should be carried out in the usual manner bearing in mind that, in the profoundly hypothermic patient, these may be needed for hours such that a team of staff or a mechanical device may be needed. The guidelines for management of fibrillation in hypothermia differ between the American Heart Association and the European Resuscitation Council [10,11]. A compromise position would be up to three doses of vasopressor and defibrillation while the core temperature remains below 30°C and subsequent doses guided by clinical response. Fluids will be required during resuscitation and may be needed in large volumes because of losses and inter-compartmental shifts. All fluids should be warmed to 38–42°C. The situation during rewarming will be unstable and require close monitoring of vital signs, electrolytes, glucose, and blood gases. Vasopressors may be needed if there is hypotension due to vasodilatation. However, they bring with them the potential for arrhythmia and peripheral vasoconstriction. Acid–base management should be by the alpha-stat method in adults, aiming to keep pH normal without temperature compensation on the blood gas measurements [12]. Other problems occurring during rewarming include coagulopathy and hypophosphataemia. Drug doses should be small and titrated to effect. Drug handling is changing moment by moment as the patient warms, and drugs given early in resuscitation may act later in unexpected ways. With this in mind, intramuscular drugs should be avoided. Complications are to be expected, such as lung injury, renal injury, and consequences of coagulopathy. Patients will require at the least a period of close observation in the intensive care unit, if not some period of organ support. There is no consensus nor good evidence as to whether a period of therapeutic hypothermia (between 32 and 34°C for some hours) is beneficial in patients being rewarmed from profound hypothermia with cardiac arrest.

PART 17.5

Rhabdomyolysis

CHAPTER 355

Pathophysiology and management of rhabdomyolysis

Josep M. Grau and Esteban Poch

Key points

- Rhabdomyolysis must be understood as an acute clinicobiological syndrome, with many traumatic and non-traumatic causes.
- Isolated raised creatine kinase values (even to thousands) does not imply a rhabdomyolysis syndrome.
- Acute kidney injury can occur in up to 50% of patients with rhabdomyolysis and can be life threatening.
- The mainstays of therapy of rhabdomyolysis is aggressive volume repletion in order to avoid hypovolaemic shock and acute kidney injury, and control of plasma potassium.
- Acute compartment syndrome must be suspected in particular in traumatic rhabdomyolysis, with closely monitoring of compartment pressure.

Introduction

Rhabdomyolysis is a potentially life-threatening syndrome characterized by the breakdown of skeletal muscle due to physical, biological, or toxic injury resulting in release of intracellular content into the circulatory system. It is associated with myalgia, muscle tenderness, swelling, and/or stiffness accompanied by weakness and raised levels creatine kinase (CK), myoglobin, phosphate, and potassium, sometimes with acute kidney injury (AKI) [1,2].

In non-traumatic muscle injury, isolated elevation of CK, even to 5–10 times normal, does not necessarily imply rhabdomyolysis. Most of the muscular dystrophies and some cases of myositis may present with extremely high CK, but never representing rhabdomyolysis. Rhabdomyolysis must be always understood as an acute syndrome, while muscular dystrophies, myositis, and connective-tissue disorders are chronic disorders.

Causes

The causes of rhabdomyolysis are summarized in Box 355.1. With respect to the category of drugs and toxins, hypolipaemiant-related rhabdomyolysis merits a comment, since such drugs are commonly prescribed. Any statin, in particular, when associated with other hypolipaemiant drugs such as fibrates can be responsible for severe rhabdomyolysis, especially in old people with chronic kidney disease [3]. Such a syndrome must be clearly differentiated from the necrotizing autoimmune statin-mediated myopathy, actually understood as a myositis variant [4].

Trauma-related rhabdomyolysis may occur after significant blunt trauma (physical assault) or crush injury (disasters such as bombings, earthquakes, building collapse, and train accidents), high-voltage electrical injury (electrocution), and extensive third-degree burns [5,6]. Rhabdomyolysis is actually noted to occur only after the acute compression of the muscle is relieved releasing the necrotic muscle components into the circulation [1].

Most reported infectious causes of rhabdomyolysis, besides the two mechanisms referred to in Box 355.1, represent isolated raised CK levels without the complete rhabdomyolysis syndrome.

Pathophysiology and clinical features

The pathogenesis of rhabdomyolysis involves direct sarcolemmal injury (e.g. trauma) and/or adenosine triphosphate (ATP) depletion within the myocyte with an increase in intracellular calcium and myocyte toxicity [1]. Sarcolemmal calcium is strictly regulated by a series of pumps, channels, and exchangers that maintain low levels of calcium when the muscle is at rest and allow its' necessary increase for actin-myosin binding and muscle contraction (Fig. 355.1). ATP depletion impairs the function of these pumps, resulting in a persistent increase in sarcolemmal calcium that leads to persistent contraction and energy depletion, and the activation of calcium-dependent neutral proteases and phospholipases, with eventual destruction of myofibrillar, cytoskeletal, and membrane proteins followed by lysosomal digestion of fibre contents and, ultimately, breakdown of the myofibrillar network resulting in disintegration of the myocyte. In addition, mitochondrial function is affected. In traumatic rhabdomyolysis, additional injury is produced by ischaemia-reperfusion and inflammation by neutrophils that infiltrate damaged muscle [1].

The damaged muscle is able to absorb and sequester huge amounts of extracellular fluid through the leaky sarcolemma. Because muscle represents 40% of body weight, sequestration of extracellular fluid leading to hypovolemic shock can occur without extensive muscle damage [7]. Besides this, sequestration of extracellular fluid and Na^+ produces muscle oedema, which can lead to a compartment syndrome in muscles contained within a fibrous, non-distensible fascia. Sequestration of circulating calcium typically produces hypocalcaemia in the early phases of the clinical picture, which can be symptomatic.

Box 355.1 Frequent causes of rhabdomyolysis (multiple causes may co-exist)

Drugs and toxins

- Alcohol, cocaine, heroin, amphetamines, antiretrovirals, hypolypemiant agents.
- Spider venom, snake bite, massive bee venom.

Trauma and related injuries

Crush injuries and disasters, burn injuries, electrical injuries.

Excessive muscular activity

Marathon, body-builders, status epilepticus, military recruits.

Temperature extremes

Neuroleptic malignant syndrome, malignant hyperthermia syndrome.

Muscle ischaemia

- Localized (tourniquets, thrombosis, embolism, compartment syndrome).
- Generalized (hypotension and shock).

Infection

- Secondary to sepsis (hypoxia, dehydration).
- Direct bacterial or fungal invasion.

Electrolyte and endocrine abnormalities

- Hyponatraemia, hypokalaemia, hypophosphataemia.
- Hypothyroidism.

Genetic Disorders

Mostly recurrent rhabdomyolysis starting during childhood:

- Deficiencies in glycogenolytic enzymes (McArdle's disease).
- Abnormal lipid metabolism (CPT II deficiency).
- Mitochondrial primary diseases.

Unknown

Sometimes recurrent.

Conversely, due to the damage of the sarcolemma, intramuscular components leak to the circulation. Potassium efflux from cells can produce life-threatening hyperkalaemia (muscle contains 75% of the total body potassium), and myoglobin release, which is oxidized and has nephrotoxic properties. In addition, purines are released forming uric acid that can contribute to kidney damage. Phosphate is also released to the circulation, producing hyperphosphataemia, especially if renal function is affected.

Hypovolaemic shock is often aggravated by the systemic effects of muscle injury with inflammation, release of nitric oxide and other vasodilators, and the cardiotoxic and vasodilatory effects of hypocalcaemia, acidosis, and hyperkalaemia [7].

AKI is the most serious complication of rhabdomyolysis in up to 50% of patients [1]. The pathogenesis implies renal vasoconstriction associated with hypovolaemic shock, and activation of sympathetic nervous system antidiuretic hormone and the renin angiotensin system, all of which favour renal salt and water conservation. In addition, myoglobin-induced oxidative injury increases vasoconstrictors and decreases vasodilators. Kidney injury results from a combination of ischaemia due to renal vasoconstriction, direct tubular toxicity mediated by myoglobin-associated oxidative injury, which is enhanced in acidic urine, tubular damage due to ischaemia, and distal tubule obstruction due to precipitation of the complex myoglobin–Tamm–Horsfall protein in addition to sloughed tubular cells forming casts. Clinically, myoglobinuria-associated AKI is manifest by features of ischaemic-toxic acute tubular necrosis, with oliguria or anuria. Characteristically, patients display red-brownish urine, with a positive dipstick test for blood (representing myoglobinuria) and normal sediment (absence of or few red cells). The presence of AKI increases the risk of clinically significant hyperkalaemia and other accompanying electrolyte disorders, typically with unusually high levels of plasma creatinine, uric acid, and phosphate. The risk of AKI not only depends on the level of plasma CK (usually higher than 20,000 IU/L), but also on the severity of the accompanying shock, acidosis and infection, since chronic elevation of CK in patients with myopathies is not usually associated with kidney damage.

Management

Medical

The main goal of therapy is the early restoration of intravascular volume to avoid the development of AKI [8,9]. Box 355.2 summarizes recommendations for the management of patients with rhabdomyolysis. Patients often require very high volumes of fluid, about 10–20 L/day. Delay in receiving supportive therapy is associated with higher incidence of AKI and mortality [8,10]. With respect to the volume to be administered, it is very important to take into account the context in which rhabdomyolysis takes place. In a disaster-associated crush syndrome, affected individuals are often young and previously healthy and can tolerate very high volumes of fluid which can be life-saving [11]. On the contrary, in rhabdomyolysis, either toxic or traumatic, occurring in the hospital setting, especially if subjects are elderly, the amount of fluid to be administered must be programmed and monitored with caution.

Administration of normal or half-normal saline seems universal, but the use of bicarbonate is not supported by scientific evidence. There are empirical advantages of alkalinization, based on animal studies. It is known that precipitation of myoglobin with Tamm–Horsfall protein in the renal tubule is favoured by acidic urine. Alkalinization also inhibits redox cycling of myoglobin and lipid peroxidation, ameliorating tubule injury, and it has been shown that met-myoglobin only induces vasoconstriction in an acidic medium in the isolated perfused kidney. The principal, and probably only, disadvantage of alkalinization is the reduction in ionized calcium, which can exacerbate the symptoms of the initial hypocalcaemic phase of rhabdomyolysis. However, the clinical benefits of alkalinization over simple volume repletion are not firmly established. In the largest series of trauma patients

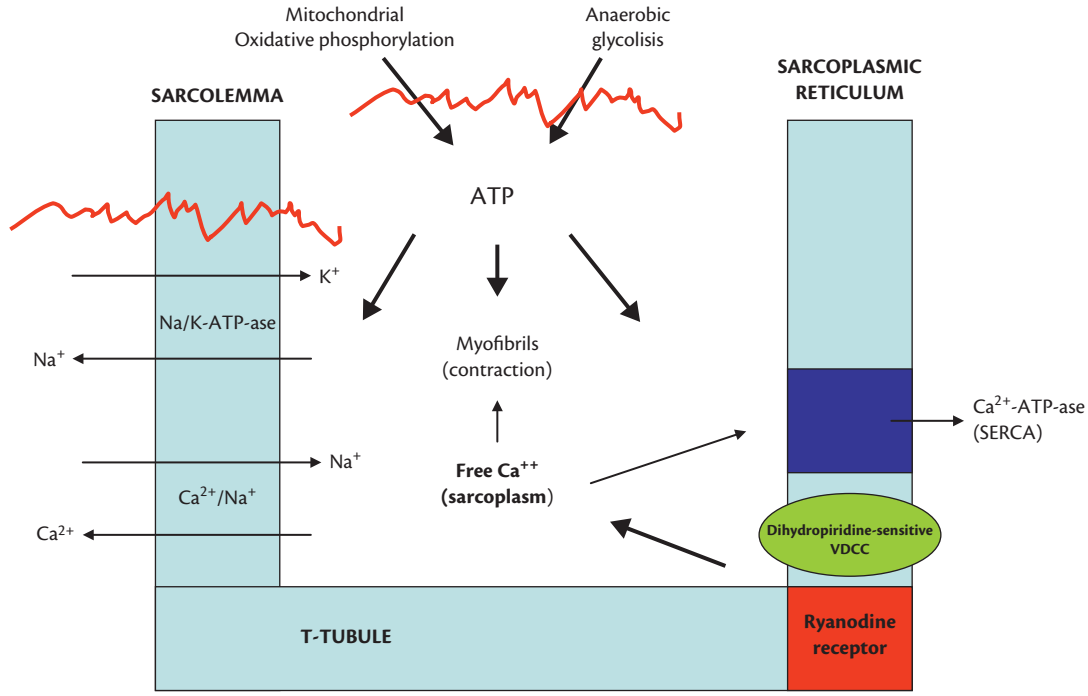

Fig. 355.1 Pathogenesis of rhabdomyolysis. Low sarcolemmal calcium is maintained by the action of the membrane Na–Ca exchanger, which allows the exit of calcium in exchange for sodium. The driving force for this exchange is the sodium concentration gradient maintained by the action of sarcolemmal Na,K-ATPase. In addition, the sarco(endoplasmic) reticulum calcium pump (SERCA) actively sequesters calcium in the sarcoplasmic reticulum and keeps sarcolemmal calcium low. The pathways leading to a rapid increase in sarcolemmal calcium necessary for contraction are the ryanodine receptor and the dihydropyridine-sensitive voltage-dependent Ca^{2+} channel. ATP depletion (red stripe), that impairs the function of these pumps, or physical damage to the sarcolemma (red stripe), both resulting a persistent increase in sarcolemmal calcium that leads to persistent contraction and energy depletion and the activation of calcium-dependent neutral proteases and phospholipases, with eventual destruction of myofibrillar, cytoskeletal, and membrane proteins.

SERCA, sarcoplasmic (endoplasmic) reticulum calcium pump; VDCC, voltage dependent Ca^{2+} channel.

[12], rhabdomyolysis developed in 85% of cases and administration of bicarbonate plus mannitol did not prevent renal failure, dialysis, or mortality, although the results suggested that it may be beneficial in patients with peak CK values >30,000 IU/L. In the only published randomized prospective trial comparing Ringer's lactate to normal saline [13], sodium bicarbonate was added in both groups if urine pH was <6.5 after 12 hours of volume repletion, and no benefits were observed.

Massive infusion of normal saline can contribute to metabolic acidosis via hyperchloraemia. Therefore, administration of both normal saline and sodium bicarbonate seems reasonable in those with metabolic acidosis. If bicarbonate is used, urine pH, serum bicarbonate, sodium, calcium, and potassium should be monitored, and if the urine pH does not rise after 4–6 hours of alkali perfusion or symptomatic hypocalcaemia develops, alkalinization should be discontinued and hydration continued with normal saline alternating with 5% glucose [1,8].

The use of diuretics is still controversial, but if used, they should be restricted to volume-replete patients. Mannitol may have several beneficial effects [14]. First, as an osmotic diuretic it increases urinary flow and the flushing of nephrotoxic agents through the renal tubules. Secondly, as an osmotic agent it creates a gradient that extracts fluid accumulated in injured muscles, improves hypovolaemia, and may prevent compartmental syndrome. Thirdly, it is a free radical scavenger. Most data on the benefits of mannitol have been obtained from animal studies that show the protective effect of mannitol may be attributable to its osmotic diuretic action rather than other mechanisms. No randomized, controlled trial has confirmed its benefit. In addition, high accumulated doses of mannitol (>200 g/day or accumulated doses >800 g) have been associated with AKI due to renal vasoconstriction and tubular toxicity, known as osmotic nephrosis. If mannitol is to be used, plasma osmolality and the osmolal gap (that is, the difference between measured and calculated serum osmolality) should be monitored frequently and therapy discontinued if adequate diuresis is not achieved or the osmolal gap rises above 55 mOsm/kg. Mannitol should not be given to anuric patients, or patients with renal failure with extracellular volume overload, particularly if they are elderly [1]. Loop diuretics also increase urinary flow and may decrease the risk of myoglobin precipitation, but no study has shown a particular benefit.

Electrolyte abnormalities must be treated promptly, especially correction of hyperkalaemia, which occurs very early in the course of the disease. Rapidly rising potassium levels (>1 mmol/L/day), even within the normal ranges can herald dangerous hyperkalaemia. Measures that cause a shift of potassium from the extracellular to the intracellular space (hypertonic glucose-insulin and bicarbonate) are only temporarily effective. The only means of removing potassium from the body are diuresis, intestinal potassium binders, or dialysis. In contrast, early hypocalcaemia should not be treated unless symptomatic or severe hyperkalaemia is also present. Calcium-containing phosphate binders should be used with caution to treat hyperphosphataemia, since the calcium load

Box 355.2. Steps in the medical management of rhabdomyolysis

- Check for extracellular volume status, central venous pressure, and urine output.*
- Measure blood chemistry (creatine kinase, creatinine, Na^+, K^+, Ca^{2+}, P, uric acid, albumin), and blood cell count.
- Perform a urine dipstick test and examine the urine sediment. Measure urine electrolytes and creatinine.
- Initiate volume repletion with normal saline promptly at a rate of approximately 400 mL/h (200–1000 mL/h depending on the setting and severity), with monitoring of the clinical course and of central venous pressure.
- Target urine output of approximately 3 mL/kg body weight/hour (200 mL/hour).
- Check serum potassium level frequently.
- Correct hypocalcaemia only if symptomatic (e.g. tetany or seizures) or if severe hyperkalaemia occurs.
- Investigate the cause of rhabdomyolysis.
- Check urine pH; if it is less than 6.5, alternate each litre of normal saline with 1 L of 5% dextrose plus 100 mmol of sodium bicarbonate. Avoid potassium and lactate-containing solutions.
- Consider treatment with mannitol (up to 200 g/day and cumulative dose up to 800 g). Check for plasma osmolality and plasma osmolal gap. Discontinue if diuresis (>20 mL/hour) is not established.
- Maintain volume repletion until myoglobinuria is cleared (as evidenced by clear urine or a urine dipstick testing result that is negative for blood).
- Consider renal replacement therapy if there is resistant hyperkalaemia of more than 6.5 mmol/L that is symptomatic (as assessed by electrocardiography), rapidly rising serum potassium, oliguria (<0.5 mL of urine/kg/hour for 12 hours), anuria, volume overload, or resistant metabolic acidosis (pH < 7.2).

*In the case of the crush syndrome (e.g. earthquake, building collapse), institute aggressive volume repletion promptly before evacuating the patient.

could favour the precipitation of calcium-phosphate in injured muscle [1,8].

If the patient develops AKI severe enough to produce hyperkalaemia and/or acidosis resistant to medical treatment, renal replacement therapy is indicated, principally with intermittent haemodialysis. Due to the molecular weight of myoglobin (17 kDa), conventional haemodialysis with regular dialysers has little effect in removing myoglobin. However, due to the pathogenic role of myoglobin in rhabdomyolysis-induced AKI, preventive extracorporeal elimination of this molecule has been studied. While plasmaphoresis has shown no significant benefit, continuous veno-venous haemofiltration or haemodiafiltration, especially with super high-flux filters and high volumes of ultrafiltration, have shown some efficacy in removing myoglobin in case reports. High-cut-off pore dialysers, which are permeable to proteins such as free light chain immunoglobulins, may remove myoglobin effectively [15]. However, until large positive randomized trials become available, preventive removal of myoglobin in rhabdomyolysis (to prevent AKI) cannot be recommended.

Other therapies with anecdotal evidence are the use of antioxidants and free radical scavengers (pentoxyfylline, vitamin E, vitamin C) to ameliorate the toxic effects of oxidized myoglobin.

Surgical

Compartment syndrome occurs when increased pressure within a compartment compromises the circulation and function of the tissues within that space. Acute compartment syndrome is a surgical emergency and most often develops after significant trauma, in particular with long bone fractures, but may also occur following minor trauma or even from non-traumatic causes.

About 70% of acute compartment syndrome are due to long bone fractures, especially with comminuted fractures of the tibia and bones of the forearm [16]. Direct trauma to a tissue compartment (crush injury), severe thermal burn, penetrating trauma, or injury to vascular structures (either arterial or venous) may also be responsible for acute compartment syndrome as may ischaemia-reperfusion injury, sometimes occurring few hours or days after revascularization procedures such as by-pass surgery, embolectomy, or thrombolysis.

The development of acute compartment syndrome includes rapid progression of signs and symptoms over a few hours. Therefore, serial evaluation is mandatory. The most important symptoms are pain (out of proportion to apparent injury) and paresthaesias. The compartment is tense with skin pallor, diminished sensation, and muscle weakness or paralysis.

Compartment pressures should be measured, and a difference between diastolic blood pressure and the compartment pressure of 30 mm Hg or less requires an immediate surgical approach [17], including relieving all external pressure on the compartment, analgesics as required, as well as oxygen supplementation. Fasciotomy to fully decompress all involved compartments is the definitive treatment for acute compartment syndrome.

SECTION 18

Pain and sedation

PART 18.1

Pain

CHAPTER 356

Pathophysiology and assessment of pain

Rebecca E. Martin and Ross D. MacPherson

Key points

- Pain is a complex physiological phenomenon with the nociceptive nervous system, both peripheral and central, demonstrating significant plasticity and sensitization.
- Modulation of nociceptive signals occurs at multiple levels within the nociceptive system and the resultant subjective experience of pain is an integration of both excitatory and inhibitory nociceptive processes.
- Visceral pain is usually diffuse and poorly localized with convergence of both non-visceral and other-visceral afferents onto the same second order neuron in the dorsal horn of the spinal cord.
- In the critical care setting communication regarding a particular individual's pain experience is difficult and numerous assessment tools have been developed to guide clinicians.
- The use of pain assessment tools to titrate analgesia drug dosages improves clinical outcomes, including reduction in ventilator time and intensive care unit stay.

Introduction

Pain is a complex phenomenon that serves a protective function by modifying behaviour to avoid tissue damage, with acute pain acting as a 'teaching signal' in development to improve survival. Pain is defined by the International Association for the Study of Pain (IASP) as 'an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or defined in terms of such damage' [1]. It is distinct from the other internal senses of the body, i.e. the somatosensory system—touch, thermal, proprioception, and pain—in that it is unpleasant at threshold. This unpleasantness, which defines pain as an experience, being both sensory and emotional, distinguishes pain from nociception, the neural process encoding noxious stimuli [1]. The IASP notes that the inability to communicate verbally does not negate the possibility that an individual is experiencing pain and is in need of suitable pain-relieving treatment, emphasizing the need for appropriate assessment and management of pain when caring for unconscious patients and those with communication barriers. Insight into mechanisms of nociception assists such clinical assessment of pain and this chapter introduces the reader to basic concepts of nociception and the assessment of pain in critical care.

The nociceptive system demonstrates rapid and significant plasticity in response to peripheral inputs with both peripheral and central changes leading to amplification of signal processing, a process referred to as sensitization. This creates both reduction in the threshold of nociception and increased suprathreshold effects, demonstrated clinically as allodynia, pain due to a stimulus that does not normally provoke pain, and hyperalgesia, increased pain from a stimulus that does normally provoke pain. Treatment goals extend beyond the removal of the pain response to a noxious stimulus, referred to as analgesia, but also attempts to preserve the protective functions of the somatosensory system, i.e. return sensitivity to baseline with antihyperalgesia and anti-allodynia effects as outlined in Fig. 356.1 [2].

An important advance in our understanding of these processes was Melzack and Wall's 1965 'gate theory' of pain [3], which proposed that modulation of sensory inputs within the spinal dorsal horn, including activity in non-nociceptive neurons, leads to either an increase or a decrease in the volume of nociceptive signals transmitted to the brain. Further understanding has since recognized the significance of descending influences from the brain, both facilitatory and inhibitory, providing a more comprehensive understanding of the sensory/discriminative, affective/motivational, and cognitive/evaluative components of pain perception and behaviour [4].

Peripheral mechanisms of nociception

A peripheral nociceptive neuron is a sensory neuron capable of encoding noxious stimuli with its cell body located in the dorsal root, trigeminal, or nodose ganglia. These neurons are anatomically pseudo-unipolar, with a central projection to either the spinal cord or the medullary dorsal horn. In addition, they have a peripheral projection terminating in 'free' unencapsulated nerve endings in the tissues. Primary afferent nociceptors are most commonly discussed in terms of their morphology and electrophysiological characteristics. Aδ fibre mechanothermal sensory neurons have myelinated, medium to small diameter fibres and C-fibre polymodal sensory neurons have non-myelinated, slowly conducting fibres. Aδ fibres, being myelinated, conduct at a faster rate and are associated with pricking, sharpness, and possibly aching pain. C-fibre nociceptors, the most numerous subclass, are typically polymodal, with populations responding to chemical, thermal, and mechanical stimuli and are associated with the perception of slow, burning pain. [5]

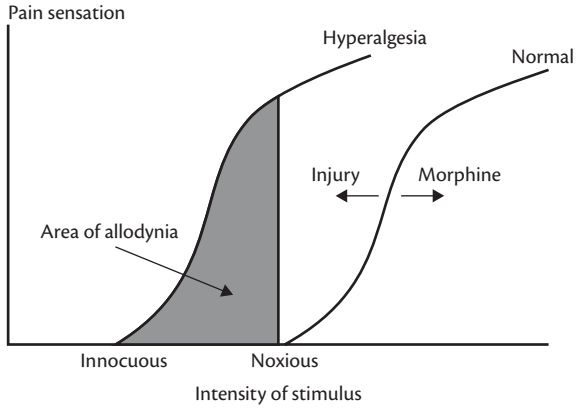

Fig. 356.1 Dose–response curve showing terminology.
Reprinted from *Annals of Emergency Medicine*, **35**(6), Ducharme J, 'Acute pain and pain control: state of the art', pp. 592–603, Copyright 2000, with permission from Elsevier and American College of Emergency Physicians.

Nociceptors have free nerve endings without specialized transducing structures so the main processes of signal transduction are intrinsic to the nerve terminal itself. For detection of noxious thermal, mechanical, or chemical stimuli, they must produce activation of the peripheral nociceptive terminal, transforming the noxious energy into generator potentials that contribute to action potentials that are then propagated along the primary afferent nociceptor. Transmission of this electrophysiological impulse is initially to the dorsal horn (DH) of the spinal cord (or of the medulla). For the perception it must be further transmitted via the brain stem and thalamus to the multitude of higher centres in the brain involved with processing nociception. Modulation of the signal occurs at multiple levels and the resultant subjective experience of pain is an integrated result of both excitatory and inhibitory nociceptive processes, in the context of the particular individual's experience.

In the clinical setting of actual or potential tissue damage, such as occurs with inflammation, infection, or ischaemia, multiple chemical mediators are released by damaged cells, from the degranulation of mast cells, from the secretions of inflammatory cells, and from sympathetic nerve terminals, as well as by the induction of enzymes such as cyclo-oxygenase-2 [6]. In addition to directly activating the primary afferent neuron, they may also modify and enhance the response characteristics of the peripheral terminal, known as 'peripheral sensitization'. An area of increased sensitivity within the area of injury occurs, which is manifest clinically as primary 'hyperalgesia'.

This inflammatory and sensitizing 'soup' of chemical mediators, acting directly via ionotropic chemoreceptors, such as those from the transient receptor potential (TRP) group and others, forms generator potentials in the nociceptive free nerve ending that contribute to membrane depolarization. They may also act via G protein-coupled receptors such as those sensitive to prostaglandins, serotonin, and bradykinin. Following activation, phosphorylation of channels as a result of changes in intracellular kinase cascades, results in alterations of channel kinetics, and threshold and sensitization of the nociceptor. [6]

When the activated nociceptive afferent transmits impulses centrally toward the spinal cord it also produces antidromic impulses in its collateral fibres, this releases transmitters in the periphery that contribute to neurogenic inflammation [4,7]. Release of substance P and calcitonin gene-related peptide (CGRP) from these antidromic fibres plays a pivotal role in the vicious cycle of peripheral sensitization as they both activate and sensitize nociceptors, which in turn leads to further release of substance P and CGRP [4]. Subsequent further activation and sensitization occurs as a result of increased capillary permeability, extravasation of bradykinin, release of 5-hydroxytryptamine (5HT) from platelets and histamine from mast cells.

Once a noxious stimulus has produced activation of the nerve terminal (signal transduction), and a generator potential equal to or above threshold has been produced, an action potential will be initiated and propagated by voltage-gated sodium channels (VGSCs). Different subtypes of VGSC exist, with NaV1.8 and NaV1.7 underlying nociceptor action potential generation, whereas propagation primarily involves the NaV1.6 subtype, which is not specific to nociception [7]. Following injury, changes in the kinetics and expression of different VGSCs contribute to hyper-excitability of nerves seen in different pain states [6,8].

Visceral nociceptors also have free nerve endings and sensitize. Some organs, such as the liver, brain, and lung lack sensory innervation, and do not respond to traumatic stimuli. Effective stimuli for visceral nociception differ: with thermal and mechanical stimuli generally ineffective, whereas pathological distention of hollow viscera or the capsules of solid organs, as well as ischaemia and infection producing nociceptive activity. Visceral afferents may travel via spinal nerves (e.g. splanchnic) or autonomic nerves (vagus) with the overall visceral input to the spinal cord being <10% of all afferent inputs [9]. Visceral pain is usually diffuse and poorly localized with convergence of both non-visceral and other visceral afferents onto the same second order neuron in the dorsal horn.

Spinal cord

Somatosensory afferents, with their cells bodies in the dorsal root ganglia, enter the CNS via the laminated dorsal horn of the spinal cord, which acts as a complex nociceptive processing unit. Although some fibres traverse a few segments in Lissauer's tract, most terminate in the superficial DH laminae I and II, with some Aδ fibres projecting more deeply to lamina V. Aβ fibres (light touch) synapse in laminae III and IV. There is convergent input of both nociceptive and tactile afferents into lamina V, either directly or via interneurons. Projection neurons may be nociceptor-specific (NS) with small receptive fields, predominantly in lamina I; low threshold, responding to innocuous stimuli only, predominantly in lamina III; or wide dynamic range (WDR) neurons, which have large receptor fields and converging inputs that are both nociceptive and non-nociceptive, predominantly in lamina V [9].

All primary sensory afferents exert excitatory synaptic effects on their second order neurons in the DH, mostly via glutamate release acting on α-amino-3-hydroxy-5-methyl-4-isaxazole-proprionic acid (AMPA) receptors. The N-methyl-D-aspartate (NMDA) subtype of glutamate receptor is minimally active in its resting state with its channel blocked by a magnesium 'plug'. However, with intense, sustained input, tissue damage or nerve injury, the magnesium blockade is removed from the NMDA channel, and an increase in the stimulus to response profile of the DH neurons is seen, called central sensitization. This plasticity is initiated by increased intracellular calcium, both via the NMDA channel and

release from intracellular stores. Changes in DH sensitivity and/or the functional connectivity of Aβ fibres, and increased descending facilitation contribute to extended sensitivity beyond the area of tissue damage or 'secondary hyperalgesia'. 'Wind up' refers to a rapid and reversible increase in responsiveness during a train of inputs, whereas 'long-term potentiation' (LTP) is a more long-lasting activity-dependent modification of individual synapses. Processes underlying secondary hyperalgesia, wind-up, and LTP are similar, but they are distinct phenomena that may all contribute to central sensitization [10–12].

Spinal modulation of activity involves the endogenous opioid system, excitatory, and inhibitory interneurons, descending influences from supraspinal sites, as well as influences from non-neuronal cells, such as microglia. Inhibitory interneurons are themselves activated by the primary afferent and act both pre- and post-synaptically. The predominant effect is post-synaptic inhibition via $GABA_A$ and glycine receptors acting on ligand gated Cl^- channel and also via G protein coupled receptors such as $GABA_B$, adenosine, and opioid receptors. Glutamate release from the primary afferent terminal may also be supressed by similar mechanisms acting pre-synaptically [12]. Voltage-gated calcium channels (VGCCs), especially the N-type, modulate neuronal excitation and transmitter release, and in chronic pain conditions are more active [8].

Central

The output from the spinal cord dorsal horn is transmitted to areas of the brain involved in sensory, emotional, autonomic, and motor processing via spinothalamic, spinobulbar, and spinomesencephalic tracts. There is no one area of the cortex identifiable as being solely responsible for pain with multiple brain regions and an extensive cortical network involved.

Pain assessment in the critical care setting

If your patient is able to communicate in any meaningful way at all, pain management becomes, at least in theory, a much more straightforward process. The patient can describe the nature and intensity of his or her pain and, more important, can tell you if any strategies that have been initiated have actually worked.

This situation is unusual in the critical care setting, and trying to accomplish this same end-point in a patient who is unable to communicate has been a challenge that many groups have tried to take on over the years.

Nurses have been particularly active in this area, and almost all of the early studies and most reviews will be found in the nursing, as opposed to medical literature, reflecting the importance placed in pain management by those staff directly caring for the patient.

There have been a number of important assessment tools proposed by various groups over the years. The Behavioural Pain Scale (BPS) [13] looks at the parameters of compliance with ventilation, facial expression, and upper limb movement to try and gauge the level of pain. While the Critical Care Pain Observation tool [14] also utilized facial expression and ventilator compliance they also proposed that body movement and muscle tension were important parameters. The Non-Verbal Pain Scale [15] was essentially adapted from a similar pain scale used in children and uses three behaviours and two physiological domains. Many of these tools have been the subject of assessment and modification, with the behavioural pain scale (BPS) being the most widely accepted system.

No matter what tool is employed assessment of pain in the non-verbal patient is no easy task. Pain levels must be assessed frequently throughout the day and particularly following painful procedures and turning. To quote one source on the subject, Mularski [16] has said 'for (pain assessment systems) to be effective . . . they must be ardently, frequently, and regularly implemented, as well as appropriately reviewed in the clinical titration of analgesia.'

Nevertheless, despite the difficulties in formulating and assessing these various pain measurement scales, there is evidence that their use is beneficial. Chanques et al. [17] and, more recently, Payen et al. [18] have both demonstrated that simply applying currently available methods for evaluation and management of pain in the intensive care unit (ICU) will most likely result in a reduction in both ventilator time, and time of ICU admission. Interestingly an earlier paper by Payen et al. [19] showed that despite a range of assessment tools being available, they had not been widely accepted in the ICU environment.

One point that comes through in all of these reviews, is that the validity of assessment tools declines in patients who are heavily sedated and are even less applicable in the paralysed patient, a situation where provision of adequate analgesia and sedation is of paramount importance. Nevertheless, despite all these difficulties, there must be a continued attempt to refine and promote such assessment systems. Even today, it appears that most hospitals do not utilize assessment protocols for analgesia in the ICU, despite these tools being available. Furthermore, it has been clearly demonstrated that by deciding on analgesia drug dosage, based on assessment, rather than intuition, will result in a reduction both in ventilator days and length of ICU stay [13]. Although as yet unproven, one group has suggested that if this strategy is followed, there may well be further reductions in delirium and ventilator-associated pneumonia [20].

CHAPTER 357

Pain management in the critically ill

Ross D. MacPherson

Key points

- There have been very few well conducted trials specifically examining pain management in the intensive care unit setting, and evidence for much of what we do is lacking.
- Pain causes significant sympathetic nervous system stimulation that can impact on all organ systems.
- The pharmacokinetics of analgesic agents, and indeed all drugs, can be altered in the critically-ill patient, although again definitive studies are few.
- An understanding of the pharmacokinetics of infusions of commonly used drugs will aid in competent prescribing.
- Whilst analgesia will usually provide some degree of sedation, sedation never equates to analgesia.

Introduction

Providing guidelines for the management of pain in the ICU presents a unique set of problems. In the first place there have been few well conducted trials on this subject and most reviews can suggest little more than general guidelines—those seeking Level 1 evidence on this topic will be disappointed, and even traditional sources of high quality evidence-based information on pain management, such as the IASP can offer little more. Of course, this will come as no surprise since the intensive care unit (ICU) population represents such a heterogeneous sample that trying to provide guidelines is very difficult. Furthermore, at stages during the patient's ICU stay, the physician will be faced primarily with decisions focusing on respiratory and cardiovascular management often of life-threatening conditions, and the problems related to pain management tend to be overlooked. It must be understood that sedation does not equate with analgesia, and while analgesia agents almost always will provide a degree of sedation, the reverse is never true. Finally, apart from the subjective feeling associated with pain, it should be understood that it is also associated with significant sympathetic nervous system activation resulting in effects on all physiological systems including respiratory, cardiovascular, gastrointestinal, and endocrine.

However, all these issues should not deter us from making a considered attempt to optimize pain management in the ICU patient. It has already been clearly identified that acute pain that is poorly managed in the ICU frequently progress to chronic pain problems having a significant impact on the patient's life following discharge from hospital [1]. Furthermore, as has been shown in the section 'Pain Assessment in the Critical care Setting' in Chapter 356, 'Pathophysiology and Assessment of Pain' adequate pain management is associated with a reduction in time involving mechanical ventilation, and earlier discharge from the ICU to the general ward [2].

Routes of administration

There are numerous routes of administration available for analgesic agents. However, most of these are unsuitable for use in the critical care setting. The major advances in, for example, sustained release oral opioid preparations, and transdermal fentayl or buprenorphine are useful where pain is established and ongoing, but take time to alter dosage, and in the case of transdermal products take many hours to achieve steady state. In general, the absorption of drugs by the oral route is unpredictable in the critically ill. For these and other reasons the intravenous route has been favoured for the management of pain in the ICU and this will be the main focus of this chapter.

Pharmacokinetics

Although detailed data are lacking, it may be that the pharmacokinetic behaviour of drugs in critically-ill patients have significant deviations from that seen in other populations. Apart from significant impairment of drug metabolism and excretion that may arise from hepatic and renal impairment in this group, there are a number of other associated factors that can affect drug disposition, the importance of which is difficult to quantify. Large shifts in the volumes and composition of body fluid compartments, reductions in albumin and glycoprotein concentrations, and acid–base disturbances can all contribute to unexpected drug behaviour [3].

Of particular interest in the ICU patient is the pharmacokinetics associated with the use of prolonged infusion.

Empirically, it has been noted that it often needed a considerable amount of time for the clinical effects of drugs that had been administered by long-term infusion for some time to wear off. It was clear that for some drugs the time taken for clearance from the body was heavily-dependent on the duration of the intravenous infusion.

In contemporary pharmacokinetics, the term context sensitive half time has been coined to describe the time taken, following the cessation of an intravenous infusion, for the blood level of a drug

to decline by half **following a particular period of infusion**. The 'context' in this case refers to the duration of the infusion. This is not a constant value (in most cases), but the time needed for a decrement in the body of a particular drug is dependent (in part) upon the time of the preceding infusion.

As can be seen in Fig. 357.1, fentanyl is generally taken as an agent with a relatively short half-life, however, as its infusion is prolonged, the time taken for the drug to be cleared increases substantially [4]. The reasons for these changes are complex, but usually involve saturation of elimination pathways (as in the case of thiopentone), or in the case of fentanyl its high lipophilicity results in the saturation of peripheral drug compartments [5].

The difficulties with morphine infusions are well known to intensivists. The primary metabolites of morphine, the -3 and -6 glucuronide are both renally cleared, and the 6 glucuronide possesses significant analgesic and sedative effects, accentuated when the metabolite accumulates in renal impairment.

Opioids

Opioids remain the mainstay of pain management in critically-ill patients. Apart from avoiding pethidine (meperidine), any of the other agents can be used, although each has its own set of individual characteristics.

Morphine is readily available and inexpensive, an important point to remember. Of the opioids, it is one of the more sedating agents, and will produce metabolites that may have prolonged activity.

Hydromorphone was initially synthesized over a century ago and has recently undergone a revival of interest. It can be given by a number of routes of administration, and while it also undergoes glucuronidation, the metabolites produced are inactive, making it an attractive prospect in patients with renal impairment [6].

Remifentanil is the newest opioid to join the stable and has a unique pharmacokinetic profile. Its metabolism by non-specific esterases (not to be confused with pseudocholinesterase) in the plasma results in a half-life that is measured in minutes, and a very stable context-sensitive half-time. It has found a niche in certain anaesthetic procedures providing a degree of haemodynamic stability and impressive analgesia. Its use is not without hazards, however, and reports of hypotension, bradycardia, and muscle rigidity have all been reported. Using remifentanil requires some finesse, since its analgesic effects are so short lived, other longer-acting agents must be added to the regime prior to its cessation, or the consequence will be a hypertensive patient in severe pain. There have been a number of promising studies of remifentanil use in the critical care setting [7]. One area where remifentanil could make a big impression is to facilitate undertaking brief, but painful procedures in the ICU. The remifentanil infusion can be commenced, titrated to effect and continued through the procedure e.g. chest tube or tracheostomy, and ceased at the conclusion.

Drugs to avoid

Pethidine (meperidine)

This drug has no role to play in modern pain management. It has no advantages at all over other available opioids. It has a high risk of dependence, is metabolized to a toxic metabolite with a long half-life, and has considerable anti-cholinergic side effects. Importantly, toxicity can occur even at so-called 'therapeutic' dosage levels. It is an unsafe drug and should be avoided [8].

Codeine

Codeine, which has also had its adherents over the years, mainly in the arena of neurosurgery is also a drug of limited efficacy. While some codeine/paracetamol combinations provide superior analgesia to paracetamol alone, codeine as a sole agent has very poor analgesic qualities [9]. Furthermore, most agree that it only exerts its analgesic efficacy by conversion to morphine a feat that cannot be accomplished by about 10% of the population who are lacking the appropriate CYP2D6 enzyme system. It has a low ceiling effect and is very constipating.

Methadone

While methadone is not exactly a drug to be avoided in the acute pain setting, it is a drug that needs to be used with caution on account of its unpredictable, complex, and variable pharmacokinetics.

Methadone is a racemic compound with the (R) isomer having a high affinity for the opioid receptor, while the (S) isomer has antagonistic effects on the NMDA receptor (like ketamine). It has a high lipid solubility and is highly redistributed to fat tissues over time, accounting for its long half-life. It has no active metabolites (despite

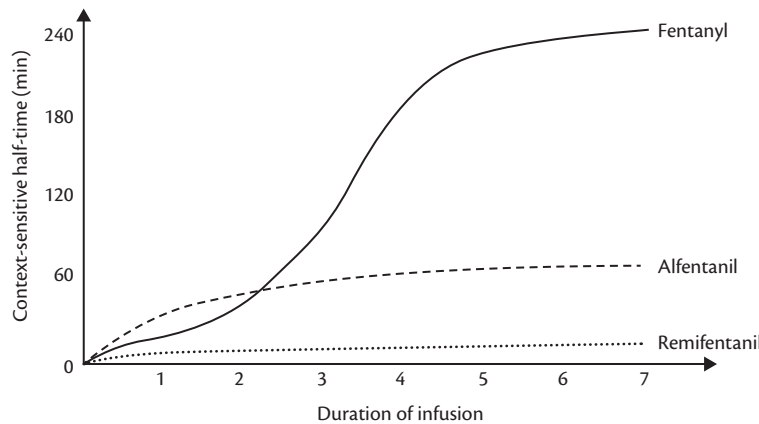

Fig. 357.1 Context-sensitive half-times of remifentanil, fentanyl, and alfentanil.

Reproduced from Roberts F and Freshwater-Turner D, 'Pharmacokinetics and anaesthesia', *Continuing Education in Anaesthesia Critical Care and Pain*, 2007, **7**(1), pp. 25–9, by permission of Oxford University Press and the British Journal of Anaesthesia.

a complex array of P450 cytochromes involved in its metabolism) and lacks the euphoric effects of traditional opioids. However, its analgesic half-life (4–8 hours) is considerably less than its elimination half-life (that can be up to 150 hours). Thus, dosing is difficult to predict and over administration can lead to accumulation, and the potential risk of increased respiratory depression. Methadone in high levels has also been implicated to initiate torsades de pointes. The risk of this event is increased in patients with pre-existing QT prolongation, hypokalaemia, and hypomagnesaemia. With so many other options available, methadone is an unlikely candidate for first line pain management in the ICU [10,11].

Adjunct agents

Paracetamol

Paracetamol is the foundation stone of modern pain management. Provided a few simple rules are adhered to, this agent enhanced the quality of opioid-induced analgesia and has an excellent side effect profile. With the parenteral form of paracetamol now available in most countries, the problems associated with administration have now been overcome. The dose should be capped at 1 g qds, and this dose should be reduced in the critically ill, elderly, or cachectic patients where the dosage should be based on paediatric guidelines (i.e. 15 mg/kg). Liver function tests should be monitored closely and the drug suspended in the face of any abnormality. The only other issue that has arisen in recent times is the possibility of increased toxicity with intravenous paracetamol in the malnourished patient where stores of glutathione, needed for paracetamol metabolism to non-toxic products, may be diminished

Ketamine

Ketamine has much to recommend it as an analgesic agent in the critically ill. It has enjoyed a re-emergence as an analgesic agent, and well known as an agent with effects at multiple receptor sites, notably the NMDA receptor.

In the past, the well-known psychomimetic effects have limited the use of ketamine. However, these effects are generally held to be a dose-related phenomenon, and since the amounts needed when ketamine is used as an analgesic agent are an order of magnitude less than when used as an anaesthetic agent, such effects are much less problematic. It is perhaps most useful as an adjunct to opioid analgesia when dosing seems to be increasing without appreciable increase in efficacy. It has a wide range of other benefits [12]. For example, in most patients (provided that they are not in severe shock) the mild sympathominetic effects tend to maintain blood pressure and cardiac output. It should be noted that these effects are centrally mediated and ketamine in fact is a direct myocardial depressant when administered in vitro. Additional benefits include the fact that it has a relatively fixed context-sensitive half time, is a mild bronchodilator, had anti-inflammatory properties, reduces opioid-induced hyperalgesia, and may reduce the emergence of chronic pain syndromes [10]. In some countries isomeric ketamine is available. The S(+) isomer is associated with improved analgesia coupled with a reduction in psychomimetic effects.

Tramadol

Tramadol use in the ICU has been restricted probably because of concerns about possible epileptogenic effects, and variable clinical efficacy. Despite these worries, tramadol should not be forgotten as an adjunct to opioid-based analgesia. It is essentially devoid of traditional opioid adverse effects, such as tolerance and dependence, and it is available in a wide variety of dosage forms. Furthermore, it is one of the few 'traditional' analgesics that has been shown to have some efficacy in the management of neuropathic, as well as nociceptive pain, making it useful in mixed pain conditions [9,13]. Serotonin syndromes is unlikely when the drug is used at the recommended dosage, and is generally encountered only at either excessive dosage or when the drug is used in combination with other serotonergic agents. The M1 metabolite of tramadol has considerable activity, and its generation is also determined on pharmacogenetic grounds, with some patients unable to synthetize this particular metabolite. The significance of this is still unclear, but it may be responsible for reduced activity of the drug.

Non-steroidal anti-inflammatory agent (NSAIDs)

NSAIDs tend to be avoided in the ICU setting, primarily because of fears concerning renal dysfunction and bleeding. While these are often quite well founded, NSAIDs should not be disregarded completely, as they are capable of providing outstanding analgesia without the usual opioid related adverse effects [14]. The key to minimizing adverse effects is to choose an agent with a short half-life such as diclofenac or ibuprofen, and to limit treatment to 3 days at a time [15]. Unlike aspirin, the platelet effects of NSAIDs are reversible, and platelet function will return to normal within hours of cessation of a short half-life agent. Furthermore, most renal impairment is associated in patients in who prostaglandins play a major role in maintaining blood flow i.e. the volume depleted. Maintaining an appropriate fluid volume and urine output will minimize the risk of adverse events.

Other modalities

There are some pain modalities that are perhaps under-utilized in the ICU. The first is the use of spinal opioids. Opioids (especially the less lipid soluble morphine) can be delivered into the CSF in doses orders of magnitude smaller than those given by any peripheral route and deliver substantial analgesia for up to 24 hours following surgical procedures. Its activity does seem to be somewhat site specific, but when ICU admission is anticipated following, for example, major urogenital, or lower limb surgery this can be considered.

The other area which has undergone a revival is the use of peripheral nerve blocks. Peripheral nerve blocks have always been part of anaesthetic technique, but technical difficulties often stood in the way of consistent results. However, with the advent of ultrasound, there has been a revival of the use of both single shot and continuous local anaesthetic infusions. Despite the popularity of these as a means of provision of analgesia there are some other factors that need to be considered. The first is that evidence as to the efficacy of the wide range of blocks currently employed is lacking. Furthermore, the process is not risk free and even with ultrasound usage, perineural haematoma or intraneuronal injections are still a major cause of morbidity. The chances of these occurring are significantly higher in the anaesthetized or sedated subject [16]. Finally, the ability to provide these blocks is still determined by the Hospital having anaesthetists with sufficient skills and equipment to be able to undertake these procedures.

Gabapentin was initially developed as an anti-epileptic agent and has since been used as a mood stabilizer and a treatment option for neuropathic pain. However, it has been increasingly used as an adjunct to general anaesthesia as there is mounting evidence that even low doses in the peri-operative period can both reduce pain perception and opioid requirements. There is also evidence that its administration can prevent the progression to chronic pain. Although an oral solution exists in some countries, there is currently no parenteral dosage form available, a fact that may limit its utility [17].

Transition to ward care

As soon as practical, patients should be transferred to a patient-controlled analgesia (PCA) device, where this is part of the usual pain management routine. PCAs have been about for more than a decade now and are an established part of acute pain management. It is interesting to note that while PCA analgesia has a high degree of patient acceptance, studies have consistently shown that in terms of adverse effects, complication, quality of pain management, and overall opioid usage, they provide no particular advantage over conventional opioid management [14,15]. Despite this, they are important in establishing a patient-centred analgesia regime. Patient education is critical for PCA analgesia to be successful, and this should be initiated well before ward discharge if possible. Pethidine must never be used in a PCA prescription, but apart from that any other opioid can be used. Although it may be counter intuitive, numerous reports have shown that a background added to a PCA has no impact on overall analgesia and should be avoided in adults.

Conclusion

Opioids delivered by infusion remain the mainstay of pain management in the ICU. Of the various opioids available hydromorphone and remifentanil provide probably the optimum degree of analgesia coupled with minimal adverse effects.

There is always room for input from specialists in pain management, and if your institution has an acute pain team, they should be encouraged to include the ICU as part of their referral base. Early involvement of the acute pain team in complex pain management issues within the critical care setting will always be beneficial, and they can provide ongoing input with pain management, as well as providing a continuum of care for the patient moving from the critical care to the general ward environment.

PART 18.2

Sedation

CHAPTER 358

Sedation assessment in the critically ill

Giovanni Mistraletti and Gaetano Iapichino

Key points

- Continuous sedation monitoring is mandatory—it guarantees patient comfort, leads the adequate use of sedatives and helps staff in communication.
- The sedation assessment is devoted to reaching an awake, calm, and cooperative state as soon as possible during the intensive care unit (ICU) stay, thus permitting the patient's early mobilization.
- Instrumental monitoring (electroencephalography, blood dosage, electromyogram) failed in bedside assessment of sedation state in conscious ICU patients. Actigraphy could offer some advantages.
- Among many different validated scales, each unit has to choose and use the most suitable for local needs. The Richmond Agitation-Sedation Scale is the most used all around the world.
- A sudden fluctuation of consciousness is the main challenge in sedation assessment. Repeated measurements are necessary to guide the adequate therapy.

The key importance of a sedation target

Patient comfort is a primary goal in the intensive care unit (ICU), and includes adequate pain control, anxiolysis, and prevention and treatment of delirium. The appropriate target level of sedation primarily depends on a patient's acute disease process, and on the therapeutic and supportive interventions required. After the first days of ICU stay, characterized by clinical stabilization and invasive procedures, the sedation target is a calm patient, awake during the day and asleep at night. The use of deep levels of sedation to facilitate mechanical ventilation or painful procedures should be minimized with ventilation setting optimization and adequate analgesia, rather than deepening unconsciousness [1,2].

Achieving and maintaining the appropriate balance of sedation and analgesia is frequently challenging. Without rational and agreed upon 'target levels' of sedation, it is probable that different members of the health care team will have disparate treatment goals, increasing the chance for iatrogenic complications and potentially delaying recovery [3].

The target level of sedation should be discussed and defined at the beginning of each staff shift, and re-evaluated regularly as the clinical condition of the patient changes. The pharmacological treatment should be written with the appropriate flexibility to allow titration to the desired endpoint, anticipating fluctuations in sedation requirements throughout the day. Frequent monitoring with validated tools improves communication among clinicians and plays an important role in detecting and treating pain, agitation, and delirium, while avoiding excessive or prolonged sedation [4].

An ongoing change in perspective

Recognition that heavy sedation may increase mortality and morbidity has led to a new model in which the emphasis is on maximizing the comfort of the patients, while they remain awake, interactive, and orientated. This new model relies on strategies, such as daily interruptions of sedation, analgesia-based sedation, enteral sedation, avoidance of paralytic agents, early physiotherapy, and use of validated tools for sedation assessment [5].

Sedation assessment with objective methods

Several objective methods for sedation assessment in critically-ill patients have been proposed, but none have yielded satisfying results. Most of them are currently still under evaluation.

Electroencephalograhy, electromyography, and auditory-evoked potential

The continuum from wakefulness to sleep involves a progressive decrease in alpha bands and an increase in beta, theta, and delta bands. Electroencephalogram (EEG) interpretation requires recognition of patterns and is made more difficult by different drug interferences.

Bispectral index (BIS) monitor is a four-channel EEG monitor, which generates a single number that correlates with depth of consciousness. It has been developed for degree of hypnosis monitoring during general anaesthesia. Correlation between BIS and validated ICU sedation scales is poor because of great BIS value variability and the electromyography (EMG) interference [6].

Based on the analysis of EEG signal irregularity, the entropy monitor (GE Healthcare, Fairfield, CT, USA) also utilizes the EMG signal, which may provide information useful for assessing whether a patient is responding to an external, painful stimulus. The prediction probability values of this monitor in differentiating between consciousness and unconsciousness are comparable with those for BIS, without adding useful information to sedation assessment.

Auditory-evoked potentials (AEP) are electrophysiological responses of the nervous system to standard sensory stimulation evoked by using headphones. An EEG pattern is recorded after each stimulus. These three methods may have a role in monitoring sedation levels only in patients needing deep sedation, or receiving neuromuscular blocking drugs, as in this circumstance sedation scales cannot be used [6].

Plasmatic drug concentration

Monitoring blood drug values is useful when a correlation between plasmatic concentration and pharmacological effect at the site of action has been well established [7]. However, critically-ill patients may be affected by renal and hepatic dysfunctions that impair their ability to metabolize and excrete drugs. Hypoxia, inflammatory mediators and abnormal diets are common in critically-ill patients, and all affect enzymatic function. Finally, ICU patients may present multi-organ dysfunctions that alter their response to drugs. In conclusion, this method cannot be recommended for sedation monitoring.

Lower oesophageal contractility and frontalis muscle electromyogram

Spontaneous, non-propulsive lower-oesophageal contractility (LOC) is definitely stress related and increases in frequency as the dose of anaesthetic is reduced. Deepening of anaesthesia resulted in progressive suppression of LOC. However, LOC has great inter-variability and is affected by drugs such as atropine. The electromyogram responsiveness is not sufficiently sensitive to monitor sedation in ICU patients [7].

Actigraphy

Actigraphy provides a continuous measure of bodily movements and was initially developed to measure sleep–wake cycles. This small electronic device containing an accelerometer continuously senses and records minimal movements, summarizing such data in numerical form.

Wrist actigraphy provides useful non-specific observations in ICU patients; even if it does not discriminate the lack (or the excess) of analgesics and sedatives from other acute neurological dysfunctions, preliminary observations suggest that the measurement of bodily movements could provide a timely indication of acute changes in neurological status, generating motor agitation or hypoactive behaviour, and it could prevent the insufficient or excessive use of sedatives [8].

This objective method is relatively new in this context. It presents interesting properties, worthy of future investigation [9].

Sedation assessment with subjective methods

Individual assessments of sedation, performed at the bedside by nurses or physicians, can be hampered by a lack of objectivity. Guidelines recommend establishing a sedation target and regularly redefining it for each patient, using a validated sedation assessment scale, with documentation of regular assessment and response.

Sedation scales: useful guides in consciously-sedated patients

Sedation scales are used to assess the depth of sedation, awareness, agitation, and response to stimuli. Use of such a scale is a key component of sedation algorithms [10]. It must be used to manage agitation and to establish a target level of sedation for medication titration, in order to promptly detect oversedation when the target level is exceeded. All sedation algorithms recommend to use a sedation scale, with Ramsay Sedation Scale (RSS), Richmond Agitation-Sedation Scale (RASS), and Riker Sedation Agitation Scale (SAS) being the most common [11].

Old and unvalidated sedation scales

The use of a scale to assess level of consciousness dates to the introduction of a 6-point scale by Ramsay et al. (RSS) almost 40 years ago [12]. Nowadays, it continues to be a widely-used scale for monitoring sedation in daily practice. This instrument identifies situations of agitation or sleep visually. Some experts consider that it is more a scale of consciousness than a tool for the measurement of sedation. RSS has been extensively tested, but it has never been validated. Moreover, it does not grade agitation. Consequently, this scale is excessively subjective and has poor validity.

Many other scales have been proposed [13], some of them are not validated. They are not recommended for clinical use.

The validated bedside sedation scales

The ideal scoring system should be easy, reliable, sensitive, and with minimal inter-observer variability. Moreover, it should give no or minimal additional discomfort to the patient. Even though a complex scoring system is not suitable for the ICU, oversimplification risks neglecting important information. Most of the proposed tools are a compromise between accuracy and time required for evaluation of sedation [14].

Recently, developed scales often combine the sedation/arousal domain with an assessment of agitation, like the SAS, the RASS, the Motor Activity Assessment Scale, the Observers' Assessment of Alertness and Sedation, the Nursing Instrument for the Communication of Sedation [15], and the Bloomsbury Sedation Score (Fig. 358.1).

Unlike other validated instruments, the RASS separates verbal from physical stimulation so that the patient's level of arousal may be graded according to the potency of the stimulus. Interestingly, RASS is valid for assessing patient's sedation over time, which has not been studied previously for other sedation scales. Moreover, RASS was validated both in spontaneously breathing/mechanically-ventilated, and in sedated/not-sedated critically-ill patients.

The multi-item sedation scales

The Adaptation to the Intensive Care Environment (ATICE) scale consists of five items—awareness and comprehension combined in a conscious domain, calmness, ventilator synchrony, and facial relaxation are combined in a tolerance domain. As for ATICE, the Minnesota Sedation Assessment Tool evaluates the level of consciousness of patients receiving invasive mechanical ventilation. It measures arousability, spontaneous muscle activity and global sedation quality. The Vancouver Interaction and Calmness Scale consists of two five-item subscales quantifying separately calmness and interaction with operators.

These more complex scoring systems are usually adopted in clinical trials to evaluate a new drug or a new objective tool for sedation assessment, whereas in daily practice easily applied scores are usually preferred.

Choosing and implementing an evaluation scale

Desirable features of a good sedation instrument for use in the ICU include:

- Rigorous multidisciplinary development.
- Ease of administration, recall and interpretation.
- Well-designed discrete criteria for each level.
- Sufficient sedation levels for effective drug titration.
- Assessment of agitation.
- Demonstration of inter-rater reliability and validity in relevant patient populations [3].

Each ICU has to choose the best tools for its patient population, and to plan specific intervention to introduce it in daily care [16].

Teaching protocols used for implementation of sedation scales have shown good results among ICU caregivers. Different methods have been used to implement evaluation tools in clinical practice. Typically, they are based on introductory in-service training for nurses and operators followed by graded, staged educational interventions at regular intervals.

Web-based, freely-available teaching interventions have been recently proposed (www.icudelirium.org, www.sedaicu.it).

Emerging problems and suggested solutions

Fluctuation of consciousness

ICU patients are prone to sudden changes in their state of consciousness due to the effects of drugs, sleep disruption, organic, and metabolic disease or delirium. Assessment of sedation once a shift is indispensable, but not sufficient. Among the different possibilities (minimal/maximal level, prevalent level, worst level), it is important to state the duration of each value within the observed shift. Sedation and agitation need to be reassessed both on a regular basis and during any clinical modification, to promptly capture all the modifications requiring intervention.

Sedation and agitation without patient awakening

It is relatively common for patients to manifest sudden aggressive behaviour when recovering from sedation and without fully awakening. For this reason, together with the effort in joining and maintaining an adequate level of conscious sedation, it is important to boost interdisciplinary communication between nurses and physicians, in order to be aware of and prevent these problems.

Differentiating sedation, coma, and physiological sleep

Making a sedation assessment during the night is frequently challenging. Most analgesics and sedatives are known to make patients sleepy, but without reaching a restorative, physiological sleep [17]. If a critically-ill patient appears calm and keeps his/her eyes closed during the night, he/she should not be stimulated just to make a sedation assessment. He/she could be observed during unavoidable procedures happening in the ICU during the night, in order to discriminate normal sleep (with arousals due to noise and light) from sedation or coma.

CHAPTER 359

Management of sedation in the critically ill

Bhakti K. Patel and John P. Kress

Key points

- Once adequate analgesia is confirmed, the need for sedation should be considered.
- Metabolism of sedatives in critical illness can be unpredictable and achieving optimal sedation without coma is a moving target.
- Choice of sedative can have clinical implications, including incidence of delirium, duration of mechanical ventilation, and intensive care unit length of stay.
- Sedative requirements vary over time and among patients necessitating regular assessment of depth of sedation and goal-directed titration.
- A sedation strategy should be employed to achieve the least amount of sedation for patient comfort that allows interaction with care providers.

Introduction

Achieving adequate sedation in the intensive care unit (ICU) strikes a balance between comfort and tolerance of the ICU setting without excessive and prolonged sedation. Patients undergoing mechanical ventilation experience pain and discomfort from their underlying medical condition(s) and the necessary procedures and nursing care required for their recovery. Once adequate pain control is assured, some patients may not require sedation at all [1]. Non-pharmacological interventions, such as verbal reassurance or repositioning may help comfort the agitated or restless patient, although these efforts alone may be inadequate or impractical, and the need for sedation paired with analgesia becomes the rule.

Sedation should be titrated to reproducible clinical goals to avoid the risk of excessive sedation as these highly potent medications often have unpredictable pharmacology in the setting of critical illness resulting in drug accumulation, drug–drug interactions and prolonged drug effect. The risks of prolonged and excessive sedation include increased duration of mechanical ventilation, ICU length of stay [2], ventilator associated pneumonia [3], and ICU-acquired weakness [4]. Therefore, titration of sedatives with either protocol driven assessment of sedative needs or daily interruption of sedatives is warranted to achieve patient comfort and avoid the complications of excessive and prolonged sedation. A 2013 consensus guideline paper on pain, agitation, and delirium has been published [5].

Sedation medications

Sedation requirements vary among patients and also with time for an individual patient. The variability of sedative pharmacology is explained in part by accumulation of sedatives in tissue stores, perturbation of metabolism of sedatives with hepatic and renal dysfunction that occurs with critical illness, and drug–drug interactions. The ideal sedative has rapid onset and offset of action, minimal accumulation in tissue stores, and less adverse effects such as delirium. Therefore, when choosing a sedative these ideal properties and the patient characteristics that affect drug metabolism (i.e. hepatic/renal dysfunction) should be considered.

Benzodiazepines

Benzodiazepines (e.g. lorazepam, midazolam, and diazepam) have potent anxiolytic, sedative, and hypnotic effects depending on the degree of binding to the γ-aminobutyric acid (GABA) receptor. Midazolam is slightly more lipophilic than lorazepam and as such crosses the blood–brain barrier more quickly. However, this rapid, but prolonged benzodiazepine effect is explained by its lipophilicity allowing accumulation in adipose tissue preventing metabolism. Furthermore, liver dysfunction that disrupts the CYP450 metabolism of benzodiazepines and renal dysfunction that contributes to the accumulation of the active metabolites of midazolam explains the prolonged sedative effect of benzodiazepines, and midazolam in particular [6].

Benzodiazepines have adverse effects including suppression of respiratory drive by shifting the CO_2 response curve to the right and rarely cause paradoxical agitation in the elderly. There also has been an emerging literature, which suggests that the prolonged sedative effects of benzodiazepines are an independent risk factor for delirium with an apparent dose related effect [7]. Given the considerable morbidity and mortality associated with this increased risk of ICU delirium, the effect of sedative choice on mortality and clinical outcomes of septic patients has also been studied. A subgroup analysis of septic patients randomized to lorazepam versus dexmedetomidine, found an increased risk of delirium, less ventilator free days and increased mortality in patients receiving lorazepam [8]. Although benzodiazepines have been first-line agents for sedation, randomized controlled trials comparing them with newer agents, such as propofol or dexmedetomidine clearly show that benzodiazepines lead to worse outcomes, including delirium, oversedation, delayed extubation, and longer time to discharge [9,10].

Propofol

Propofol is another sedative that modulates neurotransmitter release including GABA, but the exact mechanism is not well understood. Propofol has sedative, hypnotic, and amnestic effects. In contrast to benzodiazepines, however, propofol's pharmacokinetics favour rapid onset and offset allowing rapid awakening after discontinuation [6]. Thus, propofol's favourable pharmacological profile in one Canadian study of 69 mechanically-ventilated patients was shown to shorten duration of mechanical ventilation in comparison to midazolam [11]. Propofol's effect on reduced duration of mechanical ventilation persisted even in comparison to intermittent dosing of lorazepam [12], which suggests favourable pharmacodynamics of propofol over benzodiazepines independent of dosing strategy. Other similar studies have consistently demonstrated the superiority of propofol over benzodiazepines in terms of shorter time to mental status recovery, liberation from the ventilator, and cost-effectiveness [13].

Propofol is hydrophobic with delivery in a lipid emulsion and thus should be counted as a caloric source providing 1.1 kcal/mL of nutrition with regular monitoring for hypertriglyceridaemia. Propofol can induce hypotension by decreasing vascular tone especially in hypovolaemic patients. Rarely propofol infusion syndrome characterized by bradycardia, heart failure, rhabdomyolysis, hyperkalaemia, and metabolic acidosis has been described at high and prolonged infusion rates. There remains considerable debate on the appropriate dosing to avoid this rare complication, but most recommend maintaining dosages less than 4–5 mg/kg/hour.

Dexmedetomidine

Dexmedetomidine is a central α2 agonist that inhibits norepinephrine release. It has sedative and analgesic effect without causing respiratory depression, making it a potentially ideal drug for ICU sedation. Riker and colleagues demonstrated that although dexmedetomidine and midazolam achieved similar levels of sedation, dexmedetomidine sedation was associated with less ICU delirium and on average almost 2 more days free of mechanical ventilation [9]. In a recent study combining the results from two randomized controlled trials comparing dexmedetomidine to midazolam and propofol, respectively, Jakob and colleagues found non-inferiority of this sedative in achieving light to moderate sedation. Dexmedetomidine appeared to reduce the median duration of mechanical ventilation in comparison to midazolam, but not propofol. The main advantage demonstrated was improved communication between patient and nursing staff [10]. Other similar studies suggest that dexmedetomidine further decreased the need for additional opiates and sedatives, thus decreasing the time in comatose state, days of mechanical ventilation, length of ICU stay, and days with delirium. The main side effect of this sedative is bradycardia and hypotension most prominent during initial bolus dosing. Dexmedetomidine is an attractive sedative that allows the patient to remain awake, calm, and interactive without the associated complications of sedation. For occasional patients with very high levels of agitation, it may not be adequate as a sole agent.

Sedation strategies

Active titration of sedatives to match the dynamic and individualized needs of patients requires use of a standard assessment tool to measure the depth of and ongoing need for sedation over time. Such sedation assessment tools should ideally be simple, easy to use and remember, have discriminatory criteria for each level to aid in titration of sedatives, inter-user reliability, and validity across patient populations. Many sedation scales are available with varied strengths/limitations. Two of the more commonly utilized scales are the Ramsey and Richmond Agitation Sedation scale. Once the appropriate sedative is chosen, a validated sedation scale and strategy should be used to titrate these medications to achieve an awake, calm, and interactive patient able to undergo cognitive and neuromuscular evaluation. This shift in sedation goals to light (Ramsey score 1–2) over deep sedation (Ramsey score 3–4) is well tolerated and results in less ventilator days and shorter ICU length of stay [14]. There are a variety of sedation strategies to achieve these goals.

Daily interruption of sedatives

Daily interruption of sedatives is a strategy that seeks to achieve awakening as early as possible. Both sedatives and analgesia medications are discontinued until the patient demonstrates awakening or exhibits distress (agitation, ventilator asynchrony, hypertension, or tachycardia), which mandates resumed drug administration at half of the previous dose. This strategy was originally studied in a randomized controlled trial of 128 patients on mechanical ventilation, which demonstrated that daily interruption of sedation decreased the number of days on mechanical ventilation, allowed assessment of neurological status, and decreased the need for diagnostic neurologic testing [15]. A more recent trial comparing a nursing sedation algorithm in conjunction with daily interruption of sedatives to a nursing algorithm alone found no differences in ventilator days or length of stay. This trial used benzodiazepines and opiates at relatively high doses compared with other trials, which may have offset the effects of sedative interruption [16].

Patient-targeted sedation protocols

Patient-targeted sedation protocols provide a structured assessment of pain and sedation needs coupled with an algorithm that directs titration of these medications. Brook and colleagues compared a bedside nursing protocol designed for early detection of pain, preferential use of intermittent dosing of medications with reservation of continuous infusions for patients with inadequate response to intermittent therapy, and early de-escalation of continuous infusions to intermittent therapy. This strategy demonstrated shorter duration of mechanical ventilation, length of ICU and hospital stay, and need for tracheostomy in comparison to usual care [17].

Similarly, DeJonghe and colleagues used a comprehensive patient assessment tool, Adaption to the Intensive Care Unit Environment (ATICE), to guide sedative and analgesia infusions to optimize patient tolerance of the ICU environment. This sedation assessment tool incorporated tolerance of the ICU environment as demonstrated by ventilator synchrony, calmness, and facial relaxation in addition to standard assessment of consciousness [18]. Similar to other sedation tools it demonstrated high internal consistency across disciplines and validity. Alterations in patient tolerance prompted adjustment of ventilator settings and administration of opiates or sedatives, depending on the specific derangement in ICU tolerance. Once tolerance was demonstrated, the level of consciousness was addressed with titration of sedatives and opiates to achieve

an awake and interactive patient. Use of this algorithm in 102 patients without acute brain injury demonstrated shorter duration of mechanical ventilation and time to arousal [19]. Incorporation of ventilator synchrony as part of tolerance of the ICU environment highlights the importance of adjusting ventilator settings to improve patient–ventilator interaction prior to increasing sedatives.

No sedation

Given the growing evidence suggesting the benefits in decreasing the depth and duration of sedation, a no sedation strategy was recently studied. Strom and colleagues randomized 140 patients to no sedation (intermittent morphine with propofol rescue if agitation persisted) versus the control group who received usual care sedation (propofol for 48 hours followed by midazolam with intermittent morphine, using a daily interruption protocol). The results were interpreted with intention to treat analysis and demonstrated an increase in ventilator free days and decrease in hospital and ICU length of stay [1]. This strategy of no sedation was well tolerated as long-term follow-up of these patients suggested no increased incidence of post-traumatic stress disorder in comparison to daily interruption of sedation [20].

Conclusion

Achieving optimal sedation in mechanically-ventilated patients is difficult given the unpredictable metabolism of sedatives, and dynamic and variable sedative needs for individual patients. Choice of sedative and depth of sedation has implications for duration of mechanical ventilation and its associated complications. A strategy that employs goal-directed sedation favouring an awake and interactive patient with aggressive titration of medications has been associated with improved ICU outcomes.

SECTION 19

General surgical and obstetric intensive care

PART 19.1

Optimization strategies for the high-risk surgical patient

CHAPTER 360

Identification of the high-risk surgical patient

Rupert Pearse and Stephen James

Key points

- High-risk patients account for over 80% of peri-operative deaths.
- Age, co-morbid disease, limited functional capacity, and an emergency presentation for major surgery are hallmarks risk.
- The magnitude, duration, and consequences of post-operative morbidity are determined by a complex interplay between the indication for surgery, the resulting tissue injury, and patient factors.
- A number of methods including risk scoring and cardiopulmonary exercise testing can be used to identify the high-risk group.
- Efforts should be made throughout the peri-operative period to prevent the occurrence of any post-operative complications, as they all carry significant long-term implications.

The high-risk surgical population

Over 230 million patients undergo major surgery each year with mortality varying from 1% to 4% [1,2]. The low overall post-operative mortality conceals the sub-group of high-risk patients who account for over 80% of post-operative deaths [3,4]. In the UK, over 170,000 high-risk non-cardiac surgical procedures are performed each year, following which 100,000 patients develop complications resulting in over 25,000 deaths before hospital discharge [3–5]. Clinicians often fail to both identify patients at high risk of complications and allocate them to an appropriate level of peri-operative care, in particular intensive care [3,4]. Importantly, patients who develop complications but survive, will still suffer a substantial reduction in functional independence and long-term survival [6–8]. In a recent large North American study, mortality in an unselected population of surgical patients doubled from 2.0 to 4.3% between 30 and 365 days after surgery [8]. By one year, 47% of surviving patients had been readmitted to hospital.

As understanding of the impact of poor surgical outcomes has improved, it has become clear that a robust approach to pre-operative assessment of surgical risk is essential.

The high-risk surgical patient

Age, co-morbid disease, limited functional capacity, and emergency presentation are the hallmarks of the high-risk surgical patient. For example, an 80-year-old patient undergoing emergency gastrointestinal surgery would have a mortality risk of up to 50% and a complication rate close to 100%. While adverse events due to failures in surgical or anaesthetic technique receive much attention, they are comparatively infrequent. However, most patients develop some degree of post-operative morbidity as a result of physiological, endocrine, and inflammatory changes associated with the tissue injury of surgery. The magnitude, duration, and consequences of post-operative morbidity are determined by a complex interplay between the indication for surgery, the resulting tissue injury, and patient factors, such as cardiopulmonary reserve and active co-morbid disease. In some patients, the burden of post-operative morbidity will result in a recognized diagnosis, such as pneumonia or myocardial infarction, but many will also experience non-specific injury to one or more organ system such as the heart, kidneys, or brain that are only detected through increased observation and serial measurements, e.g. serum creatinine. This subclinical injury may be not be severe enough to satisfy accepted definitions of a complication or to require treatment in a critical care unit, but is associated with reduced long-term survival.

Much understanding of peri-operative complications revolves around the considerable changes in oxygen consumption that occur in this period. Although effective anaesthesia and invasive ventilation may decrease oxygen consumption, pathological abnormalities, including shivering, pain, and agitation can result in a significant imbalance between delivery and consumption, commonly seen in the first few hours after major surgery and often indicated by low central venous oxygen saturation. It has been suggested that poor global oxygen delivery is associated with reduced tissue perfusion and oxygenation, and hence post-operative complications. There is some evidence to suggest regional oxygen imbalance is associated with complications such as surgical wound infection. Increases in heart rate and arterial pressure, when coupled with systemic inflammation and the procoagulant state, may also result in myocardial injury in patients with pre-existing coronary artery disease. A large proportion of these events are silent in nature, masked by wound pain, analgesia, and residual anaesthesia, although their prognostic impact is still great.

Reasons to identify the high-risk surgical patient

Clear assessment of peri-operative risk is an important component of informed consent and may alter the surgeon's recommendation

to undergo surgery. The use of natural frequencies and a clear expression of the reference class, e.g. 'seven in one hundred patients like you' improves comprehension and the key elements of a discussion should be clearly documented. Unfortunately, a lack of information on what a patient wants to know concerning risk before consenting to surgery, tends to present the information that is most readily available. Quality of life data from observational studies can be used to describe outcomes of importance to most patients. We should avoid jargon or unclear terms.

Risk stratification can be used to determine the level of monitoring and peri-operative care required. Although risk stratification is widely believed to improve outcome there are no large prospective studies that can support this claim. It is also becoming clear the presence of a complication within 30 days of surgery is more important than any pre- or intra-operative risk factor in determining short- and long-term survival [7]. This supports the need for post-operative risk identification to detect and treat the earliest signs of problems. Outcome measures are therefore increasingly being used to underpin quality improvement frameworks. The focus on reducing the incidence of post-operative complications is predicated on the assumption this will lead to global improvements in quality and patient experience.

Risk assessment based on clinical criteria

The majority of patients are evaluated according to a clinician's subjective assessment of clinical history, physiology, and the extent of surgery. This tries to predict the interplay between the tissue injury-induced inflammatory response and the patient's pre-existing disease state. The most important comorbid diseases are heart failure, renal impairment, diabetes, liver cirrhosis, and malignancy.

The kidneys are affected by the interplay of haemodynamic, toxic, and inflammatory changes of the peri-operative course and can be seen as a marker for the global insult of surgery. Acute kidney injury (AKI) occurs in nearly 1% of patients with no pre-existing renal disease and is now well classified [9]. AKI is associated with increased long-term mortality in a variety of settings even if complete resolution occurs. Pre-existing renal disease risk factors alongside the nature of surgery (emergency, intra-peritoneal, or involving profound haemodynamic changes) are associated with a higher incidence of AKI.

Venous thromboembolism is responsible for a significant proportion of post-operative morbidity and the typical high-risk patient will have a number of important risk factors. Advanced age, malignancy, chemotherapy, immobility, and major surgery all contribute to endothelial damage, blood stasis and hypercoagulability, the key aetiological triad.

Other complications, such as respiratory failure or pneumonia, may be associated with a recognizable pattern of obesity, chronic obstructive pulmonary disease (COPD), compromised intra-operative lung mechanics and poorly-controlled pain. Similarly, malnutrition, diabetes, and obesity are associated with higher levels of wound infection. Procedures associated with the highest incidence of morbidity include all vascular or dual cavity procedures, gastrointestinal or extensive liver resection, joint replacement, and complex cardiothoracic surgery.

Beyond this familiar approach to risk assessment the need to perform a surgical procedure as an emergency is a very important factor in predicting risk (Table 360.1) [5]. This relates to the more serious nature of acute pathology, the lack of opportunity to optimize medical management of co-morbid illnesses and the presence of hypovolaemia, which may be severe. In addition, the dependence on junior medical staff often working outside office hours with minimal supervision and delays in access to an operating theatre may further hamper efforts to deliver optimal care.

Table 360.1 Impact of urgency on high-risk patients from a national prospective audit

Risk	30-day mortality
Immediate (within 1 hour)	1 in 4
Urgent (within 4 hours)	1 in 8
Expedited (within 48 hours)	1 in 16
Elective (not seen in pre-admission clinic)	1 in 20
Elective (seen in pre-admission clinic)	1 in 140

Data from Findlay G et al., Knowing the risk; a review of the peri-operative care of surgical patients, London: National Confidential Enquiry into Patient Outcome and Death, 2011. Available at: http://www.ncepod.org.uk/2011report2/downloads/POC_fullreport.pdf

Risk evaluation and corresponding strategies

Shortcomings in the identification of high-risk patients have led to investment in improvement options. One simple approach is to place those at highest risk of mortality in a pathway with the most monitoring and care. A mortality >10% could lead to an automatic intensive care referral with high dependency care being used for procedures with a mortality of 5–10%. Such an approach would include the vast majority of patients likely to sustain significant complications.

A number of risk stratification systems exist. The American Society of Anesthesiologists Physical Status (ASA-PS) score is based on subjective assessment of systemic disease, and is the most simple and commonly used tool. More complex alternatives use physiological and surgical variables to estimate predicted mortality and include the Charlson Age Co-morbidity Index, the Physiologic and Operative Severity Score for the Enumeration of Mortality and Morbidity (POSSUM) scoring system for general surgery or the EuroSCORE for cardiac surgery [10–12]. These scores can then be used to set thresholds for admission to critical care, although, in some cases, elements of the operative component will need to be estimated in advance.

An appreciation of the central role of cardiac function in the development of complications after non-cardiac surgery led to the Lee Revised Cardiac Risk Index [13]. Like all pre-operative scoring systems, they are modelled on short-term (30-day or in-hospital) event rates and there is no evidence to suggest they accurately forecast medium- or long-term outcomes. Most risk scoring systems work well for audit against expected outcome rates, but are less accurate in stratifying an individual patient's peri-operative risk.

The World Health Organization (WHO) surgical safety checklist was introduced in 2008 to reduce the most common and avoidable risks that could endanger a patient's life. Before induction of anaesthesia, before surgery, and at the end of the operation an identified

member of the team completes a number of checks in the presence of the surgical team. This ensures the team is familiar with each other and has discussed the anticipated course of events, including any expected major blood loss or anticipated critical events, and the need for antibiotic prophylaxis or imaging.

Patient-reported exercise capacity

Exercise capacity is perhaps the best predictor of longevity in the non-surgical setting and American College of Cardiology/American Heart Association (ACA/AHA) guidelines propose a pre-operative assessment of the activities of daily living as a means to evaluate this. However, subjective assessments of exercise capacity have not been shown to closely correlate to objective measures and have poor predictive accuracy for post-operative cardiac events or death. The Duke Activity Status Index and the Veterans Specific Activity Questionnaire are tools that provide a more reliable prediction of exercise capacity, but are still weak predictors of post-operative complications [14]. Therefore, these methods cannot be used as comprehensive guides to the identification or management of the high-risk surgical patient.

Exercise capacity measurement

Cardiopulmonary exercise testing (CPET) involving a cycle ergometer with simultaneous spirometry, electrocardiography, pulse oximetry, and blood pressure measurement is the standard technique for objective assessment. CPET provides a safe global assessment of the cardiovascular, respiratory, neuropsychological, and skeletal muscle systems, and has an established role in the assessment of heart failure and respiratory limitation. It can be used pre-operatively, even in the majority of patients awaiting joint replacement, and accurately detects myocardial ischemia, anaerobic threshold (ATh) and peak oxygen consumption (VO_2 peak). These three factors are predictive of post-operative complications and death in a number of different surgical settings, although large blinded studies of the predictive accuracy of this test have not been performed [15–17]. In practice, an ATh of <11 mL/min/kg or a VO_2 peak <15 mL/min/kg may be considered an indicator of high-risk, while an AT of <8 mL/min/kg or VO_2 peak <12 mL/min/kg indicates a very high risk from surgery. In either case, enhanced peri-operative care is essential.

Screening for high-risk surgical patients using plasma biomarkers

An interesting emerging technology is the use of pre-operative plasma biomarkers together with clinical data to allow a basic assessment of peri-operative risk category (low, intermediate, or high). This information could guide the use of more detailed clinical evaluation and diagnostic tests. Promising candidates include B-type natriuretic peptide (BNP or NT-proBNP), glomerular filtration rate estimated from serum creatinine (eGFR), C-reactive protein, and cardiac troponins. These biomarkers reflect levels of pre-existing organ dysfunction or pro-inflammatory states, which predispose to complications. A systematic review confirms the potential of NT-proBNP to predict short and medium term post-operative outcomes [18]. Clinical implementation is currently limited.

Box 360.1 End of surgery care bundle

- Use care bundle if POSSUM score likely to predict a mortality ≥5% OR if the patient has deteriorated during surgery.
- Risk score the patient using POSSUM.
- Check arterial blood gases to assess lactate, acid-base status, and the ratio of arterial oxygen concentration to the fraction of inspired oxygen (P:F ratio).
- Summarize fluids given and draft ongoing fluid requirements.
- Use a nerve stimulator and reverse muscle relaxant.
- Check and document temperature, plan further correction as necessary.
- Surgeon and anaesthetist to decide preferred level of care jointly and discuss any further therapeutic options.
- Recommend that all patients with a mortality risk ≥10% to go to level 2 or 3 care.
- Consider level 2 or 3 if the risk is 5–10% or there are other concerns.

Data from Anderson I et al., *The Higher Risk General Surgical Patient—Towards Improved Care for a Forgotten Group*, London: Royal College of Surgeons of England, 2011.

Post-operative assessment of risk

Late or unplanned admission to critical care carries with it a much higher mortality than planned admission [4]. Therefore, towards the end of higher risk surgery, much of which is emergent, time can be taken to re-evaluate the patient. One option is to use the surgical Apgar score [19]. This takes into account the estimated blood loss, lowest mean arterial pressure, and lowest heart rate to produce a ten point score for the prediction of 30-day complications and mortality. Another option is to employ an end of surgery care bundle (Box 360.1) [20]. Regular senior clinical input, active monitoring to detect the early signs of complications and the adherence to an enhanced recovery program are measures that can be used later in the post-operative course.

CHAPTER 361

Peri-operative optimization of the high risk surgical patient

Monty Mythen and Michael P. W. Grocott

Key points

- Flow-based cardiovascular variables, such as cardiac output and oxygen delivery predict perioperative outcome better than alternative, predominantly pressure-based, measures (e.g. heart rate, blood pressure, central venous pressure).
- Targeting flow-based goals, using fluid boluses with or without additional blood or vasoactive agents, in patients undergoing major surgery has been shown to improve outcome in some studies.
- Early studies used pulmonary artery catheters to monitor blood flow, but newer studies have used less invasive techniques such as oesophageal Doppler monitoring and pulse contour analysis.
- Meta-analysis of the current evidence suggests that this approach is unlikely to cause harm, may not reduce mortality, but does reduce complications and duration of hospital stay.
- Large multi-centre clinical trials are underway.

Introduction

The terms 'peri-operative optimization' and 'goal-directed therapy' (GDT) are commonly used to describe a bundle of care where additional therapy is given with the aim of increasing global blood flow to predefined explicit goals. The origins of this approach are usually ascribed to William Shoemaker, a Surgeon from the USA. Shoemaker et al. observed that survivors of high-risk major surgery had significantly higher cardiac index, oxygen delivery (DO_2) and oxygen consumption (VO_2) measured with a pulmonary artery catheter (PAC), compared with non-survivors. While the oxygen flux measures discriminated between survivors and non-survivors, the commonly measured haemodynamic variables (heart rate (HR), blood pressure (BP), urine output (UO), and central venous pressure (CVP), etc.) did not.

In a follow-up randomized controlled trial (RCT), the same group demonstrated a dramatic (some would say incredible) reduction in mortality (33% to 4%) when the interventional group was given additional fluid and, if required, an intravenous dobutamine infusion, with the aim of achieving specific goals for cardiac index (2.5 L/min/m^2), DO_2i (600 mL/min/m^2) and VO_2i (170 mL/min/m^2) guided by PAC [1]. There followed a series of single-centre trials that tested a similar approach and obtained similar results, notably from Boyd et al. and Wilson et al. [2,3].

In the 1990s, relatively non-invasive cardiac output monitoring became more readily available and reliable. In particular, the oesophageal Doppler monitor (ODM) developed by Singer and Bennett opened the way for testing a similar approach in a lower risk group of patients [4]. Mythen and Webb tested optimization of cardiac stroke volume measured with the ODM by the administration of additional colloid boluses compared with standard of care, and found improved indices of tissue perfusion and better clinical outcomes (reduced complications and length of hospital stay) in a small study of patients undergoing cardiac surgery [5]. There followed a number of single-centre RCTs using the ODM to guide administration of fluid boluses to achieve 'optimal' stroke volume, commonly without additional vaso-active drugs, with broadly similar results in terms of morbidity and length of hospital stay [6–8]. More recently, alternative cardiac output measurement devices have been tested with similar results [9].

Possible mechanisms and face validity

The beneficial effects are thought to result from avoiding hypovolaemia, tissue hypoperfusion, and tissue hypoxia with consequent minimization of inflammatory pathway activation. Predictors of poor outcome following major surgery include age, co-morbidities, poor functional capacity (low VO_2 at anaerobic threshold), the magnitude of tissue trauma, and surrogates of tissue hypoperfusion and hypoxia, such as lactic acidosis and low venous oxygen saturations. Studies using gastric tonometry to measure gut mucosal perfusion demonstrated occult splanchnic perfusion in patients undergoing elective major surgery that was not detectable with routine haemodynamic variables (e.g. HR, BP, UO), but was associated with reduced cardiac stroke volume suggesting central hypovolaemia. The same patients also demonstrated increased systemic inflammation. Pro-actively treating patients with a goal-directed approach that includes fluid boluses to avoid central hypovolaemia and results in a relative increase in oxygen flux should improve indices of end-organ perfusion, avoid complications and improve outcome. This is a central tenet of this approach, but the physiological goals used are diverse (e.g. specific DO_2 value versus maximum stroke volume versus oxygen extraction ratio or mixed venous oxygen saturation). Thus, the literature is difficult to interpret.

What does the evidence show?

A recently published Cochrane systematic review and meta-analysis summarized the clinical effects of increasing perioperative blood

flow using fluids with or without inotropes/vasoactive drugs to explicit defined goals in adults [10]. The authors included randomized controlled trials of adult patients (aged 16 years or older) undergoing surgery. The review included 31 studies of 5292 participants (Table 361.1). There was no difference in mortality at the longest follow-up: 282/2615 (10.8%) died in the control group and 238/2677 (8.9%) in the treatment group, RR of 0.89 (95% CI: 0.76–1.05; p = 0.18). However, the intervention did reduce the rate of three morbidities (renal failure, respiratory failure, and wound infections). The number of patients with complications was also reduced by the intervention. The authors also concluded that it was unlikely that the intervention causes harm [10] and that although the balance of current evidence does not support widespread implementation of this approach to reduce mortality, it does suggest that complications and duration of hospital stay are reduced [10].

The practice of GDT

Ideally, GDT using advanced haemodynamic monitoring should be used for all patients undergoing major surgery, but this is not practical or affordable. Thus, a risk-adapted approach is commonly recommended (see Box 361.1). The level of monitoring and intensity and duration of care should be tuned to the risk of the patient in the context of the risk of the surgery. At the highest level, a full raft of haemodynamic and other monitors are utilized including cardiac output measurement, care is delivered by a team of the most experienced clinicians and is continued into the post-operative period in a higher dependency unit. Treatment algorithms vary, but a common component is administration of additional fluid boluses to treat objective evidence of central volume deficit (e.g. reduced stroke volume measure or stroke volume variation during controlled ventilation). The addition of a vasoactive agent (e.g. dopexamine) to achieve a predetermined level of DO_2 is also advocated by some groups.

Indicators of central hypovolaemia include:

- Blood and/or fluid loss.
- Tachycardia.
- Hypotension.
- Cool peripheries.

Table 361.1 Protocol to increase global blood flow compared to control for surgical patients. Summary of findings for the main comparison. Protocol to increase global blood flow compared with control for surgical patients

Patient or population: surgical patients
Settings: hospital
Intervention: protocol to increase global blood flow
Comparison: control

Outcomes	Illustrative comparative risks* (95% CI)		Relative effect (95% CI)	No of participants (studies)	Quality of the evidence (grade)	Comments
	Assumed risk	Corresponding risk				
	Control	Protocol to increase global blood flow				
Mortality (longest follow-up)	11 per 100	10 per 100 (8–11)	RR 0.89 (0.76–1.05)	5292 (31 studies)	⊕⊕⊖⊖ low1,2	p = 0.18
Mortality (hospital or 28-day)	7 per 100	6 per 100 (5–7)	RR 0.81 (0.65–1.00)	5292 (31 studies)	⊕⊕⊖⊖ low1,2	p = 0.06
Number of patients with complications	40 per 100	27 per 100 (23–32)	RR 0.68 (0.58–0.80)	1841 (17 studies)	⊕⊕⊖⊖ low1,2	p < 0.00001
Length of hospital stay		The mean length of hospital stay in the intervention groups was 1.16 lower (1.89–0.43 lower)		4729 (27 studies)	⊕⊕⊖⊖	p = 0.002

*The basis for the **assumed risk** (e.g. the median control group risk across studies) is provided in footnotes. The **corresponding risk** (and its 95% CI) is based on the assumed risk in the comparison group and the **relative effect** of the intervention (and its 95% CI).

GRADE Working Group grades of evidence.

High quality: Further research is very unlikely to change confidence in the estimate of effect.

Moderate quality: Further research is likely to have an important impact on confidence in the estimate of effect and may change the estimate.

Low quality: Further research is very likely to have an important impact on confidence in the estimate of effect and is likely to change the estimate.

Very low quality: We are very uncertain about the estimate.

1. The majority of studies are unblinded due to the nature of the intervention and, hence, it is suggested 'unclear risk for most of the studies'.

2. Most studies had small number of patients.

CI, confidence interval; RR, risk ratio.

Box 361.1 Recommendations for the use of intra-operative fluid management technologies

The Enhanced Recovery Partnership recommends that all anaesthetists caring for patients undergoing intermediate or major surgery should have cardiac output measuring technologies immediately available and be trained to use them.

The use of intra-operative fluid management technologies are recommended from the outset in the following types of cases:

- Major surgery with a 30-day mortality rate of ≫1%.
- Major surgery with and anticipated blood loss of greater than 500 mL.
- Major intra-abdominal surgery.
- Intermediate surgery (30-day mortality ≫0.5%) in high-risk patients (age ≫80 years, history of left ventricular failure, myocardial infarction, cerebrovascular accident, or peripheral arterial disease).
- Unexpected blood loss and/or fluid loss requiring ≫2 L fluid replacement.
- Patients with ongoing evidence of hypovolaemia and or tissue hypoperfusion (e.g. persistent lactic acidosis).

- Low CVP.
- Low cardiac output.
- Reduced stroke volume.
- Systolic or pulse pressure variation (during intermittent positive pressure ventilation (IPPV)).
- Pre-load responsiveness.
- Low central venous O_2 saturation.
- Surrogate measures of tissue hypoxia (e.g. lactic acidosis).

Central hypovolaemia should respond to intravascular volume expansion therapy (i.e. a fluid bolus).

Consensus and ongoing controversies regarding GDT

There is broad consensus, certainly amongst proponents of 'enhanced recovery' or 'fast track' surgery that a goal-directed approach, individualized for each patient, risk adapted to be consistent with locally-developed guidelines and regular audited, results in better patient outcomes [11,12]. Furthermore, it is now recognized that peri-operative fluid management is a serious issue that, if poorly done, can cost higher risk patients their lives: too much or too little fluid is not in the patient's best interest. There is also broad agreement that the judicious use of vasopressors is appropriate for anaesthesia-induced hypotension. However, little, if any of this is supported by the highest levels of evidence. Thus, there are many areas of ongoing controversy, including choice of advanced haemodynamic monitor, the importance (or not) of blood transfusion as part of the intervention (and the target Hct), the use of colloid or crystalloid fluids, the use of vasoactive agents to increase DO_2, the use of vasopressors to target BP, and choice of target flow goals (numerical value of DO_2 versus maximizing SV or oxygen extraction measure—all conceptually different). Given the uncertainty about which goals to choose, and in the context of dramatically reduced use of the PAC, the best current evidence based recommendation is to target SV using colloid boluses [11,12].

The paucity of data from large RCTs to inform these decisions underlines the need for further research. The largest study to date was the Sandham study [13]. This was a RCT of the use of PACs in high-risk surgical patients. It was a multicentre study of 3803 eligible patients, of whom 1994 were randomized into two groups. Overall, there was no difference in mortality between patients who were managed with a pulmonary-artery catheter (7.8% mortality) compared with those managed using a central venous pressure catheter (7.7%). Patients managed with a PAC had a higher rate of pulmonary embolism (8 events versus 0 events; $p = 0.004$), but there was a trend towards less renal failure in patients managed using a PAC. All patients were admitted to intensive care in the post-operative period, which was not the standard of care, i.e. both groups underwent a minimum post-operative intensive care unit stay of 24 hours. Patients were a mixture of ASA grade III and IV cases, of which the majority were major vascular (around 50%) and abdominal (around 20%). This is often referred to as an optimization study, although the title of the paper talks about it being a study of randomization to PAC or no PAC. The haemodynamic algorithm for the PAC group is a set of suggested interventions, namely the administration of fluid boluses, vasoactive drugs and/or packed red blood cells, but only around 50% of patients received any intervention. The haemodynamic goals chosen were lower than those reported to produce benefit in previous studies and the majority of patients do not achieve the protocol goals in the pre- and intra-operative period. Only in the post-operative period did around 50% of patients get above the 600 mL/min/m^2 for oxygen delivery. In other words, this study was probably not designed to evaluate GDT. Of note, this study was also not properly controlled (no PAC in control group), there was loss to follow-up and, notwithstanding the reported 'no-harm' signal, there was some evidence of clinical benefit with PAC usage (reduced renal failure) [13]. At the time of writing the 'OPTIMISE' trial—a large multicentre UK trial looking at dopexamine supplemented goal-directed therapy—has completed recruitment and the results are eagerly anticipated.

In England, an Enhanced Recovery after Surgery program was rolled out nationally from 2009 to 2012 [11,12]. This programme strongly recommended a goal-directed approach to peri-operative fluid management with the development, implementation, and regular audit of local algorithms that incorporated a low threshold for the use of advanced haemodynamic monitors [11,12]. The programme delivered the goals of reduced length of hospital stay for four categories of major surgery (colorectal, gynaecology, orthopaedic, and urology), reduced bed usage, no increase in readmissions and improved patient satisfaction. A recently published DELPHI consensus process conducted in England confirmed the use of advanced haemodynamic monitors and goal-directed

peri-operative fluid management was strongly supported [12]. The results of large multicentre studies are anticipated.

PART 19.2

General post-operative intensive care

CHAPTER 362

Post-operative ventilatory dysfunction management in the ICU

Paolo Chiarandini and Giorgio Della Rocca

Key points

- Mechanical ventilation impairs respiratory function and gas exchange, even in normal subjects.
- Lung protective strategies (low tidal volume, recruitment manoeuvres, positive end-expiratory pressure) should always be adopted.
- Avoid post-operative residual curarization (PORC).
- Extubate early and avoid unnecessary mechanical ventilation to prevent pneumonia.
- Adequate analgesia and post-operative NIV in high-risk patients could help respiratory recovery and reduce complications.

Introduction

Alterations in respiratory function and gas exchanges are frequently seen in patients during anaesthesia and in the post-operative period. Hypoxaemia occurs frequently during general anaesthesia, even in patients with normal lungs, and peri-operative ventilatory dysfunction is a common and recognized problem after surgery. It contributes to surgical morbidity and mortality. Patients' pre-operative respiratory status, types of surgery (abdominal, thoracic, laparoscopic), length of procedure, and anaesthesia (mechanical ventilation, use of inhalational anaesthetics, excessive fluid administration, narcotic, and muscle relaxant use), all contribute to impairment of respiratory function (e.g. airway patency, ventilatory drive suppression, ventilation/perfusion mismatch, shunt, and atelectasis).

Ventilatory dysfunction in anaesthesia

In the anaesthetized patient there is an increase in shunt (both 'true shunt' and 'venous admixture') from 1–2% (awake) to 8–10% impairing ventilation/perfusion ratio (V/Q) and gas exchange [1]. Changes in lung volumes and respiratory mechanics also occur. Supine position and loss of respiratory muscle tone reduces end-expiratory lung volume (up to 40%) and functional residual capacity (FRC). In patients in whom closing volume is near to FRC during spontaneous breathing (elderly and chronic obstructive pulmonary disorder (COPD) patients), air trapping and auto-PEEP can develop reducing tidal ventilation when mechanically ventilated. Compliance is also reduced from a mean of 95 to 60 mL/cmH_2O, partially due to the reduction in FRC [2]. An increase in resistance is then observed. Areas of atelectasis appear in almost 90% of anaesthetized patients [3]. Consequently, a decrease in PaO_2/FIO_2 ratio can be observed. This is often not clinically relevant with haemoglobin saturation rarely decreasing below 90%, because of the use of relatively high inspiratory oxygen fractions (FIO_2 0.4). In patients in whom respiratory reserve is already diminished, either before surgery or because of surgery (i.e. lung resections), a decrease in PaO_2/FIO_2 ratio can reduce blood oxygenation in a pathological way, requiring even higher FIO_2.

Lung protective strategies in anaesthesia

Tidal volume (V_t) during spontaneous ventilation in healthy subjects is around 6 mL/kg of ideal body weight. In past years V_t of 10–15 mL/kg were frequently used during mechanical ventilation to avoid atelectasis formation, and considered safe if a plateau pressure below 30 cmH_2O was maintained. However, an excessive stretch of alveolar walls (**volutrauma**), along with increased transpulmonary pressure (**barotrauma**), the cyclic opening and closing of alveoli (**atelectrauma**) and inflammatory mediators (**biotrauma**), can induce inflammation or sensitization of the lung to ventilator-induced lung injury (VILI). The concept of 'protective ventilation' was developed in anaesthetized patients. The goal of mechanical ventilation during anaesthesia is to provide good oxygenation and CO_2 removal, and keep tidal volume and pressures as close as possible to physiological values or as low as possible, while avoiding atelectasis formation with recruitment manoeuvres and PEEP [4]. Unfortunately, at the moment, prospective randomized controlled trials have not yet demonstrated particular clinical targets.

There are several methods published to recruit alveoli, mainly based on sustained pressure for a single or multiple periods. These include intermittent 'sighs', and progressive changes in PEEP and/or tidal volume for fixed periods. Most of them result in improvement in alveolar gas exchange, but there is no consensus in one prevailing among the others [5].

There is no agreement on appropriate PEEP levels during anaesthesia. The goal is to prevent atelectasis formation, reduce airway

closure, elevate FRC, and avoid high oxygen concentrations. This must be counterbalanced by the haemodynamic effects of PEEP on venous return and the right heart. There is general clinical consensus that PEEP levels of 5–10 cmH_2O are well tolerated by patients. A recent systematic review on this topic, published by the Cochrane Anesthesia Review Group, failed to demonstrate a statistically significant impact of intra-operative PEEP on post-operative mortality and respiratory complications. However, a trend to an increase in PaO_2/FIO_2 ratio and a decrease in post-operative atelectasis appears, without increasing barotrauma and cardiac complications [6].

Atelectasis

There are three mechanisms contributing to the development of atelectasis—compression of lung tissue, absorption of alveolar air, and impairment of surfactant function [7]. All three mechanism can cause atelectasis independently or together. Airless regions in the lungs can be detected 5 minutes after induction of anaesthesia. Once these regions develop, reopening them can require airway pressures up to 40 cmH_2O [8]. Factors associated to the development of atelectasis intra-operatively are type of anaesthesia, use of muscle relaxants, position, time ventilated, inspired oxygen concentration, patient's age, and obesity. Development of atelectasis intra-operatively is associated with decreased lung compliance, impairment of oxygenation, increased pulmonary vascular resistance, and development of lung injury. The adverse effects of atelectasis persist in the post-operative period and can impact patient recovery. Atelectasis can persist for 2 days after major surgery.

Residual neuromuscular blockade

Muscle activity, mainly diaphragmatic, creates the driving force during inspiration in spontaneous breathing and modifies chest diameters to allow ventilation in such a way that is not equally distributed to all lung regions. General anaesthesia reduces FRC and neuromuscular blockade agents (NMBA) commonly used in general anaesthesia, especially in abdominal surgery, can worsen this effect.[9] In recent years, studies focusing on the effects of new antagonizing drugs for muscle blockade, have evidenced the clinical importance of post-operative residual curarization (PORC) in the early phases after surgery. The use of short-acting NMBA reduces post-operative pulmonary complications [10]. The use of clinical or subjective criteria to define decurarization (protrusion the tongue, sustained head raising for 5 seconds, vital capacity below normal, etc.) are non-specific and often unreliable. Only the use of objective monitoring tools (e.g. quantification of the train of four (TOF) ratio) can significantly decrease the incidence of PORC. The use of sugammadex (a novel and specific reversal drug) should be considered against the old cholinesterases inhibitors, such as neostigmine to reduce the incidence of PORC.

Acute lung injury (ALI)/adult respiratory distress syndrome (ARDS)

Mechanical ventilation in anaesthesia and acute respiratory failure (and its most severe form adult respiratory distress syndrome (ARDS)) share three features in common—hypoxaemia, altered chest mechanics/compliance, and consolidation/atelectasis. The basis of acute lung injury (ALI)/ARDS are inflammation of lung units and destruction of microscopic architecture, while mechanical ventilation causes alterations primarily modifying the functioning of the lungs. Clinical and experimental data show a link between the two, demonstrating mechanical ventilation can induce inflammation of the lungs and damage to the ultrastructure. This is the focus of lung protective ventilatory strategies. No clinical monitoring tool is currently able to determine when the normal lung starts injuring, probably because there is a continuum of injury triggers to the alveoli from the first positive pressure air insufflation to the last. These injury triggers depend on pressure and volume used, and time of use. Pre-operative lung status and systemic inflammation developing during surgery are also important.

Post-operative ventilatory dysfunction

Pneumonia

This is the most important infective complication that affects the respiratory system. The incidence varies from 9 to 40% and depends on different factors such as age, pre-operative status (BMI and smoking history), type of surgery, and history of cancer [10]. Atelectasis formation and pneumonia are presumed to be linked, although no experimental or clinical study has clearly demonstrated a causative effect. Nonetheless, some studies have shown reducing atelectasis formation reduces post-operative pneumonia. The best strategy to reduce the incidence of pneumonia in surgical patients is to restore physiological functions as quickly as possible. This is part of the peri-operative surgical strategy called 'fast-track surgery' that comprises a bundle of techniques aimed at shortening recovery phase and reducing complications. Early extubation is one of the most important, along with early mobilization, less-invasive surgical techniques, avoidance or fast removal of drain-tubes and catheters, etc. [11].

When mechanical ventilation must be prolonged after surgery, the risk of ventilator-associated pneumonia (VAP) increases. VAP is defined as a pulmonary infection that arises 48–72 hours after endotracheal intubation, and is a subset of hospital-acquired pneumonia (HAP). VAP represents more than 85% of ICU HAP. There are a lot of factors associated with VAP. The Institute for Healthcare Improvement (IHI) has proposed the concept of 'ventilator bundles' to allow clinicians to focus on selected evidence-based interventions that minimize the risk of pneumonia in ventilated patients—elevation of the head of the bed, daily sedation interruption, peptic ulcer disease prophylaxis and deep vein thrombosis prophylaxis. Diagnosis of VAP should be based on early and accurate identification of patients with pulmonary infection, timely collection of cultures, and initiation of antibiotics (often broad-spectrum antibiotics). The use of scores to identify infected patients, such as the Modified Clinical Pulmonary Infection Score (CPIS), has been recommended as has the use of customized antibiotic-treatment algorithm or guidelines based on local isolates and susceptibility profiles [12].

Pulmonary embolism

Before the extensive introduction of deep vein thrombosis (DVT) prophylaxis and early mobilization, the incidence of clinically relevant episodes of pulmonary embolism, was one of the major cause of morbidity and mortality in surgical patients. Since most thrombi are asymptomatic, the real incidence of DVT and pulmonary embolism (PE) is not clearly understood. However, when PE is clinically relevant, the impact on mortality,

morbidity, and health care resource utilization is so high that prevention is the most efficient therapeutic approach. Guidelines from the American College of Chest Physicians recommended routine thromboprophylaxis with low-molecular-weight heparin (LMWH) or low-dose unfractionated heparin for patients at moderate risk, with LMWH for patients at higher risk, and with graduated compression stockings and/or intermittent pneumatic compression for those with significant risk of bleeding [13]. In patients with suspected PE, the gold standard for diagnosis is chest CT-angiography, being other diagnostic test such as chest radiography, D-dimer dosage, electrocardiogram, or echocardiography, less sensitive.

Therapeutic strategies to improve post-operative pulmonary function

Strategies to improve post-operative pulmonary function or to minimize risk of complications should cover the full peri-operative period. Pre-operatively, there is no general consensus on the utilization of risk stratification scores. The same is true for functional tests (spirometry) or laboratory examinations. Clinical evaluation remains the best way to assess patient status and to guide further diagnostic work-up. Patient education measures like smoking cessation/reduction, have not given successful results if not instituted at least 2 months before surgery. Teaching the patient the proper use of manoeuvres designed to increase lung volumes after surgery seem to work better [14]. Intra-operatively, unnecessary manoeuvres that affect/damage chest and respiratory muscle integrity (type of surgical incision, use of devices to lift the thoracic cage, electrocauterization to the diaphragm) must be avoided. Protective ventilation and strategies to 'keep the lung open' (PEEP, low V_t, low pressures, and recruiting manoeuvres) should be adopted.

In the post-operative period, best results can be attained by increasing lung volumes by means of chest physiotherapy, use of incentive spirometry devices, and intermittent positive pressure breathing. In reviews and meta-analyses, no method demonstrated superiority over others, but all demonstrated the ability to decrease the frequency of post-operative pulmonary complications by a factor of two. Adequate post-operative analgesia must be assured to patients to allow good patient co-operation. Many studies have tried to demonstrate the advantage of one analgesic technique (regional versus intravenous, opioids versus local anaesthetics) over another. At the moment, no clear general recommendation can be made, except in COPD patients and thoracic surgery where epidural analgesia seems advantageous, together with a multimodal approach (e.g. anti-inflammatory agents and analgesics) [15]. The use of non-invasive ventilation in the early post-operative period, including continuous positive airway pressure with helmet or face-mask, seems a good and reasonable way to help patients' respiratory recovery and reduction of atelectasis, especially in high risk patients and those who have pre-operative respiratory dysfunction [16]. Data in general, cardiac, and thoracic surgery are encouraging, but populations studied and non-invasive ventilation strategies utilized, do not allow a recommendation for extensive use.

CHAPTER 363

Post-operative fluid and circulatory management in the ICU

Claudia Ebm and Andrew Rhodes

Key points

- Post-operative complications are common and can be reduced with appropriate circulatory management.
- Optimal management of volaemic status is the most important part of circulatory management.
- Functional haemodynamic measurements are useful in predicting volume responsiveness.
- Titrating resuscitation to achieve an optimal cardiac index and oxygen delivery has been shown to improve outcomes.
- Modern haemodynamic monitors can provide this information in a near non-invasive fashion.

Introduction

Post-operative outcomes relate at least in part to the intra- and post-operative management of the circulation. Optimizing haemodynamics and ensuring adequate blood flow through the use of intravenous (iv) fluids and circulatory support remains an essential part of the peri-operative strategy. Although fluid therapy can be titrated very easily in many patients who are at low risk of post-operative complications, those with a limited cardiovascular or respiratory reserve represent more of a challenge. For such high-risk populations, which account for up to 15% of all surgical patients and more than 80% of all post-operative complications and deaths, a sophisticated haemodynamic strategy is important [1]. Demand-orientated 'individualized' fluid administration and consecutive inotropic or inodilator therapy can help to optimize oxygen delivery and, hence, reduce complication rates and duration of hospital stay [2–4].

A sophisticated post-operative strategy requires knowledge of the pathophysiological abnormalities that commonly occur in high-risk surgical patients. Haemodynamic derangements, either directly linked to peri-operative volume depletion or as a consequence of an inflammatory response to tissue trauma, lead to a decrease in preload, impaired cardiac contractility and low cardiac performance. Local malperfusion induced by such circulatory failure with increased requirements for oxygen due to the stress response, cause a net oxygen debt, cellular hypoxia, local tissue damage, and may ultimately result in multiple-organ failure (MOF), and death. Thus, the objective of fluid and circulatory therapy is to maintain the microvascular blood flow in order to balance oxygen supply with increased demand.

Post-operative fluid balance

The optimal circulatory strategy aims to correct intravascular volume deficits, while avoiding excessive fluid administration. Precisely estimating requirements for fluid administration is a challenge and fluid overload is often a reflection of poor fluid prescribing practices based on historical misunderstanding of post-operative physiology. This may be caused by the belief that pre-operative fluid depletion due to starvation and intra-operative fluid and electrolyte loss has to be corrected aggressively to avoid haemodynamic instability and organ malperfusion. This often results in an overall positive fluid balance, often far greater than actual losses require. Following the initial post-operative 'resuscitation' many authors have therefore explored the use of a restrictive fluid strategy in the subsequent period.

In 1990, Lowell et al. [5] reported the negative consequences of fluid overload and these results were confirmed in more recent studies showing that restrictive post-operative fluid regimens reduce hospital length of stay and complication rates [6,7]. Lobo has also compared restrictive (4 mL/kg/hour) versus liberal (12 mL/kg/hour) fluid regimens in high-risk surgical patients and observed lower complication rates (20.0 versus 41.9%, $p = 0.046$) associated with the restrictive regimen [8].

It is apparent that no single 'recipe' can be used to prescribe iv fluids for all patients' needs. The optimal practice, especially in patients with limited cardiovascular reserve, is to titrate fluids individually to monitored variables in the initial phase, then move rapidly to enteral fluids with the avoidance of large volumes of crystalloids. In this context, 'goal-directed therapy' can be used to titrate fluid administration individually and in light of the cardiovascular response to a given fluid challenge (Fig. 363.1).

Goal-directed therapy

Goal-directed therapy (GDT) is pragmatic stepwise strategy to guide and manipulate fluid and inotropic support by using flow and perfusion related measurements. GDT is based on the idea

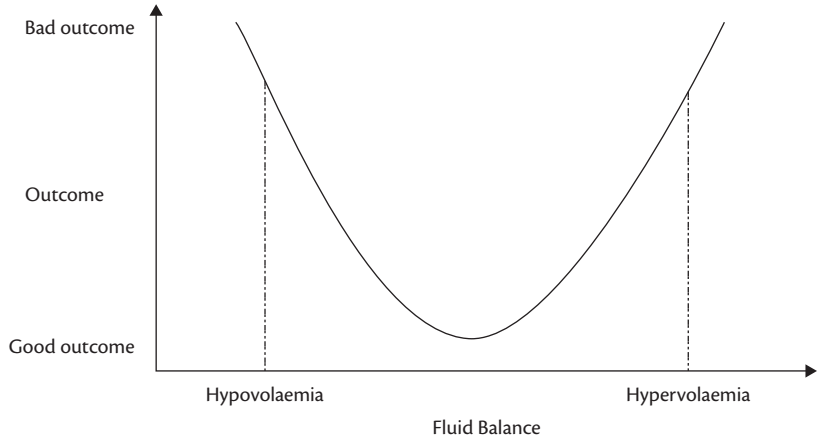

Fig. 363.1 The effect of total fluid balance on clinical outcome.

that optimal fluid therapy combined, in some circumstances with a vasodilator or positive inotropic agent, increases oxygen delivery to predefined goals. In particular, 'haemodynamic optimization' refers to optimizing tissue perfusion by manipulating stroke volume (SV), haemoglobin (Hb), and arterial oxygen saturation (SaO_2) to improve oxygen delivery (DO_2).

Aims of post-operative goal-directed therapy

The main aim of post-operative GDT is to improve cardiac performance, taking into account the pathophysiological alterations in high risk surgical patients. Haemodynamic optimization uses flow-related (cardiac output (CO) or DO_2) and perfusion (central or mixed venous oxygen saturation (SvO_2)) endpoints to guide fluid administration. The specific endpoints (targets) used have arisen from historic recognition that patients in low flow states have poorer outcomes. Shoemaker et al. [9], in a seminal work, identified the median values of cardiac index (4.5 L/min/m^2), oxygen delivery index (600 mL/min/m^2), and oxygen consumption index (170 mL/min/m^2) for survivors following major surgery and then used these targets as endpoints for resuscitation and demonstrated significant reduction in mortality. Although some of these endpoints, and the mechanisms to achieve them, have been refined over the subsequent twenty years, the main principles of this targeted approach to individualized management of the circulation remain the same.

Shoemaker's findings precipitated a series of trials targeting haemodynamic variables in order to improve outcome. In 2005, Pearse published a study in high-risk surgical patients treated with goal-directed therapy (GDT) in the post-operative recovery phase. This study advocates early resuscitation using predefined endpoints to guide fluid resuscitation coupled with manipulating cardiac output, afterload and contractility. Pearse et al. [4] randomized 122 patients to receive either conventional fluid plus circulatory management or early goal-directed therapy (EGDT) to achieve an oxygen delivery index of >600 mL/min/m^2. Individualized fluid resuscitation was commenced immediately after major surgery and maintained up to 8 hours. Although, the GDT group required more iv colloids (1907 SD ± 878 mL versus 1204 SD ± 898 mL; $p < 0.0001$) and inotropic support (dopexamine (55 patients (89%) versus 1 patient (2%); $p < 0.0001$), complication rates (44 versus 68%, $p < 0.0001$) and hospital length of stay (11 versus 14 days, $p = 0.001$) were significantly reduced in the treatment arm.

GDT can vary in a number of ways— timing (pre-, intra-, and post-operative), targets used (oxygen delivery, oxygen extraction, cardiac output, stroke volume, SvO_2, lactate), strategy (fluids and/or inotropic support), and monitoring techniques.

Timing

The original optimization studies all started in the pre-operative period and then continued through surgery into the intensive care unit (ICU) afterwards. This approach is intuitively sensible as it pre-empts problems in the circulatory system before they occur. However, for practical and logistic reasons (lack of ICU capacity and organizational difficulties) the technique never became popular and was rarely possible. Many authors have, therefore, begun to look at the effects of implementing such a strategy in the intra-operative phase or in the immediate post-operative period. GDT should be started as soon as possible and continued into the post-operative period. Although this is a pragmatic solution, it cannot be substituted for poor pre- and intra-operative practice, and it must be recognized that even optimal management in the post-operative period will never be able to compensate completely for prolonged circulatory dysfunction that has been poorly managed before the end of surgery.

Strategy

The first step in the haemodynamic management of post-operative patients is to assess tissue perfusion and oxygenation. Static measurements (central venous pressure (CVP), mean arterial pressure (MAP), urine output, pulmonary artery occlusion pressure (PAOP), etc.) have traditionally been used to estimate intravascular volume status and identify patients who are at risk of developing tissue malperfusion. However, in critically-ill patients such indices do not provide a reliable basis for preload optimization. In such situations, rather than relying on predefined absolute values, dynamic measurements can be used to predict the change in flow.

Dynamic measurements in these circumstances use one of three types of variable:

- Volume challenge.
- An assessment of preload reserve via either pulse pressure variation (PPV) or stroke volume variation (SVV).
- A passive leg raise manoeuvre [10].

Most authors have advocated the use of the 'fluid challenge', whereby a small volume of iv fluid is rapidly administered and the direct effects on changes in cardiac index monitored. More recently, the functional approach to predicting volume responsiveness has been described and used. Variations in pulse pressure (>13–15%) and stroke volume (>10%), induced by changes in intrathoracic pressure during a full respiratory cycle, have the ability to evaluate the current intravascular filling status, predict the response to fluid administration and enable the accurate administration of fluids. Fluid bolus will continue until the patient's preload is optimized. This is physiologically characterized by a move towards the flat part of the Frank–Starling curve, and clinically seen as a stagnant or decreasing SVV or PPV. In this phase, further fluid challenge would be harmful. However, such dynamic measurements are only efficacious in patients who are not breathing spontaneously and are in sinus rhythm. These circumstances are rarely applicable to the post-operative setting where other methodologies have to be used. Passive leg raising may be a practical alternative to assess the need for further fluid resuscitation. After a patient's legs are elevated to 45°, real-time changes in cardiac performance (stroke volume or cardiac output) are measured.

Haemodynamic monitoring

Technological advances allow for a more precise method to estimate cardiac output in order to detect subclinical volume depletion earlier. Cardiac output can be monitored using invasive methods, based on thermodilution techniques or the Fick method, or minimal-invasive methods that include oesophageal Doppler, transoesophageal echocardiography, lithium dilution, pulse contour analysis, or more experimental techniques, such as bioimpedance and bioreactance. While each of these has its own inherited strengths and weaknesses, the ideal system in the post-operative ICU setting should be non-invasive, continuous, accurate, reliable, and applicable to non-sedated patients.

More than 30 years ago, the pulmonary artery catheter (PAC) was introduced to monitor and manipulate the cardiovascular system in unstable patients. The widespread use of the PAC has become the topic of extensive debate, triggered by an absence of studies demonstrating a clear outcome benefit, as well as its unfavourable risk/benefit profile. Over the last decade a number of less invasive alternative tools emerged, with potential to replace the PAC. Several studies have shown oesophageal Doppler-guided optimization has the potential to improve outcome in the intra-operative phase. In the post-operative phase, however, the need for sedated patients limits its practicability. Many authors have thus started to look at less invasive techniques, such as arterial pressure-based devices that translate the arterial pressure signal line into flow-related information (pulse contour analysis).

Methodology for non-cardiac surgical patients

GDT should be initiated in the immediate post-operative phase and continued for up to 8 hours. The initial phase of optimization is characterized by rapid fluid administration. Small intravenous boluses of fluid (250 mL) are given to test the patient's preload reserve. This is repeated until the SV or CO fails to increase by a value of 10–15% from the baseline over an observation period of 20 minutes. Boluses can be repeated if the targeted endpoints subsequently increase again. As such, the physiological endpoint achieved is more of importance than the exact type of fluid. This concept has been described as 'stroke volume maximization'.

In some patients, perfusion is still inadequate despite optimal fluid loading. Several authors have used an oxygen delivery cut off of 600 mL/min/m^2 to identify this. In this group, low doses of inotropes have been shown to be beneficial in terms of reducing post-operative complications [2,11,12]. Dopexamine hydrochloride has been extensively studied the inotropic agent for this indication and a recent meta-analysis has revealed significant benefits with this approach.

Methodology for cardiac surgical patients

Post-cardiac surgical optimization has used different endpoints to the non-cardiac population. In this group, it is rarely possible to achieve an indexed value of oxygen delivery (DO_2I) of 600 mL/min/m2 and the use of increased doses of inotropic agents may be harmful. Authors have therefore chosen to either normalize the lactate and/or mixed venous oxygen saturation or just cardiac index, aiming for values greater than those previously shown to be been predictive of poor outcomes. While Polonen [13] used a SvO_2 >70% and lactate (<2 mmol/L) as therapeutic goals in the immediate post-operative phase, McKendry [14] focused on achieving a stroke volume index >35 mL/m^2. Whatever the endpoints, the technique used remains similar, and has resulted in reduced complications and length of stay for the high-risk cardiac patient.

CHAPTER 364

Enhanced surgical recovery programmes in the ICU

Michael J. Scott and Monty Mythen

Key points

- Enhanced recovery programmes (ERPs) are evidence-based peri-operative care pathways.
- Patient-centred care delivered by a multidisciplinary team improves consistency and quality of care, resulting in reduced length of stay.
- Evidence is emerging that ERPs reduce the incidence of medical complications.
- Minimally invasive surgery, individualized analgesia, and goal-directed fluid therapy are key elements for optimal outcomes to ensure early gut function and mobility.
- The use of critical care facilities within ERPs is desirable to deliver optimal post-operative care in high risk patients or in patients who have complications.

History and development of enhanced recovery pathways

Enhanced recovery after surgery (sometimes termed 'fast-track' surgery) was introduced in the 1990s by Kehlet in Copenhagen, Denmark. At that time it was standard practice for patients undergoing colonic resection surgery to be left with drips and nasogastric tubes and no enteral nutrition for days post-operatively. He focused on a multimodal approach to reduce the stress response to surgery to enable early post-operative rehabilitation. His results of getting patients home after open colonic resection within 48–72 hours seemed extraordinary at a time when the length of stay for patients undergoing colorectal surgical resection was 1–2 weeks. In order to facilitate this, many different pre-operative, peri-operative, and post-operative elements were used. Rather than focusing on the surgery itself he focused on enhancing recovery by implementing evidence based practice in the fields of analgesia, anaesthesia, nutrition, reduction of surgical stress, and early ambulation [1]. He involved anaesthesiologists, nurses, and physical therapists as active participants of the care team.

The overall aim of an ERP is to deliver an evidence-based peri-operative care pathway to improve outcome. The ERP aims to reduce surgical stress and enhance post-operative physiological function with a resulting early return of enteral diet and mobilization. The increase in adoption of laparoscopic techniques in colorectal surgery together with ERPs has led to reduced length of stay with Rockall's group demonstrating that ultra-short length of stay of 23 hours are possible even in complex colorectal resections [2].

ERP elements and grading of evidence in colorectal surgery

Table 364.1 lists the 20 most recent ERP Elements, their recommendation with evidence level and recommendation grade for elective colonic surgery [3].

Evidence base for enhanced recovery programmes

There are few large randomized controlled studies comparing ERPs with standard pathways. Fig. 364.1 shows the results a Cochrane review looking at the evidence base for reduction in length of stay and reduction in complications [4]. This showed a mean reduction of 2.51 days and a risk ratio favouring ER to reduce complications of 0.52.

Many of the ER elements have been accepted and adopted into standard surgical practice. The difference between 'new' enhanced recovery programmes (ERPs) and standard surgical pathways has therefore reduced, which has affected the ability for future studies to identify differences. It is also important to look at compliance in the treatment group, as well as which ERP elements have been included in the standard control group. The compliance and efficacy of certain elements, such as epidural analgesia and fluid management can be difficult to compare between groups due to practical implementation and efficacy.

Although it is recognized that it is the combination of all the ERP elements that leads to improved outcomes, there has been interest in trying to identify if certain elements are more important than others to obtain improved outcomes. A review by Gustafsson looked at 114 variables in a single centre using enhanced recovery over 6 years [5]. The association between adherence to the ERP protocol and post-operative symptoms, complications, and length of stay following major colorectal cancer was compared. Comparing patients from 2002–4 to 2005–7, there was an increase in compliance with ERP elements from 43.3 to 70.6% with resulting reduction of post-operative complications (odds ratio 0.73) and unwanted symptoms (odds ratio 0.53). Restriction of intravenous fluid and oral carbohydrate loading were major independent predictors. The proportion of adverse post-operative outcomes was

Table 364.1 Guidelines for perioperative care in elective colonic surgery: enhanced recovery after surgery (ERAS®) society recommendations

Item	Recommendation	Evidence level	Recommendation grade
Pre-operative information, education and counselling	Patients should routinely receive dedicated preoperative counselling Pre-operative general medical optimisation is necessary before surgery	Low	Strong
Pre-operative optimization	Smoking and alcohol consumption (alcohol abusers) should be stopped 4 weeks before surgery	**Alcohol**: low **Smoking**: high	Strong
Pre-operative bowel preparation	Mechanical bowel preparation should not be used routinely in colonic surgery	High	Strong
Pre-operative fasting and carbohydrate treatment	Clear fluids should be allowed up to 2 hours and solids up to 6 hours prior to induction of anaesthesia	**Solids and fluids**: moderate	**Fasting guidelines**: strong
	Pre-operative oral carbohydrate treatment should be used routinely. In diabetic patients carbohydrate treatment can be given with the diabetic medication	**Carbohydrate loading, overall**: low carbohydrate loading, diabetic patients: very low	**Pre-operative carbohydrate drinks**: strong **Pre-operative carbohydrate drinks, diabetic patients**: weak
Pre-anaesthetic medication	Patients should not routinely receive long- or short-acting sedative medication before surgery because it delays immediate post-operative recovery	High	Strong
Prophylaxis against thromboembolism	Patients should wear well-fitting compression stockings, have intermittent pneumatic compression, and receive pharmacological prophylaxis with LMWH. Extended prophylaxis for 28 days should be given to patients with colorectal cancer	High	Strong
Antimicrobial prophylaxis and skin preparation	Routine prophylaxis using intravenous antibiotics should be given 30–60 minutes before initiating surgery. Additional doses should be given during prolonged operations according to half-life of the drug used Preparation with chlorhexidine-alcohol should be used	High	Strong
Standard anaesthetic protocol	A standard anaesthetic protocol allowing rapid awakening should be given	**Rapid awakening**: low	Strong
	The anaesthetist should control fluid therapy, analgesia and haemodynamic changes to reduce the metabolic stress response	**Reduce stress response**: moderate	
	Open surgery: mid-thoracic epidural blocks using local anaesthetics and low dose opioids	**Open surgery**: high	
	Laparoscopic surgery: spinal analgesia or morphine PCA is an alternative to epidural anaesthesia	**Laparoscopic surgery**: moderate	
PONV	A multimodal approach to PONV prophylaxis should be adopted in all patients with >2 risk factors undergoing major colorectal surgery. If PONV is present, treatment should be given using a multimodal approach	Low	Strong
Laparoscopy and modifications of surgical access	Laparoscopic surgery for colonic resections is recommended if the expertise is available	**Oncology**: high. **Morbidity**: low. **Recovery/LOSH**: moderate	Strong
Nasogastric incubation	Post-operative nasogastric tubes should not be used routinely. Nasogastric tubes inserted during surgery should be removed before reversal of anaesthesia	High	Strong
Preventing intra-operative hypothermia	Intra-operative maintenance of normothermia with a suitable warming device and warmed intravenous fluids should be used routinely to keep body temperature >36°C	High	Strong

(*continued*)

Table 364.1 Continued

Item	Recommendation	Evidence level	Recommendation grade
Peri-operative fluid management	Patients should receive intra-operative fluids (colloids and crystalloids) guided by flow measurements to optimize cardiac output	**Balanced crystalloids**: high. **Flow measurement in open surgery**: high. **Flow measurement in other patients**: moderate	Strong
	Vasopressors should be considered for intra- and post-operative management of epidural-induced hypotension provided the patient is normovolaemic	**Vasopressors**: high	
	The enteral. route for fluid post-operatively should be used as early as possible, and intravenous fluids should be discontinued as soon as is practicable	**Early enteral route**: high	
Drainage of peritoneal cavity after colonic anastomosis	Routine drainage is discouraged because it is an unsupported intervention that is likely to impair mobilization.	High	Strong
Urinary drainage	Routine transurethral bladder drainage for 1–2 days is recommended	Low	**Routine bladder drainage**: strong
	The bladder catheter can be removed regardless of the usage or duration of thoracic epidural analgesia		**Early removal if epidural used**: weak
Prevention of post-operative ileus	Mid-thoracic epidural analgesia and laparoscopic surgery should be utilized in colonic surgery if possible	**Thoracic epidural and laparoscopy**: high	**Thoracic epidural, fluid overload, nasogastric decompression, chewing gum, alvimopan**: strong
	Fluid overload and nasogastric decompression should be avoided	**Chewing gum**: moderate	
Post-operative analgesia	**Open surgery**: TEA using low-dose local anaesthetic and opioids	**TEA, open surgery**: high **Local anaesthetic and opioid**: moderate	Strong
	Laparoscopic surgery: an alternative to TEA is a carefully administered spinal analgesia with a low-dose, long-acting opioid	**TEA not mandatory in laparoscopic surgery**: moderate	
Peri-operative nutritional care	Patients should be screened for nutritional status and, if at risk of under nutrition, given active nutritional support	**Post-operative early enteral feeding, safety**: high. **Improved recovery and reduction of morbidity**: low	**Post-operative early feeding and feeding and peri-operative ONS**: strong
	Peri-operative fasting should be minimized. Post-operatively patients should be encouraged to take normal food as soon as lucid after surgery	**Peri-operative ONS (well-fed patient)**: low. **Peri-operative ONS (malnourished patient)**: low.	**IN**: IN could be considered in open colonic resections, weak
	ONS may be used to supplement total intake	**IN**: low	
Post-operative glucose control	Hyperglycaemia is a risk factor for complications and should therefore be avoided	**Using stress reducing elements of ERAS to minimize hyperglycaemia**: low	**Using stress reducing elements of ERAS to minimize hyperglycaemia**: strong
	Several interventions in the ERAS protocol affect insulin action/resistance, thereby improving glycaemic control with no risk of causing hypoglycaemia	**Insulin treatment in the ICU**: moderate	**Insulin treatment in the ICU (severe hyperglycaemia)**: strong. **Insulin treatment in ICU (mild hyperglycaemia)**: weak
	For ward-based patients, insulin should be used judiciously to maintain blood glucose as low as feasible with the available resources	**Glycaemic control in the ward setting**: low	**Insulin treatment in the ward setting**: weak

LMWH, low molecular weight heparin; PCA, patient controlled analgesia; PONV, post-operative nausea and vomiting; TEA, thoracic epidural analgesia; ONS, oral nutritional supplementation; IN, intravenous nutrition; ERAS, enhanced recovery after surgery; ICU, intensive care unit.

significantly reduced with increasing adherence to the ERP protocol. It is therefore important even in centres with established ERPs to maintain high levels of compliance to the ERP elements using audit tools.

Those centres that have a high rate of operation completion with laparoscopic surgery and have adopted enhanced recovery with goal directed fluid therapy have a particularly good 5-year survival rate for colorectal disease [6]. It is unclear whether this is due to the reduction in stress response at the time of surgery, reduction in post-operative complications, the fact that patients receive chemotherapy sooner after primary surgery, or a combination of all these factors [7].

Controversies in ERPs

It is still unclear if all the ERP elements are necessary to obtain optimal outcomes. However, a lot of the elements interact with each other positively, which goes some way to explain why a higher compliance with the number of elements has shown an improvement in outcome.

Patients staying on the pathway are relatively straight forward and normally fulfil their pre-operative discharge goal, although when patients develop complications the outcome is more dependent on the surgical team identifying and treating the complication.

There remains controversy as to whether the elderly or those patients with significant co-morbidities are suitable for ERPs. If enhanced recovery reduces peri-operative stress and improves restoration of post-operative function, then these groups may well have most to benefit from ERPs.

Spread and adoption of ERPs

The demonstrated benefits of ERPs have led to a rapid spread and adoption by many surgical units throughout many countries. There have been publications in rectal surgery and pancreaticoduodenectomy with recommendations for other surgical specialties to follow [8].

In the United Kingdom the Department of Health set up the Enhanced Recovery Partnership Programme in 2009 to encourage adoption of ERPs. Initially the four specialties of colorectal, gynaecology, urology, and musculoskeletal surgery were rolled out. The programme was successful in bringing down length of stay and delivering high levels of patient satisfaction, while maintaining the same level of readmission rates. There has also been widespread adoption of the general principles and creation of ERPs in many of the other surgical specialties, including hepatobiliary, oesophagogastric, and breast, head, and neck surgery. The development of ERPs is now established in emergency specialties, such as fractured neck of femur and emergency laparotomy. The UK has been the first country to embed ERPs as a standard of care approved by all the relevant stakeholders including the Department of Health, health commissioning boards, and the Royal Colleges responsible for teaching and training.

The role of critical care in ERPs

There is wide variation in the use of intensive care within enhanced recovery pathways. The variation is not just between countries, but within surgical units in the same country due to different approaches to where to manage surgical patients post-operatively. There are a

variety of issues, including resource allocation, staffing issues, and practicalities of where goal-directed fluid therapy (GDFT) can be delivered. GDFT is done by using flow monitoring devices, such as the Oesophageal Doppler™ or arterial waveform analysis where fluid boluses of around 250 mL are given to see if the stroke volume increases by 10% or more [9]. This maintains the patient on the optimal part of the Starling curve and avoids relative hypovolaemia and splanchnic hypoperfusion. No more fluid is given if there is no increase in stroke volume and the clinical parameters and assessment are within the desired range. Maintaining normovolaemia in the immediate peri-operative period after cellular injury is also important. There is an increase in oxygen consumption, and cells need oxygen and nutrients to start repairing injury. There are often fluid shifts and changes in vascular capacitance, and resistance due to the use of vasopressors and regional anaesthesia. Oxygen debt during this post-operative period is highly likely to lead to complications. Currently, it is only really practical to achieve flow monitoring in the post-operative period when patients are awake with arterial pulse contour wave devices or utilizing oxygen extraction from central venous catheters. Once the period of fluid redistribution is complete intravenous fluid should be restricted to a minimum with the resumption of enteral intake as soon as tolerated and according to the surgical procedure.

It is accepted that a high-risk patient undergoing major surgery benefits from critical care and pre-emptive haemodynamic intervention, as do patients having high-risk surgery [10]. However, there is still a large group of patients who are neither high risk nor undergoing high risk surgery who have a high mortality and morbidity from surgery [11]. The problem is predicting which of those patients will need critical care and benefit from increased resource allocation. In reality, it is not always possible to predict this until the surgical procedure is complete and an assessment of the patient's condition has taken place. Therefore, assessment at the end of surgery plays an important role of where to place the patient post-operatively. The current economic pressure on health care systems to deliver more care for the same money makes ERPs attractive; however, the extra resources and costs needed to provide critical care post-operatively means it may not be practical to provide it for all patient groups.

In 2005, Khuri published data from the USA on eight types of operation identifying the predictors of 30-day mortality and long term survival [12]. It showed that a major post-operative complication had more of an effect on long-term life expectancy than pre-operative risk (Fig. 364.2). Birkmeyer has shown that the cost of inpatient episodes in the USA is much higher in centres with higher rates of complications and the average cost of a complication is $10,000 [13]. This further supports the use of critical care to support enhanced recovery pathways to optimize fluids and analgesia in the immediate post-operative period. Investment of resources at this time should lead to a reduction in complications and respective cost saving as well as benefiting the patient. Fig. 364.3 shows a practical approach to integrating goal-directed fluid therapy and utilization of critical care services in an enhanced recovery pathway.

Conclusion

Enhanced recovery pathways deliver patient-centred, evidence-based care. As well as improving patient experience and reducing length of stay there is increasing evidence that it reduces post-operative medical complications [14,15]. In order to achieve this well-structured pathways and trained multidisciplinary teams are needed with ongoing audit of compliance to maintain high quality results. ERPs enable more patients to be treated with improved outcomes with the same resources.

The use of critical care within ERPs is variable depending on local policy and patient and surgical risk factors, and whether there are significant surgical or medical issues immediately after surgery. The use of goal-directed fluid therapy may increase the use of critical care immediately post-operatively because of the lack of provision of this equipment and staff trained to use it in post-anaesthesia units or on surgical wards, but the reduction in complications may prove to be cost beneficial.

The increasing standardization of peri-operative care pathways using ERPs around the world opens up the possibility of

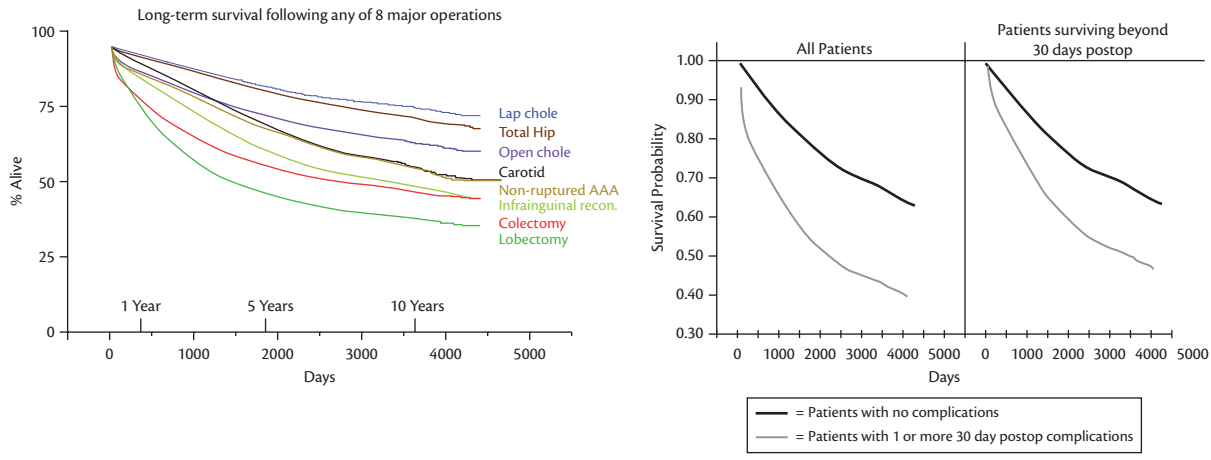

Fig 364.2 Long-term survival following surgery.

performing multicentre randomized controlled studies to identify key treatment components or strategies, and quantify their effect on short- and long-term outcomes.

It is likely that enhanced recovery principles will be incorporated into critical care pathways in the future.

PART 19.3

Obstetric intensive care

CHAPTER 365

Obstetric physiology and special considerations in ICU

Patrick J. Neligan and John G. Laffey

Key points

- A series of physiological and anatomic changes occur during pregnancy that make the mother vulnerable to a variety of insults arising from underlying disease, pregnancy related diseases, or coincidental disease.
- Early pregnancy is characterized by endocrine-related changes that alter cardiopulmonary and respiratory function to match the metabolic demands of the enlarging fetus. Later pregnancy is characterized by mechanical anomalies resulting from the presence of an expanding uterus that enlarges into the abdomen and abuts the chest wall.
- The physiological changes of pregnancy are significant, and may delay the diagnosis of critical illness and necessitate modifications to standard management approaches.
- There are two patients, mother and fetus. The fetus is generally robust despite maternal illness, and therapeutically what is good for the mother is generally good for the fetus.
- Trauma is the most common cause of non-obstetrical maternal death.

Introduction

Pregnancy is a normal physiological process that is defined by the presence of the uteroplacental complex. In order for pregnancy to commence and continue, the woman must possess sufficient physiological reserve to host an enlarging fetus that makes progressively greater metabolic demands. A series of physiological and anatomic changes occur in the mother during the course of the pregnancy that make her vulnerable to a variety of insults arising from underlying disease, pregnancy-related diseases, or coincidental disease. The intensivist must be aware of these changes as they impact upon our ability to care for these patients. In addition, intensivists must be able to recognize abnormal physiology, such as occurs in pre-eclampsia, which may result in life-threatening complications.

This chapter will outline the major physiological changes of pregnancy, and then consider how these changes impact on the care of the pregnant patient with non-obstetric critical illness.

Normal physiology of pregnancy

See Table 365.1 for physiological changes in various systems during pregnancy.

Respiratory system

As pregnancy progresses there is an increase in minute ventilation, resulting in relative hypocarbia ($PaCO_2$ is 5–10 mmHg below 'normal'). This is brought about by a 40% rise in tidal volume and a 15% rise in respiratory rate (2–3 breaths/minute); alveolar ventilation is about 70% greater [1]. In later pregnancy there is a profound reduction in functional residual capacity (FRC), resulting from reduced chest wall compliance associated with upward pressure from the uterus [1]. Consequently, administration of anaesthetics or sedatives may result in rapid development of hypoxaemia. The PaO_2 remains within normal limits throughout pregnancy. However, oxygen consumption increases progressively, so that at term mixed venous oxygen content may be significantly below normal. Oxygen consumption increases by up to 60% during labour.

The airway of the pregnant woman similarly undergoes significant changes that become more dramatic as parturition approaches—increased blood and plasma volume result in mucosal oedema and hypervascularity of the upper airways. This results in pharyngolaryngeal and vocal cord oedema and a friable mucosa. When 242 pregnant women's airways were examined at 12 weeks and subsequently at 36 weeks gestation, the percentage with Mallampati Class IV ('difficult') airways had increased by 34% [2]. Hence, difficult tracheal intubation is more likely encountered as term approaches.

Cardiovascular system

Significant changes occur in the cardiovascular system during pregnancy, due to increased vascular capacity particularly within the uterus, placenta, and breast tissue [3]. Consequently, blood volume increases progressively from 6–8 weeks gestation to 34 weeks with little change thereafter. There is physiological anaemia—the plasma volume increases 40–50%; the red cell mass increases only 20–30%. Cardiac output increases by approximately 25%, principally as a result of an increase in stroke volume (by one-third) and heart rate (by one-sixth). Total peripheral resistance falls, so the circulation is hyperdynamic. Blood pressure is normal or slightly below normal; hypertension is almost always pathological in pregnancy. Central venous pressure in the superior vena caval distribution remains 'normal', but femoral venous pressure may be higher than normal due to compression of the inferior vena caval system. There is significant venous distension, although this has little impact in critical illness [3].

Table 365.1 Physiological changes in various systems during pregnancy

System	Changes
Respiratory system	◆ Increased alveolar ventilation (70%) ◆ Relative hypocarbia ($PaCO_2$ 25–32 mmHg) ◆ Reduced FRC ◆ Increased O_2 consumption ◆ Reduced SvO_2.
Cardiovascular system	◆ **Increased cardiac output (20%)**: increased stroke volume 30%, Increased heart rate 15% ◆ Reduced total peripheral resistance ◆ Normal CVP in SVC distribution ◆ **Elevated CVP in IVC distribution**: aorto–caval compression ◆ Increased circulating volume ◆ Increased plasma volume (40–50%) ◆ **Increased red cell mass (20–30%)**: physiological anaemia
Gastrointestinal and metabolic	◆ Reduced lower oesophageal sphincter tone ◆ Reduced gastric pH: elevated risk of gastro-pulmonary aspiration ◆ Increased metabolism: • Carbohydrate^{+++} • Protein^{++} • Fat^{+} ◆ Hyperinsulinaemia and hypoglycaemia
Kidney	◆ Increase renal blood and plasma flow (50–60%) ◆ Increased glomerular filtration (50–60%) ◆ Reduced serum urea and creatinine ◆ Glycosuria ◆ Mild proteinuria
Haematopoietic system	◆ Reduced haemoglobin and haematocrit ◆ Slightly elevated leucocyte and platelet count ◆ Increased fibrinogen and clotting factors ◆ **Reduced fibrinolytic activity**: increased clotting tendency

Gastrointestinal and metabolic systems

The combination of decreased lower oesophageal sphincter tone during pregnancy, increased intra-abdominal pressure, delayed gastric emptying, and reduced gastric pH in labour, result in elevated risk and severity of gastropulmonary reflux. Pregnancy is a hypermetabolic–hypercatabolic state. There is a dramatic increase in basal metabolic rate with profound increase in glucose utilization, and lesser increases in fat and protein metabolism. Pregnant women are hence relatively hypoglycaemic. However, a cohort of patients will develop insulin resistance/hyperinsulinaemia associated with the release of human placental lactogen, cortisol, and oestrogen, that may manifest as hyperglycaemia or gestational diabetes [4].

Renal function

Renal plasma flow and glomerular filtration rate begin to increase progressively during the first trimester. At term, both are 50–60% higher than in the non-pregnant state in parallel with increases in blood volume and cardiac output. There is elevation in creatinine clearance, and serum levels of urea and creatinine are reduced by 40%. Hence, increasing serum creatinine during pregnancy is abnormal, and poses considerable risk to maternal and fetal health [5]. The dramatic increase in renal blood flow and glomerular filtration may result in overspill glycosuria and proteinuria. The renal calyses and ureters become dilated and atonic as pregnancy progresses, resulting in increased risk of urinary tract infection.

Haematopoietic system

The haemoglobin and haematocrit fall, but total body haemoglobin is increased. This is important as significant maternal blood loss occurs at delivery; the additional volume in the circulation acts as a reserve buffer, while contraction of the uterus autotransfuses the mother. Pregnancy is a hypercoagulable state—there are dramatic increases in fibrinogen and factor VII, X and XII levels [6]. There is also an increase in the number of platelets and a reduction in fibrinolytic activity. During pregnancy neither clotting nor bleeding times are abnormal.

Implications for care of critically ill pregnant patient

Sepsis

While bacteraemia in pregnancy is relatively common—reportedly between 8 and 9% of pregnancies—progression to severe sepsis and septic shock is relatively rare, with rates of sepsis of between 1 in 7654 to 1 in 8338 deliveries reported [7]. Despite this, sepsis is a major cause of maternal death in the United Kingdom, where this is well studied, largely due to a substantial increase in deaths related to Group A streptococcal genital tract sepsis [8]. Obesity and operative vaginal or caesarean delivery appear to be major risk factors [8,9].

Pregnancy predisposes to four different septic complications:

- Pyelonephritis.
- Chorioamnionitis (including septic abortion).
- Endometritis (following Caesarean delivery).
- Pneumonia.

Pyelonephritis results from colonization of the kidney with Gram-negative bacteria secondary to loss of ureteral sphincter tone associated with progesterone. Pneumonia results, at least in part, from aspiration of gastric contents consequent of loss of lower oesophageal sphincter tone and diaphragmatic elevation. Chorioamnionitis results from alterations in the pH and increased glycogen content of the vagina, resulting in loss of the barrier for bacterial entry. Chorioamnionitis may complicate chorionic villus sampling, amniocentesis, or attempted instrumental (septic) abortion.

The clinical manifestations of sepsis during pregnancy are similar to that of the non-pregnant patient. However, these 'classic' signs may be obscured by the cardiovascular alterations of pregnancy. Sepsis may rapidly progress in the pregnant patient, resulting in coagulopathy, vasoplegia, and evolving multiple organ failure. Purpura fulminans may be associated with Group A Streptococcal infection [10]. Physicians must have a high index of suspicion

for sepsis in any peripartum patient that presents with fever and evidence of organ dysfunction—confusion, oliguria, tachycardia, etc. If goal-directed resuscitation is utilized one must be aware of physiological changes of pregnancy and adjust the goals of the resuscitation accordingly. For example, although central venous pressure remains essentially unchanged during pregnancy, SvO_2 progressively decreases in the later stages. Hence, achieving goals of 70–75% may not be possible—or necessary—in this setting.

Acute respiratory distress syndrome

The physiological changes of pregnancy may predispose to acute respiratory distress syndrome (ARDS) in a number of ways. The most probable cause of acute lung injury in the pregnant patient is infection, either pneumonia or secondary to chorioamneiitis, endometritis, septic abortion, or retained products of conception. Other causes include pre-eclampsia, obstetric haemorrhage, and pulmonary aspiration of gastric contents.

The respiratory system in advanced pregnancy has distinct features that must be considered. Functional residual capacity is decreased secondary to upward displacement of the diaphragm by the gravid uterus, increasing predisposition to hypoxaemia. Hypocapnia is universal, so that what appears to be a normal range $PaCO_2$ (40 mmHg) may actually reflect ventilatory compromise. Hypercapnia is probably tolerated by the fetus better than hypoxaemia. In general, a PaO_2 of >70 mmHg is required to ensure fetal well-being.

Pregnant females are generally excluded from ARDS clinical trials, such as the ARDS network tidal volume study [11], so data regarding management is limited. However, the use of therapeutic goals for the pregnant patient that are similar to those for the non-pregnant patient seems reasonable. Manoeuvres such as prone positioning is possible, but technically difficult to perform in the pregnant patient, could compromise fetal monitoring, and abdominal compression must be avoided to prevent further cephalad displacement of the diaphragm. Recent data, from pregnant patients with H1N1-induced ARDS, reports good overall outcomes, and demonstrated the utility of extracorporeal membrane oxygenation in this population [12].

Thromboembolic and immune-embolic (amniotic fluid or fat embolism) disease may manifest with acute hypoxic respiratory failure, although the pathophysiological changes and clinical history are distinct from classic ARDS.

Thromboembolic disease

Pregnancy is a hypercoagulable state. Pregnant females are at 10 times the risk of thromboembolic disease (TED) compared with non-pregnant women, with approximately one in four deaths associated with pregnancy resulting from pulmonary embolism (PE) syndrome. The risk of death in pregnant patients admitted to the intensive care unit with pulmonary embolism is 23.1% [13]. The risk of venous thromboembolism is roughly equal for each of the trimesters, and slightly elevated in the post-partum period. This is elevated by a factor of 5 if the patient has undergone Caesarean delivery. Multiparous women are at elevated risk, as are the obese, those with endometriosis, and patients with a history of thrombophlebitis or thromboembolism. One in six cases of thromboembolism in pregnancy have antiphospholipid syndrome, an inherited disorder with a 5% risk per patient irrespective of prophylactic measures [14]. Heparin remains the mainstay of treatment for TED in pregnancy, as it does not cross the placenta, while warfarin is teratogenic and should be avoided.

Pre-eclampsia and eclampsia

Pre-eclampsia (PET), a multisystem disease specific to pregnancy, is defined as hypertension and proteinuria appearing after the 20th week of gestation and resolving within 6 to 12 weeks of delivery [15]. It occurs in 2–3% of all pregnancies and is more common in primigravida or the first pregnancy with a particular partner. Other risk factors include a positive family history, pre-existing hypertension, diabetes mellitus, multiple pregnancies, and increasing maternal age and obesity.

Pre-eclampsia is a placental disease that commences early in pregnancy and may result from an autoimmune response of the mother to the placenta [15]. Functionally, the placenta becomes ischaemic secondary to hypoperfusion and hypoxia. Vasoactive substances released by the ischaemic placenta lead to widespread endothelial damage and profound vasospasm in a variety of different organ systems. As pregnancy progresses, the demands on the placenta increase and ischaemia worsens. The mother becomes absolutely and relatively hypovolaemic. Systemic vasoconstriction, hypertension, and renal dysfunction are seen. An imbalance between vasoconstrictive thromboxane and vasodilatory prostacyclin results in platelet dysfunction, activation of the coagulation system, endothelial damage, and further vasoconstriction.

Hypertension and proteinuria are the clinical manifestations of the disease. Late complications include pulmonary oedema, hypertensive encephalopathy, cerebral irritability and seizures (eclampsia). PET is associated with significant morbidity and, if undiagnosed or untreated, mortality, for the mother and fetus. Eclampsia is an extreme complication of PET that is defined by the occurrence of seizures in the absence of other neurological disorders. Treatment includes magnesium sulphate for the prevention of eclamptic seizures [16], and anti-hypertensives such as hydralazine and labetalol [15]. PET is abrogated by delivery of the fetus.

Trauma and cardiac arrest

Trauma is the most frequent non-obstetric cause of death in pregnancy [17]. The most common cause of injury from trauma is motor vehicle crash, followed by domestic violence, gunshot wound or stabbing, and traumatic brain injury from a variety of causes [18]. Regardless of the nature and extent of the injury, trauma is associated with elevated risk of foetal demise, usually secondary to placental abruption, preterm labour, or spontaneous abortion. With penetrating trauma, major bleeding is more likely in pregnancy, as are hepato-splenic injuries, with bowel injuries less common. Placental abruption most frequently occurs during deceleration events—the inelastic placenta shears off the uterus.

During resuscitation, it is essential to avoid aorto-caval compression and to be aware of the risk of gastropulmonary aspiration in advanced pregnancy. The patient should be placed with a 15° angle to the left and the head elevated. Traditional indicators of blood loss or fluid sequestration, such as base deficit, lactate, and haemoglobin concentration may be unreliable in pregnancy and may under-represent the danger to the mother and fetus. Foetal heart monitoring provides good information about both the volume status of the mother and the oxygen delivery to the fetus. Evidence of foetal distress should alert the multidisciplinary team to ongoing blood loss or missed maternal injury. The mother should undergo

pelvic examination for the presence of bleeding, evidence of placental abruption, and to determine the current condition of the cervix. Radiological examination is crucial to determine the extent and severity of injuries, and should not be withheld for fear of injuring the fetus. Uterine shielding should be employed where possible. The highest foetal risk is from the 8th to the 15th gestational weeks. However, exposure to less than 1 RAD of radiation is low risk. A plain X-ray requires 0.2 RAD, while a CT scan requires 0.5 RAD per slice. A test for Rhesus antigenicity (Kleihauer–Betke) should be performed. A Rhesus negative patient with a positive test should be given Rhesus immunoglobulin to prevent iso-immune injury [19].

If cardiac arrest occurs in the third trimester of pregnancy, cardiopulmonary resuscitation is difficult and often ineffective. Drugs and defibrillation regimens should follow standard advanced cardiac life support guidelines. Caesarean delivery within 4 minutes will enhance viability of the fetus, while increasing maternal blood volume and releasing of aorto–caval compression, enhances the likelihood of successful maternal resuscitation [20].

Conclusion

Pregnancy is associated with a variety of physiological changes that both elevate the risk of critical illness, and present the intensivist with challenges with regard to diagnosis and management. Two patients are being treated, but what is good for the mother will benefit the fetus. Diagnostic tests, goals, and interventions are similar to the non-pregnant patient with adjustments to standard strategies based on the physiological changes in pregnancy. Critical care interventions are similar to those for the non-pregnant patient; however, more stringent physiological targets for metabolic, pulmonary, and haemodynamic control may be necessary.

CHAPTER 366

Pathophysiology and management of pre-eclampsia, eclampsia, and HELLP syndrome

Muna Noori and Catherine Nelson-Piercy

Key points

- Severe, life-threatening, hypertension requires prompt, effective treatment, which should be reflected in local management protocols.
- Systolic hypertension greater than 150–160 mmHg demands urgent treatment, as it is associated with an increased risk of intracerebral haemorrhage.
- Syntocinon, rather than ergometrine should be used to actively manage the third stage of labour, as the latter drug may cause marked hypertension.
- Women with severe pre-eclampsia need effective multidisciplinary team care, with input from intensive care specialists where appropriate.
- Delivery is the definitive treatment for pre-eclampsia or eclampsia, but should only be undertaken once the maternal condition has been stabilized.

Introduction

Pre-eclampsia is a major, multisystem disorder of human pregnancy that poses a higher risk of future cardiovascular disease [1]. It affects approximately 2–4% of first-time pregnancies in North America, Europe, and Australia [2] and is characterized by new onset hypertension (>140/90 mmHg) and proteinuria (>300 mg/24 hours or a protein:creatinine ratio >30 mg/mmol) that typically develop after 20 weeks gestation [3]. Pre-eclampsia and eclampsia were the second most common causes of direct maternal death in the United Kingdom (UK) between 2006 and 2008, responsible for 19 deaths [4]. In the majority of cases, there was substandard care in the management of hypertension, particularly systolic hypertension [5].

Pre-eclampsia is a syndrome with multiple aetiologies, which poses a challenge in its prediction and in the development of preventative strategies. There are a number of pre-pregnancy risk factors that predispose women to developing pre-eclampsia, including nulliparity, maternal age >40 years, body mass index >35 kg/m^2, pregnancy interval >10 years, previous pregnancy complicated by pre-eclampsia, family history of pre-eclampsia, multiple pregnancies, and pre-existing medical disorders characterized by endothelial dysfunction, such as hypertension and diabetes.

Pathophysiology

Pre-eclampsia is regarded as a two-stage disorder. The first stage results from inadequate placental development early in pregnancy, whereas the second stage is the maternal response to inadequate placental invasion [6].

Healthy pregnancy requires remodelling of spiral arteries at the foeto–maternal interface to create high capacitance, low resistance vessels thereby maximizing blood flow to the growing fetus. In pre-eclampsia, remodelling is incomplete and spiral arteries remain tortuous, muscular, and narrow. The resulting placental hypoperfusion leads to hypoxia, ischaemia, oxidative stress, and widespread endothelial dysfunction [7].

Theoretical mechanisms of pre-eclampsia

Several mechanistic pathways have been shown to contribute to the evolution of pre-eclampsia, including the following.

Impaired nitric oxide synthase activity

The vasodilatation of healthy pregnancy is mediated by nitric oxide (NO), which is produced by conversion of maternal L-arginine to NO by nitric oxide synthase (NOS). Impaired NOS activity is likely to play a major role in the widespread endothelial dysfunction and vasoconstriction that characterizes pre-eclampsia [8].

Exaggerated inflammatory responses

Healthy pregnancy is associated with systemic inflammation which is exaggerated in pre-eclampsia [9].

Prostaglandin imbalances

In contrast to normal pregnancy, pre-eclampsia is associated with relative underproduction of prostacyclin (PGI_2) and overabundance of thromboxane A_2 (TxA_2) [10]. The imbalance between these opposing prostanoids formed the rationale for investigations of 'low dose aspirin' therapy for prevention of recurrent, severe, preterm pre-eclampsia [11].

Immune maladaptation

A strong risk factor for pre-eclampsia is nulliparity, which implies that a previous pregnancy confers some protection from developing the disease [7].

Genetic factors

Pre-eclampsia is more common in women with a family history of pre-eclampsia.

Angiogenic imbalance in the evolution of pre-eclampsia

Recently, the role of angiogenic factors in regulation of angiogenesis and evolution of pre-eclampsia has been highlighted [12]. Healthy pregnancy relies upon an intricate balance between pro-angiogenic factors, such as vascular endothelial growth factor (VEGF) and placental growth factor (PlGF), and anti-angiogenic factors that include soluble feline mcDonough sarcoma (FMS)-like tyrosine kinase-1 (sFlt-1, which binds PlGF) and soluble endoglin (sEng). Disturbance of this balance results in the development of pre-eclampsia (Fig. 366.1).

PlGF is expressed in highest quantities in healthy pregnancy and exerts its pro-angiogenic actions by binding to the membrane bound Flt-1 receptor. A soluble form of Flt-1 (sFlt-1) is released by an ischaemic placenta into the maternal bloodstream, where it binds circulating PlGF with high affinity and interferes with PlGF's actions (Fig. 366.1). Levels of PlGF are lower in women with pre-eclampsia whereas levels of sFlt-1 are elevated up to 5–10 weeks prior to its onset [12,13]. Measurement of the ratio of maternal sFlt-1 to PlGF in the first trimester may identify women, who later develop pre-eclampsia, and when measured later in pregnancy, can differentiate women at risk of pre-eclampsia from those who subsequently develop gestational hypertension [14]. Near-patient measurement of PlGF in women with suspected pre-eclampsia presenting before 35 weeks, has a high sensitivity and negative predictive value for pre-eclampsia within 14 days [15].

Endoglin, a cell surface co-receptor for transforming growth factor β1 and β3, regulates endothelial nitric oxide synthase (eNOS) activity and modulates vascular tone. A soluble form of endoglin (sEng) interferes with interactions between TGF-β1 and its receptor, resulting in hypertension and pre-eclampsia. Levels of sEng are elevated prior to onset of pre-eclampsia, and sEng works synergistically with sFlt-1 to cause severe hypertension, proteinuria, HELLP (**h**aemolysis, **e**levated **l**iver enzymes, **l**ow **p**latelets) syndrome and foetal growth restriction (FGR) [16].

Diagnosis

Pre-eclampsia is usually diagnosed through routine antenatal screening for hypertension and proteinuria. Definitions of hypertension are outlined in Box 366.1. Many women are asymptomatic at the time of diagnosis, whereas others develop symptomatic disease, with biochemical and haematological abnormalities including severe headache, visual disturbances, vomiting, liver tenderness, clonus (≥3 beats), papilloedema, HELLP syndrome, platelet count $<100 \times 10^9$/L or abnormal liver enzymes (ALT or AST above 70 IU/L), and acute kidney injury (AKI). Furthermore, a diagnosis of FGR may precede the onset of the maternal syndrome.

Investigations

Disease severity and progression can be monitored with the following:

- Regular assessment of haemoglobin, platelet count, liver function, renal function, and electrolytes.
- Clotting studies if pre-eclampsia is severe or thrombocytopenia is diagnosed.
- Regular urinalysis to assess for proteinuria. If >1+ is detected, a urine protein:creatinine ratio should be measured, or less commonly, a 24-hour urine collection.
- Foetal monitoring to assess growth, amniotic fluid volume and fetal Doppler.

Treatment of hypertension

Hypertension greater than 150/100 mmHg requires treatment in accordance with recent guidelines from the National Institute of Clinical Excellence (NICE), irrespective of whether or not it is

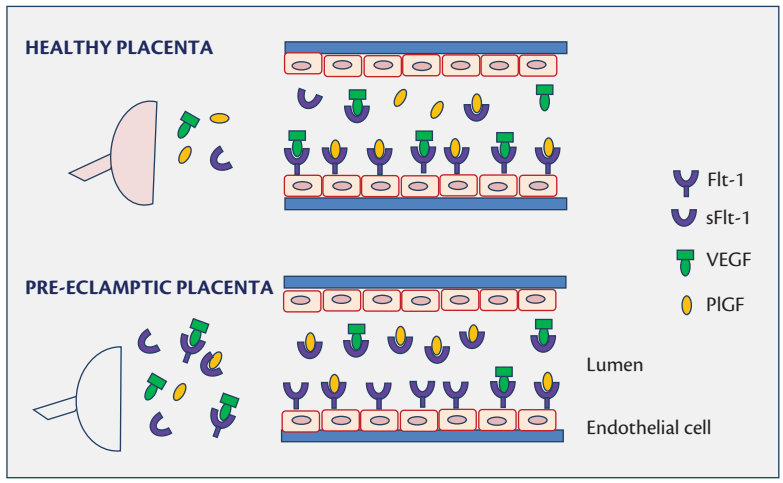

Fig. 366.1 Proposed mechanism of endothelial dysfunction in pre-eclampsia. Soluble Flt-1 binds circulating VEGF and PlGF and antagonizes their pro-angiogenic effects on endothelial cells. In healthy pregnancy, small amounts of VEGF, PlGF, and sFlt-1 are produced. In pre-eclampsia, excessive sFlt-1 binds circulating VEGF and PlGF, and prevents their interaction with endothelial cell-bound Flt-1 receptors. This results in endothelial dysfunction, reduced nitric oxide production, decreased prostacyclin, and the release of procoagulant proteins.

Box 366.1 Definitions of hypertension in pregnancy

- **Chronic hypertension**: hypertension that is present at the booking visit or before 20 weeks or if the woman is already taking antihypertensive medication when referred to maternity services. It can be primary or secondary in aetiology.
- **Gestational hypertension**: new hypertension presenting after 20 weeks without significant proteinuria.
- **Mild hypertension**: diastolic blood pressure 90–99 mmHg; systolic blood pressure 140–149 mmHg.
- **Moderate hypertension**: diastolic blood pressure 100–109 mmHg; systolic blood pressure 150–159 mmHg.
- **Severe hypertension**: diastolic blood pressure 110 mmHg or greater; systolic blood pressure 160 mmHg or greater.
- **Pre-eclampsia**: new hypertension presenting after 20 weeks with significant proteinuria.
- **Severe pre-eclampsia**: pre-eclampsia with severe hypertension and/or with symptoms, and/or biochemical and/or haematological impairment.
- **Significant proteinuria**: greater than 300 mg/24 hours or >30 mg/mmol.

diagnosed in the context of pre-eclampsia. Blood pressure below this threshold requires monitoring, rather than treatment as a diastolic blood pressure much below 80 mmHg may have a negative impact on foetal blood supply [17].

Oral labetalol, the current anti-hypertensive agent of choice, should be commenced when moderate hypertension is diagnosed. Methyldopa and/or oral nifedipine can be used in conjunction with labetalol if monotherapy is ineffective.

Pre-eclampsia: spectrum of disease

Clinical manifestations of severe pre-eclampsia include eclampsia, HELLP syndrome, disseminated intravascular coagulopathy (DIC), cerebrovascular haemorrhages, hepatocellular damage, pulmonary oedema, and adult respiratory distress syndrome (ARDS). Foetal consequences include FGR, foetal distress, placental abruption, and foetal death *in utero*.

Eclampsia

Eclampsia complicates 1% of cases of pre-eclampsia with a UK incidence of 2.7/10,000 maternities [17]. Tonic–clonic seizures are followed by a post-ictal phase. Convulsions may occur antepartum (45%), intrapartum (19%), or post-partum (36%), and arise following localized cerebral vasoconstriction and hypoxia, and are often preceded by hyperreflexia and headache. Eclampsia may be complicated by ischaemic or haemorrhagic stroke with cerebral vasospasm or oedema, or more rarely, by cortical blindness or PRES (posterior reversible encephalopathy syndrome).

Management of eclampsia

The patient should be protected from physical injury during the tonic–clonic phase, with attention to the airway. Although maternal hypoxia during the seizure may result in foetal bradycardia, the mother must be stabilized prior to delivery of the fetus.

The use of intravenous magnesium sulphate should be considered in severe hypertension or severe pre-eclampsia and should be given following an eclamptic seizure, as it reduces the likelihood of recurrent seizures [19]. Diazepam and phenytoin are not recommended to treat eclampsia [17].

Magnesium sulphate is administered as an intravenous loading dose of 4 g followed by an infusion of 1 g/hour maintained for 24 hours. Recurrent seizures should be treated with a further dose of 2–4 g. Lower maintenance doses may be required in AKI to prevent magnesium toxicity, which is characterized by loss of deep tendon reflexes when levels exceed 5 mmol/L, or respiratory depression and arrest at higher concentrations. Deep tendon reflexes and oxygen saturations should therefore be checked hourly to alert staff to possible toxicity, which can be reversed by intravenous calcium gluconate.

HELLP syndrome

HELLP syndrome develops in 5–20% of cases of pre-eclampsia, although milder presentations involving hepatic enzyme derangements and thrombocytopenia, without haemolysis, are more frequent. Features include liver tenderness, vomiting, hypertension, AKI, acidosis, or placental abruption. The pathophysiology of HELLP syndrome is unclear, but is characterized by endothelial cell injury, micro-angiopathic platelet activation and, in 20% of cases, a consumptive coagulopathy. Differential diagnoses to consider include acute fatty liver of pregnancy (AFLP) or haemolytic uraemic syndrome (HUS)/thrombotic thrombocytopenic purpura (TTP).

Management of HELLP syndrome

Delivery must be expedited once maternal blood pressure is stabilized. Fresh frozen plasma can be used to correct coagulopathy, while platelet transfusions are reserved for cases that involve active bleeding or to 'cover' surgery. Although corticosteroids given to promote foetal lung maturation prior to preterm delivery transiently improve both haematological and hepatic abnormalities in HELLP syndrome, treatment with steroids for maternal reasons is not advocated. Post-partum, HELLP syndrome usually improves, although it may develop for the first time in 30% of cases.

Management of severe hypertension or pre-eclampsia in a critical care setting

Women with severe hypertension or severe pre-eclampsia should be assessed for referral to the appropriate critical care setting using the criteria outlined in Table 366.1.

Severe hypertension should be treated immediately with one of the following, in accordance with local management protocols.

Intravenous labetalol

Intravenous labetalol given as intermittent boluses followed by an infusion once acute blood pressure control has been achieved.

Intravenous hydralazine

Intravenous hydralazine given by intermittent bolus followed by a maintenance infusion once blood pressure control is achieved. Hydralazine is a vasodilator that can cause tachycardia and headache. If hydralazine is administered intrapartum, preloading with

Table 366.1 Assessment of severity of pre-eclampsia in determining level of critical care required

Level 1	Level 2	Level 3
Pre-eclampsia with mild or moderate hypertension	Stepping down from level 3 or up from level 1	Severe pre-eclampsia
Ongoing conservative antenatal management of severe preterm hypertension	Eclampsia	Ventilatory support required
Step-down treatment following delivery	HELLP syndrome	
	Haemorrhage	
	Hyperkalaemia	
	Severe oliguria	
	Coagulation support	
	Intravenous antihypertensive treatment	
	Initial stabilization of severe hypertension	
	Evidence of cardiac failure/pulmonary oedema	
	Abnormal neurology	

Reproduced from NICE CG107 Hypertension in pregnancy: The management of hypertensive disorders during pregnancy, NICE 2010 (https://www.nice.org.uk/guidance/cg107), originally adapted from the Guideline Development Group from Intensive Care Society, Standards and Guidelines 2002, with permission.

up to 500 mL crystalloid fluid at the time of the first dose should be considered to reduce the risk of profound hypotension, and consequent placental hypoperfusion and foetal distress.

Oral nifedipine

Concurrent use of nifedipine and magnesium sulphate therapy for seizure prophylaxis can cause severe hypotension so must be used with caution. Sublingual nifedipine causes too rapid a fall in blood pressure resulting in placental hypoperfusion and should not be used.

Fluid balance

Volume expansion in women with severe pre-eclampsia may result in pulmonary oedema and should be avoided, including prior to regional anaesthesia. Fluid restriction should be continued intrapartum and post-partum unless there are other ongoing fluid losses, such as haemorrhage.

Oliguria is a common feature of pre-eclampsia, particularly with concurrent use of Syntocinon due to its anti-diuretic effect, and usually does not require treatment. Syntocinon may be administered in a concentrated form via syringe driver, to minimize the volume of fluid being given. Diuretic use should be reserved for cases complicated by pulmonary oedema.

Timing of delivery

Mild and moderate pre-eclampsia can be managed conservatively, particularly prior to 34 weeks, to minimize complications of prematurity. However, in the context of worsening pre-eclampsia or severe hypertension refractory to treatment, delivery should be expedited. Where delivery is planned prior to 36 weeks gestation, corticosteroids should be given to promote foetal lung maturation. A management plan should be agreed by the obstetrician, anaesthetist, and neonatologist.

A diagnosis of severe pre-eclampsia does not preclude induction of labour, although clinical deterioration of the mother or foetal compromise may necessitate urgent delivery by Caesarean section. Although the second stage of labour does not routinely need to be limited in women with stable pre-eclampsia, operative vaginal delivery is advocated if hypertension is uncontrolled.

Post-partum care

Although delivery addresses the underlying cause of pre-eclampsia by removing the placenta, pre-eclampsia may deteriorate post-partum or may develop for the first time after delivery. Women with severe hypertension or pre-eclampsia therefore require intensive monitoring in a critical care setting following delivery, with close attention to blood pressure, fluid balance, haematology, and biochemistry.

Conclusion

Pre-eclampsia is unpredictable and is a leading cause of maternal and fetal morbidity and mortality in the UK and worldwide. The 2006–2008 UK Confidential Enquiry into Maternal Deaths highlighted the largely avoidable causes for maternal deaths from pre-eclampsia, which included poor diagnosis, failure to appreciate the relevance and significance of new onset hypertension and proteinuria, and suboptimal treatment of systolic hypertension. Frontline healthcare professionals need regular training updates in the emergency care of women with pre-eclampsia. Furthermore, this high risk patient group requires multidisciplinary team input, with senior involvement.

CHAPTER 367

Obstetric Disorders in the ICU

Andrew Levinson and Ghada Bourjeily

Key points

- Venous thromboembolism, post-partum haemorrhage, amniotic fluid embolism, ovarian hyperstimulation syndrome, and obstetric sepsis are rare, but clinically significant complications of pregnancy.
- Knowledge of the physiological changes that occur in pregnancy is crucial when caring for women who are pregnant or immediately post-partum.
- Successful treatment of major obstetrical haemorrhage must focus on identifying and alleviating the cause of major bleeding, resuscitation, and reversal of the coagulopathy.
- When diagnosing pulmonary embolism (PE) in pregnancy, it is imperative to remember that the risk of undiagnosed and untreated PE outweighs the potential fetal oncogenic and teratogenic risk.
- Sepsis remains an important cause of maternal morbidity and mortality. Early recognition and intervention of pregnancy-related sepsis is essential.

Introduction

Critical illness in pregnancy is a rare, but potentially catastrophic event for the mother and fetus. Treatments of critically-ill pregnant patients must take into account the physiological changes in pregnancy and focus on stabilizing the pregnant woman.

Only 1% of all obstetric patients in industrialized countries are admitted to intensive care units (ICU). However, once in the ICU, the mortality of these patients can be high, with current estimates of from 12% to 20%. Acute respiratory distress syndrome (ARDS) remains the leading cause of mortality in pregnant women in the ICU [1]. Disorders specifically related to pregnancy account for 55–80% of admissions of pregnant women to the ICU [2].

In caring for critically-ill pregnant women, it is important to understand the normal physiological changes in pregnancy (Table 367.1). Vital signs that may be interpreted as abnormal, in fact, can be part of the patient's normal physiological response to changes in pregnancy.

Obstetrical haemorrhage

Epidemiology

Severe haemorrhage in both the antepartum and immediate post-partum period is one of the most common obstetric admissions to the ICU. Haemorrhage is also the most common cause of maternal mortality in both the developing world and in industrialized nations [3]. Recent studies suggest that a large percentage of maternal deaths due to obstetrical haemorrhage are preventable if the care provided is more timely and follows best practices.

Pathophysiology

Recognition and management of obstetrical haemorrhage is complicated by the fact that 300–500 cm^3 of blood loss is not uncommon in normal delivery. Tachycardia may be the only initial presenting symptom as patients may not become hypotensive until one-half of blood volume has been lost. Aorto–caval compression by the gravid uterus can also accentuate haemodynamic instability.

Causes of antepartum haemorrhage include placental anatomic abnormalities, uterine rupture, and atony, as well as trauma to the uterus or the lower genital tract and retained products of conception. Risk factors for haemorrhage include obesity, chorioamnionitis, prior caesarean delivery and previous history of post-partum haemorrhage. Coagulopathies can be both a primary impetus or a resulting complication of major obstetrical haemorrhage [4].

Treatment

Successful treatment of major obstetrical haemorrhage requires a coordinated rapid response by all members of the care team (Box 367.1). Effective treatment must focus on identifying and alleviating the cause of major bleeding, resuscitation, and reversal of the coagulopathy. Treatment efforts should focus on obtaining large-bore peripheral intravenous (iv) access and resuscitation to maintain effective circulation and oxygen delivery. If haemorrhage continues, treatment includes administration of prostaglandins, balloon tamponade or packing of the uterus, central venous and arterial access, and the transfusion of red blood cells (RBC), platelets, and fresh frozen plasma (FFP). If bleeding does not respond to medical treatments, interventions to mechanically stop bleeding, such as uterine artery ligation, embolization, or uterine compression sutures are recommended as potential next steps. Studies suggest that there is little evidence that any one measure is superior to another, therefore, management should be based on availability and local expertise. If these measures fail or the patient becomes unstable, emergent hysterectomy becomes inevitable.

Massive transfusion protocols may prevent the unnecessary delay in the administration of life-saving blood products. There is poor quality evidence to support one specific ratio of RBCs, plasma and/or cryoprecipitate, and platelets in massive

Table 367.1 Physiological changes in pregnancy

Cardiac changes	**Change**	**Normal range in pregnancy**
Blood pressure	↓	10–15 mmHg decrease in first 2 trimesters
Blood volume	↑	30–50% increase
Cardiac output	↑↑	5–7 L/m^2/min (40% increase)
Central venous pressure	↔	<13 mmHg
Colloid oncotic pressure	↓	10–15% decrease
Ejection fraction	↔	70%
Heart rate	↑	Increases by 10–20 bpm
Pulmonary artery pressure	↔	≤25 mmHg
Pulmonary capillary wedge pressure	↔	<13 mmHg
Stroke volume	↑	70–100 mL/beat
Systemic vascular resistance	↓	25–30% decrease
Respiratory changes		
ABG's		
pH	↑	Mild respiratory alkalosis
PaO_2	↑	Average 100–105
$PaCO_2$	↓	28–32 mmHg
HCO_3	↓	18–22 mEq/L
A–a gradient	↑	Increase in late gestation to approximately 20 weeks
Oxygen consumption	↑	20% Increase, further increase during labour and delivery
Minute ventilation	↑	50% increase
Respiratory rate	↔	No change
Tidal volume	↑	40–50% increase
Total lung capacity	↓	4–5% decrease
Functional residual capacity	↓	20% decrease by term
Residual volume	↓	
Vital capacity	↔	
Diffusion capacity	↔	Minimal change
Forced expiratory volume in 1 second	↔	
Peak expiratory flow rate	↔	
Haematological changes		
Anti-Xa assay (heparin)	↔	Levels likely drop around mid-gestation
Clotting factors	Most ↑	
Fibrinogen	↑↑	500–600 mg/dL
Hb (haemoglobin)	↓	10–13 g/dL
Platelet count	Gradual ↓ to term	150,000–200,000
PT, PTT, NR	↔	
RBC mass	↑	20%
WBC	↑	10,000–16,000/mm^3

↑ Increase; ↓ decrease; ↔ no change.

Box 367.1 Management caveats

Management team

Intensivist, anaesthesiologist, obstetrician, obstetric internist, neonatologist.

Airway intubation

- Airway assessment even in urgent intubations.
- Difficult airway cart readily available including laryngeal mask airway.

Airway management

- **Avoid aspiration**: elevate head of bed, cricoid pressure, consider bicitra.
- **Lower dose of sedatives/anaesthetics**: hypoxaemia and hypercapnia occur faster in pregnancy.
- **Pre-oxygenate**: manual ventilation may increase risk of aspiration.
- Smaller endotracheal tube size may be necessary.
- Intubation to be performed by the most experienced provider.
- CXR for tube placement with abdominal shield.

Haemodynamics

- **Echocardiography:**
  - Systolic and diastolic dimensions slightly increased.
  - Systolic function slightly increased.
  - Moderate increase in the size of the right chambers and the left atrium.
  - Progressive dilation of pulmonary, tricuspid, and mitral valve annuli.
  - Some degree of pulmonary, tricuspid, and mitral regurgitation.
- **CVP, PAOP**: unchanged; CVP may not correlate with PAOP in pre-eclampsia.

Pharmacokinetics

- Volume of distribution.
- Hepatic clearance.
- Renal clearance.
- No clear recommendations for weight-based dosing.

Resuscitation

- **Airway:**
  - Early intubation.
  - Cricoid pressure until intubation achieved.
- **Breathing**: 100% oxygen.
- **Circulation**: Manual leftward displacement of the uterus.
- **Defibrillation**:
  - Standard ACLS protocol.
  - Ensure removal of fetal monitors.
- **Drugs:**
  - Standard ACLS doses; may need to increase dose of vasopressin.
  - Caution with sodium bicarbonate (may not transfer through placenta readily).
  - Caution with alpha-adrenergic agents (effect on placental perfusion); alpha adrenergic agents use is justified in these circumstances.
- **Delivery:**
  - Initiate peri-mortem delivery if resuscitation unsuccessful.
  - Alert appropriate neonatologist and obstetrician as soon as cardiac arrest occurs.

transfusion, although current clinical practice in trauma patients seems to favour closer to a 1:1:1 ratio [5]. While there are no randomized data to support its use, recombinant factor VIIa has been reported to stop bleeding in women with refractory obstetrical haemorrhage.

Pulmonary embolism

Epidemiology

Venous thromboembolism (VTE) is a common and potentially fatal complication of pregnancy. In the United States the incidence of VTE is 0.6–2 per 1000 pregnancies and the maternal mortality is 1.1 per 100,000 deliveries, making VTE one of the leading causes of maternal mortality. Deep venous thrombosis (DVT) is by far the most common form of VTE in pregnancy [6] and occurs predominantly on the left side.

Pathophysiology

During pregnancy, all Virchow's triad elements are accentuated, including venous stasis, vascular injury, and hypercoagulability. Venous stasis is caused both by hormonal factors and mechanical compression by the growing uterus of the pelvic vessels. Vascular injury can occur with any type of delivery. Hypercoagulability in pregnancy is due to increased levels of procoagulant factors, decreased fibrinolysis, and anticoagulant activity [7].

Diagnosis

When choosing the right diagnostic test, it is imperative to remember that the risk of undiagnosed and untreated PE outweighs the potential fetal oncogenic and teratogenic risk [7]. False-negative results may result in missed diagnosis and high mortality. False positive findings may result in complicated labour plans, unnecessary anticoagulation, and limited contraceptive options.

Approaches to the diagnostic management of suspected PE in pregnancy have not been validated and remain controversial. Current guidelines are based on very low quality clinical evidence [8]. Clinical decision tools and D-dimers have not been validated in pregnancy.

In patients with leg symptoms, compression ultrasonography (CUS) can be done first. Although CUS circumvents the use of radiation, it has low yield in patients without leg symptoms suspected of PE outside pregnancy. Given the higher prevalence of isolated pelvic DVT in pregnancy, the yield of CUS is even lower.

In patients without leg symptoms, current guidelines recommend that chest radiograph (CXR) should be obtained first. If CXR is normal, half-dose perfusion scintigraphy exposes the breasts to less radiation than multidetector computed tomography-pulmonary angiogram (MDCT-PA), and usually shows a high proportion of normal and near normal scans in pregnancy. Ventilation scans are needed only if perfusion scan shows segmental defects (Fig. 367.1). Drawbacks of this approach are the inability to make an alternative diagnosis, the slightly higher, although acceptable, fetal radiation compared with MDCT-PA, and the lack of clinical pretest probability tools to aid in interpreting the findings. In patients with abnormal CXR, ATS guidelines [8] recommend obtaining MDCT-PA. Breast radiation exposure incurred by MDCT-PA can be reduced with breast shields by 30–50% without affecting image resolution. In haemodynamically-unstable pregnant patients, we recommend proceeding directly to MDCT-PA as the first test, as it is fast, can determine clot burden, and rule out other life-threatening diagnoses that can mimic PE such as dissection.

Management

There is a paucity of studies looking at the efficacy of treatments for VTE in pregnancy. Treatment is generally unchanged compared with the non- pregnant population and includes low molecular weight heparin (LMWH), unfractionated heparin (UFH) or thrombolysis, and in rare cases inferior vena cava (IVC) filter placement [9]. LMWH is the preferred therapy. Although pregnancy-specific complications have been described in case studies and small series with thrombolytics, clinicians should not hesitate to use these drugs in pregnancy in conditions associated with high mortality, such as PE with haemodynamic instability or refractory hypoxaemia. Temporary IVC filters can be placed in pregnancy. Labour and delivery should be planned carefully and anticoagulation withheld prior to planned induction of labour depending on the risk of VTE recurrence, the risk of bleeding, and the need for regional anaesthesia [6].

Pregnancy-related infections

Common obstetric infections include endometritis, chorioamnionitis, septic abortion, septic thrombophlebitis, and wound infections. Chorioamnionitis is the infection of the chorioamniotic membranes and the amniotic fluid. Endometritis and wound infections are complications of caesarean deliveries and are likely under-reported. Septic abortion is associated with short-term mortality and morbidity, and long-term complications. The incidence of ICU admissions due to septic abortion has steadily declined since the legalization of abortion in many industrialized countries. Septic thrombophlebitis is in the differential diagnosis of peripartum patients with a fever and is usually treated with anticoagulation, although its clinical significance is controversial. Mastitis is a common infectious complication seen in post-partum women, but is rarely the source of serious complications.

Epidemiology

Sepsis remains an important cause of maternal morbidity and mortality. Morbidity from sepsis occurs in 0.1–0.6 per 1000 pregnancies [10]. In industrialized countries, 2.1% of maternal deaths are estimated to be due to severe sepsis or septic shock. In recent years, the percentage of admissions for maternal sepsis due to non-bacterial maternal infections and antepartum pelvic infections has significantly increased. Obesity, maternal age less than 25, and caesarean section have been identified as risk factors for obstetric sepsis.

Pathophysiology

Physiological changes during pregnancy, including peripheral vasodilatation and tachycardia, may delay the recognition of sepsis in pregnant women. Despite these physiological changes, gravidas likely have a more favourable outcome of sepsis than their non-pregnant counterparts because they are younger, have fewer co-morbidities, and rarely harbour resistant organisms.

Diagnosis and management

Pregnant women are routinely excluded from clinical trials, including those in sepsis. As a result, there is little randomized clinical data to support specific treatments. It is standard practice to follow international guidelines for treatment of severe sepsis and septic shock, such as early-goal directed therapy for rapid fluid resuscitation, with a few caveats. Systolic blood pressure of <90 mmHg is not an uncommon finding in a normal pregnancy due to the reduction in systemic vascular resistance. Studies of haemodynamic changes of pre-eclampsia suggest that CVP may not consistently correlate with pulmonary artery occlusion pressures. However, CVP likely remains the best available approach to assessing intravascular volume. It is unclear whether colloid infusions are superior to crystalloids. It is likely that all vasopressors reduce placental perfusion. The most common organisms isolated in maternal infections are *E. coli*, Enterococci, and β-haemolytic streptococci. Dosing of antibiotics should take into consideration pregnancy pharmacokinetics (Box 367.1). Drugs with a better fetal safety profile should be used when possible. Adequate source control is the key to successful management. Ultrasound can be useful in identifying pelvic sources of infection.

Amniotic fluid embolism

Amniotic fluid embolism (AFE), also known as anaphalactoid syndrome of pregnancy, is an uncommon, but potentially catastrophic complication occurring in labour or the immediate post-partum period. It is characterized by severe cardiopulmonary collapse and subsequent multi-organ dysfunction.

Epidemiology

Current estimates of the incidence of AFE in industrialized countries range from 1.9 to 6.1 cases per 100,000 births, with mortality rates of 20–90%. Proposed risk factors for AFE include advanced maternal age, placental pathologies, complicated labour and delivery, obstetric interventions, uterine trauma, and fetal distress. Whether induction of labour increases the risk of AFE remains controversial [11].

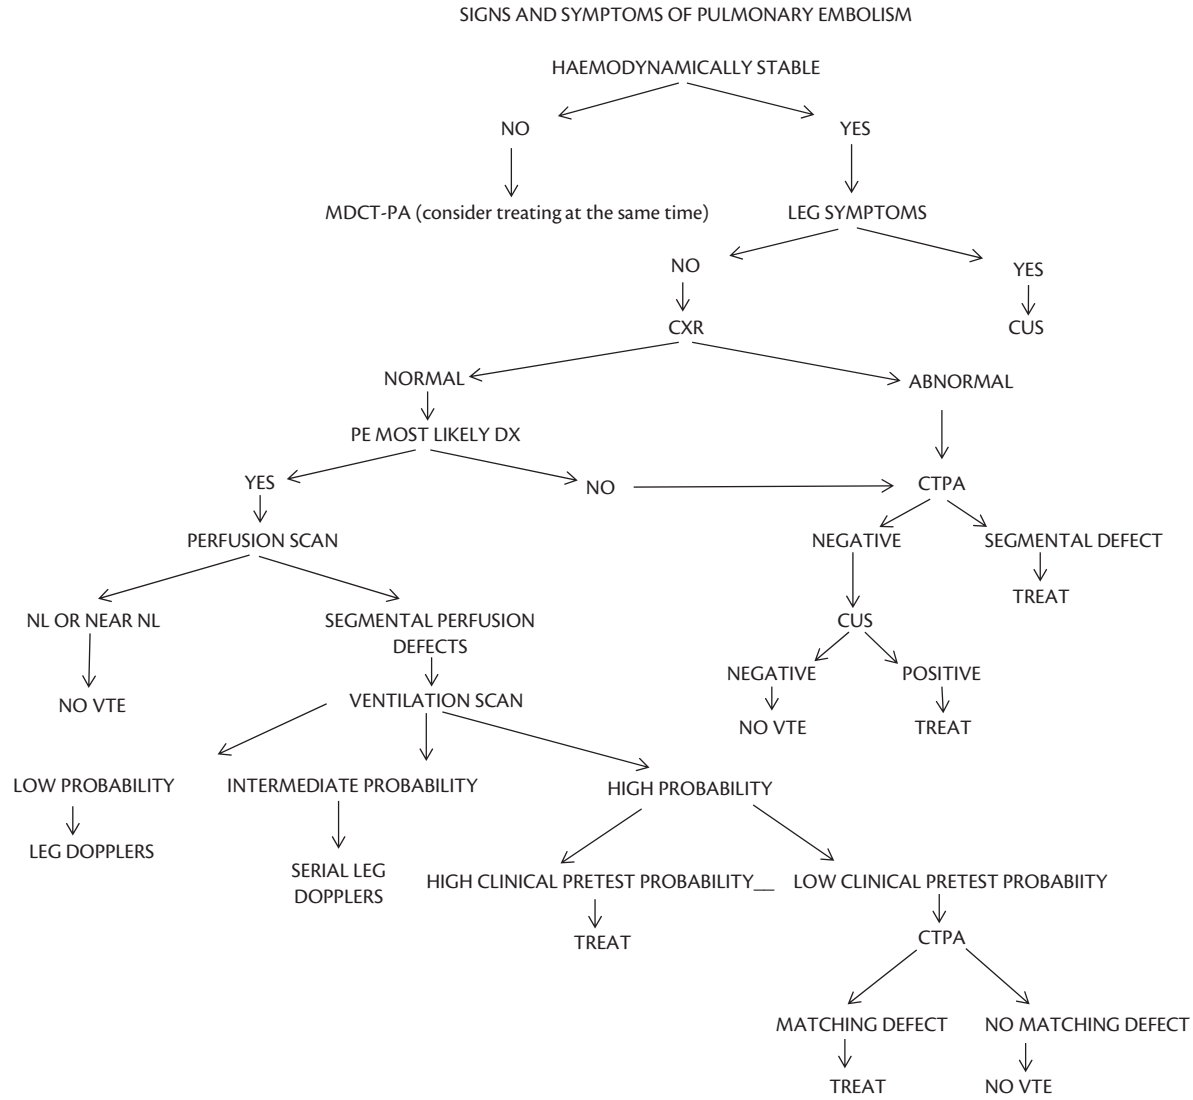

Fig. 367.1 Proposed algorithm for the work-up of pulmonary embolism in pregnancy.
CUS, compression ultrasounds; MDCT-PA, multidetector computed tomography pulmonary angiogram; VTE, venous thromboembolism; PE, pulmonary embolism; NL, normal; CXR, Chest radiograph.

Pathophysiology

The pathogenesis of AFE is poorly understood. Animal studies suggest that amniotic fluid entering the maternal systemic circulation leads to the obstruction or vasospasm of the pulmonary vasculature, and results in cardiopulmonary collapse. Subsequent investigations suggested that elevated pulmonary pressures may, in fact, be secondary to left ventricular dysfunction. A hypothetical biphasic course is proposed where the initial phase of acute pulmonary hypertension and ventricular failure are followed by left ventricular dysfunction. An immunological or inflammatory response to amniotic fluid is another suggested mechanism [12].

Clinical diagnosis

AFE is a clinical diagnosis characterized by the sudden onset of haemodynamic instability, respiratory failure (cardiogenic or non-cardiogenic pulmonary oedema), disseminated intravascular coagulation (DIC), coagulopoathy, encephalopathy, and seizures. In pregnant women with sudden cardiopulmonary collapse, other potential causes such as PE, septic shock, heart failure, and major obstetrical haemorrhage should also be considered. The detection of fetal squamous cells in the pulmonary vasculature has been reported in asymptomatic women at term and is not a specific finding. There is little data to support the use of laboratory testing to establish the diagnosis of AFE.

Management of complications

Treatment of AFE should focus on supportive care and correcting haemodynamic instability. High flow oxygen or mechanical ventilation are usually needed. Hypotension should be rapidly reversed with initial aggressive fluid resuscitation followed by vasopressors. Central venous access and arterial access should be obtained if the patient remains haemodynamically unstable after fluid resuscitation. In refractory shock, invasive or non-invasive means of measuring cardiac output should be considered.

Caesarean should be considered in the case of severe shock with the hope of improving both maternal and fetal outcome [13]. Massive bleeding, coagulopathy, and subsequent DIC should be treated similarly to massive obstetrical haemorrhage. The use of recombinant factor VII has been described in the literature, but caution is advised as one review suggests worse outcomes when it is administered [14]. Experimental treatment with inhaled nitric oxide and other pulmonary vasodilators, exchange transfusion, extracorporeal membrane oxygenation (ECMO), and continuous veno-venous haemofiltration (CVVH) have been described in small series and case reports [15,16], but there is little evidence to support their use routinely.

Ovarian hyperstimulation syndrome

Severe ovarian hyperstimulation syndrome (OHSS) is a rare iatrogenic complication of the administration of exogenous gonadotropins in an effort to induce ovulation during assisted reproduction (ART). In the mild and moderate stages, women undergoing ART present with abdominal bloating, mild abdominal pain, nausea and vomiting, small ascites, and mildly enlarged ovaries. All of these signs and symptoms are often self-limiting and managed as an outpatient. In the severe stages, however, massive ovaries, large volume ascites, symptomatic pleural effusions, oliguria, haemoconcentration, and thromboembolism can be life-threatening and require close monitoring in a critical care setting.

Epidemiology

The incidence of moderate OHSS is 3–6% and 0.1–2% for severe OHSS. Risk factors for OHSS include age greater than 30, very high serum oestradiol, multiple ovarian follicles, and pregnancy [17].

Pathophysiology

The pathogenesis of OHSS remains incompletely understood. Oestradiol levels are often elevated, but not currently thought to have a primary role in the pathogenesis, although high levels may be associated with disease severity. Patients are at increased risk of worsening complications if they are newly pregnant because rising levels of endogenous human chorionic gonadotropic hormone may further worsen ovarian hyperstimulation.

Current research suggests that vascular endothelial growth factor (VEGF) plays a major role in the pathogenesis of OHSS by increasing vascular permeability. Other factors, such as angiotensin-II and insulin-like growth factor are thought to also work to increase vascular permeability, leading to the loss of albumin from the intravascular space and the subsequent development of electrolyte imbalances. Ultimately decreased oncotic pressure causes the rapid accumulation of abdominal ascites and pleural effusions. Massive ascites can lead to intra-abdominal hypertension and eventually abdominal compartment syndrome, further worsening organ dysfunction [18]. Patients with OHSS are at elevated risk for VTE, likely due to hormonal influences. These patients have a higher prevalence of upper extremity DVT.

Diagnosis

OHSS is a clinical diagnosis and should include a recent history of ovarian stimulation, and ovulation or exogenous gonadotropin administration. In very rare cases, OHSS can occur spontaneously. Alternative diagnoses such as ovarian torsion and other ovarian pathology, acute appendicitis, and infectious aetiologies should be excluded.

Treatment

There is little evidence to support current treatments for OHSS. Patients with mild and moderate OHSS should have monitoring for weight gain, fluid accumulation, and hepatic and renal function. Patients with severe symptoms of OHSS should receive iv fluid resuscitation to expand intravascular volume, monitoring for worsening intra-abdominal hypertension. Large volume paracenteses may be needed to alleviate symptoms with the goal of improving renal perfusion by decreasing abdominal hypertension. If dyspnoea and large pleural effusions do not improve with paracentesis, therapeutic thoracentesis may be needed. Thromboprophylaxis with UFH or LMWH should be initiated due to the very high incidence of thromboembolic complications.

Conclusion

Specific disorders related to pregnancy account for the vast majority of ICU admissions for pregnant women. Knowledge of the physiological changes that occur in pregnancy is extremely important. A thorough understanding of the effective management practices for the most common obstetrical reasons for ICU admission is essential for providing effective critical care to women in the antepartum and immediate post-partum period.

SECTION 20

Specialized intensive care

PART 20.1

Specialized surgical intensive care

CHAPTER 368

Intensive care management after cardiothoracic surgery

Matthew Barnard and Nicola Jones

Key points

- Monitoring and maintaining organ perfusion and cardiac output are as important to survival after cardiac surgery as in all general intensive care patients.
- Cardiac tamponade is common and easily missed. Diagnosis should not be delayed for diastolic collapse.
- Atrial fibrillation is very common after cardiac surgery (30%). Ventricular arrhythmias are uncommon and should raise suspicion of coronary graft compromise.
- Restriction of intravenous fluids and peri-operative protective ventilatory strategies can improve outcome after thoracic surgery.
- Prompt attention to atelectasis, infection, and air leak after thoracic surgery will improve outcome.

Cardiac surgery

Cardiovascular disease has declined over the last 20 years in most developed countries but still accounts for 30% of deaths [1]. Despite substantial changes in patient demographics, altered disease patterns, and novel technological developments, models of future activity suggest that demand for cardiac surgery will continue [2]. Few believe that coronary artery bypass graft (CABG) surgery will be completely eliminated in the next 10–15 years, but models incorporating such a scenario predict that surgery will be sustained due to an ageing population, and a 25% overall increase in valve and non-CABG surgery. Despite a demographic shift towards older and sicker patients, operative mortality has been reduced. The principles of general critical care apply to cardiac surgical patients.

Cardiovascular management

Ischaemia

All cardiac surgical patients are monitored for ischaemia with 5-lead ECG ST analysis confering greater specificity than sensitivity. Troponin levels following cardiac surgery are difficult to interpret. Reference ranges are not well established and troponin-I levels increase significantly in the first 48 hours post-operatively above current diagnostic levels for acute coronary syndromes including patients who have not had myocardial infarction [3]. Diagnostic criteria for ischaemia include clinical symptoms, ECG changes, and echocardiography. New echocardiographic regional wall abnormalities developing since completion of surgery are suspicious of ischaemia. However, wall motion abnormalities also occur in stunning, hibernation, and infarction.

Treatment is with standard therapies including antiplatelet medication, intravenous nitrates and anti-anginal medication. Early consultation with cardiologists and repeat angiography are important if ECG or echo changes are significant or persist beyond 2–3 hours.

Ventricular dysfunction

Impaired left and right ventricular function can be due to pre-existing impairment, aortic cross-clamping with insufficient myocardial protection or peri-operative infarction. Clinical manifestations of reduced cardiac output require assessment of ventricular filling, and global and regional ventricular function. Pulmonary artery catheters provide information on cardiac output and resistances, but do not improve outcome. Assessment with echocardiography identifies regional and global hypokinesia, and should distinguish between hypovolaemia, tamponade, and ventricular outflow obstruction. Doppler interrogation of transmitral flow may demonstrate restrictive LV filling (reduced E wave deceleration and tissue E wave velocity).

Treatment includes addressing underlying causes, and inotropic or mechanical support (Box 368.1). Inotropic therapy includes catecholamines, phosphodiesterase inhibitors and calcium sensitising agents. Hypertrophic left ventricles (hypertension, aortic stenosis, hypertrophic cardiomyopathy) can exhibit preserved systolic function with greatly impaired diastolic function [4]. Catecholamines such as epinephrine can further impair diastolic function leading to a spiral of worsening function and metabolic acidosis. Phosphodiesterase inhibitors are useful in this situation. Effectiveness of treatment is monitored by clinical assessment including arterial pressure, peripheral perfusion, and urine output, together with serial measurements of cardiac output, serum lactate, and echocardiography.

Tamponade

Pericardial collection is common and is suggested by reduced cardiac output, hypotension, tachycardia, elevated central venous pressure, oliguria, acidosis, and elevated lactate. Pericardial collection and tamponade are more common in patients with coagulopathy, pre-operative antiplatelet therapy, re-operations, major aortic surgery, and complex surgery with prolonged bypass time. The spectrum of impairment extends from mild decrease in arterial blood pressure to collapse and cardiac arrest. High clinical suspicion,

Box 368.1 Treatment of ventricular dysfunction

- **Beta-adrenergic agonists**: e.g. dobutamine 2–20 μg/kg/min.
- **Phosphodiesterase III inhibitors**: e.g. milrinone 50 μg/kg followed by infusion 0.5 μg/kg/min.
- Noradrenaline or phenylephrine if systematic vascular resistance low.
- Correction of hypocalcaemia.
- Intra-aortic balloon counterpulsation.
- Pulmonary vasodilator (nitric oxide, epoprostenol) if predominant right ventricular failure.
- Ventricular assist devices.

together with severe haemodynamic compromise indicates a need for immediate chest re-opening. If the clinical condition permits, confirmation should be obtained by transthoracic or transoesophageal echocardiography. It is important to appreciate that the traditional echocardiographic finding of 'right ventricular diastolic collapse' occurs late and is not an essential diagnostic criterion.

Arrhythmias and pacing

Common post-operative arrhythmias include atrial fibrillation, atrial tachycardias, sinus and nodal bradycardias, and heart block. Ventricular arrhythmias are less common, and should provoke consideration and exclusion of ischaemia or bypass graft occlusion.

Atrial fibrillation is the commonest arrhythmia and occurs between post-operative days 1–5 in 30–50% of patients. It is usually self-limiting. Serum potassium and magnesium should be normalized. Treatment includes β-blockers, amiodarone, flecainide, and electrical cardioversion. Atrial fibrillation beyond 24 hours mandates consideration of anticoagulation.

Epicardial pacing electrodes (usually two wires, but can use a single active wire with an indifferent wire attached elsewhere in the body—usually subcutaneously with a hypodermic needle) are applied to either atrium, ventricle, or both during surgery. They are useful for temporary epicardial pacing in the setting of bradycardia, heart block, or to optimize heart rate. Atrial pacing modes are preferred in the presence of intact AV conduction as native ventricular conduction is associated with improved (coordinated) ventricular function. This advantage is reduced if the PR interval is prolonged. Daily checks are undertaken for pacing threshold, sensing threshold, capture, underlying rhythm, and pacemaker function. Heart block beyond 48 hours warrants referral to electrophysiologist for consideration of permanent pacing [5].

Mechanical support

Patients who fail to wean from cardiopulmonary bypass or develop cardiogenic shock in the post-operative period, refractory to volume loading and inotropes, may be considered for mechanical support. The simplest form is the intra-aortic balloon pump; this is a specialized arterial catheter with a helium filled balloon that is usually inserted percutaneously into the femoral artery. The balloon inflates during diastole, increasing coronary perfusion, and deflates prior to systole, thereby decreasing ventricular afterload and creating a modest improvement in systemic perfusion. If more significant ventricular assistance and circulatory support is required then this can be provided by either veno-arterial extracorporeal membrane oxygenation (VA-ECMO) or a ventricular assist device (VAD). Early institution can improve survival, but should only be undertaken if the underlying cause is thought to be reversible or the patient is a candidate for bridge to transplantation. Complications of mechanical support include bleeding, infection, and vascular compromise.

Respiratory management

Causes of respiratory dysfunction are listed in Box 368.2. Lung volumes are reduced following sternotomy, due to altered chest wall mechanics, effusions, and pain. Radiological evidence of atelectasis occurs in nearly all those in whom an internal mammary artery is harvested and in a majority of other patients. It is caused by surgical compression, pain, drowsiness, pleural effusions, and inadequate expectoration. Management includes sitting upright, incentive spirometry, physiotherapy, continuous positive airway pressure or bi-phasic positive airway pressure. Pneumonia and acute lung injury occur in cardiac surgical patients with similar manifestations as non-cardiac patients. Diagnosis and management follow similar principles.

Central nervous system management

The spectrum of neurological injury following cardiac surgery encompasses stroke (irreversible cerebral injury), reversible ischaemic neurological deficit (RIND), cognitive dysfunction, and delirium.

Pathophysiological mechanisms vary:

- **Global injury**: prolonged hypoperfusion.
- **Watershed injury**: regions supplied by terminal branches of cerebral arteries e.g. parietotemporal cortices.
- **Focal injury**: arterial occlusion by emboli.
- **Diffuse –microfocal injury (wide micro-embolism)**: probably occurs in the majority of cases.

Diagnosis includes clinical criteria (National Institutes of Health Stroke Index) [6] and CT or MRI imaging. The mainstay of therapy involves supportive measures, such as maintaining cerebral perfusion and arterial blood pressure, treating hyperthermia and hyperglycaemia, supportive treatment of raised intracranial pressure, antibiotics, anticoagulants, physical therapy, and rehabilitation. Acute thrombolysis is generally contraindicated in the immediate post-operative period, even in proven thromboembolism, due to the risks of massive haemorrhage.

Box 368.2 Causes of respiratory dysfunction after cardiac surgery

Sternotomy-related lung mechanical alterations

- Atelectasis.
- Pleural effusion.
- Acute lung injury/inflammatory response to CPB.
- Pneumonia.
- Pneumothorax.

Renal management

Cardiac surgery associated acute kidney injury is common and is an independent predictor of mortality. Renal dysfunction is categorised according to severity, incorporating degree of oliguria, percentage decrease in glomerular filtration rate/rise in creatinine, and persistence of dysfunction over time.

Management is supportive with the emphasis primarily on attempted prevention of injury. A variety of pharmacological protection strategies have been attempted including vasodilators, dopamine agonists, diuretics and antioxidants. To date none have proved efficacious. Approximately 1% of patients require renal replacement therapy with a 50% peri-operative mortality [7]. Approaches aimed at prevention are outlined in Box 368.3.

Haematological management

Post-operative bleeding is common after cardiac surgery and is attributable to:

- Surgical bleeding.
- Residual heparinization.
- Fibrinolysis or cardiopulmonary bypass (CPB) induced coagulopathy/impairment of platelet function.
- Pre-operative anti-platelet agents.

Management includes investigation of the cause, administration of drugs and blood products, and surgical intervention. In addition to routine coagulation screening, thromboelastography (TEG) is useful as it provides a quick, point of care assessment of whole blood haemostasis. Platelet function testing or platelet mapping are also available as point of care technologies, and are useful in patients on anti-platelet agents.

Specific management:

- Haemodynamic control.
- Protamine.
- Normothermia.
- Antifibrinolytics.
- **Blood component therapy**:
  - *Platelets*—if low platelet count, narrow TEG maximum amplitude, recent anti-platelet drug administration.
  - *Fresh frozen plasma/prothrombin complex concentrate*—significant depletion of clotting factors is uncommon.
- **Surgical exploration**: significant losses (more than 400 mL blood loss in less than 4 hours) require surgical exploration (2–5% of patients).

Box 368.3 Prevention of renal dysfunction after cardiac surgery

- Normovolaemia, optimize cardiac output, and arterial blood pressure.
- Avoid nephrotoxic agents.
- Maintain glycaemic control.
- Maintain flow/pressure during CPB.
- Avoid excessive haemodilution.
- Haemofiltration during CPB.

Infection management

Sternal wound infection is an uncommon, but potentially devastating complication. Deep sternal wound infection occurs in 2% [8]. It is more common with diabetes, internal mammary grafts, cardiopulmonary bypass, and obesity. In a study of 9500 patients, coagulase negative staphylococci were isolated in 46%, *Staphylococcus aureus* in 26% and Gram-negative bacteria in 18% [9]. Antimicrobial sensitivities often differ from patients' normal flora (suggesting infection is initiated from the peri-operative environment). 90% of coagulase negative staphyloccoal infections are resistant to flucoxacillin [10].

Management includes:

- Local dressings.
- Antimicrobials.
- Debridement and irrigation.
- Radical debridement in the presence of mediastinitis.

Plastic surgery is usually necessary for chest wall reconstruction. Vacuum dressings have greatly simplified the treatment of wound dehiscence and sternal breakdown if conservative treatment is favoured.

Thoracic surgery

The last decade has seen a dramatic increase in thoracic surgical activity with a 60% increase in operations. Improvements in operative mortality have led to surgery being undertaken in higher-risk patients [11]. This has significant implications for post-operative care.

General management principles

Admission to an intensive care unit is usually required for continued ventilatory assistance or invasive monitoring and haemodynamic support. The following principles should be applied to promote recovery.

Early tracheal extubation

Intubation and positive pressure ventilation increase the risk of persistent air leakage, bronchopleural fistula, pulmonary infection, and acute respiratory distress syndrome (ARDS). Immediate tracheal extubation should be planned in all patients unless significant complications preclude it.

Restriction of intravenous fluids

Positive fluid balance is a risk factor for the development of post-resection ARDS [12]. A restrictive approach to fluid administration is recommended and in general patients should receive no more than of 20 mL/kg of fluid in the first 24 hours after surgery. Vasopressors may be required to maintain adequate perfusion pressure, particularly when epidural analgesia is used.

Effective analgesia

Pain causes shallow breathing and poor cough resulting in retention of secretions, atelectasis and respiratory failure. Other adverse effects include myocardial ischaemia, arrhythmia and development of chronic pain. Traditionally, thoracic epidural has been considered the most effective form of pain relief; however, it causes complications including hypotension, which can lead to inappropriate fluid loading. Paravertebral block is a good alternative as it can provide comparable analgesia with fewer side effects [13].

Early mobilization and physiotherapy

Deep breathing, incentive spirometry, chest physiotherapy, and early mobilization have been recommended to minimize post-operative complications. Evidence to support the effectiveness of these interventions is limited, although benefit may be seen if used in combination and delivered by specialized therapists [14].

Early drain removal

Early removal reduces pain and facilitates mobilisation. The majority of surgeons leave the drains *in situ* until fluid output is less than 250mL/day. Following pneumonectomy some place a drain, and clamp and open it once per hour. Suction is never applied. Others do not place a drain and instead aspirate air from the pleural space. The key element is to ensure is that the mediastinum is midline on the post-operative chest radiograph.

Respiratory management

Respiratory complications include sputum retention, atelectasis, pneumonia, re-expansion pulmonary oedema, and ARDS, all of which can lead to respiratory failure. Non-invasive ventilation (NIV) can be used to improve gas exchange and avoid re-intubation. However, absence of initial response or presence of cardiac co-morbidity predict failure and a high risk of mortality. If re-intubation is required then it should be undertaken early and a protective ventilatory strategy used to reduce the risk of ventilator-induced lung injury. If a prolonged period of ventilation is expected, consideration should be given to tracheostomy. In circumstances of severe respiratory failure, where recovery of residual lung function is anticipated, extracorporeal support can be considered to provide gas exchange temporarily and facilitate protective ventilation. This is rarely associated with survival.

Alveolopleural fistula (APF) is a common surgical complication following thoracic surgery and results in an air leak that is defined as persistent if it continues beyond 7 days. It is due to the development of an abnormal communication between the pleural space and pulmonary parenchyma, distal to a segmental bronchus. Positive pressure ventilation increases the air leak, so steps should be taken to minimize transpulmonary pressure in order to reduce fistula flow and encourage healing. Mechanical ventilation strategies include use of volume control ventilation, reduction of inspiratory pressure, tidal volumes, respiratory rate, positive end expiratory pressure, and inspiratory times. Most air leaks will settle spontaneously over a few days, although if they are persistent, management strategies include:

- Occlusion or pressurization of the chest tube.
- Lung isolation and independent lung ventilation.
- High frequency ventilation
- Repair of the fistula.

Bronchopleural fistula (BPF) is a serious complication with a high mortality, particularly in those who have undergone pneumonectomy. It is distinguished from an APF as an abnormal communication between the pleural space and lobar or segmental bronchi. The main hazards are contamination of the remaining lung and tension pneumothorax. Immediate management involves positioning the patient with the affected side down and isolating the good lung using a double lumen endotracheal tube (bronchial lumen to the good side) under direct bronchoscopic guidance. If a chest tube is not in situ then spontaneous ventilation should be maintained until one is inserted. After intubation, peak airway pressures should be minimized. Broad spectrum antibiotics are indicated. Surgical management involves immediate closure or wide open drainage.

Lobar torsion is a rare complication that may prove fatal if not recognized. It represents a rotation of the bronchovascular pedicle with resultant airway obstruction and vascular compromise. Bronchoscopy is diagnostic and emergency re-exploration is required.

Cardiovascular management

Cardiovascular complications include peri-operative myocardial infarction (MI), arrhythmia, and right ventricular failure. Non-fatal peri-operative MI occurs in 1–5% of patients. Antiplatelet therapy is limited by the risk of surgical bleeding. Atrial fibrillation is the most common arrhythmia. Initial management should focus on a rhythm-control strategy. Use of amiodarone is contentious, particularly following pneumonectomy, due to the risk of pulmonary toxicity. Consideration should be given to anticoagulation. Right ventricular failure can occur after lung resection due to reduction in the pulmonary vascular bed, which acutely increases afterload. Basic principles of management include maintenance of systemic perfusion pressure, optimization of cardiac inotropy and reduction in right-ventricular afterload using pulmonary vasodilators, such as epoprostenol or phosphodiesterase inhibitors.

Cardiac herniation is a rare and catastrophic complication of pneumonectomy that occurs when the heart herniates into the hemithorax through a defect in the pericardium. The chest drain should be taken off suction immediately and the patient transferred to surgery in the lateral decubitus position with the operated side uppermost.

Renal management

Acute kidney injury (AKI) is estimated to occur in 1–8% of patients following lung resection, and is associated with cardiopulmonary complications and prolonged hospitalization. No relationship has been demonstrated between intra-operative fluid restriction or crystalloid balance in the first 24 hours following surgery. Recovery usually occurs and management is supportive.

Haematological management

Post-operative bleeding after pulmonary resection is uncommon, but may require urgent re-exploration. Chest tube drainage of greater than 100 mL/hour for more than 2 hours is cause for concern. Patients require fluid resuscitation and, if present, coagulopathy should be corrected.

Infection management

Infection is a relatively frequent complication after thoracic surgery, most commonly pneumonia, empyema, and surgical site. Antibiotic selection should take into consideration that patients may have suffered multiple episodes of pre-operative respiratory tract infection and have chronic airway colonisation with resistant organisms.

CHAPTER 369

Intensive care management after neurosurgery

Kamalakkannan Subhas and Martin Smith

Key points

- Close monitoring is required in the first 6–12 hours following neurosurgery as deterioration in clinical status is usually the first sign of a potentially fatal complication.
- Cardiovascular and respiratory disturbances adversely affect the injured or 'at risk' brain, and meticulous blood pressure control and prevention of hypoxia are key aspects of management.
- A moderate target (7.0–10 mmol/L) for glycaemic control is recommended, avoiding hypoglycaemia and large swings in blood glucose concentration.
- Pain, nausea, and vomiting are the most common complications after neurosurgery, and a multimodal approach to pain management and anti-emesis is recommended.
- Disturbances of sodium and water homeostasis can lead to serious complications and a structured approach to diagnosis and management minimizes adverse outcomes.

Introduction

The main focus of the post-operative management of neurosurgical patients is the prevention, prompt detection, and management of surgical complications, and other factors that put the brain or spinal cord at risk. This relies on frequent clinical examination and monitoring, and optimization of systemic and cerebral physiology [1]. The majority of patients do not require complex monitoring or intervention beyond the first 12 hours after elective surgery, although prolonged intensive care unit management may be required for those who develop complications, or after acute brain injury.

Monitoring

Besides the close monitoring and assessment of cardiac and respiratory functions, frequent neurological monitoring is essential because deterioration in clinical status is usually the first sign of a potentially fatal complication after neurosurgery [2]. The Glasgow coma scale (GCS) provides a standardized method for evaluating a patient's global neurological status by recording best eye opening, motor and verbal responses to physical and verbal stimuli. Although not designed for this purpose, the GCS is widely used to monitor the level of consciousness after neurosurgery. More recently, a new coma score, the Full Outline of UnResponsiveness (FOUR) score, has been introduced to address some of the shortcomings of the GCS by incorporating brainstem reflexes and respiration [2]. Localizing signs such as pupil responses and limb weaknesses should also be recorded. A reduction in conscious level or the development of new localizing signs should prompt an urgent CT scan to identify a surgically remedial cause.

Serial clinical assessment performed by an experienced nurse is the simplest and most effective neurological monitor, but clinical evaluation is unable to detect changes in sedated patients. Multimodal intracranial monitoring, including measurement of intracranial pressure (ICP), cerebral oxygenation, cerebral blood flow, and brain tissue biochemistry, has a key role in guiding individualized management strategies after acute brain injury, but the indications for monitoring after elective neurosurgery are less well defined [3].

Emergence from anaesthesia and extubation

Rapid awakening after general anaesthesia permits early clinical assessment, but extubation should only be considered in a fully awake, normothermic, and haemodynamically stable patient with no new neurological deficit [4]. Pre-existing impairment of neurological status is no longer considered an absolute contraindication to early post-operative extubation [5]. Approximately 10% of neurosurgical patients require post-operative ventilation and sedation to allow stabilization of intracranial and systemic variables (Box 369.1). Sedation and analgesia should be titrated to allow frequent neurological examination, while preserving haemodynamic stability. Propofol is a widely-used sedative agent in neurosurgical patients and, in association with ultra-short acting opioids, allows reliable clinical assessment within a few minutes of stopping the infusion [6]. An ICP monitor should be placed if prolonged sedation is required [3].

Airway complications

Macroglossia and airway swelling secondary to venous obstruction may occur during prolonged posterior fossa or craniocervical junction surgery in the prone position, and post-operative oedema or haematoma can cause acute airway obstruction after anterior cervical spine or carotid surgery. Where there is potential for airway compromise in this way, the presence of a leak around

Box 369.1 Indications for post-operative ventilation and sedation after neurosurgery

Neurosurgical factors

- Resection of large tumour with midline shift.
- Intra-operative brain swelling.
- Large intra-operative blood loss.
- Cranial nerve damage.
- Long-lasting surgery.
- Seizures during emergence.
- Pre-operative reduced conscious level.

Systemic factors

- Cardiovascular instability.
- Hypothermia (temperature <35°C).
- Respiratory insufficiency.
- Coagulopathy.
- Severe metabolic disturbance.
- Comorbidities, particularly severe cardiac and respiratory disease.

the endotracheal tube and an adequate swallow must be confirmed prior to extubation. Re-intubation is likely to be technically demanding so skilled personnel and appropriate equipment should be immediately available.

Blood pressure management

Both hypertension and hypotension can adversely affect the injured or 'at risk' brain [1] and meticulous blood pressure control is essential in the early post-operative period. Cardiovascular disturbances may be related to neurogenic effects (such as direct brainstem and neurohormonal effects), emergence from anaesthesia, and concurrent drug therapy for medical comorbidities. After elective neurosurgery systolic blood pressure is generally maintained between 120–150 mmHg, although more specific targets are relevant in certain conditions [7].

Hypertension

Hypertension is common after intracranial neurosurgery and may cause complications, such as intracranial bleeding and cerebral oedema, or be a consequence of them [8]. Treatable causes such as pain, full bladder, or shivering should be excluded before administration of anti-hypertensive agents. To reduce blood pressure, drugs such as labetalol and esmolol are preferred, whereas calcium-channel blockers, nitrates, and sodium nitroprusside should be avoided because they are cerebral vasodilators and may increase ICP [7].

Hypotension

Hypotension is less common than hypertension and may occur because of hypovolaemia (particularly if osmotic diuretics have been administered during surgery) and brain injury-related neurogenic peripheral vasodilatation or stunned myocardium syndrome. Even short periods of hypotension can compromise cerebral or spinal cord perfusion, and should be treated aggressively, initially by fluid challenges. Euvolaemia and normal serum osmolality are the fluid resuscitation goals after neurosurgery, with some evidence that aggressive fluid resuscitation strategies may be detrimental to the injured brain. Intravascular volume should be maintained with isotonic crystalloids, and 0.9% saline is a justified choice despite a lack of evidence of superiority. Hypo-osmolar and glucose-containing solutions should be avoided [9].

If pharmacological blood pressure augmentation is required vasopressors, such as phenylephrine, metaraminol, and noradrenaline, are the most appropriate first choice since they are associated with increases in cerebral blood flow (CBF) [7]. Patients with previous cardiac disease or neurogenic myocardial failure may require additional inotropic support.

Blood pressure control in specific situations

Blood pressure control requires special attention in certain post-operative situations.

Emergence hypertension

Emergence from anaesthesia is associated with systemic hypertension in 70–90% of patients after cranial neurosurgery and may cause cerebral hyperaemia and raised ICP (4). The short-acting cardioselective β-blocker esmolol is useful in managing emergence hypertension.

Post-operative intracranial haemorrhage

Systolic blood pressure > 200 mmHg is a major risk factor for intracranial haemorrhage after intracranial neurosurgery and should be treated aggressively. The risks associated with lower levels of hypertension are less clear [10].

Cerebral hyperaemia

The cerebral hyperperfusion syndrome (CHS) occurs in 3% to 12% of patients after treatment of intracranial atherosclerotic or carotid disease. An acute rise in CBF occurs because some parts of the cerebral vasculature remain paretic and unable to constrict in response to higher flow in areas that were previously accustomed to low intravascular pressures because of restricted flow. In severe cases, CHS is associated with cerebral haemorrhage, severe brain swelling and death. Arterial blood pressure should be aggressively reduced if CHS develops, and a target systolic pressure between 90 and 140 mmHg has been recommended [11].

Respiratory management

Neurosurgical patients commonly develop respiratory complications. Brainstem compression by post-operative haematoma or hydrocephalus can cause respiratory arrhythmias and hypoventilation, and reduced level of consciousness, poor bulbar function, and lack of mobility increase the risk of pulmonary aspiration and infection. Neurogenic pulmonary oedema develops in up to 50% of patients with severe brain injury and may present acutely in the post-operative period.

There is no specific evidence to guide arterial blood gas targets after neurosurgery, but the prevention of hypoxia and maintenance of normocapnoea are paramount [5]. Protective ventilation strategies minimize the risk of ventilator-induce lung injury, but can

conflict with brain-directed strategies in some patients; therapy may thus be a compromise determined on a case-by-case basis [12].

Glycaemic control

Hyperglycaemia is common because of the stress response to surgery and the use of corticosteroids to reduce peri-tumoural oedema. High blood glucose is detrimental to the injured or 'at risk' brain and associated with a higher rate of infectious complications, but the optimal glucose level in neurosurgical patients is uncertain [13]. 'Tight' glycaemic control increases the risk of hypoglycaemia and has not been shown to improve outcome after acute brain injury [14]. A moderate target for glycaemic control is thus recommended, aiming to maintain blood glucose levels between 7.0 and 10 mmol/L, and avoiding hypoglycaemia and large swings in glucose [13].

Fever and infectious complications

Wound infection rates after craniotomy are low (< 4%), but increased substantially by repeated surgery. Untreated wound infections can lead to meningitis, cerebrititis, or brain abscess. Intraventricular catheters are complicated by infection in up to 11% of cases, with the risk of infection increasing after 5 days. Antibiotic impregnated or silver-coated ventricular catheters reduce the overall infection risk. Pneumonia is the most common infective complication after neurosurgery because of the increased risk of pulmonary aspiration in patients with reduced conscious level or poor bullbar function.

Fever, leukocytosis, and elevated CRP may be related to a post-operative or brain injury-related inflammatory response, but should always prompt investigation for an infective cause. Pharmacological methods of maintaining normothermia, such as paracetamol, are used routinely; physical cooling methods may have a role in some patients, although shivering must be avoided [15].

Pain control and sedation

Up to 80% of patients experience moderate to severe pain that can persist for several days after craniotomy [16]. Adequate analgesia not only ensures patient comfort, but also avoids pain-related hypertension. A multimodal approach to pain management, incorporating local anaesthetic wound infiltration, paracetamol, and opioids is recommended. Codeine and tramadol are still frequently used after intracranial neurosurgery, but morphine provides superior analgesia and has a good safety profile [17]. The use of NSAIDs remains controversial because of the perceived risks of intracranial bleeding and impaired bone healing after spinal surgery. Local anaesthetic nerve blocks are effective in reducing the incidence of chronic pain, but do not modify acute pain [16]. The pre-operative administration of gabapentin may improve pain control in the first 48 hours after neurosurgery in selected patients.

Post-operative nausea and vomiting is one of the most frequent complications after neurosurgery. Vomiting, which is highly unpleasant and may also result in hypertension and raised ICP, occurs in approximately 40% of patients. Multimodal treatment with ondansetron, dexamethasone and droperidol is recommended [18].

Sodium disturbances

Disturbances of sodium and water homeostasis are common after neurosurgery and can lead to serious complications and adverse outcomes [19].

Hyponatraemia

Hyponatraemia may occur because of administration of hypotonic fluids in the presence of high levels of antidiuretic hormone (ADH) in the peri-operative period. Other causes after intracranial neurosurgery and brain injury include the syndrome of inappropriate ADH secretion (SIADH) and the cerebral salt wasting syndrome (CSWS). An expectant and supportive treatment strategy is best in asymptomatic patients since the sodium disturbance is often transient and self-limiting. Prompt treatment is indicated in those with acute symptomatic hyponatraemia in order to minimize the risk of neurological complications and death. Electrolyte-free water restriction forms the mainstay of treatment of SIADH, but may be contraindicated in the early post-operative period, and after brain injury, where euvolaemia is essential to maintain cerebral perfusion. Pharmacological treatment is an option in resistant cases; democlocycline inhibits the renal responses of ADH, and ADH-receptor antagonists, such as conivaptan, inhibit the binding of ADH to renal receptors. The primary treatment of CSWS is volume and sodium resuscitation. 0.9% saline is generally indicated although, in acute symptomatic hyponatraemia, hypertonic saline is recommended.

Hypernatraemia

Hypernatraemia can be related to the use of sodium-containing osmotic diuretics such as mannitol, or the development of cranial diabetes insipidus (CDI), which is particularly common after pituitary surgery and severe acute brain injury. The aims of the management of CDI are two-fold—replacement and retention of water, and replacement of ADH. In conscious patients, free access to water may be all that is required as the CDI is often self-limiting. In unconscious patients enteral water should be administered via a gastric tube, guided by accurate assessment of volume status. If urine output continues > 250 mL/hour, synthetic ADH, in the form of small titrated doses of 1-deamnio-8-D-arginine vasopressin (desmopressin), should be administered.

Deep vein thrombosis prophylaxis

Neurosurgical patients are at high risk of venous thromboembolic disease. Combined mechanical and pharmacological prophylaxis is more effective than a single modality. Sequential pneumatic calf compression devices and graduated compression stockings should be continued postoperatively until the patient is ambulating. Low molecular weight heparin is safe after the first post-operative day.

Specific neurosurgical considerations

Post-operative complications occur in up to 27% of neurosurgical patients overall, with major complications leading to poor outcome and death occurring in 3–7% [4].

Immediate post-operative haematoma

Most post-operative intracranial haematomas occur within the first 6 hours after craniotomy. Risk factors include the pre-operative use of antiplatelet agents, including aspirin, peri-operative coagulopathy and excision of large vascular meningiomas and arteriovenous malformations. Decreased level of consciousness, new pupillary abnormalities or other focal signs are the presenting clinical

features, emphasizing the importance of close monitoring in the early post-operative period.

Intracranial hypertension

Intracranial hypertension (ICP > 20 mmHg) is common after elective supratentorial surgery but the implications of modest and relatively short-lived rises in ICP, some of which may be related to emergence hypertension, are unclear since few patients have an associated clinical deterioration [4]. More persistent and severe intracranial hypertension may be related to the development of a post-operative haematoma, or cerebral oedema. Reduction in conscious level, with or without focal signs, should prompt an urgent CT scan, but treatment of raised ICP should be started immediately if the patient shows signs of brainstem dysfunction and imminent herniation.

Seizures and status epilepticus

Seizures occur in almost 20% of patients after intracranial neurosurgery, usually within the first 48 hours [2]. The presence of clinical seizures is rarely in doubt, but non-convulsive seizures are more difficult to diagnose. Seizures should be considered in patients with reduced consciousness, or those who fail to wake after surgery. An EEG should be performed when other causes, such as intracranial bleeding, have been excluded.

Post-operative seizures must be brought rapidly under control because of the risks of secondary cerebral damage and/or progression to status epilepticus. A benzodiazepine such as lorazepam is effective and, in a critical care environment, small doses of propofol are a useful alternative. Recurrent seizures require the introduction of long-acting anticonvulsant agents. Levetiracetam has a better safety profile than established agents such as phenytoin, but there is currently no evidence to support the choice of one drug over another. Many patients continue to receive prophylactic anticonvulsants prior to craniotomy, but there is little evidence to support this practice [20], and they should be discontinued within the first post-operative week in those who do not have seizures.

CHAPTER 370

Intensive care management after vascular surgery

Alexander Timothy Dewhurst and Brigitta Brandner

Key points

- Vascular patients have multiple co-morbidities.
- Serious post-operative complications, such as myocardial infarction, cerebrovascular accident, acute renal failure, and mesenteric ischaemia contribute to mortality.
- Recent developments in endovascular stent technology allow the treatment of high risk patients.
- The post-operative management of high risk vascular patients should be multidisciplinary with early involvement of intensive care staff.
- The long-term outcome and cost benefit of endovascular versus open surgical procedures are yet to be established.

Introduction

Vascular patients often have multiple co-morbidities and are at risk of major complications. Their management strategy requires a multidisciplinary approach with defined clinical pathways. Vascular emergencies require immediate resuscitation and transfer to a tertiary cardiovascular centre.

Epidemiology

The prevalence of peripheral arterial disease (PAD) is in the range of 12–14% of the population with 20% of over 70s being affected [1]. Abdominal aortic aneurysm (AAA) occurs in 9% of over 65s. It predominates in males in the ratio of 5:1 [2]. The prevalence of thoracic aortic disease (aneurysm and dissection) is in the order of 16 per 100,000 per year [3].

Types of vascular surgery

Emergencies

Increasing numbers of Stanford Type B descending aortic dissections are now being treated with endovascular stents [4,5]. Pre-operative blood pressure control to reduce the risk of further dissection or rupture may require admission to an intensive care unit (ICU). Arterial cannulation and intravenous infusion of a β-blocker or vasodilator are required to control blood pressure. The systolic pressure should be kept below 140 mmHg. It is important to ensure adequate analgesia. A left-sided haemothorax is common and may compromise respiratory function depending on its size. Surgeons prefer not to decompress the haemothorax because of its splinting effect on the aorta. If transfer to a tertiary centre is required for treatment, good communication is essential.

Traumatic transection of the descending thoracic aorta can present after rapid deceleration injuries. Most with complete transection do not survive. Partial transection or contained rupture may present for urgent vascular stenting. In 80% of cases the site of transection occurs just distal to the origin of the left subclavian artery near the attachment of the ligamentum arteriosum. Resuscitation and stabilization of blood pressure are paramount. There is weak evidence that endovascular stenting provides better morbidity and mortality (9 versus 19%) over open surgical repair. The mortality for medical therapy alone is 46% [6].

Ruptured or leaking AAA present with the clinical triad of abdominal or back pain, a pulsatile abdominal mass, and hypotension. It carries a high mortality of 40–70%. Surgical referral is urgent. Treatment in high volume centres reduces mortality so patients may require resuscitation in the emergency department and transfer to a tertiary centre [7]. Restricting intravenous volume resuscitation (permissive hypotension) during the acute phase of resuscitation reduces the degree of bleeding, haemodilution and coagulopathy. Emergency AAA repairs are admitted to intensive care post-operatively. Patients are often mechanically ventilated, and may be hypothermic, acidotic, and coagulopathic.

Critical limb ischaemia occurs in 1–2% of patients with PAD. Patients have a severely painful, white pulseless limb and require urgent surgery to revascularize the limb. Treatment includes embolectomy, angioplasty, stents, or bypass procedures. Post-operatively patients can develop compartment syndrome, rhabdomyolysis, and renal failure. Their vascular grafts may fail with further limb ischaemia and the possibility a non-viable limb requiring amputation. At 1 year a quarter will have required an amputation and a quarter will have died from a cardiovascular cause [8].

Elective cases

ICU admission of elective vascular cases should be considered for the following operations:

- Intervention for PAD in the high risk patient.
- Carotid endarterectomy in selected patients.
- Open aortic surgery including aorto-bifemoral by-pass surgery.
- Infrarenal endovascular aneurysm repair in high risk patients.

- Fenestrated endovascular aneurysm repair.
- Thoracic endovascular aneurysm repair (TEVAR).
- Hybrid procedures

Lower limb PAD

Patients with significant concurrent coronary artery disease (CAD), aortic stenosis, cardiac failure, cerebrovascular disease (CVD) or renal impairment will require high dependency unit admission after surgery for invasive monitoring.

Open surgical repair of AAA

AAA is defined as an aortic diameter of greater than 3 cm. At 5.5 cm it is recommended that AAA be repaired to reduce the risk of rupture. The choice of open surgical repair or endovascular stent depends on the patient's risk factors and the anatomy of the aneurysm [9]. In patients with low to medium risk, repair by open surgical technique is appropriate.

Patients who return to intensive care following an elective AAA repair are expected to be extubated. Thoracic epidural analgesia has advantages over opioid based pain relief in improving respiratory function and quality of pain relief.

Open surgical repair of thoraco-abdominal aortic aneurysm

Open surgical repair of thoraco-abdominal aortic aneurysm (TAAA) is a high-risk procedure. It requires the patient to be placed in the right lateral position. A thoraco-abdominal incision is performed through the diaphragm exposing the descending aorta. Left lung deflation is required for surgical exposure and a spinal cerebrospinal fluid (CSF) drain is inserted to provide spinal cord protection. The aorta is clamped above and below the aneurysm leading to central hypertension and distal hypotension. Clamping the proximal aorta results in a sudden increase in left heart afterload and can lead to acute left ventricular failure. Partial left heart by-pass is used to offload the left ventricle and provide distal perfusion.

ICU care is complex and involves the management of acute lung injury, myocardial failure, cerebral haemorrhage, spinal cord ischaemia, mesenteric ischaemia, and renal failure.

Endovascular repair of aortic disease

Endovascular stenting of the aorta can be performed throughout the length of the aorta including the iliac arteries. In extensive thoraco-abdominal disease the entire descending aorta may be stented with fenestration and stenting of renal and mesenteric vessels. These cases may involve complex hybrid procedures where various vessels are bypassed with vascular grafts. Patients are at risk of similar complications seen in open procedures, although the reported rates of mortality and complications are lower [9]. However, patients who are deemed unfit for open surgical repair or general anaesthesia, and who undergo endovascular repair, have significant early mortality and morbidity [10].

Carotid endarterectomy

The benefit of carotid endarterectomy compared to medical treatment has been demonstrated [11,12]. Patients presenting for surgery should have a recent carotid duplex ultrasound scan and a CT scan of the brain. The criteria for carotid stenosis grading should be based on published guidelines and the decision to proceed to surgery depends on the degree of stenosis and presence of symptoms [13].

A few patients require ICU, depending on their co-morbidities and severity of neurological symptoms if they have suffered a stroke or transient ischaemic attack (TIA).

Hyperperfusion syndrome (HPS) occurs as a result of disordered cerebrovascular autoregulation. It is characterized by ipsilateral headache, hypertension, seizures, and focal neurological deficit. It is most common in patients who have had a high-grade stenosis corrected and have more than doubled their cerebral perfusion compared with baseline. This can occur up to 5 days after surgery. Patients should be admitted to a high-dependency unit for control of their blood pressure and neurological observation.

Regular assessment of the surgical wound should be performed as post-operative haemorrhage maybe dramatic and the resulting haematoma can rapidly compromise the airway. Tracheal re-intubation maybe difficult because of airway distortion and urgent surgical decompression of the haematoma maybe required before re-intubation is possible. A difficult airway trolley should be available.

Common co-morbidities in vascular patients

Cardiovascular

Between 30 and 60% of vascular patients have underlying coronary artery disease [14]. Ischaemia maybe silent and often occurs in the post-operative period.

Many patients will be taking aspirin and other anti-platelet agents. Stopping these agents places the patient at risk of in-stent thrombosis and myocardial infarction.

Respiratory

Smoking-related lung disease is common in vascular patients. Patients with a productive cough and poor pulmonary reserve are at risk of post-operative respiratory failure. Post-operatively patients may need prolonged respiratory support with either non-invasive or invasive techniques. Bronchoscopy maybe required in patients with severe sputum retention.

Renal

Vascular surgery to major vessels, particularly to the aorta, is complicated by renal dysfunction in 10–25% cases.

Risk factors for renal dysfunction are:

- Pre-existing renal impairment.
- Intraoperative ischaemia.
- Nephrotoxic agents (particularly contrast medium).
- Embolization of atherosclerotic debris.
- Pro-inflammatory response.
- Genetic predisposition.

There are no pharmacological agents that prevent renal dysfunction. Maintenance of hydration and adequate renal perfusion pressure are important in preserving function.

Cerebrovascular disease

Microvascular disease of the cerebral circulation is common in elderly vascular patients. Underlying occult cognitive deficit may

be revealed in the post-operative period. Confusion and delirium may complicate and delay recovery.

Specific management issues relating to vascular patients

Spinal cord ischaemia

Spinal cord ischaemia or infarction occurs after open surgical repair of TAAA (8–28%) and TEVAR (4–7%) [15].

The risk factors are:

- Aneurysm extent.
- Open surgical repair.
- Failure to re-implant spinal arteries.
- Emergency operation.
- Prior distal aortic operation.
- Cross-clamp time.
- Severe peripheral vascular disease.
- Anaemia.
- Hypotension.

Manoeuvres aimed at reducing spinal cord dysfunction include reduction of ischaemic time, increasing cord tolerance to ischaemia, increased spinal cord perfusion, and monitoring cord function. There are no pharmacological agents that prevent or treat spinal cord ischaemia.

Late onset spinal cord dysfunction can present in high-risk patients who become hypotensive or severely anaemic. There are reports that increasing spinal cord perfusion can reverse this dysfunction [16]. Augmentation of blood pressure using vasopressors in combination with lumbar CSF drainage may increase spinal cord perfusion [17,18]. It is important to ensure cardiac output and haemoglobin levels are adequate.

Lumbar drains maybe used in patients who are going to receive partial or full anticoagulation. The complications associated with the technique include headache, persistent CSF leak, catheter fracture, meningitis, and direct nerve injury. In addition, intracranial hypotension, subdural haematoma, intracranial haemorrhage, and spinal haematoma have been reported.

Mesenteric ischaemia

Acute intestinal ischaemia is life threatening. Occlusive mesenteric ischaemia can occur from embolism or thrombosis. Non-occlusive mesenteric ischaemia may occur in low cardiac output states when vasopressors are being used or with vasospasm after revascularization. Intestinal ischaemia should be suspected in patients who develop abdominal pain following transaortic catheter procedures, after a new arrhythmia or recent myocardial infarction.

Patients present with severe abdominal pain, out of proportion to the physical signs. Blood tests reveal leucocytosis, lactic acidosis, and raised amylase in 50% of cases. Plain abdominal X-ray may show dilated bowel loops. CT scan with contrast may demonstrate ischaemia and is often requested by surgical teams. However, in non-occlusive ischaemia it may provide a false negative result and consideration should be given to the risk of contrast nephropathy. Mesenteric arteriography is the definitive investigation. An expedient laparotomy by a surgeon capable of resection of or revascularization of viable ischaemic bowel maybe life saving.

Anticoagulation

During surgery, partial or full anticoagulation maybe required with unfractionated heparin. Thomboprophylaxis is required post-operatively and is commonly provided by the use of low molecular weight heparin (LMWH).

During open vascular surgery and endovascular stenting, with or without cardiopulmonary bypass, heparin will be administrated to prevent thrombotic complications.

Neuro-axial anaesthesia and lumbar CSF drains are often employed during vascular surgery. The main concern with the use of neuro-axial blockade and lumbar CSF drains is the risk of spinal or epidural haematoma formation in patients receiving anticoagulants. Guidelines on the use of regional anaesthesia in patients receiving antithrombotic agents have been published, and these should be followed for both the insertion and removal of catheters [19].

To summarize, the recommendations are as follows:

- Catheters should not be inserted or removed within 10–12 hours of a dose of LMWH or heparin.
- LMWH or heparin should not be given until 1–2 hours after catheter insertion or removal.
- In the event of a bloody tap consider postponing surgery.
- Consider insertion of catheter day before surgery.
- Patients should be monitored neurologically post-operatively.
- Early radiological investigation if neurological symptoms occur.

Analgesia

Thoracic epidural analgesia results in significantly lower pain scores in the first three post-operative days and reduces the duration mechanical ventilation, cardiovascular complications, acute respiratory failure, and gastrointestinal complications [20]. Non-steroidal anti-inflammatory drugs are often contraindicated due to comorbidities and the increased risk of renal failure, secondary to the procedure or the use of contrast during endovascular procedures. Paracetamol reduces opioid requirements. The choice of opioid depends on the patient's comorbidities and often the side effects are the limiting factor to control pain. Neuropathic pain relief can be of benefit particular in severe ischaemic and post-amputation pain.

CHAPTER 371

Intensive care management in hepatic and other abdominal organ transplantation

Ivonne M. Daly and Ali Al-Khafaji

Key points

- Outcome is determined by the pre-operative physiology, quality of the donated organ, and intra-operative events.
- An understanding the physiology of end-stage liver disease is critical to post-operative management.
- The intensivist must anticipate, rather than respond to problems in these patients with reduced physiologic reserve.
- Infection, not rejection, is the most common cause of mortality after transplant. The goal is a fine balance between prevention of rejection and avoidance of infection.
- Attention to additive nephrotoxicities of medications is critical to management after transplant.

Introduction

The transplanted organ needs good oxygen delivery, microvascular flow, clearance of toxins and balance of electrolytes, and immune suppression that balances risks of rejection and infection to recover from the insults of ischaemia and reperfusion. Each abdominal organ failure causes medical problems that persist for days to months after transplant and require special management.

Care of the recipient

Cardiovascular

Cardiovascular complications are the leading cause of death with a functioning allograft among renal, hepatic, and pancreatic allograft recipients, and may account for 30% of post-transplant mortality [1]. Intra-operative events, including volume shifts, massive bleeding, and post-perfusion syndrome, can negatively affect the heart. When the organ is reperfused, acidosis, hyperkalaemia, cytokine release from the new liver, and hypothermia, both from the implanted organ and from infusions of chilled blood can lead to haemodynamic instability. Most patients will require volume resuscitation and, possibly, vasopressor support during the first few hours after transplant. Inotropes and vasopressors are initiated if haemodynamic values are still inadequate after adequate volume resuscitation.

Hypertension can be related to steroids and other immunosuppressants or, in kidney transplant patients, to the underlying disease. Labetalol or hydralazine are appropriate first line agents for treatment of hypertension. Atrial fibrillation should be treated with β-blockers or amiodarone. Calcium channel blockers should be used with caution since they affect tacrolimus metabolism.

For orthotopic liver (OLT) and multivisceral transplant patients, an understanding of cirrhotic cardiomyopathy is essential. Patients with end-stage liver disease (ESLD) have a hyperdynamic circulation with increased cardiac output and decreased peripheral vascular resistance. Many also have diastolic dysfunction and prolongation of the QTc interval [2,3]. In up to 50% of cirrhotic patients, the myocardium is less responsive to catecholamines—in these patients, the increase in cardiac output expected with sepsis, bleeding, or surgery may not occur. Congestive heart failure may suddenly develop after transplant, when vasopressors are initiated or in states of volume overload [4]. Right heart failure can lead to congestion and dysfunction of the allograft. Cirrhotic cardiomyopathy may be reversible after OLT, but the natural history of requires further investigation [3].

It is difficult to recommend specific fluid for resuscitation, although albumin improves long-term renal function in hepatorenal syndrome [5]. Vasopressors are frequently required to improve distributive shock and restore organ perfusion. In patients who develop cardiovascular collapse, an urgent echocardiogram is required to exclude cardiac tamponade related to extension of the surgical incision.

Pulmonary

The primary goal of respiratory management is adequate oxygen delivery without the use of excessive pressure or volume. Kidney and pancreas transplants are usually extubated in the operating room (OR), but liver transplants, small intestine, and multivisceral transplants are usually returned to the ICU intubated. When indicators of graft function are promising, patients with normal lung function may be extubated within hours of surgery. Due to impaired drug metabolism, short-acting analgesics are preferred.

Hepatopulmonary syndrome (HPS) and porto-pulmonary hypertension (PPHTN) are two distinct pulmonary problems that occur in patients with ESLD.

HPS is defined by the presence of hypoxia due to ventilation—perfusion mismatch, intrapulmonary shunting, pulmonary vasodilation, and limitation of oxygen diffusion in patients with ESLD

and portal hypertension. Liver transplantation remains the definitive treatment and most HPS resolve within 1 year after transplantation [6,7].

PPHTN is pulmonary arterial hypertension due to increased pulmonary vascular resistance in the presence of portal hypertension and a pulmonary artery wedge pressure <15 mmHg. Vasoactive substances that are metabolized in the liver travel to the pulmonary circulation via portosystemic shunts causing vasoconstriction. Mean pulmonary artery pressure >45 mmHg increases the risk of graft failure due to venous congestion and right ventricular dysfunction. Pulmonary artery pressures can improve after liver transplantation [6].

The risk of ventilator associated pneumonia is very high due to malnutrition, muscle weakness, and immune suppression.

Renal

Most patients will have some degree of renal injury after non-renal organ transplant. Haemodynamic instability, haemorrhage, inferior vena cava clamping, and peri-operative hyperglycaemia are associated with AKI and worsening of pre-existing renal dysfunction. Many have impaired renal function prior to transplantation; predictably, these patients have worse outcomes.

The use of large volumes of citrated blood products can cause ionized hypocalcaemia and mild metabolic alkalosis. Hypophosphataemia occurs during liver regeneration, when a partial allograft is used. In the setting of renal insufficiency after transplant, the main indications for renal replacement therapy are severe electrolyte imbalance, metabolic acidosis, and volume overload impairing oxygenation and congesting the allograft. Continuous renal replacement therapy is better tolerated than intermittent dialysis.

Blood levels of calcineurin inhibitors must be monitored to limit their contribution to renal dysfunction. Induction protocols that delay initiation of calcineurin inhibitor do not improve renal outcomes (class 2C evidence) [8]. Medications that reduce systemic blood pressure (angiotensin-converting enzyme inhibitors,) reduce glomerular perfusion (non-steroidal anti-inflammatory drugs,) or are directly nephrotoxic (aminoglycosides, amphotericin) should be avoided.

In hepatorenal syndrome (HRS), renal vasoconstriction occurs in the presence of splanchic vasodilatation. This results in activation of the renin-angiotensin-aldosterone system causing fluid retention and massive ascites. Although OLT is the definitive treatment for HRS, some patients will require long-term renal replacement therapy and eventually kidney transplantation.

Endocrine

Adrenal insufficiency occurs in some patients with chronic illness and can become more common in the post-operative period due to the use of steroids. Hyperglycaemia is common due to the stress of surgery and the use of steroids during induction. Many patients require insulin after transplant. After pancreas transplant, 'resting' the pancreas with a low dose insulin infusion aimed at maintaining blood glucose between 4.5 and 7.8 mmol/L is associated with improved islet cell function [9].

Haematological

Patients are at increased risk of bleeding and thrombotic complications immediately after transplant. Tachycardia, hypotension associated with falling haemoglobin, or significant bloody drainage from the surgical drains or the incision should prompt notification of the transplant team for possible re-exploration, especially if the bleeding persist despite coagulation correction.

After transplant, patients are prone to deep vein thrombosis (DVT) and thrombotic complications of the vascular anastomoses. Correction of coagulopathy or thrombocytopenia should be done in consultation with the transplant team. Correction of coagulopathy increases the risk of thrombosis, and, in the case of OLT, masks graft dysfunction. Many advocate replacing platelets only if the count is below 20×10^9/L or if there is active bleeding. Because the pancreas is a low-flow organ, it is at particularly high risk of thrombotic complications. Sequential compression devices and possibly heparin are used for DVT prophylaxis.

Patients with ESLD have disordered coagulation that places them at increased risk of both bleeding and thrombosis. As the liver allograft recovers, it begins to make procoagulant factors II, VII, IX, and X before making anticoagulant factors Protein C, S, and anti-thrombin III. Thrombocytopenia can persist for up to 2 weeks after OLT due to hypersplenism, consumption, and sequestration by the allograft.

Infection

Maintaining immune suppression to prevent rejection of the allograft while minimizing infection is a fine balance. Infection is the most common cause of mortality and morbidity in the first month after transplant [10]. Small intestine, multivisceral, and pancreas transplants [11] have the highest risk of infection due to intestinal anastomoses and increased gut permeability that occurs in states of rejection. In OLT patients, a hepatojejunostomy increases the risk of infection relative to a bile duct-to-bile duct anastomosis. Infections at the surgical site are also potentiated by prolonged surgery, extensive dissection, and massive blood transfusion.

Infections with antibiotic resistant organisms and fungal infections are common. In the setting of unresolved infection, limiting immunosuppression should be considered in consultation with the transplant team.

Regimens for prophylaxis against opportunistic infection vary. All patients receive prophylaxis against *Pneumocystis jiroveci pneumonia* and cytomegalovirus (CMV) (class 1A evidence). CMV is an immunomodulating virus—patients with active CMV disease have a higher incidence of bacterial and fungal infections and a higher incidence of chronic rejection. Kidney transplant patients receive CMV prophylaxis with valganciclovir for 6 months. Antifungal prophylaxis is indicated in cases with difficult dissection, massive transfusions, bile leaks, retransplants, patients with preoperative renal failure or fulminant hepatic failure (class 1A evidence). *Aspergillus* infections affect 1% of transplant recipients with 60% mortality [10]. Treatment should be early with an echinocandin and voriconazole. Kidney transplant patients also have a high incidence of *Clostridium difficile* infections, and routinely receive prophylaxis against this organism.

Nutrition

Many patients presenting for abdominal organ transplant have nutritional deficiencies that increase the risk of post-operative infections and respiratory complications. Protein catabolism is markedly increased after transplant. In liver and multivisceral transplant patients, drainage of ascites, and pleural effusions predisposes to protein malnutrition. Intestinal transplant patients are particularly malnourished.

Small volume tube feeds can be started within 12–24 hours of a transplant that does not involve an enteric anastomosis (class 1c evidence) [12]. OLT and pancreatic transplant patients with bile duct- or pancreatic duct-to-intestine anastomoses are fed 5 days later. In intestinal transplant patients, parenteral nutrition is resumed normally on post-operative day 1 and enteral feeding is started if the ostomy is healthy, non-oedematous, the first small intestine mucosal biopsy does not show findings compatible with rejection, and signs of intestinal function are evident. An elementary enteral formula is usually started on post-operative day 7. Oral intake is started if the patient tolerates full enteral feeding without a nasogastric tube.

Neurological

Calcineurin inhibitors, steroids, and electrolyte imbalance can alter mental status. Analgesia and sedation may be challenging in intestinal transplant patients, because many have chronic pain and narcotic tolerance from multiple abdominal surgeries. Delirium is common and often multifactorial, particularly after OLT. In these patients, clearance of sedatives and analgesics may be limited. Hepatic encephalopathy may persist from the pre-operative state, or arise in the setting of primary transplant non-function. Flumazenil can improve mental status related to liver failure and can help identify the cause of mental status changes. A comatose patient warrants an electroencephalogram to rule out status epilepticus.

Care of the allograft

All transplanted organs are at risk of surgical complications including bleeding, vascular thrombosis, and anastomotic leaks. Doppler ultrasound may be used to assess vascular patency. Transplants with enteric anastomoses are prone to leakage of intestinal contents. OLT recipients may have bile leaks, and kidney transplant recipients may have lymphoceles, haematomas, and leaks of urine from the uretero-bladder anastomosis. All transplants may suffer impaired function due to factors associated with the donor, harvest and ischaemia time.

Graft function can be impaired by haemodynamic instability, the use of vasopressors, hypoxaemia, and electrolyte imbalance in the donor prior to harvest. Infections in the donor at the time of harvest necessitate appropriate antibiotic therapy in the recipient. Duration of hypoxia before harvest is important in donors after cardiac death. Macrosteatosis and fibrosis are associated with delayed graft function in OLT. Delayed graft function and reperfusion injury also correlate with the organ's cold ischaemia time and donor's age.

Organs are at increased risk of delayed graft function and primary non-function when harvested from less than ideal donors [13]. Some grafts with delayed function recover, but delayed function is commonly associated with increased mortality.

Immune suppression and risk of rejection

After transplant, the need for immune suppression is usually lifelong, and serious side effects accumulate over time. The mechanism of action, uses, and side effects of commonly used immune suppressive agents are described in Table 371.1 [14]. When life-threatening infections occur after transplant, a decrease in immune suppression should be considered.

Acute cellular rejection (ACR) is mediated by T cells and can occur as early as a few days after transplant. ACR can be asymptomatic, but can present with fever, right upper quadrant/back pain, and tenderness over the allograft. OLT recipients will have elevated transaminases; kidney transplant recipients will also have an increase in creatinine; pancreas transplant recipients will have increased glucose; intestinal transplant recipients will have an increase in stomal output. Episodes of ACR are treated with corticosteroids, an increase in baseline immunosuppression, or if severe, T cell depletion therapy. Antibody-mediated hyperacute rejection is a very rare entity due to advances in tissue typing.

Liver

The most sensitive early markers of adequate liver function are normalization of the prothrombin time. The prothrombin time is elevated in liver failure and quickly returns to normal once factor V is produced by hepatocytes, usually within hours of implantation. Adequate allograft function is also indicated by resolution of acidosis and clearance of lactate. Transaminases peak during the first 24–48 hours with normalization after 72 hours. Delayed graft function manifests with rising transaminases, bilirubin, and prothrombin time. Rising bilirubin and transaminases in a previously healthy graft should trigger a liver ultrasound to exclude vascular thrombosis, stenosis, and biliary leaks. A biopsy to exclude ACR sometimes is done.

The hepatic artery is the most common site of thrombotic complications. Hepatic artery thrombosis occurs in 2–5% of OLT and is a major cause of allograft loss if revascularization is not accomplished urgently. Hepatic artery thrombosis manifests with dramatic elevation of aspartate transaminase and alanine transaminase that are typically in the thousands.

Several risk factors have been reported for early hepatic artery thrombosis including retransplantation, use of arterial conduits, prolonged operation and cold ischaemic times, low recipient weight, severe rejection, variant arterial anatomy, and low volume transplantation centres. Thrombosis rates are higher after split-liver and living-related transplants, because of the smaller calibre of vessels and the complex arterial reconstruction required. Prompt re-exploration with thrombectomy and revision of the anastomoses is indicated if the diagnosis is made early. If hepatic necrosis is extensive, a retransplant may be indicated.

Primary non-function (PNF) is a devastating complication seen in less than 5% transplants, with mortality > 80% without a retransplant. The cause of PNF is unknown, but several donor factors like advanced age, increased fat content of the donor liver, longer donor hospital stay before organ procurement, prolonged cold ischaemia (>18 hours), and reduced-sized grafts may predict its development. Unfortunately, no medical treatment is effective for PNF. If a retransplant is to influence outcome, it must be done before multi-organ failure develops.

Kidney

Patients are not usually critically ill after a kidney transplant, but may be admitted to the ICU if comorbidities complicate care. Patients with peripheral vascular disease are at increased the risk of embolic events and may require ICU monitoring.

Urine output is replaced with hypotonic fluid to avoid over-administration of glucose and to match the dilute urine that is produced by the allograft. Oliguria in the setting of adequate intravascular volume suggests acute tubular necrosis or reperfusion injury, delayed graft function, acute cellular rejection, ureteral/

Table 371.1 Immune suppressive agents

Name	Mechanism of action	Uses and cautions	Side effects
Tacrolimus	◆ Calcineurin inhibitor ◆ Inhibits IL-2 production	◆ Mainstay of most regimens ◆ Monitor blood levels	Seizures, hyperkalaemia, nephrotoxicity, hyperglycaemia, focal neurological deficits, tremor, hypertension
Ciclosporin	Similar to tacrolimus	◆ Used when tacrolimus is not available ◆ Associated with a higher incidence rejection compared with tacrolimus (class 1a evidence) ◆ Monitor blood levels	Seizures, gingival hyperplasia, hirsutism, hyperkalaemia, hepatotoxicity, nephrotoxicity, gastroparesis
Glucocorticoids	Broad anti-inflammatory effects		Hypertension, psychosis, hyperglycaemia, adrenal suppression, osteoporosis, pancreatitis, electrolyte abnormalities, peptic ulcers, myopathy
Mycophenolate mofetil	Inhibits purine synthesis, limiting lymphocyte proliferation and function	◆ Used for steroid resistant ACR and in renal sparing protocols ◆ Increases risk of CMV complications	Hypertension, hyperkalaemia, bone marrow suppression, impaired wound healing, GI effects
Sirolimus	Inhibits response to IL-2 by inhibiting cell cycle enzyme	◆ Used in combination with tacrolimus in steroid-free and renal sparing regimens ◆ Causes delayed wound healing	Wound dehiscence, bone marrow suppression, hyperlipidaemia, fever, gastro-intestinal effects
Basiliximab Daclizumab	Antibody the alpha subunit of IL-2 receptors	Induction therapy	Fever, hypotension, increased incidence of opportunistic infections
Alemtuzumab	Anti-CD-52 antibody on mature lymphocytes	Induction therapy	Associated with infusion bronchospasm, pulmonary oedema, ARDS, hypotension, arrhythmias
Antithymocyte globulin	Antibody to T-cells generated in rabbit or horse	◆ Induction for prevention of graft versus host disease ◆ Treatment of steroid-resistant ACR	Symptoms of cytokine release Increased risk of post-transplant lymphoproliferative disorder
Muromonab-CD3 (OKT3)	◆ Monoclonal antibody to CD3 ◆ Activates t-cells before inducing apoptosis	Treatment of steroid-resistant ACR	Symptoms of cytokine release

Data from Perry I and Neuberger J, 'Immunosuppression: towards a logical approach in liver transplantation', *Clinical & Experimental Immunology*, 2005, **139**(1), pp. 2–10.

bladder anastomotic leak, or seroma compromising the flow of blood or urine. Oliguria should prompt irrigation of the urinary catheter. If oliguria persists despite adequate vascular volume and haemodynamics ultrasound should be used to assess vascular patency, to rule out anastomic leaks and compression by a fluid collection. Thrombosis at the arterial or venous anastomosis is suspected with abrupt cessation of urine production [13].

Delayed graft function requiring dialysis in the post-operative period does not necessarily portend a need for retransplant. The transplanted kidney can spontaneously recover after several weeks/months.

Pancreas

Patients are at high risk for thrombosis at the anastomotic site, since the pancreas is a relatively low-flow organ. Pancreatic venous drainage to the portal system is accomplished with an interposition graft, which adds to the risk of thrombosis. Manipulation of the organ during harvest is associated with pancreatitis after transplant. Post-operative pancreatitis occurs in 16% of pancreas recipients.

The duodenal stump associated with the pancreatic duct may be attached to the bladder, which allows monitoring of urinary amylase as an indicator of rejection, but results in significant loss of bicarbonate into the urine. The native pancreas is left in situ to provide exocrine function. When the stump is attached to the intestine, exocrine function of the transplanted pancreas is preserved, and bicarbonate is reabsorbed by the intestine. Patients are also at high risk from enterocutaneous fistulae from the poorly vascularized duodenal stump [9,11].

Hyperglycaemia is the hallmark of rejection of an isolated pancreas transplant. Abdominal pain and tenderness over the pancreas allograft is a late sign and is often indicative of an allograft that has already thrombosed. In a combined kidney/pancreas transplant, graft tenderness, and elevated creatinine signal rejection.

Small Intestine and mulitvisceral transplant

A multivisceral transplant refers to an en-bloc allograft that includes liver, stomach, duodenum, pancreas, small intestine, and, variably, spleen, kidney, and or right colon. Patients are admitted to the ICU after MVT due to the stress and fluid load of the very long surgery and due to the need for delayed abdominal closure. These transplant recipients are at high risk of enteric leaks. Aorto-enteric fistula from unrecognized enteric leak close to aortic graft is the most feared complication.

The intestinal graft contains copious lymph tissue, so immune suppression can be challenging. In these patients, rejection is associated with loss of barrier function with translocation of bacteria or lipopolysaccharide into the bloodstream. Rejection after intestinal transplant is heralded by stomal output that becomes bloody or increases in volume; however, this may not be apparent in the immediate post-operative period. Surveillance mucosal biopsies are done twice weekly through the ileostomy during the first few weeks. Abdominal pain is a late sign of rejection and may denote a thrombosed allograft [15].

Conclusion

Peri-operative care of the transplant patient can be extremely rewarding. Transplant recipients can have dysfunction of almost every organ system, yet most have the potential to recover fully. In the immediate post-operative period, intensivists must anticipate problems related to the disordered physiology that exists before transplant. The intensivist should consider the needs of the allograft, as well as the needs of the patient as a whole. Graft function is related to the quality of the donated organ and surgical technique. Meticulous attention to the level of immune suppression and the risk of infection is critical to ensure the best possible outcome.

CHAPTER 372

Intensive care management in cardiac transplantation

Keshava Rajagopal and Bartley P. Griffith

Key points

- Cardiac transplant recipients are both surgically and medically complex.
- Appropriate recipient selection, donor selection, and technically well-performed operations are critical contributors to the best outcomes.
- Low cardiac output syndrome following heart transplantation has numerous pre-, intra-, and post-operative outcomes, and is the most important peri-operative morbid complication contributing to patient mortality.
- Achievement and maintenance of optimal allograft function is mandatory in the heart transplant recipient.
- Other important peri-operative issues in the heart transplant recipient relate to invasive mechanical ventilation—oxygenation/ventilation and its relationship to the pulmonary circulation, blood product transfusion, and immunosuppression strategies.

Donor organ management

After identifying a suitable cardiac transplantation donor (Box 372.1), the donor heart is procured. The donor is systemically anticoagulated, and a catheter for administration of preservation solution is placed in the ascending aorta. The superior vena cava is ligated. The heart is unloaded of volume by exsanguination. The ascending thoracic aorta is cross-clamped, and hypothermic preservation solution, of which several types exist, is administered antegrade via the ascending aorta into the coronary arteries. The heart is cooled topically with ice. After the preservation solution has been administered, the heart is excised, leaving adequate lengths of ascending aorta, left atrium, main pulmonary artery, and both vena cavae. It is placed in a cold storage container for transportation.

Transplant procedure

The recipient is systemically anticoagulated with heparin for cardiopulmonary bypass (CPB). The ascending aorta is directly cannulated, or another systemic artery is cannulated. Both cavae or branches of the superior/inferior vena cava are cannulated. CPB is initiated, typically with mild systemic hypothermia (32–34°C). The ascending aorta is cross-clamped and the native heart is excised. The donor heart is then implanted. The left atrial anastomosis is performed first, since it is most posterior. A left ventricular vent catheter is placed to allow for left-sided cardiac de-airing. Next, the ascending aortic anastomosis is performed. At the completion of this anastomosis, an ascending aortic vent/antegrade cardioplegia catheter is placed to facilitate both left-sided cardiac de-airing, and delivery of a dose of warm blood cardioplegia that may be administered antegrade via the ascending aorta. During this time, a bolus dose of steroid (methylprednisolone) is administered intravenously. The aortic cross-clamp is released, thereby reperfusing the heart. Cardiac allograft ischaemic time is minimized by using this approach of performing the left-sided cardiac anastomoses and releasing the aortic cross-clamp. The heart is defibrillated if necessary. The main pulmonary arterial anastomosis is constructed next, followed by the caval anastomoses (in the more commonly performed bicaval technique; classic bi-atrial technique utilizes a right atrial anastomosis as opposed to individual caval anastomoses). Ventricular and atrial epicardial pacing wires are placed, pacing initiated if needed, pharmacological inotropic/vasoactive support is initiated, invasive mechanical ventilation is resumed at full levels, and CPB is eventually discontinued. Heparin anticoagulation is reversed with protamine, decannulation accomplished, and the procedure concluded.

Peri-operative management

Cardiovascular system

Cardiac allograft function is the most important determinant of outcome after heart transplantation. Ventricular and/or valvular dysfunction may be left ventricular (LV), biventricular (BiV), or right ventricular (RV); these may manifest intra-operatively or early in the post-operative period, and have a variety of aetiologies (Box 372.2).

Technical complications may result in allograft dysfunction. An undersized donor aorta anastomosed to a relatively larger recipient aorta may result in dilatation of the sinotubular junction of the allograft and aortic valve regurgitation [1]. Coronary arterial compromise and myocardial ischaemia may result from injury to the left circumflex coronary artery (or coronary sinus) during creation of the left atrial anastomosis. The mitral valve may also be distorted by the left atrial anastomosis, causing mitral valve regurgitation [2], particularly if an excessively shortened left atrial cuff is prepared. The main pulmonary artery is often short if lungs are procured from the donor, and pulmonary valve regurgitation may result due to imperfections in the anastomosis. More commonly, the main

Box 372.1 Standard donor criteria for cardiac transplantation

- Adequate donor organ size (<20% size mismatch between donor and recipient).
- Donor age <65 years.
- Anticipated organ ischaemic time <4 hours.
- Good donor biventricular function (ejection fraction >55%, pulmonary artery occlusion pressure <18 mmHg, central venous pressure <12 mmHg) on no or low levels of inotropic support, assessed non-invasively and/or invasively via right-sided cardiac catheterization.
- Absence of important coronary arterial disease (when specifically assessed based upon risk factors) or structural heart disease (e.g. valvular heart disease).
- Major blood group (ABO) compatibility.
- Absence of extracranial malignancy, or no evidence of disease >5 years after treatment.
- Absence of bloodstream infection.

Box 372.2 Aetiologies of allograft dysfunction following heart transplantation

- Technical (i.e. anastomotic) complications.
- Intracoronary arterial air embolization.
- Hyperacute rejection.
- **Acute rejection**: cellular, humoral.
- **Primary graft dysfunction**: ischaemia/reperfusion injury.

pulmonary artery is excessively long resulting in twisting or kinking of the main pulmonary artery [3]. Superior vena caval anastomotic stenosis is relatively common and may manifest late after transplantation [4]. Finally, the inferior vena cava is often short if the liver is obtained from the donor, and this can result in impingement of the coronary sinus after creation of the inferior vena caval anastomosis; the results of this may be catastrophic, with impaired cardiac venous drainage and myocardial oedema [5].

LV and/or RV dysfunction can occur due to coronary arterial air embolization that typically manifests with ST changes on ECG, or less commonly, with ventricular arrhythmias. This is usually a transient problem, and can be treated by increasing the systemic arterial pressure, and intra-operatively, also by ascending aortic venting and/or coronary sinus retroperfusion. Intra-operative allograft failure may rarely occur due to hyperacute rejection, mediated by pre-existing donor-specific antibodies [typically against donor major histocompatibility complex (MHC) molecules] in the recipient [6]. This complication rarely occurs in the modern era because of screening assessments of panel-reactive anti-MHC antibodies (PRA) and antibodies against MHC Class I chain A (MICA) in recipients, and virtual and/or prospective cross-matching for pre-sensitized recipients. Acute cellular rejection (ACR) is much more common, may occur early in the post-operative period, and can afflict any of the cardiac chambers [7]. Consequently, LV/BiV/RV dysfunction—systolic and/or diastolic—may be present; arrhythmias, more commonly supraventricular, may occur as well. Transjugular venous endomyocardial biopsy makes the diagnosis of acute rejection.

Primary graft dysfunction (PGD), is thought to be a consequence of ischaemia-reperfusion injury [8]. PGD may also manifest with LV/BiV/RV dysfunction, but most commonly presents with RV-predominant dysfunction. Although the RV may be more tolerant of ischemia-reperfusion injury than the LV due to the lower afterload and requisite oxygen consumption, the incidence of RV ischemia-reperfusion injury is greater than that for the LV due to inferior RV myocardial protection [9] in the procured cardiac allograft. The RV is also less tolerant of and more often exposed than the LV to 'afterload mismatch.' Afterload mismatch refers to an elevation in ventricular afterload relative to contractility, and is essentially secondary systolic ventricular dysfunction [10]. The RV has lower contractility and acute contractile reserve than the LV. Moreover, while pulmonary vascular resistance is generally much lower than systemic vascular resistance (and, consequently, under these normal circumstances, RV and LV outputs are matched since ventricular contractility is matched to afterload), patients with end-stage heart disease often have chronically elevated pulmonary vascular resistance. This may be further increased acutely during the transplantation procedure, particularly due to the effects of CPB.

Pharmacological support of cardiac allograft function is utilized routinely in the peri-transplant period. Inotropic support using monoamines/catecholamines that are agonists for the β-adrenergic receptors [11] (dobutamine, dopamine, adrenaline, isoprenaline, noradrenaline) is instituted empirically, even with normal biventricular systolic function, due to positive chronotropic effects that can be beneficial in the early peri-operative period—when the denervated allograft often displays chronotropic dysfunction. Of these inotropes, isoprenaline is the most potent chronotrope, and is frequently used beyond the early peri-operative period to maintain an adequate heart rate. Afterload reduction of both the LV and RV, but particularly for the RV, is beneficial and often necessary. The cAMP phosphodiesterase inhibitors (e.g. milrinone) are especially useful because of mixed positive inotropic and arteriolar vasodilatory properties [12]. Selective pulmonary vasodilators, such as inhaled nitric oxide or epoprostenol are employed frequently, particularly in the setting of pre-existing systemic vasodilatation [13]. Importantly, intentional augmentation of LV afterload may be useful in the treatment of isolated RV dysfunction; this is due to systolic ventricular interdependence (enhanced rightward motion of the interventricular septum), and increased right coronary arterial blood flow [14]. Finally, keeping the chest open is routine in the treatment of peri-operative RV dysfunction.

Uncommonly, allograft dysfunction may be so severe that mechanical circulatory support must be instituted (Table 372.1). LV dysfunction refractory to inotropic/vasoactive support may respond to intra-aortic balloon counterpulsation (IABP). In addition, although little evidence suggests that IABPs are useful in the treatment of RV dysfunction, right coronary arterial blood flow is enhanced, and this may prevent RV ischaemia in the setting of RV distension and dysfunction. Severe ventricular dysfunction, which most commonly afflicts the RV, may be treated using short-term ventricular assist device (VAD) support of the affected

Table 372.1 Mechanical cardiopulmonary support strategies

ventricle(s), most commonly using extracorporeal devices [15]. Severe peri-transplant cardiorespiratory failure is generally treated using systemic veno-arterial (V-A) extracorporeal membrane oxygenation (ECMO); V-A ECMO essentially functions as CPB, is also easily instituted using existing CPB cannulae when in the operating room, and supports both ventricles as well as the lungs [16].

Cardiac tamponade may occur after any cardiac surgical procedure, and is common when excessive antecedent bleeding occurs. Transthoracic echocardiography may identify the presence of a pericardial effusion, with respirophasic transmitral flow variation, RV diastolic collapse, and inferior vena cava distension consistent with tamponade physiology. Pulmonary arterial catheters are routinely used in heart transplant recipients peri-operatively; tamponade is suggested by diastolic equalization of the pulmonary artery occlusion and central venous pressures, and this is the most sensitive diagnostic sign for post-cardiac surgical tamponade [17]. However, both non-invasive and invasive assessments for tamponade are frequently inaccurate; consequently, a high index of suspicion must be present. Late tamponade may occur beyond 1 week post-transplant, and often is associated with the first endomyocardial biopsy. Its presentation is frequently insidious and non-specific, with general malaise, dyspnoea, mild systemic arterial hypotension, and rising creatinine. When suspected or diagnosed, emergent mediastinal re-exploration is mandatory.

Pulmonary system

Intra-operatively, invasive mechanical ventilation is used, but is typically discontinued for the CPB portion of most cardiac surgical procedures. However, pulmonary atelectasis occurs, and this may elevate the pulmonary vascular resistance [18], thereby exacerbating RV afterload mismatch that may manifest when preparing to separate from CPB. Consequently, maintenance of modest levels of invasive mechanical ventilatory support may be beneficial (e.g. respiratory rate of 10 breaths/minute, tidal volume 4–6 mL/kg, positive end-expiratory pressure of 5). Full mechanical ventilator support is reinstituted when preparing to wean and separate from CPB.

Since important pulmonary disease is a contraindication to isolated heart transplantation, heart transplant recipients typically do not have important peri-transplant pulmonary dysfunction. The principal exception to this is high-LA pressure pulmonary oedema secondary to allograft LV dysfunction, the management of which has been discussed. However, low-pressure pulmonary oedema can be due to pro-inflammatory effects of CPB that increase alveolocapillary membrane permeability, and transfusion-related acute lung injury—also characterized by increased alveolocapillary membrane permeability. Prolonged invasive mechanical ventilation using lung-protective strategies is implemented in such circumstances, and systemic veno-venous (V-V) ECMO may be necessary in rare cases of isolated respiratory failure (i.e. in the absence of cardiac failure) following heart transplantation.

Haematological/immunological system

Peri-operative blood product transfusion is minimized, with target haemoglobin levels determined in the context of the adequacy of O_2 delivery, assessed by mixed venous O_2 saturation; transfusion of platelets, fresh frozen plasma, etc., is based upon clinical assessment of coagulopathy in the context of laboratory coagulation measures. Patients who are chronically anticoagulated with warfarin are usually administered vitamin K prior to transplantation, and intra-operatively, the CPB circuit can be primed using plasma. All cases using CPB require intra-operative anticoagulation, almost always using heparin. Heparin is reversed using protamine after weaning from CPB is complete. Post-operatively, serial assessments of haemoglobin, platelet count, and coagulation measures are obtained; transfusion criteria are the same as those used intra-operatively. Factor complex concentrates and/or recombinant coagulation factors may be useful as well.

Transplant recipients receive a bolus dose of steroid, typically methylprednisolone (1 g intravenously). This is administered prior to graft reperfusion, i.e. after aortic cross-clamp release. Subsequently, a steroid taper is initiated, and most transplant recipients are maintained on low-dose glucocorticoid. The remainder of the immunosuppressant regimen is comprised of an antiproliferative agent (mycophenolate mofetil or azathioprine) and a calcineurin antagonist (tacrolimus or ciclosporin).

Recipients with high PRA levels ('sensitized') are at high risk for acute graft rejection; this is largely mitigated by the standard usage of flow-cytometric 'virtual' cross-matching, and in cases of a local organ donor from whom blood may be obtained prior to transplantation, cytotoxicity assay actual cross-matching [19]. In patients who have a positive post-operative cross-match, or more broadly those with an elevated PRA, induction immunosuppression therapy may be utilized [20]. A variety of induction agents exist, which are most commonly polyclonal antisera (e.g.

T cell-depleting anti-thymocyte globulin), monoclonal antibodies (e.g. T cell depleting muromonab anti-CD3, anti-IL2Rα basiliximab, B cell-depleting rituximab, anti-CD52 alemtuzumab), or immunoglobulin fusion (e.g. CTLA4-Ig belatacept). These agents are used in an attempt to reduce the rates of acute cellular and humoral rejection. Finally, recipient antibodies can be depleted in the peri-transplant period using plasmapheresis. If acute rejection is identified peri-operatively, higher doses of steroids, antiproliferative agents, and calcineurin antagonists are used. Induction immunosuppressant agents are also often used to treat acute rejection, with the choice of agent determined by the type of rejection: cellular versus humoral.

Other

Heart failure is a common pre-renal aetiology of renal dysfunction, and consequently, pre-transplant renal dysfunction may be present in the recipient. Renal failure following cardiac surgery is poorly understood, and may occur as a consequence of several factors—most importantly intra-operative hypotension of any aetiology, including pre-operative low renal blood flow, and the effects of CPB on renal blood flow. Calcineurin antagonists are noteworthy as nephrotoxic agents unique to transplant recipients. Induction immunosuppression and withholding calcineurin antagonists in the early post-transplant period are thought to attenuate peri-transplant renal dysfunction. Thus, pretransplant renal insufficiency is a common indication for usage of induction immunosuppressants.

Infectious complications early after heart transplantation are unusual, but in the long-term, are the leading causes of heart transplant recipient mortality. Broad spectrum antibiotics are generally used in the early perioperative course, but are generally discontinued within 48–72 hours post-transplant.

CHAPTER 373

Intensive care management in lung transplantation

Keshava Rajagopal and Bartley P. Griffith

Key points

- Lung transplant recipients are both surgically and medically complex.
- Appropriate recipient selection, donor selection, and technically well-performed operations are critical contributors to the best outcomes.
- Acute respiratory failure following lung transplantation has numerous pre-operative, intra-operative, and post-operative outcomes, and is the most important peri-operative morbid complication contributing to patient mortality.
- Achievement and maintenance of optimal allograft function is mandatory in the lung transplant recipient.
- Other important peri-operative issues in the lung transplant recipient relate to cardiac function—particularly of the right ventricle, blood product transfusion, and immunosuppression strategies.

Donor organ management

After identifying a suitable lung transplantation donor (Box 373.1), the donor lung(s) is/are procured. Inspiratory and expiratory mechanics are assessed based on clinical (inspiratory lung expansion and expiratory lung recoil) and mechanical ventilatory (airways resistance, lung compliance) parameters. Valsalva recruitment manoeuvres are performed as needed, taking care not to use excessive ventilator pressures (peak inspiratory pressure >40 cmH_2O) or cause lung hyperinflation. Selective pulmonary venous blood gas sampling permits assessment of the gas exchange functions of each lung (and the upper and lower lung zones within a lung), and is essential when single lung transplantation is to be undertaken.

The donor is systemically anticoagulated, and a cannula for administration of preservation solution is placed in the main pulmonary artery and directed towards the pulmonary valve. During procurement prostaglandin E_1 is administered into the main pulmonary artery [1]. The lung preservation solution—of which several types exist, is administered via the main pulmonary artery after left atrial venting and each pleural space is packed with ice. The former main pulmonary arterial cannula is used to individually cannulate and administer preservation solution retrograde via the pulmonary veins. This serves to flush out material within the pulmonary circulation. The lungs are excised en bloc, leaving adequate lengths of pulmonary artery, left atrium, and trachea. The excised lungs are placed in a cold storage container for transportation.

Transplant procedure

The incision and surgical approach are determined based upon whether single or bilateral lung transplantation is to be undertaken. CPB or V-A ECMO are selectively utilized under the following circumstances: (1) severe right ventriclular (RV) dysfunction or elevation of the pulmonary vascular resistance—pulmonary arterial clamping is poorly tolerated in these situations, and/or (2) severe hypoxemia or hypercapnia—since single lung ventilation and sequential lung transplantation are poorly tolerated in these situations. Under the second set of circumstances, V-V ECMO may be utilized. [When CPB is utilized for bilateral or right lung transplantation, the patient is systemically anticoagulated with heparin, and the ascending aorta and right atrium can be cannulated; central systemic venous cannulation for left lung transplantation is challenging, and typically, femoral arterial and venous cannulation are utilized.] Selective single lung ventilation is initiated, and the contralateral native lung is excised. In this process, the pulmonary artery and veins supplying the excised lung are controlled; a modest dose of heparin (e.g. a 50–100 unit/kg bolus dose administered prior to implantation of each lung, in contrast to a 300 unit/kg dose for cardiopulmonary bypass (CPB)) is administered. The ipsilateral pulmonary artery is clamped as proximally as possible, while the ipsilateral pulmonary venous confluence/portion of left atrium is dissected out and clamped. The appropriate donor lung is brought to the field. The mainstem bronchial anastomosis is created first. Next, the pulmonary arterial anastomosis is created. The pulmonary venous/left atrial anastomosis is created last. Prior to tying the anastomotic suture line, a bolus dose of steroids is administered intravenously; the pulmonary arterial clamp is partially released, allowing for antegrade de-airing, and the left atrial clamp is released, facilitating retrograde de-airing. The anastomotic suture line is then tied. The allograft is ventilated. Controlled reperfusion of the lung is undertaken to prevent over perfusion of the allograft and facilitate free radical washout, releasing the pulmonary arterial clamp in graded fashion; this is thought to mitigate ischemia-reperfusion injury. Once this process is completed, selective ventilation of the lung allograft is performed. The second native lung is then excised as described. Implantation of the second lung allograft is performed as described. Bilateral invasive mechanical ventilation is re-initiated, and when relevant, weaning and separation from CPB

Box 373.1 Standard donor criteria for lung transplantation

- Adequate donor organ size (assessed radiographically).
- Donor age <65 years.
- Anticipated organ ischaemic time <8 hours.
- Good donor pulmonary function (PIP <30 cmH_2O with tidal volume >6 cm^3/kg—static compliance >25 cm^3/cmH_2O, PaO_2 >300 on FIO_2 100% and PEEP 5 cmH_2O).
- Absence of important chronic pulmonary disease (e.g. asthma requiring mechanical ventilation, chronic obstructive pulmonary disease, restrictive lung disease, pulmonary vascular disease, etc.).
- Absence of major radiographic abnormalities thought to be irreversible (e.g. pulmonary nodules suggestive of malignancy).
- Bronchoscopic assessment without secretions that cannot be cleared.
- Major blood group (ABO) compatibility.
- Absence of extracranial malignancy, or no evidence of disease >5 years after treatment.
- Absence of bloodstream infection.

performed. Anticoagulation is reversed, decannulation accomplished when CPB has been used, and the procedure concluded. The dual lumen endotracheal tube is exchanged for a single lumen tube, and flexible fibreoptic bronchoscopy is performed to examine both bronchial anastomoses and evacuate intrapulmonary blood/secretions.

Peri-operative management

Cardiovascular system

Patients undergoing lung transplantation are excluded from having important and irreparable cardiac disease. Uncommonly, concomitant cardiac operations (e.g. coronary artery bypass grafting, valve repair/replacement) may be undertaken in otherwise low-risk recipients [2]. Excluding cases of concomitant cardiac surgery, cardiac dysfunction may occur following lung transplantation. Isolated left ventricle (LV) dysfunction is uncommon, even when CPB is used, since lung transplantation is performed under conditions of normal coronary arterial blood flow and myocardial perfusion. Clamping the left-sided pulmonary veins for left lung transplantation can injure the left circumflex coronary artery that may, in turn, result in LV lateral wall ischemia and dysfunction. Intraoperative transoesophageal echocardiography may identify this, and repositioning the clamp resolves the problem.

More commonly, RV dysfunction may occur following lung transplantation. This is because of pre-existing chronic cor pulmonale in some lung transplant recipients that may not improve immediately after lung transplantation due to acutely elevated allograft pulmonary vascular resistance. Elevated pulmonary vascular resistance may be due to lung ischemia-reperfusion injury, or the effects of CPB (**3**). Afterload reduction of the RV is beneficial and often necessary. The cAMP phosphodiesterase inhibitors (e.g. milrinone) are especially useful because of mixed positive inotropic and arteriolar vasodilatory properties [4]. Importantly, intentional augmentation of LV afterload may be useful in the treatment of isolated RV dysfunction; this is due to systolic ventricular interdependence (enhanced rightward motion of the interventricular septum), and increased right coronary arterial blood flow [5]. Inhaled pulmonary vasodilators are particularly useful in the lung transplant recipient, as they enhance ventilation–perfusion matching. Consequently, inhaled nitric oxide and/or epoprostenol are used liberally in peri-operative lung transplant recipients [6].

Pulmonary system

Lung allograft function is the most important determinant of outcome after lung transplantation. Respiratory failure after lung transplantation has several possible aetiologies, which are reviewed later and summarized in Box 373.2.

Technical complications of lung transplantation may involve the bronchial, pulmonary arterial, and/or pulmonary venous anastomoses. Bronchial anastomotic complications are by far the most common, and historically have had profound negative impact on lung transplantation outcomes [7]. Anastomotic dehiscence, which manifests in the acute peri-operative setting (although not necessarily evident on intra-operative completion bronchoscopy), is a catastrophic complication mandating emergent re-operation. For this reason, daily surveillance bronchoscopy is essential in the peri-operative lung transplant recipient, particularly when invasively mechanically ventilated. Imperfections in the pulmonary arterial anastomosis, as well as kinking due to excessive donor/recipient pulmonary arterial length, may cause pulmonary arterial stenosis, or even less commonly, thrombosis. This increases the vascular resistance of the allograft, impairing perfusion and ventilation–perfusion matching. Intra-operative transoesophageal echocardiography can identify anastomotic stenosis, although not reliably. Passage of the pulmonary arterial catheter beyond the arterial anastomosis can directly determine whether a resistive pressure drop, i.e. anastomotic stenosis, is present. This can be performed intra-operatively under echocardiographic guidance, or in the intensive care unit under fluoroscopic guidance; catheter passage across the anastomosis should not be performed without image guidance, as anastomotic disruption and lethal haemorrhage can occur. In addition, peri-operative ventilation-perfusion scanning, which is performed routinely, may identify impaired graft blood flow [8], consistent with a haemodynamically important pulmonary arterial stenosis, although impaired allograft perfusion is not specific for a pulmonary arterial stenosis. Imperfections in the left atrial anastomosis can also cause stenosis. This causes increased resistance to pulmonary venous drainage and elevations in pulmonary venous and capillary pressure. Allograft pulmonary oedema

Box 373.2 Aetiologies of allograft dysfunction following lung transplantation

- Technical (i.e. anastomotic) complications.
- Hyperacute rejection.
- **Acute rejection**: cellular, humoral.
- **Primary graft dysfunction**: ischaemia/reperfusion injury.
- Pneumonia.

can occur with disastrous sequelae [9]. Fortunately, intra-operative echocardiography evaluates the pulmonary veins well, due to their posterior location. Transoesophageal echocardiography or magnetic resonance imaging can be used post-operatively. Revision of the left atrial anastomosis is necessary if evidence of stenosis is present.

As is the case in heart transplantation, hyperacute lung allograft rejection is nearly non-existent in the modern era due to current screening strategies. However, acute rejection in the early peri-operative period is more common than in heart transplantation [10]. Rejection may manifest with impaired lung mechanics, hypercapnia, and hypoxaemia clinically, often in the setting of new or worsening infiltrates on chest imaging. Bronchoscopy with biopsy is the essential diagnostic test to evaluate allograft rejection [10]. Treatment of rejection similar to that for acute cardiac allograft rejection.

Primary graft dysfunction (PGD) complicates up to 20% of lung transplant operations. Hypoxaemia, with or without hypercapnia, is present, usually with radiographic evidence of pulmonary oedema. In some patients, this can be managed non-invasively. However, the majority of patients require prolonged invasive mechanical ventilation. Lung-protective (i.e. employing low tidal volumes and ventilator pressures) mechanical ventilatory strategies are used. If hypoxaemia and hypercapnia persist, while treating with lung-protective invasive mechanical ventilation, higher level ventilator support is avoided. Most lung transplant surgeons advocate a strategy of extracorporeal lung support in this setting; since co-existent cardiac dysfunction is usually not present, V-V ECMO is usually sufficient [12].

Haematological/immunological system

Peri-operative blood product transfusion is minimized, with target haemoglobin levels determined in the context of the adequacy of O_2 delivery, assessed by mixed venous O_2 saturation; transfusion of platelets, fresh frozen plasma, etc., is based upon the clinical assessment of coagulopathy in the context of laboratory coagulation measures. Transfusion-related acute lung injury is a particular concern following lung transplantation, because of the sensitivity of the previously ischaemic and newly-reperfused allograft to noxious stimuli that elevate the already increased alveolocapillary membrane permeability, and the absence of normal lymphatic drainage in the allograft. Consequently, blood product transfusion is strictly controlled following lung transplantation.

Immunosuppression for lung transplantation is similar to that used for cardiac transplantation. Specifically, most recipients are treated using a combination of steroids, antiproliferative agents, and interleukin-2 synthesis-suppressing (thus impairing T cell-mediated immune responses) calcineurin antagonists [13]. Similar criteria for induction immunosuppressant usage are used for heart and lung transplantation: positive cross-match, high rejection risk (e.g. elevated panel reactive antibody (PRA)), and renal insufficiency. Plasmapheresis is also a useful adjunct in recipients with positive cross-match or high donor-specific antibody titers; novel anti-plasma cell proteasome inhibitors have similar utility. An important difference between heart and lung transplantation, however, is the absolute incidence of acute and chronic graft rejection. Rejection is more common after lung transplantation than heart transplantation, and in the long-term (bronchiolitis obliterans syndrome (BOS)) [14], is the most important reason for poorer outcomes after lung transplantation in comparison with transplantation of other solid organs.

Other

Lung transplant recipients generally do not have impaired cardiac output or renovascular disease. Peri-transplant renal insufficiency is usually a consequence of intentional volume restriction to avoid allograft oedema and pleural effusions, and nephrotoxic medications. Fluid restriction is maintained in the lung transplant recipient, even at the expense of moderate renal dysfunction. Nephrotoxic medications are minimized, and peri-operative renal insufficiency usually resolves. Calcineurin antagonists are noteworthy as nephrotoxic agents unique to transplant recipients. Induction immunosuppression and withholding calcineurin antagonists in the early post-transplant period is thought to attenuate peri-transplant renal dysfunction. Thus, pre-transplant renal insufficiency is a common indication for usage of induction immunosuppressants.

Infectious complications are extremely common following lung transplantation, due to colonization of the recipient (particularly in infectious lung diseases) and transmission of donor-derived infection [15]. Broad spectrum antibacterial, antifungal, and even antiviral drugs are instituted and maintained in the majority of lung transplant recipients. Frequent bronchoscopy is thought to be important in protection from graft pneumonia, although little evidence exists to support this practice.

Gastrointestinal complications are also very common in lung transplant recipients. Pre-existing gastro-oesophageal reflux disease contributes to native lung disease, and in the absence of surgical treatment, contributes to impaired long-term allograft survival [16]. In addition, the lung transplantation operation may incur injury to the vagus nerve(s) and/or the recurrent laryngeal nerves, which cause impaired gastric emptying and airway protection, respectively. Aspiration-induced lung injury is thus a major contributor to the development of long-term allograft dysfunction [17]. For this reason, when possible, patients with gastro-oesophageal reflux disease undergo surgical fundoplication—usually post-lung transplant. In addition, many lung transplant surgeons advocate liberal usage of gastrojejunostomy tubes (gastric port for medication administration, jejunostomy port for continuous feeding) and maintenance of nil by mouth status early after lung transplantation.

PART 20.2

Oncological intensive care

CHAPTER 374

ICU selection and outcome of patients with haematological malignancy

William M. Townsend and Emma C. Morris

Key points

- The concept that patients with haematological malignancies should not be considered for intensive care admission is outdated and inappropriate.
- There are no absolute contraindications to intensive care unit (ICU) admission in this patient cohort.
- It is important to promptly identify patients who may benefit from ICU admission, ideally prior to the development of organ failure.
- Close liaison between the critical care and haematology teams is vital.
- Formal review of the appropriateness of continued intervention in critically unwell haematology patients should be performed on a regular basis.

Introduction

The admission of patients with haematological malignancy and, in particular, recipients of haematopoietic stem cell transplants (HSCT) to the intensive care unit (ICU) has been the subject of much controversy and conjecture. The poor survival previously observed in many units led some to question the validity of continuing to admit such patients to the ICU. However, over recent years, evidence of improved outcomes, in combination with better treatments and longer survival for many of these malignancies, has challenged the notion that such patients should be denied admission. An underlying diagnosis of a haematological malignancy is no longer considered a contraindication to ICU admission. Nevertheless, it is recognized that providing critical care to this patient population presents particular challenges.

This chapter details the commonest reasons for ICU admission in patients with haematological malignancy and reviews their outcome. Important aspects relevant to their critical care are highlighted.

The scale of the problem

The number of ICU admissions of patients with haematological malignancy depends on the size and activity of the local haematology and oncology departments. In tertiary referral centres managing large numbers of such patients and performing allogeneic HSCTs, a high proportion of ICU admissions will be from this cohort, placing a significant burden on the critical care department. In the UK, 1.5% of all ICU admissions involve patients with haematological malignancy [1].

The prevalence of haematological malignancies is increasing worldwide due in part to the ageing population (with the exception of acute lymphoblastic leukaemia and Hodgkin lymphoma, which peaks in childhood or young adulthood, respectively), and longer survival secondary to improved therapies. HSCT is increasingly utilized as a potentially curative procedure for a wide range of haematological malignancies; between 2005 and 2012 the number of allogeneic HSCTs in Europe increased by 37% [2]. It is likely that the number of ICU admissions will continue to increase.

Reasons for ICU admission

Patients with haematological malignancy can become critically unwell due to the underlying disease itself, as a consequence of cytotoxic chemotherapy, or following HSCT. The commonest reasons for ICU admission are discussed in the following section.

Disease

Acute leukaemia

Patients with acute myeloid leukaemia (AML) and acute lymphoblastic leukaemia (ALL) often present with a short history of days to weeks. Approximately 10% of patients with newly-diagnosed acute leukaemia require ICU admission due to consequences of leukostasis, cytopenias, sepsis, or haemorrhage (which may be due to thrombocytopenia or disseminated intravascular coagulation (DIC)) [3]. Rapid identification and treatment of early complications, initiation of appropriate supportive care and commencement of definitive induction chemotherapy are all important aspects of care.

For patients admitted with newly-diagnosed acute leukaemia, the course of the critical illness is influenced by the untreated leukaemia. Timely treatment of the underlying malignancy will have implications for long-term outcome, so it is important to consider initiating chemotherapy on the ICU alongside critical care support and interventions (see Box 374.1) [4].

Box 374.1 Overview of AML and ALL

Acute leukaemias

Acute leukaemias are life-threatening malignancies characterized by rapid and uncontrolled proliferation and accumulation of blasts in the bone marrow with subsequent failure of normal haematopoiesis.

The prognosis and clinical course are highly variable. Children with ALL have an excellent prognosis with cure rates >80%, while survival in adults is <50%. The prognosis of AML depends on specific cytogenetic and molecular characteristics, as well as patient-related factors, in particular age. Patients <60 years with good prognostic factors have a 60–70% chance of cure, whereas older patients with adverse cytogenetics have a very poor prognosis.

The current challenges in acute leukaemia are in predicting and preventing relapse in those with poor risk disease, and improving the survival of elderly patients.

Acute promyelocytic leukaemia (APML)

APML is a sub-type of AML that requires special mention because of its association with severe DIC causing significant morbidity and mortality due to intracerebral and pulmonary haemorrhage. Patients with APML are often critically unwell at diagnosis, but it has a very good long-term prognosis with survival rates of 70–80%, largely due to the efficacy of treatment with all **trans**-retinoic acid (ATRA).

Full supportive care for these patients is warranted with meticulous attention to correction of coagulopathy often requiring large volumes of blood products [16].

Chronic myeloid leukaemia (CML)

This typically develops insidiously, but can present in an acute phase with a marked leukocytosis. Few patients with CML require ICU admission due to the underlying disease, although leukostasis, hyperviscosity, organ infiltration, and complications of cytopenias can all lead to acute deterioration. Treatment and prognosis have been revolutionized by the use of tyrosine kinase inhibitors [5].

Chronic lymphocytic leukaemia (CLL)

This indolent malignancy predominantly affects the elderly. Chronic disease-related immune suppression, hypogammaglobulinaemia, or severe immune-mediated cytopenias may cause decompensation and the need for ICU input.

Lymphoma

Although most patients with Hodgkin or non-Hodgkin lymphoma are managed as outpatients, critical illness can occur, typically due to bulky lymphadenopathy causing organ compromise. This is seen most commonly in the highly proliferative non-Hodgkin lymphomas (NHL), such as diffuse large B cell lymphoma (the commonest type) and Burkitt lymphoma. Large mediastinal masses, commonest in Hodgkin lymphoma and primary mediastinal diffuse large B cell lymphoma may cause superior vena cava or airway obstruction requiring ICU input. Critical illness may also be due to lymphomatous organ infiltration of the central nervous system (CNS) or gastrointestinal tract. CNS infiltration, which may be primary or secondary, can lead to a reduced conscious level and seizures. Involvement of the gastrointestinal tract, occurring most commonly in mantle cell lymphoma, marginal zone lymphomas, Burkitt lymphoma, and some T cell lymphomas, can cause obstruction or perforation at the time of presentation or after starting chemotherapy. Lymphoid masses typically reduce rapidly in size following initiation of treatment and surgical intervention is rarely required, but ICU support may be necessary until organ compromise has resolved. Patients with bulky disease are at risk of tumour lysis syndrome and acute renal failure after initiation of chemotherapy (see Box 374.2).

Multiple myeloma

Myeloma has a median age of presentation of 65–70 years and is characterized by bone marrow infiltration, lytic bone lesions with pathological fractures, paraproteinaemia, and renal failure. Electrolyte disturbance (hypercalcaemia), hyperviscosity due to paraproteinaemia and renal failure may all precipitate ICU referral.

Treatment

Infections

The most frequent treatment-related reason for ICU admission is infection. Myelosuppression following cytotoxic chemotherapy or after HSCT, prolonged impairment of adaptive immunity,

Box 374.2 Lymphomas: classification, prognosis, and treatment

Hodgkin lymphoma

The incidence peaks at 30 years. Presentation is commonly with lymphadenopathy, often mediastinal, and constitutional 'B' symptoms—night sweats, fever, and weight loss. Treatment of early stage disease is with combination chemotherapy and radiotherapy with excellent cure rates and long-term survival >90%. Advanced stage disease treated with chemotherapy alone has a 5-year survival of 80–90%. In the relapsed setting, autologous HSCT is typically used in second remission with good success [17].

Non-Hodgkin lymphoma

NHL comprises a heterogeneous group of malignancies, which can be broadly divided into low- and high-grade. Low grade NHLs usually respond well to chemotherapy in combination with monoclonal antibody treatment, although relapses are inevitable with subsequent remissions of sequentially shorter duration. Follicular lymphoma, the commonest low grade NHL, has a median survival of approximately 12 years with current treatments.

High-grade NHLs progress rapidly and often present with large volume lymphadenopathy. The commonest subtypes are diffuse large B cell lymphoma (DLBCL) and Burkitt lymphoma. Current treatment is with combination chemotherapy and anti-CD-20 monoclonal antibody. Prognosis depends on several factors including stage of disease, performance status and age. Good risk patients have a 5-year survival >75%, while poor risk disease has a 5-year survival of approximately 25%. The risk of relapse in DLBCL patients achieving remission with first line therapy is 30–40% [18].

breakdown of the mucosal barriers to infection, long duration of hospital admissions, frequent use of broad-spectrum antibiotics, and the placement of in-dwelling central venous catheters all place these patients at high-risk of potentially life-threatening infection. Despite clinical evidence of sepsis, blood cultures are only positive in 25–30% of cases of febrile neutropenia. With a prolonged duration and severity of immunosuppression, the risk of infection increases, as does the range of likely pathogens with atypical bacterial infections, fungal infections, and viral reactivation, especially herpes viridae, becoming increasingly common. Routine antifungal prophylaxis in high-risk patients and monitoring for cytomegalovirus (CMV) reactivation after allogeneic HSCT are essential components of supportive care.

Fluid overload and electrolyte imbalance

Patients undergoing intensive chemotherapy and HSCT frequently receive large volumes of intravenous fluid in the form of crystalloids, drugs, and blood products. The combined volume can cause pulmonary oedema and, occasionally, the need for ICU support especially in patients with cardiac co-morbidities. Severe electrolyte imbalance is also commonly experienced and can lead to arrhythmias.

Tumour lysis syndrome

Rapid lysis of tumour cells leads to release of cellular contents that are catabolized to insoluble uric acid. This can cause tumour lysis syndrome (TLS), which comprises rapid-onset renal failure and electrolyte imbalance (hyperkalaemia, hyperphosphataemia, and hypocalcaemia). TLS occurs most commonly following initiation of treatment for acute leukaemia or high-grade lymphomas where there is a large tumour burden. Significant tumour lysis can also be precipitated by corticosteroids in the treatment of lymphoma.

ICU admission post-HSCT

There is considerable variation in the reported rates of ICU admission after HSCT. This may be due to differences in local practice and whether reports differentiate between autologous and allogeneic HSCT. Overall, 15.7% of patients undergoing HSCT worldwide are admitted to ICU, although up to 40% of allogeneic HSCT recipients will require admission due to complications [6]. Fewer admissions have been reported after reduced intensity (RI) conditioning regimens than after myeloablative HSCT.

In the conditioning and pre-engraftment periods, the reasons for ICU admission include sepsis (bacterial, fungal, or viral), respiratory failure, fluid overload, cardiac dysfunction, arrhythmias, capillary leak syndrome, diffuse alveolar haemorrhage, hepatic veno-occlusive disease, mucositis, and gastrointestinal haemorrhage. Chronic complications of allogeneic HSCT, such as chronic graft versus host disease, viral reactivation, and prolonged suppression of both humoral and adaptive immune systems can precipitate ICU admission long after the transplant procedure (see Box 374.3) [7].

Box 374.3 Haematopoietic Stem Cell Transplantation: important differences in type of HSCT

Autologous HSCT

Most commonly used in consolidating the treatment of multiple myeloma or relapsed lymphoma. After conditioning chemotherapy, previously collected autologous haematopoietic stem cells (HSCs) are reinfused after thawing. The period of profound cytopenias is typically 8–12 days and is frequently accompanied by mucositis and neutropenic sepsis. Following recovery of peripheral blood counts, most patients experience rapid recovery with fewer long-term sequelae than after allogeneic HSCT.

Allogeneic HSCT

Allogeneic HSCT offers a chance of cure for many patients with haematological malignancy. The HSC source is either a human leukocyte antigen (HLA)-matched **sibling** donor, or an HLA-matched **unrelated donor**. **Umbilical** cord and **haploidentical** HSCTs are employed where no suitable sibling or unrelated donor can be identified. HSCs are harvested either from the bone marrow or collected by leukapheresis after mobilization into the peripheral blood with G-CSF. Conditioning can be either myeloablative or RI. RI transplants have lower levels of acute toxicity and have allowed allogeneic HSCTs to be offered to older patients. Although RI conditioning regimens are less toxic than myeloablative regimens, the prolonged immunosuppression required to permit engraftment of the donor HSCs leads to more late effects, particularly infections and/or graft versus host disease.

Patient outcomes

A retrospective analysis of data from the Intensive Care National Audit and Research Centre (ICNARC) Case Mix Programme database in the UK revealed that the ICU and hospital mortality of 7689 patients with haematological malignancy (including HSCT recipients) was 43.1 and 59.2%, respectively [1]. This is supported by a number of single-centre observation studies reporting similar rates of survival in recent years. The ICU mortality for patients who have undergone HSCT is reported to be 65%, although this underestimates the mortality for allogeneic HSCT recipients, as much of the published literature does not distinguish between autologous and allogeneic HSCT [6]. These survival outcomes represent a dramatic improvement from earlier studies that reported ICU mortality rates of 80–95%; indeed, some recent single-centre studies have demonstrated improved outcomes over time [8–10].

Predicting outcomes

Several studies have investigated whether outcome can be correlated with patient characteristics or clinical variables.

Age

Age is an important risk factor for long-term survival. It features in the prognostic scores used in AML, Hodgkins lymphoma (HL), and NHL, but a clear association of increasing age with short-term ICU survival has not been demonstrated.

Disease status

For patients admitted to ICU with a new presentation of an untreated malignancy, the short-term outcome is unrelated to characteristics of the underlying disease. However, long-term survival after ICU discharge can be anticipated to be inferior in patients with relapsed, refractory or poor risk disease [11].

Neutropenia

The effect of neutropenia on ICU outcome is unclear; some studies report an adverse association, while others fail to identify it as an independent adverse risk factor. Growth factors such as granulocyte colony-stimulating factor (G-CSF) shorten the period of neutropenia. Although widely administered to neutropenic patients in ICU, no survival benefit has yet been demonstrated.

Infection

Superior outcomes have been reported for patients in whom bacterial sepsis is identified as the cause of admission, reflecting the reversibility of the critical illness [12].

Organ failure

Organ failure has been consistently demonstrated to be the single most important indicator of ICU survival, with an increasing number of organ failures associated with a worse outcome. From the ICNARC database, patients with one, three, and five organ failures had ICU mortality rates of 50, 84, and 98% respectively [1].

Respiratory failure

Respiratory failure and the subsequent need for invasive mechanical ventilation is an important predictor of ICU outcome, especially in HSCT recipients; short-term survival in allogeneic HSCT recipients is reported to be 60–80% when ventilation is not required compared with 18–26% in ventilated patients [7,13]. A longer duration of ventilation and the severity of hypoxaemia prior to intubation have been associated with an adverse prognosis among ventilated patients with haematological malignancy. Non-invasive ventilation has been investigated in hypoxaemic haematology patients; while its use was initially reported to be associated with better outcomes and lower rates of intubation than oxygen therapy alone, recent trials have yielded less clear-cut results [14].

Type of HSCT

Due to the lack of distinction in the literature, it is difficult to draw firm conclusions about the impact of different types of HSCT on ICU outcome. The survival rate of patients admitted after autologous HSCT is superior to allogeneic HSCT recipients; furthermore, despite having an older median age, recipients of reduced intensity (RI) allogenic HSCT have superior ICU outcomes compared with myeloablative allograft recipients [15]. Most published series have failed to identify the stem cell source, whether from peripheral blood or bone marrow, and sibling or unrelated donor, as an independent predictor of ICU outcome.

Predictive scores

The Acute Physiology and Chronic Health Evaluation (APACHE) and serial organ failure (SOFA) scores remain predictive of ICU mortality in patients with haematological malignancies, but have been found to be poorly calibrated and underestimate mortality [1]. Organ failure scores may more accurately predict ICU mortality if reassessed at day 5 of ICU admission, although this does not aid prospective identification of patients suitable for ICU admission. Although many single-centre studies have identified combinations of risk factors that predict outcome, there are no predictive scoring systems specific to patients with haematological malignancy or to recipients of HSCTs that have been validated in prospective multi-centre studies.

Long-term outcomes

It is important to consider not only the immediate outcome, but also the long-term prognosis. Treatments are improving with the prospect of cure for more patients than ever before. In studies assessing the long-term survival of patients with haematological malignancy admitted to intensive care, the 6-month survival was approximately 20%, while for those allogeneic HSCT recipients who survived ICU admission, the subsequent 1- and 5-year survival was 61 and 51%, respectively [15]. This impressive long-term survival should serve to support the argument for admission of such patients to critical care.

Reasons for improved outcomes

There are many possible reasons for the improvements in outcome, including better supportive care on the haematology ward, e.g. antifungal prophylaxis, monitoring, and pre-emptive treatment for CMV reactivation, prompt initiation of treatment for sepsis, and better selection of which patients are most suitable for ICU admission. It is also likely that early identification of critically-ill patients using physiological track and trigger systems, and early warning scores, input from critical care outreach teams, and early ICU transfer prior to the development of organ failure has had a beneficial impact on outcome. Finally, the treatments for haematological malignancy are continuing to improve and this, too, will have an impact on long-term survival.

Admission policies, and withholding or withdrawing care

Determining precise admission policies and providing recommendations to identify patients unsuitable for ICU admission remains controversial. The improved long-term survival for haematological malignancy per se, and the improved ICU outcomes for these patients suggest that the same criteria used in patients with non-malignant conditions should be applied when determining the appropriateness of ICU admission. In most instances, it is appropriate to admit critically unwell patients to the ICU, although the appropriateness of ongoing treatment must be formally reviewed on a regular basis. When patients are identified on the ward as being unlikely to benefit from ICU admission, due to either refractory disease with no further possible lines of treatment, or due to frailty, a pre-emptive decision not to admit in the event of critical illness should be considered and, where possible, discussed with patients and their relatives. Close liaison between the ICU and haematology teams is essential, as is communication with the patient and their relatives.

CHAPTER 375

Management of the bone marrow transplant recipient in ICU

Andrew Retter

Key points

- Bone marrow transplant recipients are amongst the most complicated patient's admitted to intensive care. They should always be managed jointly with a haematologist specifically trained in their management.
- There are two types of bone marrow transplant. An autologous transplant is where the patient's own cells are returned to them and an allogeneic transplant where the patient receives donor stem cells.
- Only allogeneic bone marrow transplants can develop graft-versus-host disease.
- All transplant recipients are heavily immunosuppressed and are inherently vulnerable to atypical infections presenting in an unusual manner. There must always be a low threshold to consider infection and a low threshold for investigation and empirical treatment.
- Cytomegalovirus (CMV) viral loads should be checked twice weekly in allograft recipients. CMV viral loads do not need to be routinely checked in patients who have received an autologous transplant.

Introduction

In recent decades outcomes of patients with haematological malignancies have progressively improved due to a better understanding of the underlying disease, increased intensity of chemotherapy regimens, and advances in supportive care. Despite these gains, a proportion of patients will relapse and chemotherapy alone will not provide a cure. Bone marrow transplants (BMT) enable escalation of therapy to treat patients with relapsed disease or those who are at a particularly high risk of relapse. BMT recipients are amongst the sickest and most complicated patients admitted to critical care. Their admission is usually precipitated by a complication directly related to their transplant or underlying disease.

Leukaemia and other cancers consist of hierarchies of cells at various levels of differentiation. Tumours arise from malignant stem cells, which themselves are derived from mutations occurring in normal stem cells [1]. Normal and malignant stem cells repair DNA efficiently, resist apoptosis, and have several mechanisms to excrete toxic drugs [2,3]. Therefore, although chemotherapy can destroy a tumour almost completely, tumour stem cells can survive and cause relapse. BMT allows potential cure of patients at high risk of relapse, or whose underlying disease has been relatively resistant to initial treatment.

There are two types of BMT. The first and simplest form, **autologous bone marrow transplant**, involves collection of stem cells from the patient and their return at a later time. As the patient's own stem cells are returned there is no risk of graft-versus-host disease (GvHD). The second type, **allogeneic BMT**, involves transfusion of donor stem cells to a patient. The key therapeutic mechanism in is the introduction of immunologically active cells from the donor. These cells have the potential to recognize the patient's malignant stem cells and eliminate them [4]. This graft-versus-leukaemic effect reduces the risk of relapse. It is most effective at treating slow-growing cancers. Graft-versus-host disease only occurs in allogeneic BMTs. As with solid organ transplantation, immunosuppression is an essential component of allogeneic transplants to prevent rejection of the donor stem cells (see Fig. 375.1).

Allogeneic BMT can be either myeloablative or non-myeloablative. Initial models regarded allogeneic BMT as a means of escalating the intensity of chemotherapy administered. Transplantation was seen as an 'antidote' to otherwise lethal conditioning. It was thought essential to clear the bone marrow to create space for the new stem cells to repopulate. These concepts are now recognized as over-simplistic. Conditioning serves two purposes:

- It helps to eradicate residual disease.
- It provides immunosuppression allowing engraftment of the transplanted stem cells [5].

The appeal of reduced intensity conditioning (RIC) is that it removes many of the limitations associated with high-dose regimens, so older patients are now eligible for transplantation as are those with underlying medical problems. There has been a progressive tendency to move towards RIC in all but the youngest of patients over the last decade. Treatment complications vary between conditioning regimens and the individual indications for each transplant. Allogeneic BMT provides improved survival,

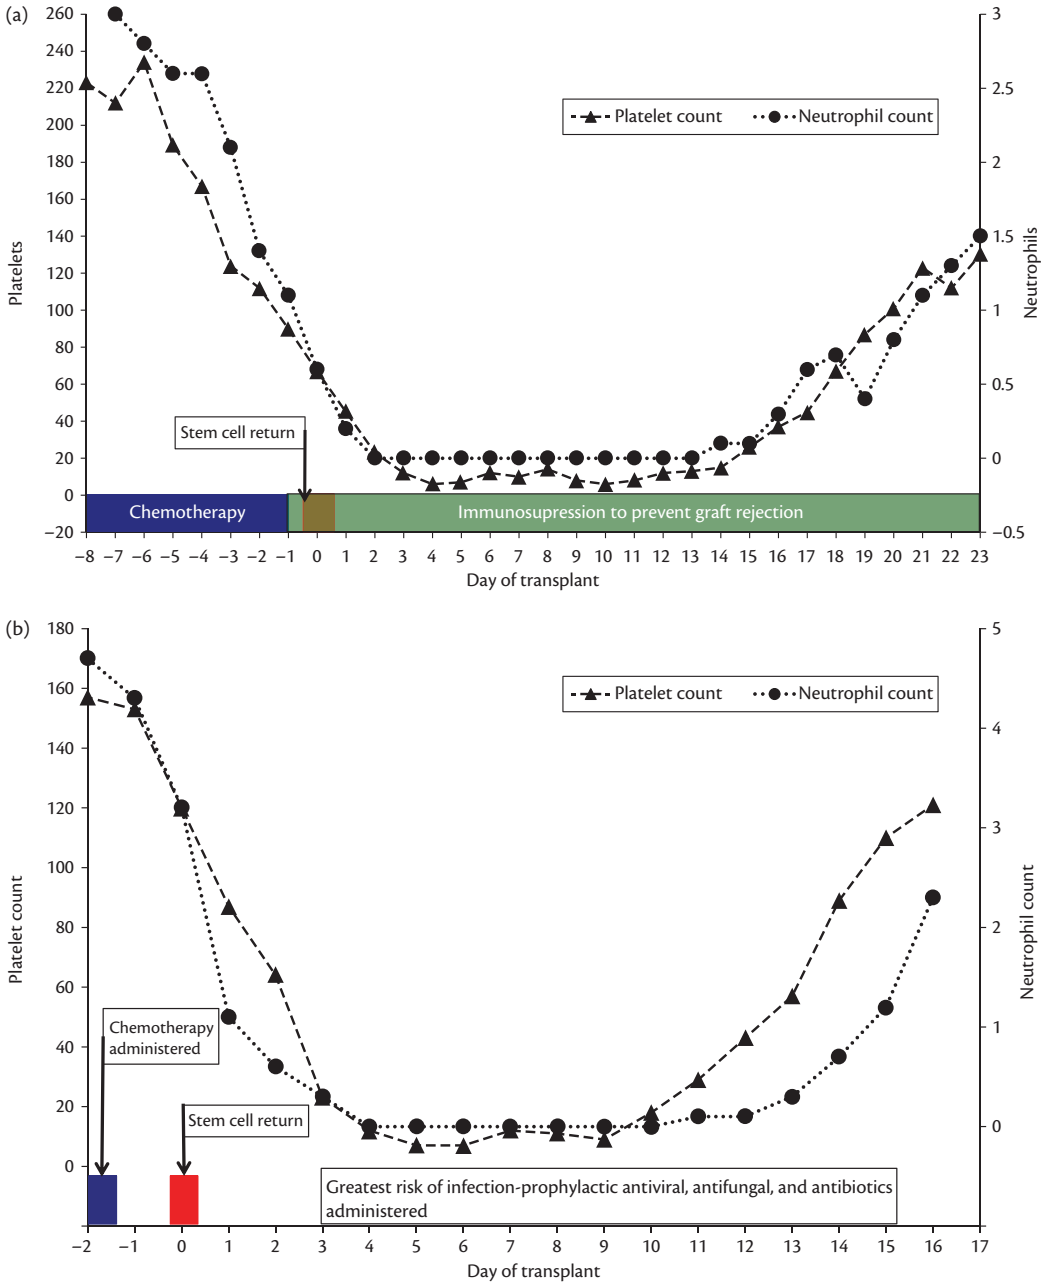

Fig. 375.1 The two graphs depict the fall and recovery of a typical patient undergoing a bone marrow transplant. (a) Pattern of myelosupression and treatment in an allogenic patient. illustrating the greater intensity of chemotherapy in allogenic bone marrow transplants and highlighting the need for immunosuppression in the post-transplant period. (b) Pattern of myelosupression and treatment in an autologous bone marrow transplant.

however it is associated with substantial short- and long-term morbidity and mortality. Around 40% of allogeneic BMT patients will be admitted to intensive care [6].

A summary of the management of BMT patients is given in Table 375.1.

Toxicities associated with bone marrow transplant

The toxic effects of BMT increase with age, particularly in those over 50 years old, and it is generally precluded in patients over 65 years. Complications after transplantation are usually classed as either early (<100 days) or late (>100 days). Early complications of transplantation include infections, (bacterial, fungal, herpes simplex virus, and cytomegalovirus), haemorrhage related to severe thrombocytopenia, acute graft-versus-host disease, haemorrhagic cystitis, interstitial pneumonitis, veno-occlusive disease, and cardiac failure. Late complications include infections (classically encapsulated bacterial and viral, especially varicella zoster virus) chronic graft-versus-host disease, chronic pulmonary disease, autoimmune disease, infertility, and secondary malignancies. The management of specific infectious complications requires a high

Table 375.1 Check list for the management of bone marrow transplant patients

1	Review transplant protocol—is any more chemotherapy required?
2	Ensure GvHD prophylaxis and immunosuppression prescribed
3	Measure ciclosporin level and confirm therapeutic range
4	Determine timing for CMV surveillance
5	Confirm blood product support with haematology and inform local blood bank to ensure provision of irradiated blood products

level of vigilance, and should be managed in conjunction with microbiologists and haematologists. Given the immunocompromised state of BMT patients, prolonged antimicrobial courses are almost always given. The most common non-infectious complications are discussed in the next section.

Graft-versus-host disease

GvHD remains a major complication and cause of mortality. The incidence of acute GvHD is between 10-80% [7]. Diagnosis is based on clinical findings. Any organ system can be affected, most commonly skin, gastrointestinal tract, and liver. The grading system is summarized in Table 375.2. The most severe forms can cause toxic epidermal necrolysis, fulminant hepatic failure, intestinal failure or severe respiratory failure. The grade of acute GvHD correlates with overall survival with transplant-related mortality of grades III and IV reported as 65 and 90%, respectively.

Every patient should be examined daily for GvHD. Initial management involves optimization of their ciclosporin level (target 200–250 μg/L). Patients with grade 3–4 GvHD also require 2 mg/kg methylprednisolone. Topical steroids are given for skin GvHD and oral non-absorbable steroids for gut GvHD. If these fail, a large number of second line agents are available, although none has been shown to be particularly successful when compared with another. The mortality of severe refractory GvHD is very high. These patients are extremely challenging to manage; their care should be coordinated with a dedicated haematologist specialized in managing BMT recipients.

Veno-occlusive disease (or sinusoidal obstructive syndrome)

Veno-occlusive disease (VOD) usually occurs within the first 14 days post-BMT. There is a toxic insult to the hepatic sinusoidal endothelium (presumably as a side-effect of treatment). Endothelial cells desquamate and occlude the microvascular lamina producing a pro-inflammatory response and collagen deposition in hepatic venules leading to liver failure. The diagnosis is difficult to make as the differential includes severe sepsis, acute GvHD, haemolysis, and cholestasis related to medication. Patients complain of right upper quadrant pain and there is a progressive hyperbilirubinaemia with fluid retention and weight gain. Management is supportive. Care must be taken to exclude the differential diagnoses, and to correct any fluid or electrolyte imbalance. Defibrotide, a mixture of single-stranded phosphodiester nucleotides, stimulates plasminogen activator inhibitor, and may help to ameliorate VOD and improve outcome [8].

Ciclosporin toxicity

Ciclosporin is the most commonly used agent for GvHD prophylaxis, although similar principles apply to other immunosuppressive agents, such as mycophenolate mofetil, tacrolimus, or sirolimus. Careful attention must be paid to an allogeneic BMT patient's ciclosporin level when they are admitted. Their condition may mandate the use of intravenous ciclosporin. Plasma levels should be assessed twice weekly to ensure that no large unanticipated deviation from target levels occurs. Low levels can lead to severe GvHD or possible rejection of the donor graft, whereas high levels can cause hypertension, renal toxicity, tremors, seizures, and thrombotic micro-angiopathy. Levels should not be taken from a central line through which ciclosporin has been given as the drug binds to the catheter lumen and can give falsely high, inaccurate results.

Infections associated with bone marrow transplantation

Patients undergoing bone marrow transplantation have compromised innate, cell-mediated, and humoral immunity. This

Table 375.2 Consensus criteria for grading acute GvHD

Stage	Skin	Liver (bilirubin)	Gut
1	Rash <25% BSA[α]	35–50 μmol/L	Persistent nausea, diarrhoea <0.5 L/day
2	Rash 25–50% BSA	51–102	Diarrhoea 1–1.5 L/day
3	Rash >50% BSA	103–255	Diarrhoea >1.5 L/day
4	Generalised erythroderma	>255	Severe abdominal pain or ileus

BSA[α], total body surface area (calculated using the 'rule of 9's).

leads to a high risk of infection, in particular atypical infections. Infections are considered as either pretransplant, pre-engraftment (days 0–20), post-engraftment (days 20–100 post-transplant), and late (>100 days post-transplant). Most commonly, pre- and post-engraftment infections are seen in the ICU. Typically, the first infection seen in the pre-engraftment stage is a bacterial infection; however, respiratory symptoms should raise the possibility of an opportunistic fungal infection, in particular *Aspergillus, Cryptococcus*, or *Candida*.

Fungal infections in bone marrow transplant recipients

The incidence of invasive fungal infection depends on the type of transplant. They are proven in 6% of HSCT recipients. In one series, 90% of patients who developed invasive aspergillosis died [9]. The most common organisms are *Candida* and *Aspergillus*. Neutropenia $\leq 0.5 \times 10^9$/L for >10 days is the most significant risk factor. Patients with chronic GvHD are also at increased risk. Clinical features suggestive of invasive fungal infection include a progressive upper respiratory tract infection, maxillary swelling and tenderness, peri-orbital swelling, palatal necrosis, and popular or nodular skin necrosis. To confirm the diagnosis, hyphae must be detected from a histological or cytological specimen, or a mould should be grown. Depending on the patient's symptoms it is appropriate to consider broncho-alveolar lavage, urine culture, CSF analysis, or tissue biopsy. Clinical features consistent with a lower respiratory tract infection require investigation with an urgent high resolution CT scan with 1-mm slices taken at 1-cm intervals. The 'halo' and air crescent sign, and cavitation are consistent with fungal infection. If empirical treatment is required, local guidelines should be followed. The key principle is to minimize the toxicity associated with antifungal therapy. The British Society of Clinical Haematology Guidelines recommends either liposomal amphotericin or caspofungin as initial therapy [10].

Cytomegalovirus surveillance, prophylaxis, and treatment

Cytomegalovirus (CMV) is a herpes virus which has the ability to remain latent within the body for prolonged periods. Reactivation of the virus is a major concern, and a cause of significant morbidity and mortality in allogeneic BMT recipients. Complications include retinitis, pneumonitis, and colitis. Once established, these are difficult to treat and require prolonged therapy so patients should receive prophylaxis with acyclovir 800 mg tds. Early pre-emptive treatment of viral reactivation can prevent progression to CMV-related organ impairment and failure. All allograft patients should have blood taken twice a week in the early post-transplant period. Occasionally, the level is seen to rise and fall without intervention. Two progressive increments in the CMV level, or a viral load >5000 copies, will require an escalation from prophylaxis to formal treatment. The first line agent is ganciclovir, but this can be myelosuppressive so treatment may need to be switched to foscarnet. Treatment should be continued for a minimum of 2 weeks and only ceased when two consecutive tests confirm that the viral load is undetectable. The risk of recurrent viraemia is high once a patient has reactivated CMV. Any patient with a suspicion of CMV disease should be started on therapy while awaiting the results of the CMV viral load.

Blood product support in bone marrow transplant recipients

Patients undergoing BMT require extensive blood product support. They are at risk of transfusion-associated graft versus host disease. Red cell antigens are not major histocompatibility antigens and haemopoietic stem cell components may be transplanted between red cell antigen (ABO) disparate donors. This can lead to confusion as to the patient's blood group. All bone marrow transplant patients admitted to critical care should have their blood group tested and any special transfusion requirements confirmed with their transplant team and the blood transfusion services. This is particularly important if the patient is admitted to a hospital in which they have not been previously treated. As a general principle the haemoglobin should be maintained above 7 g/dL and platelet count above 10×10^9/L. Platelet transfusion thresholds will be higher if the patient is bleeding or has severe sepsis.

Transfusion-associated GvHD (TA-GvHD) is rare, but almost universally fatal. It occurs when viable white blood cells are transfused from donor to recipient. These white cells detect a disparity with the donor human lymphocyte antigen type and mount a cell-mediated immune response. The features resemble acute GvHD and typically manifest between 10 and 14 days after the transfusion. Irradiation of blood components renders the white cells non-viable and prevents the development of TA-GvHD. All BMT recipients should receive irradiated blood products from at least 14 days prior to transplantation. Irradiation is only required for cellular blood products, which include red blood cells, platelets, and granulocytes. Fresh frozen plasma and cryoprecipitate do not need to be irradiated.

CMV-negative blood components

Recently published position statement by the advisory committee on the safety of blood tissue and organs suggest it is no longer necessary to give BMT recipients CMV-negative products as leukodepletion effectively removes the virus [11]. However, cellular blood components have the potential to transmit CMV and, historically, it was a cause of high morbidity and mortality in BMT patients. Transplant units are currently developing local policies in view of this guidance.

Management of tunnelled venous (Hickman®) lines

Tunnelled venous lines are central to the management of BMT patients. They provide a secure route for administration of chemotherapy, and permit regular administration of blood products and antibiotic support. However, data relating to their safety are lacking. There remains significant concern over the ability to sterilize an infected tunnelled line and the potential for it to act as a sanctuary site for bacteria. Studies of colonized CVP lines suggest that, despite treatment with high-dose antibiotics and the use of antibiotic locks, colonization persists in 35–40% of cases. This constitutes a high risk in BMT recipients who are severely immunosuppressed. Therefore, any such patient admitted to the

ICU with septic shock should have their tunnelled line removed as soon as is practical. The use of antibiotic locks is not recommended and they should not be used to try to 'save-a-line'. Most patients will require administration of a pool of platelets to elevate the platelet count >50 × 10^9/L prior to removal of a tunnelled line. The use of lidocaine with adrenaline is helpful in reducing blood loss when removing the line.

Outcomes for BMT recipients admitted to the ICU

The mortality from severe sepsis in haematology patients is significantly higher than age- and APACHE II-matched controls. ICU survival rates ranging from 17 to 48.3% have been reported [12]. The mortality of BMT patients receiving mechanical ventilation is approximately 90%, but only 78% for those who require renal replacement therapy [13]. These figures do not mean that ICU admission is futile; indeed, mortality rates are improving, although this is generally based on small single-centre studies only. Patients can be managed on non-invasive ventilation and this is associated with improved outcomes. No specific alterations are required for the initiation of ventilation or renal replacement therapy in BMT patients and standard ICU practice with lung-protective ventilation should be followed.

In view of the high mortality, it is important that open and realistic discussions regarding the probable outcome of patients admitted to the ICU are conducted soon after admission with the patient and their family. Ideally, this should be led by a senior intensivist and haematologist. Early referral to palliative care may be appropriate.

CHAPTER 376

Management of oncological complications in the ICU

Niall S. MacCallum

Key points

- Cancer pain is complex and requires multidisciplinary management.
- Cytotoxic therapies can induce toxicity in all major organ systems.
- Management of complications include cessation of cytotoxic therapy and supportive care.
- There are very few proven prevention/treatment strategies.
- Intensivist knowledge of individual cytotoxic therapy allows a better understanding of likely compromised organ systems and physiological reserve.

Introduction

Cancer incidence continues to rise year on year; more than one in three people will be diagnosed with cancer during their lifetime. UK data from 2010 cites prostate, breast, lung, and colorectal cancers as the most common (see Table 376.1).

Complications can be due to treatment (surgery, radio-, chemo-, endocrine, and biological therapy) or disease. Those relevant to critical care are discussed here with the exception of neutropenic sepsis and bone marrow transplant/graft versus host disease that are discussed elsewhere.

Complications

Pain

The aetiology of cancer-related pain is complex and varied. The World Health Organization analgesic ladder has limitations in this context so more comprehensive models have been developed that utilize a mechanism-based multimodal approach [1].

Management should be multidisciplinary, often led by specialists in pain medicine and palliative care, but should also include psychologists and therapists. Accurate assessment is required. Opioids remain the backbone of management, and are used in combination with other agents, e.g. non-steroidal anti-inflammatory agents, anti-epileptics, sodium channel blockers, interventional procedures, and other therapies that treat or palliate cancers.

Management of post-operative pain in cancer patients on high-dose opioids remains challenging. Understanding of the pharmacokinetics of analgesic agents should underpin a detailed management plan to avoid inadequate analgesia, the development of withdrawal symptoms (more likely following an extended period of strong opioid use) or tolerance. Baseline provision of opioids should continue, with supplemental short-acting opioids and non-steroidal anti-inflammatory agents, paracetamol, clonidine, and local anaesthetic infiltration as these have opioid 'sparing effects'. Regional and neuro-axial blocks are recommended where appropriate though further data are needed to ascertain whether these techniques affect disease recurrence.

Chemotherapeutic complications: pancytopenia

Neutropenia

Although definitions vary, a neutrophil count below 0.5×10^9 cells/L is generally accepted. Causative factors are cytotoxic chemotherapy and/or sepsis. The neutrophil count reaches a nadir at 5–7 days for most chemotherapeutic regimens, and can take >2 weeks to recover. Granulocyte-colony stimulating factors (G-CSF) and the cytotoxic regimen affect both the degree and duration of neutropenia. The former is most commonly used in conjunction with 'high-risk regimens', but practice varies widely. The UK National Institute of Clinical Excellence does not advise starting G-CSF unless part of a chemotherapeutic regimen [2].

Anaemia

There is no evidence that critically-ill cancer patients should be subject to higher transfusion thresholds than the currently accepted practice of a haemoglobin level of 70 g/L [3]. Peri-operative blood transfusions not only worsen short-term surgical outcomes, but may also lead to an increased risk of cancer recurrence [4].

Thrombocytopenia

Platelet transfusion thresholds of $10–20 \times 10^9$/L are based on studies demonstrating little or no increased risk of bleeding, but a substantial reduction in the use of platelet transfusions. It is common practice to raise this threshold (e.g. to 50×10^9/L) in the presence of deranged coagulation or active bleeding, and preceding interventions [5].

Methotrexate

Bone marrow suppression can be a dose-limiting side effect of therapy, but is usually more prevalent in low-dose regimens (e.g. for managing rheumatoid arthritis), rather than the high-dose regimens used for malignant disease. Administration of folinic acid to bypass the metabolic block induced by methotrexate avoids host-induced toxicity without diminishing anti-tumour activity.

Table 376.1 Commonest cancers in the United Kingdom in 2010 represented as percentage of all cancers excluding non-melanoma skin cancer

Commonest cancers in the United Kingdom in 2010	Percentage of all cancers excluding non-melanoma skin cancer

Mechanisms whereby reduced folate rescues normal, but not malignant cells are incompletely understood.

Chemotherapeutic complications: cardiac toxicity

The increasing age and cardiac co-morbidities of patients receiving chemotherapy is likely to cause more adverse events, the spectrum of which is expanding following the recognition of additive cardiac toxicities of chemotherapeutic agents and the increased use of targeted 'biological' therapies [6].

Anthracyclines

Doxorubicin and other anthracyclines may cause cardiomyocyte and interstitial injury via oxidative stress and the induction of apoptosis. Acute clinical manifestations include atrial fibrillation, heart failure, myocarditis, and myocardial infarction. Chronic manifestations are due to dose-dependent cumulative toxicity leading to diastolic and systolic dysfunction. Factors increasing the risk of cardiac toxicity include age, combinations of cyclophosphamide, taxanes, or trastuzumab, and mediastinal irradiation. Delayed late toxicity manifest as left ventricular dysfunction is reported in 5–10% of patients in remission. Strategies for prevention of cardiac toxicity have largely lacked success. There may be a role for prolonging the duration of administration. While cardiovascular drugs show promise in animal models, these have either not been translated into human use or sufficiently investigated. Antioxidant drugs have not shown efficacy in humans with the exception of dexrazoxane, an iron-chelating compound, which led to lower reductions in left ventricular ejection fraction.

Alkylating agents

High-dose cyclophosphamide (e.g. as induction therapy for bone marrow transplantation) is linked to acute heart failure and often associated with pericardial effusion. Mechanism may be related to glutathione redox cycling. Pathological findings include necrosis, endothelial injury, microvascular thrombi, and ischaemia. If patients survive the acute episode, the left ventricular dysfunction is reversible. Cisplatin can result in hypertension, myocardial ischaemia and left ventricular dysfunction.

Antimetabolites

The risk of cardiac toxicity (myocardial ischaemia, acute heart failure, hypotension, ventricular arrhythmias) with agents such as fluorouracil and capecitabine is increased in patients with cardiac co-morbidity or associated risk factors. Acute coronary syndromes can occur despite normal coronary angiography. Pharmacological interventions to prevent recurrent ischaemia have not proved to be effective.

Microtubule inhibitors

Paclitaxel and docetaxel may cause bradycardia, ventricular arrhythmias, myocardial ischaemia and left ventricular dysfunction. They also potentiate anthracycline cardiotoxicity.

Targeted therapies

Monoclonal antibodies and tyrosine kinase inhibitors are associated with left ventricular dysfunction, which is often transient. The mechanism of action is purported to be via target genes. The incidence is increased with age, pre-existing cardiac disease, and combination radio- or chemotherapy, particularly with anthracyclines where sequential therapy is advocated.

Management should be placed in the context of improved cure rates for many cancers. Clinically significant cardiac toxicity occurs in up to 10% of patients. Evaluation should be performed prior to administering chemotherapy to identify patients at increased risk. They should be closely monitored, preferably in collaboration with a cardiologist. Routine investigations include electrocardiograms and cardiac imaging. Troponin levels may assist in risk assessment, but the role of other biomarkers (e.g. B-type natriuretic peptide) is less clear. Critical care management is supportive. Follow-up should occur at regular intervals and for a longer duration in those who develop cardiac toxicity. Early initiation of angiotensin-converting enzyme inhibitors and β-adrenergic receptor blockade has shown promise for long-term recovery of left ventricular dysfunction.

Chemotherapeutic complications: pulmonary toxicity

Toxicity post-exposure to chemotherapeutic agents occurs in 20% of patients. The wide spectra of pulmonary manifestations and important differential diagnoses (infection, disease progression, interstitial lung disease, pulmonary oedema, and non-chemotherapeutic drug effects) continue to pose challenges. Furthermore, lack of clear diagnostic criteria lead to a diagnosis based on exposure and exclusion of other aetiologies. Many adverse drug reactions are idiosyncratic and unpredictable. Pathogenesis is poorly understood, with direct cytotoxicity being the most likely mechanism. Pre-existing lung disease, increasing age, smoking (e.g. with bleomycin), previous radiotherapy, cumulative dose (e.g. nitrosourea) and/or specific combinations of chemotherapeutic agents (e.g. gemcitabine and paclitaxel) are associated with increased risk.

Oxygen therapy is well recognized to increase pulmonary toxicity in certain circumstances, e.g. with bleomycin or mitomycin. There is also an increased prevalence of pulmonary infection attributable to certain chemotherapeutic agents [7,8].

Investigation often reveals a reduction in transfer factor and a restrictive pattern on pulmonary function testing. Radiographic patterns include reticular or nodular markings, ground glass opacities, consolidation, and pleural effusions. Broncho-alveolar lavage fluid leukocyte counts are usually elevated, but have no diagnostic specificity. Generic management includes balancing the risk-benefit of discontinuation of therapy and supportive care. Steroid therapy (after exclusion of infective aetiology) may have a role. However, evidence remains largely observational. Specific chemotherapeutic agents are discussed in the following section and others are listed in Table 376.2.

Antimetabolites

The folic acid analog methotrexate induces pulmonary toxicity in <10% of patients. Incidence varies with indication, co-administration of cytotoxic agents, and pulmonary co-morbidities. Hypersensitivity pneumonitis is most prevalent, but organizing pneumonia, interstitial pneumonia, non-cardiogenic pulmonary oedema, pulmonary fibrosis, and pleural effusions also occur. Suggested mechanisms include hypersensitivity reactions and direct toxic effects. Lymphoproliferative disease may appear during, and regress following, methotrexate therapy. Diminished immune surveillance and Epstein–Barr virus infection may also be implicated.

Cytotoxic antibiotics

Bleomycin causes severe pulmonary fibrosis in up to 10% of patients and, less commonly, organizing pneumonia and hypersensitivity pneumonitis. Toxicity is cumulative dose (≥400 units) dependent. Risk factors include renal dysfunction, exposure to high oxygen levels, radiation therapy, age >40 years, and smoking. Mechanisms include oxidative damage, augmentation of inflammatory mediators, (pulmonary) deficiency in the inactivating enzyme and genetic factors. Additional management includes titration of inspired oxygen to target lower oxygen saturation (SaO_2 88–92%).

Mitomycin induces a breadth of pulmonary toxicity in ~10%, particularly at higher doses (>20 mg/m^2), including bronchospasm, acute lung injury, interstitial pneumonitis, pulmonary hypertension, thrombotic micro-angiopathy, and pleural disease. Risk factors include co-administration of cytotoxic agents (e.g. vinca alkaloids) and high FiO_2 (>0.5). Thrombotic micro-angiopathy has similar characteristics to thrombotic thrombocytopenic purpura/haemolytic uraemic syndrome, and is associated with acute lung injury, cumulative dose exposure, and certain drugs (e.g. fluorouracil). Pathology varies depending on the type of injury. Additional management includes plasma exchange for thrombotic micro-angiography and titration of inspired oxygen to lower oxygen saturation targets (SaO_2 88–92%).

Table 376.2 Chemotherapeutic agent induced pulmonary toxicity

Agent	Toxicity	Notes
Alkylating agent: Busulfan Chlorambucil Cyclophosphamide Fosfamide Melphalan Oxaliplatin	◆ Acute lung injury ◆ Chronic interstitial fibrosis ◆ Alveolar haemorrhage ◆ Chronic interstitial pneumonitis ◆ Pneumonitis (acute and chronic) ◆ Interstitial pneumonia, methemoglobinaemia ◆ Pneumonitis, bronchospasm ◆ Interstitial and/or eosinophilic/cryptogenic organizing pneumonia, alveolar haemorrhage	Used prior to haematopoietic stem cell transplantation **Acute**: cessation and steroid therapy result in complete resolution **Chronic**: poorly responsive to steroids **Risk factors**: radiotherapy, oxygen therapy, co-administration of cytotoxic agents that cause pulmonary toxicity Limited evidence for steroids β-adrenergic agents Limited evidence for steroids
Angiogenesis inhibitor: thalidomide	Thromboembolic disease, non-thromboembolic pulmonary hypertension, interstial fibrosis, lymphocytic alveolitis, eosinphilic pneumonia, organizing pneumonia	
Antibiotic: doxorubicin	Interstitial and/or organizing pneumonia	
Antimetabolite: Cytarabine Fludarabine Gemcitabine	◆ Non-cardiogenic pulmonary oedema ◆ Interstitial pneumonitis ◆ Interstitial pneumonitis, non-cardiogenic pulmonary oedema, alveolar haemorrhage, pleural effusion, eosinophillic pneumonia	Cessation and steroid therapy results in resolution Cessation and steroid therapy results in amelioration. Potent radiosensitizer **Risk factors**: co-administration (bleomycin, paclitaxel), pre-existing pulmonary fibrosis
Camptothecin: irinotecan	Fibrosis, pleural effusions	Limited evidence for steroids
Nitrosourea: carmustine	Pulmonary fibrosis (acute and late onset)	Limited evidence for steroids **Risk factors**: cumulative dose, co-administration with cyclophosphamide
Proteasome inhibitors: Bortezomib, carfilzomib	Severe dyspnoea	Limited evidence for steroids **Reported**: interstitial lung disease, pulmonary hypertension

Microtubule inhibitors

Taxanes (paclitaxel and docetaxel) induce a spectrum of pulmonary toxicity in <5%, including interstitial pneumonitis and capillary leak syndrome, the former via an immune-mediated delayed hypersensitivity reaction. Capillary leak syndrome subsequent to docetaxel administration can lead to non-cardiogenic pulmonary oedema and effusions. Risk factors include dose, associated use of growth factors, pre-existing lung disease, co-administration with cytotoxic agents (e.g. gemcitabine) and radiotherapy. Steroid administration has some evidence of benefit in capillary leak syndrome.

Targeted therapies

Molecularly-targeted anti-cancer therapy is increasingly utilized and associated with pulmonary toxicity. Rituximab (B-cell depleting anti-CD20 monoclonal antibody) is increasingly used in critical care settings: dyspnoea and bronchospasm are common. Interstitial pneumonia occurs in <10% and is more likely to occur with co-administration of other cytotoxic agents. Rituximab-associated acute lung injury has a mortality of 30% [9].

Chemotherapeutic complications: renal toxicity

Chemotherapeutic agents are associated with electrolyte disorders, development of acute kidney injury, urate nephropathy, renal calculi, or bladder toxicity [10,11]. Intra-vascular volume depletion, concomitant non-chemotherapeutic nephrotoxic drugs (e.g. aminoglycosides), obstructive uropathy secondary to underlying tumour, and idiopathic renal disease related to other co-morbidities are potential risk factors for renal dysfunction. Chemotherapeutic agents can affect the glomerulus, tubules, interstitium, or microvasculature of the kidney. Most chemotherapeutic agents have significant renal clearance.

Platinum analogues

Mechanisms contributing to renal dysfunction include tubular epithelial cell toxicity (necrosis and apoptosis), microvascular vasoconstriction, and increased expression of pro-inflammatory mediators. Toxicity is manifest as renal dysfunction (up to 50% of patients), but salt wasting, a Fanconi-like syndrome and anaemia (through erythropoietin deficiency) are also reported. The incidence of renal impairment depends on the dose and frequency of administration, and increases with subsequent courses. In combination with bleomycin or gemcitabine, cisplatin is associated with a thrombotic micro-angiopathy-induced renal dysfunction. Renal dysfunction can be prevented with lower doses of cisplatin in combination with intravenous isotonic crystalloid. Carboplatin is less nephrotoxic than cisplatin.

Alkylating agents

Cyclophosphamide and ifosfamide toxicity is manifest as haemorrhagic cystitis or hyponatremia (via an increased effect of anti-diuretic hormone). Hyponatraemia normally resolves after discontinuing the chemotherapeutic agent. Therapies to prevent haemorrhagic cystitis include hyperhydration, bladder irrigation, and mesna (2-mercaptoethane sodium sulfonate). Mesna is protective during oxazaphosphorine therapy, but must be present in the bladder at the time of chemotherapy administration. Ifosfamide is more likely to cause nephrotoxicity than cyclophosphamide.

Antimetabolite

High-dose methotrexate can reversibly decrease glomerular filtration and cause tubular injury by precipitation. Dehydrated patients or those who excrete acidic urine are at greatest risk. An adequate diuresis and urinary alkalinization (urinary pH >7) minimizes the risk of precipitation. However, despite wide use, benefits remain unproven. Methotrexate toxicity can be treated with glucarpidase generating an inactive metabolite.

Nitrosoureas

Prolonged therapy carmustine can induce interstitial nephritis, although underlying mechanisms are poorly understood. Melphalan is associated with inappropriate anti-diuretic hormone secretion.

Cytotoxic antibiotics

Mitomycin toxicity is manifest as renal failure and micro-angiopathic haemolytic anaemia. It is related to cumulative dose, and most likely due to endothelial injury.

Tumour lysis syndrome

Tumour lysis syndrome (TLS) occurs after initiating cytotoxic therapy, most commonly for high-grade lymphomas (e.g. Burkitt's) and acute lymphoblastic leukaemia, but also for other tumour types with a high proliferative rate, large tumour burden, or increased sensitivity to cytotoxic therapy [12]. Prerenal failure, pre-existing renal abnormalities and hyperuricaemia are contributory factors. Clinical TLS is defined by the presence of laboratory TLS (≥2 of hyperuricaemia, hyperphosphataemia, hyperkalaemia, hypocalcaemia) and ≥1 of a 50% increase above the normal range of serum creatinine, cardiac arrhythmia/sudden death, or seizure. Clinical TLS significantly increases morbidity, treatment-related complications, and the risk of death.

Substantial tumour cell lysis releases large amounts of intracellular potassium, phosphate and nucleic acids, the latter leading to hyperuricaemia via enzymatic degradation by xanthine oxidase and secondary hypocalcaemia. Increased uric acid excretion can result in uric acid precipitation in renal tubules, a decrease in renal blood flow, impaired autoregulation and inflammation, culminating in acute kidney injury (AKI). Hyperphosphataemia causes calcium phosphate deposition in the renal tubules, also leading to AKI.

Hyperuricaemia and hyperphosphataemia also enhance precipitation of uric acid and calcium phosphate crystals in each other's presence.

Uric acid is poorly soluble in water, particularly in an acidic environment (distal tubules and collecting system) leading to crystal deposition and acute uric acid nephropathy. Hypouricaemic agents (e.g. allopurinol, rasburicase) have significantly reduced the risk. Nephrocalcinosis is now the major cause of AKI in TLS. Calcium phosphate deposition in the heart may lead to cardiac arrhythmias.

Allopurinol competitively inhibits xanthine oxidase, thereby increasing hypoxanthine levels and blocking uric acid production. Hypoxanthine is more water-soluble than uric acid. However, allopurinol will also increase xanthine excretion, and this may precipitate in the renal tubules, paradoxically inducing an AKI and/or xanthine calculi.

Urate oxidase, which oxidizes uric acid to the significantly more soluble allantoin, is not present in humans. Rasburicase, an exogenous urate oxidase, markedly reduces uric acid levels within hours.

Rasburicase is contraindicated in glucose-6-phosphate dehydrogenase deficiency as it can cause methemoglobinaemia and haemolytic anaemia.

The hallmark of management is prevention. This can be based on a (disease-specific) risk stratification [13] and may include:

- **Fluid hydration**: aggressive fluid therapy (to minimize crystal precipitation) targeting a urine output of 2 mL/kg/hour; diuretic therapy may be supplementary in the absence of hypovolaemia or obstructive uropathy.
- **Urinary alkalinization**: not recommended in the absence of metabolic acidosis and may promote calcium phosphate deposition. It is not needed for patients receiving rasburicase.
- **Hypouricaemic agents**: in principle, rasburicase is recommended for high-risk patients, and rasburicase or allopurinol for intermediate risk cases. With regard to rasburicase treatment, G6PD deficiency should be excluded, uric acid levels should be monitored, and allopurinol administered if only a single dose has been used.

Chemotherapeutic complications: hepatic toxicity

Chemotherapy-induced hepatotoxicity can be direct or may potentiate pre-existing liver disease [14]. Altered hepatic drug metabolism may potentiate toxicity. Mechanisms are varied and include hepatocellular injury, inflammation, cholestasis, endothelial damage, and thrombosis. Hepatic sinusoidal obstruction syndrome is caused by non-thrombotic obliteration (fibrin deposition) of small intrahepatic veins, leading to obstruction and centrilobular hepatocellular necrosis; it occurs most commonly following haematopoietic stem cell transplantation and may be drug-induced (e.g. dacarbazine, dactinomycin, azathioprine).

Clinical presentations range from deranged biochemical indices to fulminant hepatocellular failure. Management is supportive with withdrawal of the likely agent. Distinction between chemotherapy-induced hepatotoxicity and other aetiologies of hepatic failure, such as tumour progression and exacerbation of co-existing liver disease can be challenging. Imaging may be helpful.

Chemotherapeutic complications: neurotoxicity

Chemotherapeutic agents can be directly neurotoxic or act indirectly via metabolic, vascular or autoimmune paths. Chemotherapy-induced peripheral neuropathy (CIPN) is the most common problem. Differential diagnoses include metastatic disease, paraneoplastic syndromes and co-existing neurological dysfunction. Risk factors include dose, duration, and co-administration of neurotoxic agents (e.g. platinum analogs) [15].

CIPN is frequently associated with treatment for breast or colon cancer. Sensory neuropathy is more common than motor, while autonomic neuropathy is uncommon except with vincristine. Management includes agent cessation or dose and/or duration adjustment. Many neuroprotective agents aimed at preventing or treating neuropathy have been tried, however, the evidence base remains weak.

Platinum analogs are commonly associated with neurotoxicity. Cisplatin is associated primarily with peripheral neuropathy and ototoxicity. The risk of neuropathy is cumulative dose-dependent and recovery often incomplete. Ototoxicity is manifest as high-frequency sensorineural hearing loss; concomitant cranial radiotherapy is synergistic. Other chemotherapeutic agents and associated neurotoxicity are listed in Table 376.3.

Chemotherapeutic complications: nausea and emesis

Chemotherapy-induced nausea and vomiting can be extremely distressing and challenging to treat. Three types of emesis have been defined:

- Acute, occurring within the first 24 hours after chemotherapy.
- Delayed, after 24 hours, more difficult to manage with anti-emetics, frequently associated with platinum analogs.
- Anticipatory, a conditioned response in those with severe symptoms from previous chemotherapy.

Table 376.3 Chemotherapeutic agent-induced neurotoxicity

Agent	Toxicity	Notes
Dihydrofolate reductase inhibitor: methotrexate	◆ Aseptic meningitis ◆ Transverse myelopathy ◆ Encephalopathy ◆ Leukoencephalopathy	Typically following intrathecal administration, indistinguishable from other aseptic meningitides More common with concurrent radiotherapy More frequent with high dose therapy
Cyclophosphamide analog: ifosfamide	Encephalopathy	Greater risk with renal dysfunction
Platinum analogues: oxaliplatin	◆ Acute neurosensory complex ◆ Sensory neuropathy	Cumulative dose-dependent
Proteasome inhibitors: bortezomib	Painful sensory neuropathy	
Taxanes, anti-microtubule agents: paclitaxel, docetaxel	Sensory neuropathy	Cumulative dose dependent
Thalidomide	◆ Peripheral neuropathy (sensory and motor) ◆ Somnolence ◆ Autonomic neuropathy	Dose dependent and cumulative
Vinca alkaloids: vincristine	◆ Axonal neuropathy ◆ Autonomic neuropathy ◆ Focal mononeurothy	Dose-related severity

Mechanisms are many, complex, and incompletely understood. Afferent inputs include the chemoreceptor trigger zone and the gastrointestinal tract (vagus and splanchnic nerves) triggering efferent signals from the brainstem (vomiting centre). Many neurotransmitters (e.g. dopamine, serotonin, substance P) are implicated as their antagonists demonstrate clinical benefit. Some chemotherapeutics interact directly with the chemoreceptor trigger zone, while others initiate release of neurotransmitters through direct cytotoxic effects on intestinal cells.

The principle of management is prevention. Chemotherapeutic regimens are categorized on the probability of inducing emesis [16]. Anti-emetics with the highest therapeutic index: 5-hydroxytryptamine (5-HT3) receptor antagonists, glucocorticoids and neurokinin-1 (NK1) receptor antagonists (e.g. aprepitant) form the mainstay of treatment and are synergistic. 5-HT3 antagonists have a lesser role in delayed emesis. The anti-emetic properties of glucocorticoids are probably a class effect; dexamethasone is most evaluated and commonly used. Other agents (e.g. prochlorperazine, metoclopramide, cannabinoids, olanzapine) are reserved for specific situations or when first-line agents prove refractory. Complementary therapies (e.g. supplemental ginger, acupuncture) play a modest role.

Miscellaneous chemotherapeutic complications

Chemotherapeutic regimens can affect mucous membranes, skin, hair, and nails through various mechanisms. Differential diagnoses include cutaneous adverse non-cytotoxic drug reactions, pre-existing conditions, infection, graft-versus-host disease, metastatic disease, paraneoplastic phenomena, and cutaneous manifestations of the underlying cancer.

Musculoskeletal toxicity is reported, most commonly manifest as arthralgia and/or myalgia, but also arthritis, scleroderma, Raynaud's phenomenon, osteonecrosis, and elevated creatine kinase.

Radiotherapy complications

Radiation therapy can induce interstitial fibrosis in both heart and lung [17]. In radiation-associated cardiotoxicity there is narrowing of blood vessels with endothelial cell damage. The ratio of capillaries to myocytes is reduced, leading to necrosis and fibrosis. This can be manifest clinically as coronary artery disease, or valvular, myocardial, and conduction system fibrosis. Risk factors include total radiation dose, fractional dose, exposure of heart, and concomitant cardiotoxic agents. Patients with breast cancer or Hodgkin's lymphoma are at risk of developing cardiac toxicity.

Radiation-induced lung injury is more likely in patients with genetic susceptibility. Pro-inflammatory mediators are upregulated following irradiation with direct cytotoxic effects, inflammation, and fibrosis. Transforming growth factor-β, and platelet-derived growth factor induce fibroblast collagen deposition and fibroblast growth factor. Risk factors include the volume of lung irradiated, radiation dose, concurrent chemotherapy (e.g. bleomycin), and induction chemotherapy. Clinically, apparent radiation pneumonitis occurs in up to 10–15% of breast and lung cancer patients, with radiological abnormalities present in up to two-thirds. Diagnosis is based on correlation between onset of symptoms and timing of radiation, imaging, pulmonary function tests and bronchoscopy. Glucocorticoids may play a role in modulating disease, but prospective evidence is lacking [18].

Gut toxicity can occur when the gastrointestinal tract is exposed to radiation therapy. Effects can be early (e.g. nausea and diarrhoea) or late (e.g. ulceration, stricture formation and obstruction, malnutrition). The mechanism of action is a direct cytotoxic effect on the epithelial layer leading to mucosal thinning, inflammation, and fibrosis. Risk factors include radiation dose, concurrent chemotherapy, and vasculopathy. Management is symptomatic and includes endoscopic dilation for strictures.

Radiotherapy is also directly hepatotoxic. Injury is worsened with addition of chemotherapeutic agents (e.g. vincristine) that are also associated with radiation 'recall' injury. Radiation hepatitis is manifest by veno-occlusive disease progressing to fibrosis, cirrhosis, and hepatic failure.

Thromboembolic disease

Thromboembolic disease is a common cause of mortality and morbidity in cancer patients who have a 6-fold increased risk compared with the normal population. When adjusted for prevalence, the most common malignancies associated with thrombosis are pancreatic, ovarian, and central nervous system cancers. Low molecular weight heparin may be superior to oral anticoagulation [19].

SECTION 21

Recovery from critical illness

PART 21.1

In-hospital recovery from critical illness

CHAPTER 377

Chronic critical illness

Catherine L. Hough

Key points

- Chronic critical illness (CCI) is common, with estimated point prevalence of over 100,000 patients in the United States, and expectations for a rapid rise.
- CCI encompasses much more than the respiratory system, with effects on metabolism, skin, brain, and neuromuscular function.
- During CCI, patients have a high burden of symptoms and impaired capacity to communicate their needs.
- Mortality and quality of life are generally poor, but highly variable, with one-year mortality over 50% and most survivors suffering permanent cognitive impairment and functional dependence.
- Caring for the chronically critically ill is a substantial burden both to patients' families, and to the health care system as a whole.

Introduction

For most patients in the intensive care unit (ICU), change happens quickly. However, there are patients—collectively termed the 'chronically critically ill'—who neither quickly resolve organ failures nor die, remaining dependent on mechanical ventilation and other life-sustaining therapies for weeks, months, or more. This chapter will discuss chronic critical illness (CCI), beginning with definitions and epidemiology. Clinical features and outcomes will be presented, as will the impact of CCI on family members and the health care system.

Definitions

As a state where a critically ill patient is no longer dying or recovering, CCI is easiest to recognize late, or in hindsight. Definitions generally focus on duration of critical illness of mechanical ventilation, ranging from ≥48 hours to ≥4 weeks of ventilator support. A consensus definition of prolonged mechanical ventilation, the condition most commonly associated with CCI, is ≥21 days of mechanical ventilation [1]. Since administrative data typically do not include precise duration of mechanical ventilation, alternative definitions have been developed for health services research using tracheotomy in combination with either ≥96 hours of mechanical ventilation or ICU length of stay ≥21 days [2]. Tracheotomy is an appealing marker of CCI; it is reliably coded in administrative data and represents both a commitment to ongoing life support as well as an expectation of need for ongoing ventilator support. However, utilization of tracheotomy is highly variable; inclusion in the definition may markedly underestimate CCI incidence. A pragmatic definition of CCI for clinical use suggests at least 10 days of mechanical ventilation with no expectation for imminent death or ventilator liberation [3].

Epidemiology

The incidence of critical illness is increasing in the United States, with an estimated 2.7 hospitalizations involving mechanical ventilation for each 1000 people each year, for a total of nearly 800,000 hospitalizations [4]. The number of patients receiving ≥96 hours of mechanical ventilation is also increasing, including nearly 40% of all patients receiving ventilation. The incidence of CCI is also rising, occurring in 4–10% of ICU admissions in the United States and United Kingdom [3]. In North Carolina, the incidence of CCI nearly tripled between 1993 and 2004 [5].

It may be challenging to identify a patient who will go on to develop CCI early in the course of acute illness. A 'typical' CCI patient initially looks like most critically-ill patients: aged 50–70 years, with pneumonia or sepsis, afflicted with several pre-morbid conditions, and severely ill. Certain factors are independently associated with CCI [6], duration of ventilation [7] or ICU stay [8]: ICU admission diagnoses (pneumonia, acute respiratory distress syndrome, aortic dissection/rupture, head injury, and intracranial haemorrhage); patient factors (age, prior functional status); and physiological variables (severity of illness scores, tachypnoea, hypoxaemia). However, models to predict CCI or even readiness for ventilator liberation, perform poorly [9].

Clinical features

Most CCI patients have respiratory failure requiring prolonged mechanical ventilation. A smaller proportion may require ongoing life support for other organ failures (e.g. vasopressor support, renal replacement therapy). In addition, the syndrome of CCI is marked by profound multisystem dysfunction. Acute brain dysfunction, in the form of coma and delirium, is common in CCI. Neuromuscular dysfunction (including atrophy, critical illness myopathy and neuropathy) is omnipresent in CCI and likely plays an important role in ventilator weaning. There are changes in body composition (including loss of lean muscle mass, increased fat, and anasarca) and complex neuroendocrine changes, with loss of pulsatile secretion of anterior pituitary hormones due to decreased hypothalamic stimulation [3].

Characteristic metabolic changes occur in CCI, including protein catabolism, hypoalbuminaemia, stress hyperglycaemia, and

bone hyper-resorption [10]. Cardiac dysfunction may accompany acute critical illness, exacerbated by baroreceptor dysfunction and deconditioning. Patients are at risk for infectious complications, due to loss of barriers, altered immune function, and exposure to multi-drug resistant organisms. Treatment factors, including immobility, fluid overload, under- or over-feeding, ventilator-associated lung injury, phlebotomy and transfusion, and heavy use of sedatives, may play important roles in occurrence and outcome of CCI.

CCI is marked by high levels of symptom distress. In one study of fifty CCI patients on mechanical ventilation, difficulty with communication was nearly universally endorsed, and was highly and frequently distressing for patients [11]. All 16 symptoms assessed were endorsed by at least half of the patients surveyed, and half of all patients rated their lack of energy, dry mouth, hunger, thirst, worry, sadness, and nervousness as moderate to severe.

Treatment

There is little empiric evidence to guide the care of CCI, either for specific processes of care, or for venues or models of care delivery. As CCI is typified by multisystem involvement, care should be integrated and interdisciplinary. Liberation from ventilation is a crucial component; observational studies have suggested that protocolized weaning by non-physician care providers is associated with marked reductions in weaning time [12]. Recently, a randomized controlled trial in a long-term acute care hospital (LTACH) demonstrated that a protocol of tracheotomy collar trials may be superior to pressure support [13]. Many questions remain about the 'best' approach to ventilator weaning in CCI. Similarly, there is little to help identify patients who may benefit from tracheotomy placement, and ideal timing remains uncertain [9].

A significant task in the care of CCI is prevention of complications. Processes of care that prevent infection (e.g. hand washing, isolation, avoidance of unnecessary antibiotics, and limiting catheter use) and skin breakdown require vigilance. There are important roles for nutritionists (e.g. prioritizing enteral feeds, targeting protein and caloric intake) despite minimal empiric evidence [10]. Early integration of rehabilitation therapies can help maintain focus on functional recovery. Equally important is palliative care to help address and alleviate symptom distress, to continue to re-explore goals of care, to enhance communication, and to plan for transitions in care beyond the acute care environment. Families are frequently ill informed about expected outcomes, including survival, functional impairment, and caregiving needs, with a high degree of discordance between anticipated and actual outcomes [3].

Outcomes

Understanding expected outcomes and matching care to patient values is especially important in CCI, given the cost, duration, and high symptom burden. Outcomes after CCI are variable, and may be magnified by heterogeneity of definition and cohort. For example, defining CCI by placement of tracheotomy for prolonged mechanical ventilation or by LTACH admission may identify a cohort with better outcomes since clinicians may select these treatments in patients with better anticipated survival.

Among ventilator-dependent patients with CCI, 30–54% of patients achieve ventilator liberation and discharge from acute care hospital [14]. Unfortunately, the risk of death remains high. One year survival ranges from 31–52% across definitions of CCI [14]. Initial discharge home is rare; multiple re-admissions and transfers between institutional settings are common after CCI [15]. Survivors have a high burden of functional impairment and dependence; studies have consistently shown that less than 12% of one-year survivors are capable of independent living. Survivors have persistent deficits in physical function, but many are too impaired to participate in follow-up, leading to an underestimate of physical impairment [3]. While outcomes are poor for most with CCI, there is considerably variability in likelihood and quality of survivorship. Patient factors, such as age, number of residual organ failures, and inciting factor for CCI, can identify patients at highest and lowest risk of death [16]. High quality care of the patient and caregiver requires recognizing likely outcome, discussing with family, and guiding care accordingly.

Impact on informal caregivers and the health care system

The cost of CCI is high, as experienced by patients, families, and the health care system. Studies of families show a high degree of depression and post-traumatic stress symptoms that may be long-lasting [17]. Family members report deterioration of their own physical health. The financial impact may be significant, from loss of work and medical costs, even among insured. Notably, negative effects on physical and mental health are seen in families who provide care at home as well as those using institutional care. Improving family outcomes is an important target of research in care of CCI, with studies underway of strategies to decrease distress.

CCI is a significant—and growing—challenge for the health care system. Accounting for less than 10% of all mechanically-ventilated patients, CCI patients use up to 40% of ICU beds and critical care resources. It has been estimated that overall health care costs of CCI surpassed 20 billion dollars in 2009 [2], and are continuing to rise. Cost-effectiveness is widely variable, given the broad range of expected outcomes, and is heavily driven by age. Since costs are most substantial early in the hospital course, early recognition of patients who are unlikely to gain value from prolonged mechanical ventilation and offering alternative goals of care is critically important.

Creating alternative models and venues of acute care delivery is important as well. In the United States, use of LTACHs after critical illness is rising rapidly [18], with increasing admissions among Medicare beneficiaries of 38.1 to 99.7 per 100,000 from 1997 to 2006. An increasing proportion of LTACH patients received mechanical ventilation over this period of time (16.4–29.8%). Despite suggestion that LTACH utilization may be an avenue to decrease costs and increase value of care to the CCI, a recent study of over 200,000 Medicare beneficiaries with CCI demonstrated that while LTACH care is associated with equivalent survival to short term acute care with decreased costs, payments are higher among LTACH patients due to an elevated cost-to-charge ratio [19]. Novel health care delivery approaches and venues may improve the future of care of CCI.

CHAPTER 378

Promoting physical recovery in critical illness

Gregory A. Schmidt and Kevin Doerschug

Key points

- ICU acquired weakness starts within the first day of critical care.
- Muscle dysfunction can cripple skeletal muscles, but also the diaphragm.
- Early ICU interventions can change long-term outcomes.
- Muscles should be stimulated: posture, physical therapy, minimal sedation, and active mobilization.
- Think liberation from the burdens of critical illness rather than protection of the sick.

Introduction

Many patients survive critical illness only to suffer profound debility, dependence on others for activities of daily living (ADLs), or inability to work. For example, survivors of the acute respiratory distress syndrome (ARDS) are often not limited by persistent decrements in lung function, but rather from neuromuscular weakness that interferes with daily activities and persists years after the critical illness subsides [1]. Intensive care unit (ICU)-acquired weakness (ICU-AW) is identified in roughly one-in-four survivors after one week of mechanical ventilation. Advancements in survival from critical illness coupled with a rise in the incidence of conditions like severe sepsis combine to produce a huge burden of post-ICU incapacity. Yet evidence is accumulating that these long-term ravages can be modified by clinicians' actions in the first week of critical illness. This chapter explores the factors that exacerbate muscle loss and strategies to preserve strength and function. We conclude with specific recommendations for building and nurturing a team to facilitate mobilization and recovery of even the sickest patients.

Pathophysiology of ICU-acquired weakness

A complete discussion of the mechanisms of ICU-AW is beyond the scope of this chapter. However, a brief review of pathophysiology and contributing factors will help practitioners understand how to promote physical recovery more effectively. Early electrophysiological studies of this syndrome identified axonal degeneration consistent with acute polyneuropathy in the setting of sepsis. Subsequent research revealed myopathy, as demonstrated by myosin loss in skeletal muscle, also contributes to ICU-AW. Two aspects of the time-course of ICU-AW are remarkable:

- Muscle is lost as early as the first day of critical illness [2].
- Weakness may persist for years [1].

Both accelerated muscle proteolysis as well as decreased muscle protein synthesis contribute to sepsis induced myopathy [3,4]. Importantly, muscle catabolism is opposed when muscles are actively contracting. In parallel, perhaps the greatest causal factor of ICU-AW is muscular silence, a hypothesis that may explain the contributory role of sedatives, neuromuscular blocking drugs, controlled mechanical ventilation, and bed rest. Exercise induces the production of transcription factors that ameliorate stress-induced atrophy.

Promoting recovery

There is ample evidence that the details of care provided in the ICU can be related to longer-term neuromuscular outcomes.

Avoiding harm

Knowledge of the factors associated with muscle weakness suggests several approaches to avoid compounding the effects of critical illness with iatrogenic harm. Ventilator settings that lead to fully passive mechanical ventilation are best avoided. While there may be some patients who are so ill that any activity provokes life-threatening oxyhaemoglobin desaturation or ventilator dyssynchrony, most patients should have settings adjusted so as to encourage inspiratory muscle activation. This is more an issue of choosing appropriate goals for ventilation, rather than selecting a particular mode, since even high levels of pressure-support are sufficient to produce diaphragm dysfunction. One approach is to gradually reduce the level of ventilatory support until the patient is making regular, but unlaboured and synchronized, inspiratory efforts, regardless of the arterial partial pressure of carbon dioxide.

In a randomized, controlled trial of ARDS, cis-atracurium infusion was associated with reduced mortality, decreased systemic inflammation, and a trend toward **less** ICU-AW [5]. One hypothesis for this is that patient-ventilator dyssynchrony resulted in excessive tidal volumes, which in turn lead to systemic inflammation, and that this was averted through short-term therapeutic paralysis. Clearly more work is needed to fully understand and guide neuromuscular blockade during critical illness. Until definitive work is

complete, many practitioners continue to avoid generalized use of these agents.

Most patients receiving mechanical ventilation receive sedative and analgesic medications aimed at improving patient-ventilator synchrony and relieving discomfort. Intravenous sedation serves to decrease patient movement: continuous sedative infusions may silence muscle to an extent resembling pharmacologic paralysis. Several trials have examined methods to decrease the impact of sedation during mechanical ventilation, with daily interruption of continuous sedative infusions [6] representing the most common strategy. Such practices decrease time on the ventilator and allow for more purposeful movement while on the ventilator, thus avoiding the muscle disuse that perpetuates ICU-AW. In addition to increasing patient movements, less sedation also facilitates more meaningful participation in physical therapy. Many of the interventions aimed to prevent complications and promote physical recovery have been gathered in the 'ABCDE' bundle:

> A = Awakening; B = Breathing trials coordinated; C = Choice of sedatives and analgesics; D = Delirium monitoring; and E = Early mobility and exercise [7].

Clinicians have historically viewed the active patient as an accident waiting to happen. Sedatives are often prescribed to keep the patient motionless in a misguided effort to maintain homeostasis. Caregivers hesitate to allow patient movement, fearing that this will impede ventilation or circulation, or dislodge supportive devices. Increasing evidence suggests that this fully supportive care does not maintain homeostasis, but rather allows for neuromuscular atrophy.

This attitude of over-protecting the fragile patient (as opposed to liberating them from noxious interventions) is seen also when seeking to 'wean' patients from mechanical ventilation. Clinicians are often slow to recognize that their patient no longer needs the ventilator. Protocols that initiate daily spontaneous breathing trials without the requirement of physician orders lead to more rapid extubation than those that require physician input [8]. These spontaneous breathing trials are more likely to lead to extubation when paired with daily awakening trials, and also reduce mortality [9]. While the effect of these practices on ICU-AW have not been specifically evaluated, it seems reasonable to assume that an awake and extubated patient is better prepared for physical recovery than one who remains tethered to the ventilator.

Many other devices have consequences for patient mobility. For example, it is easier to imagine walking with a critically-ill patient bearing a subclavian, rather than femoral, central venous catheter. Yet decisions regarding catheter site selection are usually dominated by concerns regarding anatomy, infection, bleeding, and thrombosis, rather than whether a given site will impede physical therapy. Similar issues surround the timing of tracheostomy or the pros and cons of inserting an arterial cannula. A remarkable example is the shift in philosophy surrounding extracorporeal life support. Historically, patients with catastrophic respiratory failure undergoing extracorporeal therapies have been deeply sedated, respecting the catastrophic cost of cannula disconnection. Now, there is increased recognition that, while alternative therapies (such as high frequency ventilation or lung-protective ventilation) generally preclude mobilization, extracorporeal support can potentially free the patient from sedation and even from the ventilator entirely, making physical therapy realistic and practical [10].

Thus, a crucial component of promoting physical recovery is to establish a culture of awareness surrounding the mobility impact of medical decisions. It is essential that caregivers recognize when patients can be freed of both drugs and devices and to institute protocols for sedative interruption, daily spontaneous breathing, and removal of invasive devices.

Early mobilization to promote recovery

Immobility leads to myopathy and weakness, thus mobility seems a reasonable defence against ICU-AW. Interestingly, even movements that don't require active muscle contraction are helpful. One study of continuous passive range of motion for nine hours daily during mechanical ventilation with neuromuscular blockade revealed that this simple intervention, applied unilaterally to a leg, prevented the muscle protein losses seen in the untreated leg [11].

A survey of physical therapy involvement in ICU patients revealed that few hospitals appear to emphasize this intervention [12]. Most require a specific physician consultation to initiate physical therapy, and only 10% of hospitals have established criteria to initiate physical therapy in the ICU. In summary, there is a significant spectrum of physical therapy utilization even in ICUs where it is available.

A few groups have sought to evaluate more aggressive physical therapy than that commonly provided during critical illness. In one study, 103 subjects that required mechanical ventilation for more than 4 days were prospectively enrolled for intervention [13]. A team that included a physical therapist, respiratory therapist, nurse, and critical care technician delivered therapy twice daily. Therapy was initiated when the subject was awake and free of catecholamine drips, the fraction of inspired oxygen was less than 60%, and PEEP no higher than 10 cm H_2O. During sessions, subjects progressed as tolerated from sitting on bed without support to sitting in chair, to ambulation. The study recorded 1449 activity events, nearly 600 of which included intubated patients. In sessions that involved subjects with an endotracheal tube, nearly half included ambulation. Importantly, no accidental extubations occurred, and other adverse events occurred in fewer than 1% of sessions. This study is reassuring that ambulating intubated patients can be safe and feasible. Although this is considered a landmark study, its implications are limited by the lack of a comparison group to evaluate efficacy. Further, this study enrolled subjects that had already received 4 days of mechanical ventilation and thus may have already suffered significant loss of strength.

A subsequent study addressed these limitations in a before-and-after study design as they implemented a standardized early mobility therapy protocol in seven ICUs [14]. With implementation of the early mobility protocol within 48 hours of intubation, physical therapy was initiated in 91% of patients compared with just 13% in the control arm. The early mobility protocol was also associated with significant decreases in ICU and hospital length of stay.

The first randomized, controlled, multicentred study of early mobility enrolled subjects within 72 hours of intubation, and specifically timed mobilization sessions to coincide with daily sedative interruptions [15]. Subjects in the intervention arm initiated physical therapy within 2 days of intubation, while the median time from intubation to first therapy session in the control arm was 7.4 days. The primary outcome was the rate of return to independent functional status at hospital discharge and the intervention was

significantly superior to standard care. This intervention also lead to more ventilator-free days and a shorter duration of delirium. Intervention subjects achieved important milestones previously thought unattainable during mechanical ventilation: 43% transferred to chair and 24% were able to walk—some as far as 30 m.

Barriers to mobilizing the critically ill

The evidence to support early mobilization is compelling, and continues to mount, yet widespread adoption of early mobilization remains heterogeneous. This failure of the medical community to fully embrace aggressive recovery programs in critical illness likely stems from some combination of fear of patient decompensation or injury and a persistent culture that lacks urgency to liberate patients from critical illness. Fortunately, these barriers are surmountable and these are addressed in the following section.

Safety of early ICU mobilization

The rigorous studies of early mobilization all demonstrate tremendous safety with the protocols implemented. Teams generally consist of at least three clinicians including physical therapist, nurse, and a third team member who can assist with patient stability. Additional safety comes from persistent, but careful progression through a mobility protocol that identifies suboptimal physiology that may limit the next step. One such progression, adapted from Schweickert [15], is shown in Table 378.1. During ambulation, a wheelchair pushed by a clinician provides additional safety by allowing quick access to a resting position should the patient develop fatigue or distress.

It is worth emphasizing that very ill patients still tolerate active physical therapy. For example, in one trial the first day of physical therapy averaged 1.5 days following intubation; therapy was provided on 89% of ventilator days; and in 23% of sessions patients were being treated for shock with vasoactive drug infusions [16]. Published ICU mobility protocols imbed stop criteria that temporarily defer initiation of a session, or halt sessions already in progress. Rather, the haemodynamic responses to mobility were monitored, and therapy halted or discontinued if significant changes occurred. Remarkably, only 4% of sessions were terminated for safety concerns [16]. With these measures in place, the initial trials of early ICU mobilization report few adverse events. The most commonly reported were periods of patient-ventilator asynchrony. Falls to knees without injury did not occur in two studies [14,15], but occurred rarely in another [13]. Accidental extubations were not seen in these early studies.

Table 378.1 Progression of ICU mobilization

Step 1 Unconscious patients	Passive range of motion, all limbs	
Step 2 Interactive patients	Active assisted and active independent ROM in supine position	Upright bed position, up to 30 minutes bd, temporally separated from ROM
Step 3 Absence of orthostasis	Upright sitting with, then without, support	Activities of daily living
Step 4 Able to sit without support	Sit-to-stand, up to 10 repetitions	Transfer from bed to chair
Step 5 Able to stand	Pre-gait exercises	Ambulation

Adapted from *The Lancet*, **373**(9678), Schweickert WD et al., 'Early physical and occupational therapy in mechanically ventilated, critically ill patients: a randomised controlled trial', pp. 1874–82. Copyright © 2009, with permission from Elsevier.

When implementing a new mobility culture, the champions should anticipate some resistance from clinicians unconvinced of safety. At times, such resistance arises from physicians, primary care clinicians, bedside nurses, and even family members. Leadership should invest in identifying those who support mobilization to encourage their support, but also work with sceptics to provide education and listen to concerns.

The risks of early mobilization, although rare, are immediate, obvious, and potentially catastrophic. In contrast, the benefits are delayed 2–3 weeks [15] and may never be witnessed by the intensive care team, leading some clinicians to 'first do no harm'. Furthermore, when occasional (but, ultimately, predictable with some frequency) adverse events complicate mobilization, there is a risk that an emotional, short-term-oriented response can threaten an entire mobility programme. ICU leadership must emphasize the foundation for mobilization; acknowledge prospectively that rare patients may be harmed; and be prepared to defend the mobility team if their role is questioned. In the event of a complication, a 'just culture' approach is encouraged, rather than finger-pointing.

With increasing recognition of the benefits of early mobilization patients, many institutions have developed ICU mobilization teams. Given the past trend of prolonged deep sedation during critical illness, any progress toward mobilization should be applauded. Merely awakening and participating in active range of motion is progress when it follows a culture of deep sedation and 'protective support'; nevertheless, this clearly falls short of ambulating 30 m while intubated. Thus, caregivers should not consider these early activity milestones as endpoints of ICU therapy. Critical illness is a degenerating disease. Without progress, further injury—in this discussion, weakness—will come. In a progressive culture of early ICU mobility, the caregivers should strive for progress, not simply supportive maintenance. This progressive culture represents a paradigm shift from past practices of excluding patients considered too sick to mobilize to a notion that the most severely-ill patients have the greatest needs for mobilization.

In addition to changing the culture of physical recovery in the ICU, critical care practitioners must work with caregivers beyond the ICU to ensure that recovery continues. In fact, at one institution, more than half of the patients that were able to walk in the ICU had a decrease in activity level on the first full ward day [17]. The reasons for this decrease in activity level were not examined in the study. However, it seems likely that an urgency to liberate the patients from the effects of critical illness was not sufficiently engrained in the culture beyond the ICU walls.

Adjuncts to early mobilization

With increasing attention to early promotion of physical recovery from critical illness, caregivers have applied novel equipment to this quest. Cycle ergometry, with passive or increasingly active motion, increases functional status at the time of ICU discharge [18]. Ergonomic lifting devices can support patients, further increasing safety and effectiveness of ICU ambulation (see Fig. 378.1). Many ICU bed manufacturers now make units specifically designed to facilitate upright posture and transfer to standing positions. As the

acceptance of ICU mobilization increases, equipment to aid the ambulation of critically-ill patients is becoming widely available.

If the beneficial impact of mobilization follows from provoking muscles to contract, perhaps neuromuscular electrical stimulation (NMES) could play a role, especially in patients who cannot otherwise be mobilized. NMES forces muscular contraction without requiring patient effort, so may be applicable for deeply sedated patients. NMES has been shown to preserve muscle mass during critical illness and prevent ICU-acquired weakness [19]. These results have not been seen consistently, however [20]. Conflicting results may represent differences in NMES methodology or other factors and thus further studies of NMES in critical illness are needed.

Conclusion

Many critically-ill patients will survive the acute crisis with limiting neuromuscular debility. Early interventions to reduce sedation, speed liberation from the ventilator, and enhance early physical therapy can improve long-term functional outcomes significantly. A team approach, engaged leadership, and administrative support are essential components for successful implementation.

CHAPTER 379

Promoting renal recovery in critical illness

Nattachai Srisawat and John A. Kellum

Key points

- Renal recovery post-acute kidney injury (AKI) can be classified as complete or partial recovery (chronic kidney disease (CKD)), based on the degree of renal function that returns.
- Evidence demonstrates that AKI can progress to CKD, and end stage renal disease (ESRD).
- There is no patient survival or renal recovery advantage for high intensity renal replacement therapy.
- Potential predictors of renal recovery include both of conventional markers (clinical variables, urine output, etc.) and novel biomarkers (pNGAL, uNGAL, uHGF, uCystatin C, pIL-6, pIL-8, pIL-10, pIL-18, pMIF, pTNFR-I, pDR-5, uIGFBP-7, uTIMP-2).
- Serum creatinine might not be a good marker for renal function due to the decreasing of muscle mass after the severe illness and other confounding factors.

Introduction

How to facilitate renal recovery is a key question in the management of acute kidney injury (AKI). Two large randomized controlled trials, the Acute renal failure Trial Network (ATN) study [1] and the Randomized Evaluation of Normal versus Augmented Level Renal Replacement Therapy (RENAL) study [2] have shown a significant number of AKI patients who failed to return to baseline renal function following an episode of AKI. Importantly, the rate of recovery was 3-fold different across these two trials suggesting that risk of non-recovery is variable and perhaps affected by treatment. This chapter explores the definition, mechanism, epidemiology, and outcome predictors of renal recovery with the goal of improving AKI outcomes.

How to define renal recovery?

First of all, an understanding of the definition of renal recovery is needed. In 2004, the Acute Dialysis Quality Initiative (ADQI) [3] proposed the following definition of renal recovery: 'complete renal recovery' was defined as return to pre-morbid renal function, and 'partial renal recovery' was defined as an improvement in **R**isk **I**njury **F**ailure **L**oss **E**nd stage renal disease (RIFLE) classification (R, I, or F) and not requiring long-term renal replacement therapy (RRT), but failing to return to baseline renal function'. Non-recovery was therefore defined as persistent requirement of RRT, or no change in RIFLE score during hospitalization. Since baseline renal function is hard to quantify precisely, most authors operationalize a return to baseline as a return to within 150% of baseline serum creatinine. Most of the studies evaluating AKI recovery have studied only patients receiving RRT. Therefore, renal recovery can be defined more simply as patients who are alive and dialysis-free. However, patients who die after coming off dialysis might also be considered as 'AKI non-recovery' and it is sometimes difficult to assess whether a patient dying after AKI has truly recovered renal function. The optimal duration of follow-up for patients with AKI needs to be defined. The consensus from the second ADQI conference suggests using from 60 to 90 days of follow-up for the evaluation of all-cause mortality.

Which parameter should be assessed to define renal function after renal recovery? Serum creatinine might not be a good marker to use due to the decreasing of muscle mass after the severe illness and other confounding factors. Therefore, the measurement of glomerular filtration rate by radioisotope clearance might be an alternative.

Partial recovery after AKI is particularly important because most of these patients will have, by definition, chronic kidney disease (CKD). If they did not have CKD prior to AKI, then this will be new onset CKD. We need to better understand what happens to these patients. Do they ultimately recover? Do they progress as other patients with CKD?

In summary, renal recovery can be defined as complete or partial recovery based on returning of renal function, while non-recovery generally includes patients who do not survive or who require chronic dialysis (Fig. 379.1).

Mechanisms of renal recovery and repair

The pathobiology of AKI appears to involve a complex interplay between tubular injury, renal haemodynamics, and inflammation (Fig. 379.2). Surviving renal proximal tubular epithelial cells (RPTCs) play a major role in the repair process and appear to follow a program which shares a number of similarities with the series of events observed during kidney development. RPTCs first appear to undergo dedifferentiation (i.e. loss of apical-basal polarity, lack of tight junctions, accompany with a decrease in the expression of epithelial cell marker and an increase in the expression of mesenchymal cell or fibroblast markers), and then proliferation. When the cell population has expanded sufficiently to physically replenish

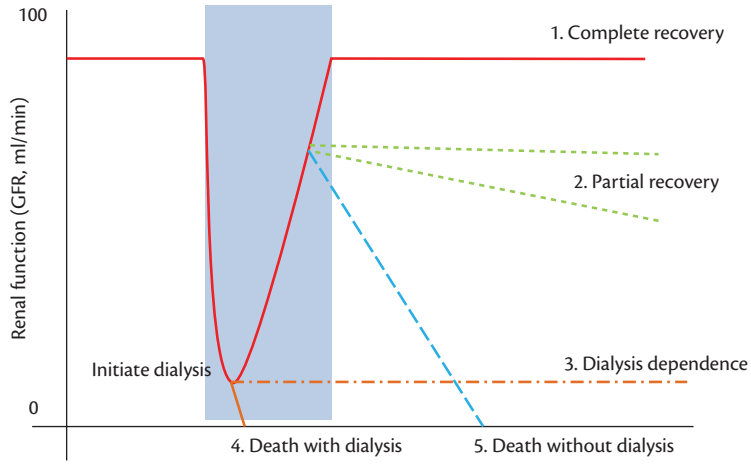

Fig. 379.1 Schematic showing the natural history of AKI. Patients who developed AKI may experience. (1) Complete recovery. (2) Partial recovery with progressive to CKD. (3) Development of ESRD (dialysis dependence). (4) Death with dialysis dependence. (5) Death without dialysis.

sloughed epithelium, cells undergo a redifferentiation process characterized by a decrease in mesenchymal cell markers and increase in epithelial cell markers to finally restore the physiologic function of RPTCs [4].

A number of growth factors such as the hepatocyte growth factor (HGF), epidermal growth factor (EGF), insulin-like growth factor-1 (IGF-1), bone morphogenic protein-7 (BMP-7), and the transforming growth factor-β (TGF-β) help renal repair by interaction with the transmembrane receptors of the tubular epithelial cells. Ultimately, the renal repair process requires redifferentiation of transformed renal epithelial cell function to restore tubular morphology [5].

Various other mechanisms have been implicated in controlling the repair process [6], many of which could be exploited as diagnostic or therapeutic targets. Recently, a cell-cell communication mechanism that regulates development, tissue homeostasis and

repair has been identified to play a potential role in repair and regeneration after AKI—known as Notch [7]. Generally absent in the mature kidney, Notch is reactivated after AKI, and could be responsible for cellular differentiation, proliferation, and repair [8]. This notion is supported by studies from various laboratories independently observing a linkage between increased expression of Notch2 and its target Hes1, and increased proliferation renal tubular epithelial cells in the setting of various insults [9].

Another important mechanism is cell-cycle regulation. When epithelial cells, including those lining the proximal tubule become injured or even stressed, they may deviate from normal cell-cycle progression. Cells that become 'arrested' at G2/M may adopt a pro-inflammatory phenotype that is also pro-fibrotic [10]. There may also be a therapeutic value in blocking the initiation of G2/M arrest, or using of various agents to stimulate cell-cycle progression [11].

Epidemiology of renal recovery

Studies of AKI outcome have been heterogeneous in terms of patient populations, aetiologies of AKI, outcomes, and duration of follow-up. We can divide the studies into two major groups based on study population. First, studies have focused on patients who receive RRT, and considered renal recovery as dialysis independence. Almost all studies of this type have been conducted in the ICU setting. AKI outcomes from the major clinical trials show mortality rates ranged from 35 to 60% [1,2]. Unfortunately, these trials did not necessarily report how many patients died while still receiving RRT. The renal recovery rate among survivors of severe AKI (dialysis independence) varied from 75 to 90%. However, these statistics hide the fact that survival following severe AKI is poor and more patients die following discharge than enter chronic dialysis (Fig. 379.3).

Secondly, studies have focused on AKI more broadly and have performed long term follow up (more than 2 years). Most of these studies have included AKI across all severity groups, not only severe AKI. Outcomes usually included mortality, CKD and end-stage renal disease (ESRD) rates (per 100 person-years). The major obstacle to drawing conclusions from these studies as to the relationship between AKI and CKD or ESRD is the presence of various confounders that can affect long-term outcomes after AKI (Fig. 379.4).

Clinical predictors of recovery

One set of current tools for predicting renal recovery is the clinical severity scores. Uchino et al. [12] tested two general illness severity scores (APACHE II and SOFA), and four AKI-specific severity scores in 1742 patients as part of the BEST Kidney Study. Unfortunately, none of these scoring systems tested had a high level of discrimination or calibration to predict outcome for AKI patients. Thus, although not specifically tested, it seems unlikely that any of the current severity scores can provide good prediction for renal recovery. We still need a study that is directly designed to identify the factors associated with renal recovery.

Urine output is one of the conventional and oldest known biomarkers. Although oliguria is a common event in the ICU and urine flow is one of the diagnostic and staging criteria for AKI, only a few studies have focused on the role of urine output as a prognostic renal biomarker. A recent study by Macedo and colleagues [13] found olgiuric patients without change in serum creatinine have an increased mortality, increased dialysis requirements, and longer lengths of ICU and hospital stay than patient without AKI. Subsequent analysis data from the BEST kidney study [14] found that the urine output had area under the receiver operating characteristics curve (AUC-ROC) for successful discontinuation of CRRT was 0.85, although it fell to 0.67 when diuretics were used.

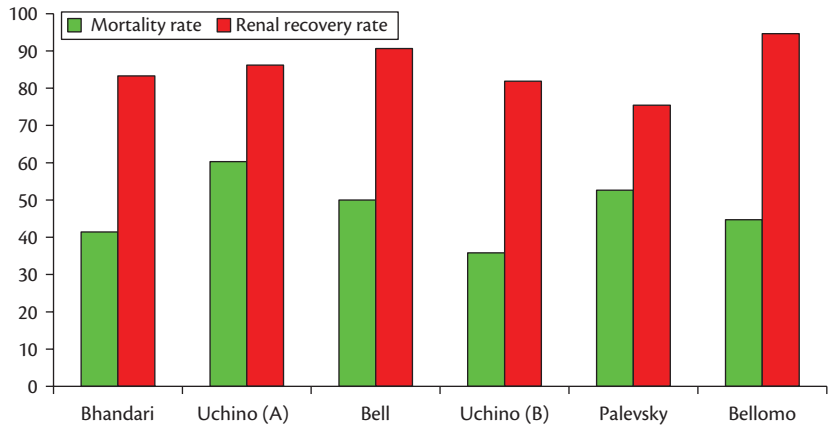

Fig. 379.3 Summary of hospital mortality and renal recovery (dialysis independence) in survivors from severe AKI (including only studies with more than 1000 patients). Novel biomarkers for recovery

Based on the physiology of renal recovery, a number of biomarkers have the potential to predict renal recovery. Neutrophil Gelatinase-Associated Lipocalin (NGAL) has been extensively studied in the field of AKI. In the late phase of AKI, NGAL is believed to play a role as a growth and differentiation factor for restoring tubular epithelial function with the assistance of siderophore-iron complexes. However, most of the previous studies have tested plasma/urine NGAL as a marker for early diagnosis of AKI, and only a few studies which have examined plasma/urine NGAL as a prognosticate marker of clinical outcome.

We examined plasma of patients on the first day of which they experienced severe AKI (defined as RIFLE-F) [15]. The elevated pNGAL levels were associated with renal non-recovery. Although the absolute predictive value of pNGAL alone was only fair (AUC 0.74). These data are most notable for two reasons. First, because AKI can cause CKD and ESRD, decisions regarding long-term care (for example, use of dialysis, vascular access, and follow-up) are often made in a piecemeal approach. If objective metrics coupled with clinical assessment can improve prognostic accuracy, a better informed decision can be made for survivors of AKI. Secondly, the association between pNGAL and renal non-recovery suggests that renal injury is ongoing, and even if a patient is undergoing dialysis, therapies directed at mitigating ongoing injury may have a role in AKI treatment.

We also conducted the **Bio**logical **Mark**ers of Recovery for the Kidney (BioMarK) study as an ancillary to the ATN study [16]. Urine samples were collected on days 1, 7, and 14 from 76 patients who developed AKI and required renal support. We explored whether levels of uNGAL, uHGF, uCystatin C, uIL-18, uNGAL/MMP-9, and urine creatinine could predict subsequent renal recovery. Patients who recovered had higher uCystatin C on day 1 and lower uHGF on day 7 and 14. For predicting recovery, decreasing uNGAL and uHGF in the first 14 days was associated with greater odds of renal recovery.

Using the BioMarK cohort, 11 plasma inflammatory and apoptosis markers on renal recovery, and mortality in 817 critically-ill subjects receiving RRT [17] was also examined.

The study found that increased concentrations of plasma IL-8, IL-18 and TNFR-I were independently associated with slower renal recovery [adjusted hazard ratio (AHR) range for all markers, 0.70–0.87]. Higher concentrations of IL-6, IL-8, IL-10 and IL-18; MIF; TNFR-I and DR-5 were associated with mortality. In an analysis of multiple markers simultaneously, increased IL-8 and TNFR-I were associated with slower recovery, and increased IL-8; MIF and TNFR-I were associated with mortality [17].

Finally, markers of cell-cycle arrest have recently been shown to predict human AKI [18,19]. Insulin-like growth factor-binding protein (IGFBP)-7 and tissue inhibitor of metalloproteinase (TIMP)-2 are both linked to cell cycle arrest during the very early phases of cell injury. In response to cell stress IGFBP7 and TIMP2 are expressed in the tubular cells. IGFBP7 directly increases the expression of p53, p21, and TIMP2 stimulates p27 expression. These effects are conducted in an autocrine and paracrine manner and the p proteins in turn, block the effect of the cyclin dependent protein kinase complexes (CyclD-CDK4 and CyclE-CDK2) on the cell cycle promotion, thereby resulting in transient cell cycle arrest. It is likely that this effect is protective when temporary and helps avoid injured cells from dividing, which can result in apoptosis of both daughter cells. However, prolonged cell cycle arrest may lead to maladaptive repair and fibrosis. Supporting this, Kashani et al. using a large cohort of critically-ill patients at risk for AKI, found that a urinary [TIMP-2]·[IGFBP7] value above 2.0 was associated

with almost a four-fold increased risk of major adverse kidney events at 30 days [17].

Strategies to facilitate renal recovery

Mode of renal replacement therapy and renal recovery

ATN [1] and RENAL [2], have provided high-quality data to help understanding of the impact of RRT on renal recovery. Unfortunately, there appears to be no patient survival or renal recovery advantage for high intensity RRT. At day 28, survivors in the RENAL study demonstrated a 13.3% rate of RRT dependence, compared with 45.2% in the ATN study. At day 60, 24.6% of survivors in the ATN study were still receiving RRT. Table 379.1 shows a direct comparison of the two trials. Overall, the cohorts were closely matched and yet survival to day 60 and recovery of renal function (off dialysis) by day 28 was substantially better in RENAL.

Much has been made of the earlier start of treatment in RENAL compared with ATN in terms of time from ICU admission (2.1 versus 6.7 days), yet the BUN at the start of therapy (another surrogate for timing) was nearly identical. Another difference between the two trials that could have accounted for the differences in outcomes was the exclusive use of CRRT as the initial mode of RRT in RENAL compared with a strategy that allocated patients to CRRT only if they were haemodynamically unstable (on vasopressor therapy) in ATN.

Fluid balance and renal recovery

There is an emerging body of evidence that the consequences of fluid overload, in excess of 5–10% of bodyweight, in critically-ill patients are significant with worsening organ dysfunction and mortality [20]. Fluid overload increases the risk of intra-abdominal compartment syndrome and increase renal venous pressure. Renal interstitial oedema can lead to decrease glomerular filtration, distorted tissue architecture, and impaired tissue perfusion.

Bouchard et al. [20] analysed the data from The **P**rogram to **I**mprove **C**are in **A**cute **R**enal **D**isease (PICARD). They found patients with fluid overload experienced significantly higher mortality within 60 days of enrolment. Among dialysed patients, survivors had significantly lower fluid accumulation when dialysis was initiated compared w4ith non-survivors after adjustments for dialysis modality and severity of illness. The adjusted odds ratio for death associated with fluid overload at dialysis initiation was 2.07 (95% CI 1.27–3.37).

Table 379.1 Comparison of the RENAL and ATN studies

	RENAL	ATN
Age (years)	64.5	59.6
Male (%)	946 (64.6%)	793 (70.6%)
Baseline eGFR ≤ 60 mL/min*	473 (58%)	361 (41.6%)
Mechanical ventilation	1082 (73.9%)	905 (80.5%)
Severe sepsis	723 (49.3%)	708 (63%)
Oliguria	874 (59.7%)	877 (78%)
Time in ICU prior to randomization (days)	2.1	6.7
BUN at start of RRT (mg/dL)	65.8	66.3
Alive at Day 60	57.5%†	47.4%
Dialysis independence at Day 28 (survivors only)	86.7%	54.8%

*% Based on number with known baseline.

†Kaplan–Meier estimate (55.3% were alive at 90 days).

Data from; VA/NIH Acute Renal Failure Trial Network, Palevsky PM et al., 'Intensity of renal support in critically ill patients with acute kidney injury', *New England Journal of Medicine*, 2008, **359**(1), pp. 7–20; and RENAL Replacement Therapy Study Investigators, Bellomo R et al., 'Intensity of continuous renal-replacement therapy in critically ill patients', *New England Journal of Medicine*, 2009, **361**(17), pp. 1627–38.

Conclusion

Increasing evidence demonstrates that AKI may result in important long-term adverse outcomes. Therefore, methods to identify which patients are likely to develop this complication are urgently needed as are treatments to mitigate this risk. Biomarkers may also be useful in predicting renal recovery and may therefore play an important role in disease management.

CHAPTER 380

Recovering from critical illness in hospital

Saxon Ridley

Key points

- Between 10% and 27% of patients survive intensive care unit (ICU), but die before hospital discharge. Some of these deaths may be avoidable.
- Complications and adverse events after ICU increase patient discomfort, hospital length of stay and costs.
- Such complications can be mitigated by attention to detail before and after ICU discharge.
- Processes and delivery of care are more important than specific treatment intervention.
- Comprehensive communication and handover at discharge is probably the most important element in ensuring smooth transition to the general ward.

Introduction

Discharge from the intensive care unit (ICU) is only the start of the patient's convalescence. Adverse events including mortality and complications can occur on the general ward before hospital discharge. Ward mortality after intensive care ranges between 10 and 27% [1,2]. Clinical deterioration on the general ward leads to increased lengths of stay, costs, and longer patient recovery. If serious, such relapses may prompt re-admission to intensive care. Post ICU mortality, clinical deterioration on the ward, and ICU re-admission are dependent upon events before or after ICU discharge.

Patient morbidity after ICU discharge

Classification

The problems besetting patients following discharge to the general ward may be classified in at least three ways.

Post-intensive care syndrome

Because of the wide range of problems that may affect critical illness survivors, Needham et al. [3] proposed that the term 'Post Intensive Care Syndrome' should be used. The syndrome may affect both the patient and their family; the problems fall into three categories:

- Mental health (e.g. anxiety, depression and post-traumatic stress disorder (PTSD)).
- Cognitive impairment (causing decreased executive function, poor memory, attention defects, and reduced mental processing).
- Physical impairment (due to alterations in pulmonary and neuromuscular function).

Organ system classification

While any organ dysfunction can potentially slow a patient's recovery, the most relevant organ systems for the survivors of ICU are pulmonary, neuromuscular, physical function, psychiatric, and cognitive.

Pulmonary

Reductions in lung volumes, compliance and diffusion capacity will occur after acute lung injury and the adult respiratory distress syndrome (ARDS). Fortunately these are usually mild and in the longer term (i.e. after hospital discharge) recover. However, while on the general ward inadequate respiratory reserve combined with laryngeal dysfunction will predispose to pulmonary infections. Decreased diffusion capacity is inversely related to the duration of mechanical ventilation [4].

Neuromuscular

Critical illness polyneuropathy and/or myopathy may develop in up to 50% of ICU patients with sepsis, multiple organ failure, or prolonged mechanical ventilation [5]. This may severely disable patients by impeding walking or respiratory capacity after ICU discharge. Abnormalities within the axon, neuromuscular junction and muscle have all been implicated and may be caused by inflammatory axonal injury, muscle breakdown, sodium channel dysfunction, and failure of mitochondrial energy production. Predisposing factors on ICU include hyperglycaemia, systemic inflammatory response syndrome, sepsis, and multiple organ failure [5,6].

Physical function

Virtually all ICU survivors suffer some degree of physical dysfunction in the first week after discharge from ICU. A cohort of previously healthy ARDS survivors had a 40% decrease in their activities of daily living (ADLs) 28 days after ICU discharge [7]. Specific ICU related risk factors for physical impairment include exposure to systemic corticosteroids, new ICU acquired illnesses, and slow resolution of lung injury in the ICU.

Psychiatric

General ICU survivors suffer a median 28% (range 8%–57%) prevalence of clinically significant depressive symptoms in studies using a validated questionnaire [8]. Patient risk factors include pre ICU psychiatric symptoms, younger age, poorer education, and being female. ICU-related risk factors include poor recall of the ICU stay, traumatic or delusional ICU memories, and level of ICU sedation.

Cognitive

Duration of ICU delirium has been associated with cognitive impairment at 1 year [9]. Brain atrophy has been observed on

magnetic resonance images (MRIs) of critically ill patients with delirium, but it is unclear whether atrophy is a risk factor for, or an effect of, a common neurological insult. Potential ICU related risk factors include hypoglycaemia, hypoxemia, hypotension, and sedation.

Pathological classification

Post ICU problems can be classified by relating the adverse event to the original ICU admission diagnosis:

- Same pathology or disease process precipitates the clinical deterioration (e.g. another exacerbation of acute pancreatitis).
- New, but related pathology (e.g. enterocutaneous fistula following bowel resection, atrial fibrillation following an oesophagogastrectomy).
- New and unrelated pathology (e.g. pulmonary embolism, cardiovascular accident, chest infection following abdominal surgery).
- Exacerbation of pre-existing co-morbidities (e.g. chronic renal failure or chronic obstructive pulmonary disease).

Avoidance and amelioration

While some post-ICU complications are unavoidable, many may be prevented by ensuring a smooth transition from ICU to the general ward. Processes rather than specific interventions are more important.

Prior to ICU discharge

- **Minimizing the impact of the general supportive measures**: avoiding hyperglycaemia, without implementing tight glucose control, may reduce critical illness polyneuropathy and/or myopathy. Although corticosteroids and neuromuscular blocking agents are not consistently associated with critical illness polyneuropathy and/or myopathy, these drugs are best used only when necessary. Lighter sedation or daily breaks may prevent PTSD [10]. Screening for and treating delirium (e.g. reducing benzodiazepine use) and preventing hypoglycaemia may help preserve cognitive function and offset psychiatric problems.
- **Completion of critical care**: with the higher nurse to patient ratio on ICU, advanced treatments such as tracheostomy care and renal replacement therapy can be safely applied. There is conflicting evidence as to whether decannulation prior to ICU discharge adversely affects mortality. However, tracheostomies are commonly associated with prolonged length of ICU stay and hence complications of critical illness. If possible, it may be safer for the patient to be decannulated on ICU. Although patients with tracheostomy may be stable medically, their nursing requirements may not be met on a busy general ward.
- **Rehabilitation**: prior to discharge or as early as possible, a short clinical assessment to determine the patient's risk of developing physical and non-physical morbidity should be performed [11]. The reassessment should pay particular attention to:
  - *Physical, sensory and communication problems*—e.g. unable to get out of bed independently or mobilize over short distances, obvious significant physical or neurological injury, lack of cognitive functioning to continue exercise independently, requiring ≥ 35% oxygen, presence of pre-morbid respiratory or mobility problems.
  - *Underlying factors*—e.g. as pre-existing psychological or psychiatric issues (e.g. substance abuse, low-self-esteem, poor or low self-image and/or body image issues, relationship difficulties including those with the family and/or carer).
  - *Symptoms that have developed during the critical care stay*—e.g. delusions, intrusive memories, anxiety, panic episodes, nightmares, flashbacks, or depression.

Early rehabilitation on the ICU improves short-term physical function [12]. However, timing is important as rehabilitation is most effective when started as early as possible (i.e. before ICU or hospital discharge).

At ICU discharge

- **Effective communication**: a fundamental component of safe transition to the ward is effective communication between the critical care team and ward team. A formal structured handover of care will ensure that nothing is omitted and should include [11]:
  - Summary of critical care stay, including diagnosis and treatment.
  - Monitoring and investigation plan.
  - Plan for ongoing treatment, including drugs, nutrition, and therapies, infection status and any agreed limitations of treatment (e.g. Do Not Resuscitate (DNR) orders).
  - Physical and rehabilitation needs.
  - Psychological and emotional needs.
  - Specific communication or language needs.
  - Quantifying prognosis in general terms including whether the patient is suitable for re-admission to ICU, usefully reinforces the underlying expectations of outcome.
- **Timing**: increased pressure for ICU beds may result in premature discharge of patients, who may then be at an increased risk of adverse events. Night-time discharges to the general ward are associated with higher hospital mortality, independent of illness severity or discharge Therapeutic Intervention Scoring System scores [13]. Also weekends may predispose to excess discharges so that patient load is adjusted to ICU capacity. Patients discharged in the early weekend (00:00 Friday to 23:59 Saturday) had a greater risk of dying (24.6% versus 17.7%) and re-admission to ICU (17.5% versus 10.1%) [14].

After ICU discharge

- **Location**: for some recovering ICU patients, their requirements for on-going care are too great to be safely managed on the general ward. Under such circumstances stepping down to an intermediate care area (e.g. High Dependency Care Unit in the UK) can provide a useful bridge to prevent adverse outcomes that may have otherwise occurred. Such intermediate care areas are most useful in countries where the provision of critical care beds (measured in terms of ICU bed numbers per 100,000 population) is relatively poor, such as the UK. Intermediate care areas are ideally suited to monitoring patients and managing single organ failure. They can ensure that the ICU survivor continues on a positive course. For example, cardiac surgical re-admissions before cohorting in a step down unit over a 1 year period ranged from 6.7 to 8.9%. After six months of cohorting such patients, the re-admission rate fell to 4% [15].
- **Follow-up**: critical care outreach services (in the UK), rapid response teams (in the USA) and medical emergency teams (in

Australia) aim to improve the management of acutely deteriorating patients on the hospital ward. Part of their role is to oversee the progress of patients recently discharged from ICU. Critical care outreach services reduce deaths, cardiac arrests, hospital length of stay, ICU length of stay and cost [16]. Outreach services may also facilitate ICU re-admission where appropriate. Compared with contemporaneous patients admitted to the same ICU, critical care outreach visits were associated with a significantly higher re-admission rate (risk ratio 1.43) [17].

Re-admission to ICU

Importance

Re-admission to intensive care in the same hospital admission is a measure of critical care quality. Re-admission is demoralizing for patient and family, associated with clinical deterioration and an increase in hospital mortality. Furthermore re-admission denies critical care resources to other patients and will increase costs.

Re-admission rate

Re-admission rates vary depending upon case mix, delivery of care and local resources. Prior to 2000, re-admission rates were reported at 5–16% [18]. However, more recent figures suggest that the re-admission rates may be lower at 4.6% (6024/129674 UK patients [1] and 3632/79090 Canadian patients [19]).

Risk factors

Factors present on ICU that are significantly associated with subsequent re-admission are [18]:

- Weakness (e.g. previous cerebrovascular accident (CVA), deficit from Guillain–Barré or critical illness weakness).
- History of respiratory or cardiac disease.
- Colonization with a resistant organism.
- History of depression.
- Age >65 years.

The reasons for re-admission were most commonly impairments of organ systems:

- Respiratory (39%).
- Cardiovascular (18%).
- Neurological (15%).
- Gastrointestinal (11%).
- Metabolic (8%).
- Septic (7%).
- Haematological (5%).

Outcome

The mortality of re-admitted patients is higher than that of patients who experience a single ICU admission. The patient's physiological reserve has been degraded during the first ICU admission and the patients are less fit to survive a second episode of critical illness. The decision to re-admit a patient is an evaluation of the patient's ability to mount a satisfactory response against new pathophysiological insults. Causes of death on the ward are usually nosocomial infections (mainly respiratory), relapse of primary illness (e.g. stroke, cancer, heart failure) and progressive global deterioration.

Minimizing re-admissions

Avoiding complications and adverse events after ICU discharge will reduce ICU re-admissions. One of the most useful tasks around ICU discharge is to formally record the patient's prognosis including whether ICU re-admission is warranted should a relapse occur. Between 13% and 16% patients have DNR orders established during the ICU stay [19]. Outreach teams can help facilitate discussions about DNR orders so that ICU re-admission at the point of, or shortly after, cardiac arrests is avoided.

Conclusion

Preventing complications and adverse events after ICU discharge is dependent upon processes and delivery of care rather than specific therapeutic interventions. There are simple measures that can be taken on ICU (e.g. initiating rehabilitation, completing critical care by avoiding premature discharges) to improve the patient's chances of a smooth convalescence. Probably the most important aspect of safe transfer to the general ward is comprehensive handover of the patient's care to the receiving team. Continued follow-up by the critical care services will supplement communication and improve timely decision making.

PART 21.2

Complications of critical illness

CHAPTER 381

Physical consequences of critical illness

Margaret S. Herridge and Jane Batt

Key points

- Functional dependencies and decreased health-related quality of life are important consequences of critical illness and are related to Intensive Care Unit acquired weakness (ICU-AW) and a broad range of physical disabilities.
- Physical morbidities may not be reversible.
- Functional limitations may vary by age group, ICU length of stay, and burden of comorbid illness.
- ICU-AW is likely related to upregulation of the ubiquitin proteasome pathway with differential repair of muscle and nerve injury across different risk groups.
- Family caregivers also experience psychological morbidity and are important risk modifiers of patient outcome over time.

Background

Critical illness causes decrements in physical and neuropsychological function, incurs increased health care utilization and cost, and compromises the mental health of family caregivers [1–4]. Disability may not be remediable and may lead to a change in disposition secondary to acquired functional dependencies.

Physical health and outcome measures after critical illness

The evolution of our understanding of physical disability after critical care has progressed from an emphasis on early cardiopulmonary physiological outcomes to generic health-related quality of life (HRQoL). Early data reported significant decrements in physical function without elucidation of major contributing factors. More recent data support the link between ICU-AW and physical functioning captured as the physical component score of the SF-36 and modified by neurocognitive dysfunction and mood disturbances [1-4]. Currently, there is an emphasis on functional independence as a key patient- and family-centred outcome and how this informs HRQoL across patients of different age and underlying health.

Health-related quality of life

HRQoL is a cornerstone of the outcomes literature, but it is also intensely personal and may have important limitations in its ability to inform the nuances of rehabilitation programs.

The ARDS outcomes literature is intriguing because of the relatively homogenous nature of its outcomes compared with other groups of critically ill patients. In 1994, McHugh and her colleagues reported on pulmonary function and HRQoL using the Sickness Impact Profile (SIP). SIP scores rose in the first 3 months and only slightly thereafter and patients' pulmonary symptoms were only modestly associated with overall disability [5]. Weinert et al also reported functional impairment in their lung injury survivors with important decrements in role-physical and physical function domains of the SF-36 [6]. Davidson and investigators evaluated differences in health-related quality of life in ARDS survivors and comparably ill controls using the SF-36 and a pulmonary disease specific measure (St. Georges Respiratory Questionnaire (SGRQ)). Like other reports, all domains of the SF-36 were reduced, with the largest reduction in the role-physical domain. Although ARDS survivors scored worse on the SGRQ compared to other critically ill patients, it was uncertain whether this was lung-related or due to other extrapulmonary contributors [7].

Another HRQoL measure, the quality of health and well-being (QWB), was employed by Angus and colleagues [8] to measure quality-adjusted survival in ARDS survivors in the first year after hospital discharge. The mean QWB scores for their ARDS cohort was lower than a control population of patients with cystic fibrosis and when scores were disaggregated, the most common complaints were musculoskeletal and constitutional. Orme and colleagues [9] evaluated HRQoL and pulmonary function outcomes in ARDS patients treated with higher tidal volume versus lower tidal volume ventilation strategies. Similar to other studies, each group reported important reductions in physical functioning and although minor pulmonary function abnormalities were recorded and correlated with decreased HRQoL, the relative importance of the pulmonary contribution to the reported disability was unclear.

Long-term functional disability

Impaired physical function is reported in many papers over many years by a variety of investigators. These findings are also clearly persistent. Davidson reported these outcomes at 23 months after critical illness [7] and Herridge et al have noted persistent physical limitation at 2 and again at 5 years after ICU discharge [1] Physical dysfunction, partially or completely attributed to ICU-AW, may contribute to the reported reduction in the physical component score (PCS) of the SF-36.

In survivors of sepsis and critical illness, Iwashyna and others noted a persistent and incremental reduction in function compared to premorbid status. Using a study sample of older patients (median age 77), they reported the acquisition of 1.57 new limitations (CI 0.99–2.15) for those who had no limitations prior to their episode of critical illness and for those with some antecedent disability further decrements were noted. Physical decline persisted for at least 8 years after the episode of sepsis and clearly represented a pivotal decline in the patients' independent function [3].

Recently, Unroe and coworkers reported on new and persisting morbidity after chronic critical illness [2]. Patients had a mean age of 55, were unemployed, retired or disabled at the time of recruitment and had at least 2 comorbid illnesses. Only 9% of this cohort was alive and living independently at one year and negative risk prognosticators included more comorbid disease, older age, and discharge to a post-acute care facility. The mean cost per patient was $306,135 (SD, $285,467) for an estimated $3.5 million per independently functioning survivor at 1 year.

Neuromuscular dysfunction

The concept of a continuum of weakness has been borne out by recent work. Muscle injury begins within hours of the initiation of mechanical ventilation [10], is demonstrable with bedside testing at one week after ICU admission using the MRC scoring system [11] and persists with limitation for years after ICU discharge.

ICU-AW is ubiquitous in severe lung injury and complex critical illnesses and contributes to poor long-term function. A Round Table Conference developed a classification framework for ICU-AW [12] where ICU-AW is comprised of a nerve or muscle lesion or a combination of each.

Critical illness polyneuropathy

In 1984, Bolton and colleagues first described Critical Illness Polyneuropathy (CIP) in 5 critically ill patients requiring prolonged mechanical ventilation [13]. Patients had a primary axonopathy on electrophysiological testing with clinical manifestations of a mixed sensorimotor neuropathy. CIP occurs in a variable proportion of longer stay ICU patients (40%–100%) and primarily affects the limb and respiratory muscles. Limb involvement is symmetrical, and affects lower extremity, proximal muscle groups preferentially.

Aetiology and pathophysiology

SIRS and sepsis

CIP is associated with microcirculatory derrangement and axonal injury and occurs commonly in sepsis. Recent work demonstrates increased E-selectin on the endoneurial and epineurial vessels of peripheral nerves in septic patients with evidence of mediation by pro-inflammatory cytokines such as TNF-α and IL-1 [14].

Hyperglycaemia

Hyperglycaemia is an important risk factor for ICU-AW. Van den Berghe and others reported that tight glycaemic control in a surgical population reduced CIP, from 51.9% in control subjects to 28.7% among insulin treated patients [15]. The pathophysiology of tight glycaemic control and neuroprotection is unclear, but emerging insights include a protective effect on mitochondria and the deleterious effect of oxidant injury and apoptosis. Deranged nitric oxide may also play a role. Asymmetric dimethylarginine inhibits nitric oxide production and is an independent predictor of mortality in critically ill patients. Siroen et al showed recently that insulin modulates levels of asymmetric dimethylarginine and this may be an additional pathway by which insulin improves this outcome. Insulin may play a key role by inhibiting pro-inflammatory transcription factors that hasten neuroregeneration in critical illness [16].

Pharmacological agents

It is unclear whether we can implicate specific drug exposures in the pathogenesis of ICU-AW. Early reports of treatment in status asthmaticus suggested a link between neuromuscular dysfunction and the use of neuromuscular blockers and systemic corticosteroids. However, these concerns have not been borne out by recent reviews. Reports linking aminoglycoside, vasopressor, and renal replacement therapy use with neuromuscular dysfunction are confounded by the coexistence of sepsis or SIRS and inability to establish a causal link. In a recent randomized controlled study by Papazian et al, early exposure to 48 hours of paralytic therapy in patients with severe ARDS did not confer additional risk for weakness in the ICU survivors as assessed by the Medical Research Council score assessing strength [17].

Critical illness myopathy

The incidence of Critical Illness Myopathy (CIM) varies between 48 to 96% based on muscle biopsy and includes critical illness myopathy, acute quadriplegic myopathy, thick filament myopathy and necrotizing myopathy. It is characterized most commonly by a diffuse, non-necrotizing myopathy associated with fatty degeneration of muscle fibres, atrophy, and fibrosis. Patients are paretic and unable to wean and the clinical presentation may be indistinguishable from CIP. Only muscle biopsy can differentiate between these lesions.

Selective loss of myosin filaments in association with corticosteroid or neuromuscular blocker exposure and immobility is characteristic of thick filament myopathy. This may be a precursor to acute necrotizing myopathy since this form of CIM may progress to myonecrosis. Acute necrotizing myopathy is characterized by extensive myonecrosis with vacuolization and phagocytosis of muscle fibres and occurs with multiple organ dysfunction.

The pathophysiology of CIM involves derranged membrane excitability, inflammation, and catabolism evidenced by an observed increase in urinary nitrogen loss. There is evidence for the upregulation of the calpain and ubiquitin proteolytic pathways and this occurs in concert with an increase in apoptosis.

Inactivity in critically ill patients propagates inflammatory mediators that cause the following: protein loss in differentiated muscle cells; promotion of oxidative injury and disruption of insulin receptor signalling leading to impairment of myofibril growth and repair [18]. IL-1, IL-6 and TNF- μ have pro-inflammatory properties, augment proteolysis and have been implicated in muscle degradation, loss of muscle mass, and decrease in strength. IL-10 may play a role in mediating apoptosis and myocyte proteolysis through the inhibition of pro-inflammatory mediators. There is also evidence of muscle membrane inexcitability related to inactivation of sodium channels at the resting potential (sodium channelopathy). Allen and colleagues recently reported altered muscle-fibre excitability and muscle membrane dysfunction as the primary abnormality in CIM.

Clinical phenotypes in critical illness and the spectrum of disability

Recent cohort studies and administrative datasets suggest that heterogeneous disability after critical illness may be organized into discrete aetiologically neutral clinical phenotypes with different risks and recovery trajectories over weeks and months after critical illness.

Ubiquitous injury

The imbalance between protein synthesis and protein degradation appears to be universal in critical illness. Proteolysis in diaphragm and muscles of the axial skeleton occur within hours of mechanical ventilation and appear ubiquitous. Levine and colleagues [10], in their landmark work, noted that patients from very diverse clinical groupings had similar muscle injury related to upregulation of the ubiquitin-proteosome pathway. In further studies, these same investigators reported important decreases in myosin heavy chains and atrophic AKT-FOXO signalling play pivotal roles in myofibre atrophy and decreased diaphragm force generation. Other investigators have highlighted the induction of autophagy and mitochondrial dysfunction in human muscle as nonspecific contributors to muscle injury. These important observations support the hypothesis that muscle injury is not specifically linked to underlying disease or aetiology.

Differential repair

Muscle injury may be inevitable, but repair appears variable across patient groups with most recovery occurring by 6 to 12 months after critical illness [1]. The observation of variable outcome reinforces the construct of a spectrum of disability related to age, comorbidities and duration of ICU stay. The current literature supports these as key determinants of functional independence and HRQoL [1-4]. It is possible that these simple patient and clinical characteristics may act as proxies for nerve and muscle reserve and/or organ injury that predated the critical illness.

Additional physical morbidity

ICU-AW and neuropsychological dysfunction represent major disabilities. However, many other physical consequences of critical illness, although less frequent, may also affect physical HRQoL. These have been evaluated most comprehensively in ARDS survivors and include pulmonary dysfunction, entrapment neuropathy, late tracheal stenosis, heterotopic ossification, and cosmetic changes that have been linked to emotional outcomes, social isolation, and sexual dysfunction (Fig. 381.1) [1].

Pulmonary function abnormalities

The lung is a very resilient organ after severe ARDS. Most survivors have normal or near normal pulmonary function and when there are impairments, these are typically mild restrictive changes and a mild associated reduction in diffusion capacity [1,5,9]. Orme et al reported abnormal pulmonary function associated with decreased health-related quality of life one year following hospital discharge [9] and Neff and colleagues reviewed 30 studies that evaluated pulmonary function in ARDS survivors [19] and found important variability in the proportion of patients with obstructive (0%–33%) and restrictive (0%–50%) defects and compromised diffusion capacity (33%–82%). Herridge and collaborators showed normal to near normal pulmonary function achieved by 6 months to one-year after ICU discharge with continued stability over the 5-year study period. Evaluation of detailed chest imaging in these patients also showed minimal structural change to the pulmonary parenchyma at 5 years after ICU discharge [1,20]. Population heterogeneity may account for this broad spectrum of

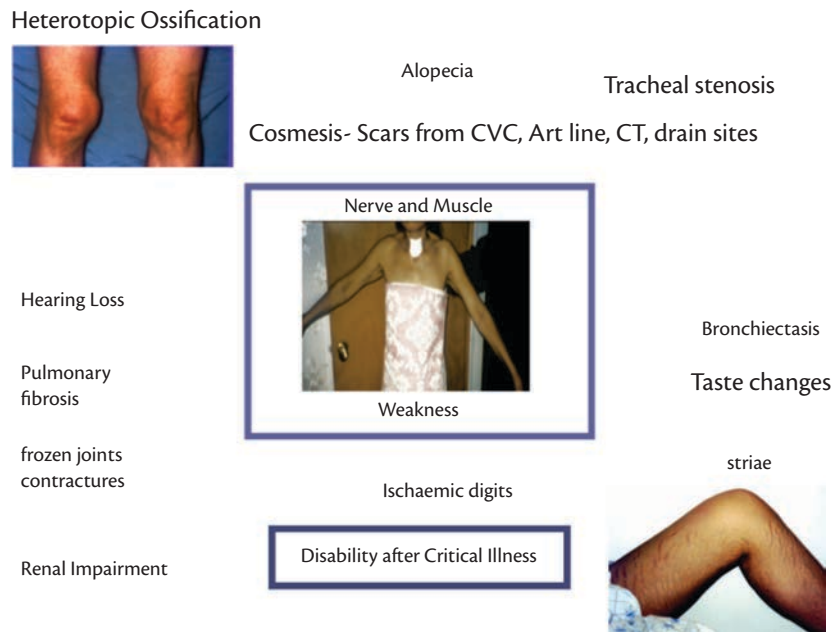

Fig. 381.1 The spectrum of disability after an episode of critical illness. ICU Acquired weakness is the central physical morbidity but other, less frequent issues are also noted here.

Courtesy of Margaret Herridge.

pulmonary dysfunction and specifically to evolving definitions or severity of ARDS, different ventilatory strategies, prior lung disease or smoking.

Entrapment neuropathy and joint contractures

The prevalence of peroneal and ulnar nerve palsies was six percent in the Toronto ARDS Outcomes study [1]. A small proportion of patients were affected, but when these nerve palsies occurred, they represented an often devastating injury with a prolonged recovery. In some cases, these injuries precluded the patients' ability to return to their original work. Contractures also contribute importantly to impaired long-term rehabilitation after critical illness.

Heterotopic ossification

Heterotopic Ossification (HO) is the deposition of para-articular ectopic bone and is associated with polytrauma, burns, pancreatitis, and ARDS and in the context of paralysis and prolonged immobilization. The prevalence of HO in the Toronto ARDS cohort was 5% and all patients had large joint involvement with the subsequent development of functional dependencies [1]. Survivors of critical illness should be evaluated for this since it may be modifiable with surgical debridement.

Cosmesis

Critical illness transforms the patient's physical appearance and some patients suffer enormous emotional distress from their altered appearance which leads to social isolation and sexual dysfunction. Examples include scars from complex wound infections, occipital (Fig. 381.2) or sacral ulcers related to immobility, laparotomy, chest tube, central line, arterial line and tracheostomy insertion, burns, striae from volume overload, and facial scars from prolonged non-invasive mask ventilation.

Caregiver and family burden in critical illness

Critical illness affects the entire family and caregivers represent important risk modifiers for patient outcome. Recent data show most ICU survivors who required long-term mechanical ventilation still required the assistance of a family caregiver one year after their critical illness. Current published evidence suggests that the provision of complex care after critical illness may have a negative effect on caregivers, and may jeopardize their HRQoL outcomes. Caregivers may also be at risk for post-traumatic stress disorder emotional distress, burden, depression, and anxiety.

Fig. 381.2 Persistent occipital bed sore in survivor of complex critical illness 1 year after ICU discharge.
Courtesy of RECOVER program.

Conclusion

Patients sustain important disability after critical illness, regardless of inciting aetiology. ICU-AW is the most prevalent physical sequela and many would argue is ubiquitous. Emerging literature would suggest that there are different risk phenotypes based on age, burden of comorbid illness and duration of ICU stay and within these groups, there may be differential injury and repair of muscle and nerve injury. This observation may have important implications for risk stratification and the development of rehabilitation models that are better tailored to individual need and outcome trajectory. Family caregivers develop significant mood disorders and since they are important risk modifiers of outcome, need to be integrated into family-centred post ICU care and follow-up programs.

CHAPTER 382

Neurocognitive impairment after critical illness

Ramona O. Hopkins and James C. Jackson

Key points

- Neurocognitive impairment after critical illness is highly prevalent, occurring in up to 60% of patients.
- Neurocognitive impairment after critical illness is persistent, with evidence suggesting that it is likely permanent in some cases.
- Neurocognitive impairment after critical illness is often diffuse and affects multiple domains of functioning including memory, attention, and executive functioning.
- A number of mechanisms of injury and associated risk factors for neurocognitive impairment have been identified including inflammation and hypoxia.
- The development of interventions to improve neurocognitive impairment is a high priority both during and after critical illness and specific interventions are beginning to show promise in reducing such impairment.

Introduction

In the past several decades the number of survivors of critical illness has increased, at least in part due to a sustained and concerted effort by the critical care community to improve survival. A large number of studies over the past 20 years indicate surviving critical illness is not benign, as many survivors will develop long-term physical, neurocognitive, and psychiatric morbidities that adversely impact functional and quality of life outcomes. A recent systematic review of ~25 prospective investigations in critically-ill cohorts, including populations of medical, surgical, sepsis, and acute respiratory distress syndrome (ARDS) patients found a high prevalence of neurocognitive impairments months to years after hospital discharge [1–3]. Fig. 382.1 shows prevalence in neurocognitive impairments in representative studies in several critically-ill populations. Most neurocognitive outcome studies to date are small single centre cohort studies, but similar findings of severe and persistent neurocognitive impairment were recently reported in a large single centre study [4] and a large prospective multi-centre cohort study [5].

Onset of neurocognitive impairments

Several longitudinal cohort studies in older adults that assessed cognitive function before and after critical illness indicate that the onset of neurocognitive impairments occurs after intensive care unit (ICU) admission [2,3]. In older sepsis patients from the Health and Retirement Study in which neurocognitive function was assessed before and after sepsis, moderate to severe new neurocognitive impairment and new functional limitations were associated with severe sepsis [2]. The new neurocognitive impairments and functional limitations remained present years after ICU discharge (measured 1, 2, and 3 years after hospital discharge) and were severe enough that they resulted in increased utilization of caregiver support, increased admission to a nursing home, and depression in these patients. A study in elderly Medicare beneficiaries found critical illness was associated with development of dementia after accounting for risk factors [3]. During the three year follow-up period, new diagnosis of dementia occurred in 17.8% of the sepsis survivors. Independent risk factors for dementia included factors associated with critical illness including severe sepsis or infection, renal replacement therapy, and neurologic dysfunction. Importantly, older age increased the dementia prevalence in individuals who were 85 years or older (33%), which is almost double the rate of the group as a whole [3]. Not only are the neurocognitive impairments new, but as the data from the previously mentioned studies suggest, the impairments are severe and adversely impact patients' functional abilities [2,3] in a manner that is significantly limiting, as is characteristically observed in dementia. For example, the severity of the cognitive impairments is similar to the severity of impairment in individuals with mild Alzheimer's disease or moderate traumatic brain injury [4]. Thus, one adverse consequence of critical illness is development of new severe neurocognitive impairments.

Neurocognitive impairments occur not just in older individuals, but are prevalent across all age ranges in adults, highlighting the fact that cognitive deficits in survivors of critical illness are not a function of advanced age. Data from a recent study found 34% of patients' age <49 years had cognitive impairments at 12 months a rate that was similar to older patients (50–64 years and >65 years) and cognitive impairments were common even in those without significant medical comorbidity [4]. A recent systematic review found the prevalence of neurocognitive impairment was 11–62% of critically-ill patients in studies that used standard neuropsychological tests [1]. In the five studies that administered only cognitive screening tests or questionnaires to assess neurocognitive function, the prevalence of cognitive impairment was somewhat lower—ranging from 11 to 56%. While these rates are broadly similar, the authors note 'in general studies with

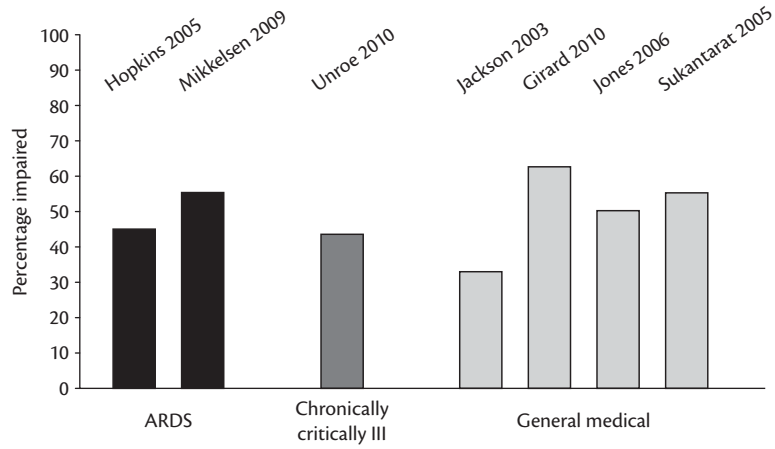

Fig. 382.1 Neurocognitive impairment rates across ICU populations [6,7,16].
Data from various sources (see references); Mikkelsen ME et al., 'Cognitive, mood and quality of life impairments in a select population of ARDS survivors', *Respirology*, 2009, **14**(1), pp. 76–82; Sukantarat KT et al., 'Prolonged cognitive dysfunction in survivors of critical illness', *Anaesthesia*, 2005, **60**(9), pp. 847–53; Jackson JC et al., 'Six-month neuropsychological outcome of medical intensive care unit patients', *Critical Care Medicine*, 2003, **31**(4), pp. 1226–34; and Unroe M et al., 'One-year trajectories of care and resource utilization for recipients of prolonged mechanical ventilation: a cohort study', *Annals of Internal Medicine*, 2010, **153**(3), pp. 167–75.

extensive neuropsychological testing reported a higher incidence of neurocognitive impairment than those with screening test data.' Neurocognitive impairments persist months to years, but few studies have followed patients beyond three years, a possible weakness of current research. Neurocognitive impairments are reported in multiple cognitive domains including memory, attention, language, executive function (broadly defined as decision making, ability to organize, prioritize, and manage time), processing speed, and visuospatial function [1]. The most frequently assessed neurocognitive domain was memory followed by executive function. Impairments in memory and executive function often lead to functional impairments. Assessments of executive function in ARDS survivors found nearly 1 in 2 ARDS survivors (48%) demonstrated impairment in executive function [6]. For example, an investigation of 30 ICU survivors employed a novel problem solving and planning task and found 87% of survivors had significant executive function deficits one week after discharge and the deficit persisted in half of all patients up to 2 months later [7]. Data to date suggest neurocognitive impairments are new, prevalent, persistent, affect multiple neurocognitive domains, and are sufficiently severe to impact functional ability.

Trajectories of neurocognitive outcome

Questions remain regarding the nature of neurocognitive changes following critical illness including whether impairments are stable or prone to change over time—reflecting either improvement or decline (for an example of possible trajectories of change using hypothetical follow-up times, refer to Fig. 382.2). Evidence to date offers support for the view that in the early period after critical illness, individuals typically demonstrate significant improvement over a span of several months before they plateau and reach what for many is a new baseline [1,4]. For some, this new baseline reflects a level of cognitive ability which is at or only slightly below their pre-ICU level and which may reflect largely 'normal' functioning. Alternatively, for others, this new baseline may reflect significant and chronic cognitive impairment which, while potentially less severe than was demonstrated in the immediate period after

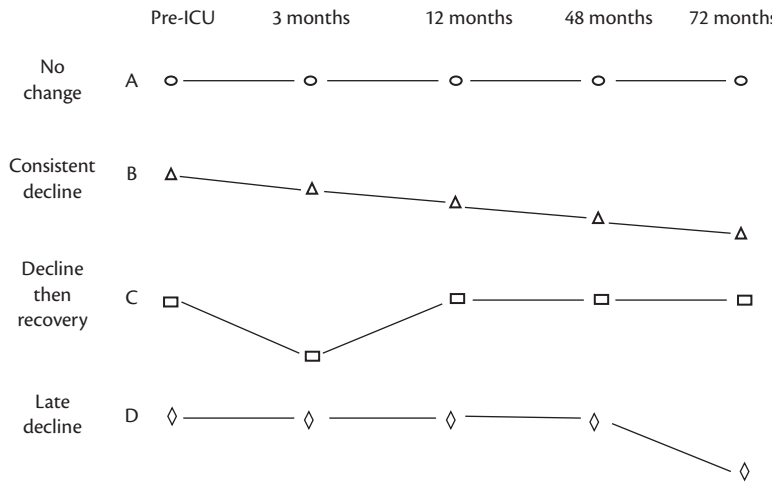

Fig. 382.2 Potential neurocognitive outcome trajectories.

hospital discharge, is substantially below their pre-ICU baseline and what is required for effective daily functioning. In a subset of patients, there may be additional decline over time, likely due to the effects of increased age, other risk factors such as comorbid disease (e.g. cardiovascular disease), or the existence of undiagnosed mild cognitive impairment or preclinical dementia at the time of ICU hospitalization. It may be that individuals with pre-existing conditions such as mild cognitive impairment experience an unusually rapid transition to dementia (including Alzheimer's disease) and that this accelerated neurocognitive decline may be fostered by the effects of critical illness—notably factors such inflammation and hypoxia (discussed later), both of which have been implicated in animal models in the development of Alzheimer's disease [8,9]. In these patients, it is potentially misleading to think of a 'new baseline' because, unlike their counterparts, their neurocognitive function never plateaus, but rather persistently declines over time.

Mechanisms and risk factors of neurocognitive impairment

There is growing, but limited information regarding mechanisms of neurocognitive impairment following critical illness, which are likely heterogeneous and interact with patient risk factors such as comorbid diseases or older age and factors associated with critical illness (e.g. inflammation, cytokine activation, hypoxia), its consequences (e.g. delirium, glucose dysregulation), or interventions (e.g. sedative use). Potential pathways to neurocognitive decline and associated mechanisms and risk factors are portrayed via Fig. 382.3. Mechanisms of brain injury include hypoxia [6,10], hypotension [6], glucose dysregulation [11,12], and inflammation and cytokine activated immune system deregulation [13,14]. These mechanisms likely interact with risk factors such as older age, delirium, and sedative use. In the case of delirium and sedatives, it is unclear whether these are risk factors on pathway to neurocognitive impairment (and, as such, may amplify the effects of key mechanisms) or whether they are directly injurious to the brain [15]. A study by Girard et al., found delirium duration was associated with worse neurocognitive functioning after adjusting for age, education, pre-existing cognitive functioning, illness severity, sepsis, and others, highlighting the potential long-term adverse consequences of delirium on neurocognitive functioning [16]. A study by Jackson et al. which analysed data from the Awakening and Breathing Controlled Trial, subjects in the intervention arm who received both spontaneous awakening trials and spontaneous breathing trials had better neurocognitive functioning at 3 month follow-up, though this effect dissipated at 12 month follow-up [17]. The Bringing to Light the Risk Factors and Incidence of Neuropsychological Dysfunction in ICU (BRAIN-ICU) survivors study found a longer duration of delirium was independently associated with cognitive impairment (global cognition and executive function scores) at both 3 and 12 months [4]. These data suggest that external factors such as sedation may be limited to the short-term, and may have little or no bearing on long-term neurocognitive outcomes. Alternatively, factors such as delirium may have both short- and long-term effects, and could be an early expression of a brain injury, with neurocognitive impairment being the long-term expression of this acute brain dysfunction. A comprehensive discussion of mechanisms and risk factors is beyond the scope of this review and has been addressed elsewhere [18].

ICU and post-ICU interventions

In an ideal world, it would be possible to eliminate or modify risk factors contributing to neurocognitive impairment in survivors of critical illness although, as a practical matter, this is extremely difficult and has not been currently achieved. As such, it may be important to develop and implement interventions that could partially prevent or ameliorate cognitive deficits both in the ICU and after. In an in-patient context, various approaches to fluid management and to nutrition have been employed to improve ICU survivor and long-term outcomes. The Adult Respiratory Distress Cognitive Outcomes Study (ACOS), which measured long-term outcomes in survivors of the Fluid and Catheter Treatment Trial (FACTT), found a liberal fluid management strategy was associated with

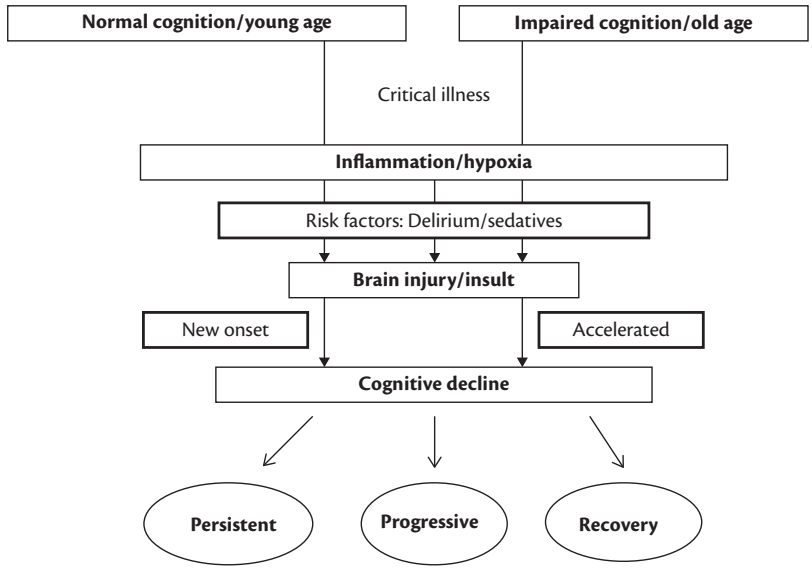

Figure 382.3 Potential pathways of neurocognitive outcome following critical illness

better cognitive outcomes [10]. However, there were significant limitations of the ACOS study, including low consent rate, attrition, and missing data, which temper these findings. In the ALTOS study which assessed one year outcomes in patients with acute lung injury who were enrolled in the EDEN randomized trial that compared full energy enteral feeding vs. low energy permissive underfeeding in ICU patients, there was no difference in neurocognitive outcomes between the treatment arms at six months or one year [5]. Taken together, these studies provide little guidance regarding the efficacy of ICU related interventions that may prevent or ameliorate neurocognitive impairments.

In addition to in-hospital interventions, efforts are increasingly focusing on post-ICU rehabilitation which has taken a variety of forms—including physical and cognitive rehabilitation as a way of positively impacting post-ICU neurocognitive functioning. In a small randomized study that assessed the effects of six weeks of physical rehabilitation in ICU survivors with prolonged mechanical ventilation found a 20% improvement in the cognitive component of the functional independence measure (FIM) score, a widely used metric in rehabilitation medicine, in the treatment group and a decline of 32% in the control group [19]. In a randomized trial in medical and surgical ICU survivors who received a protocolized rehabilitation program that included in-home physical and cognitive rehabilitation targeting executive dysfunction [20]. While very small and clearly preliminary in nature, the study by Jackson et al., demonstrated that patients in the intervention group had better neurocognitive and overall daily functioning than their counterparts. These interventions, both pilot studies with small sample sizes, appear to improve—although not eliminate—deficits and they may be promising, though their results should be replicated in larger more definitive investigations.

Conclusion

A large and growing body of evidence demonstrates that neurocognitive impairment is a common and persistent morbidity in survivors of critical illness and one associated with adverse functional outcomes. Neurocognitive impairments has been shown to occur in up to 60% of individuals, are reported across ICU populations, and affect specific neuropsychological domains including memory, attention, and executive functioning related areas. Mechanisms that undergird the development of this impairment are not yet well described though a number of factors are implicated including hypoxia and inflammation which are notable among numerous others as are risk factors such as delirium. Relatively little attention has been paid to interventions to reduce or ameliorate these impairments, though efforts aimed at patients after hospital discharge appear to be relatively more promising (to this point) than those occurring in an inpatient context. Neurocognitive impairment—whether new or worsening—is a substantial burden for patients and their families and carries with it significant public health consequences which until recently have been largely underestimated or unrecognized. A pressing need exists to direct clinical and research related resources to this problem.

CHAPTER 383

Affective and mood disorders after critical illness

Daniel W. Klyce and James C. Jackson

Key points

- Clinically significant depressive symptoms occur in approximately a third of survivors of critical illness (more in certain sub-populations) and persist over time.
- In survivors of critical illness, symptoms of depression and symptoms of ongoing physical illness often mimic each other, making it difficult to arrive at a proper diagnosis.
- Pre-existing depression and physical debility predict symptoms of depression in survivors of critical illness after discharge, but the contributions of 'in hospital' factors to outcomes is less clear.
- Interventions focused on addressing depressive symptoms in critically ill patients both in and out of the hospital are promising, but largely unstudied.
- The integration of the disciplines of psychology and psychiatry into the treatment of survivors of critical illness is an important goal and should be pursued.

Introduction

Patients who survive critical illness or injury to be discharged from intensive care units (ICUs) are often faced with an arduous course of recovery and rehabilitation. Beyond the potential risk of negative physical health outcomes, a growing body of evidence indicates that these patients are also at risk for significantly poorer mental health outcomes and health related quality of life. Commonly observed psychological sequelae of critical care included generalized anxiety, symptoms of post-traumatic stress, impaired neurocognitive functioning, and affective or mood impairment. Although still relatively small in scope, research related to psychological and neuropsychological outcomes has bourgeoned in the last decade. Within this area of research, post-ICU depressive disorders have emerged as an early focus of study. This section will review the following topics related to post-ICU affective disorders—prevalence rates, assessment and identification, risk factors, empirical support for early interventions, and important questions for future research.

Scope of the problem

In their systematic review, Davydow et al. [1] reported a 28% median point-prevalence rate of clinically significant symptoms of depression. Furthermore, they reported the prevalence of depressive disorders diagnosed by a clinician 2 months post-discharge at 33%. In a related review of depression among survivors of acute respiratory distress syndrome (ARDS), Davydow et al. [2] reported a point prevalence range of 17–43%, with a median of 28%. Similarly, Jackson et al. [3] cited evidence that depression is observed among 25–50% of ICU survivors and that symptoms of depression may continue to be observed at rates much higher in than the general population (i.e. up to 58% [4]) 2 years post-ICU discharge.

Although these reviews provide much-needed information about the prevalence of post-ICU affective impairment, they also identify multiple methodological limitations related to defining the scope of the problem. A pervasive problem in research involving ICU survivors is attrition, often with more than half of the original sample lost to follow-up—despite considerable effort invested in retention over time. Consequently, even methodologically strong studies often are based on less than desirable sample sizes with little data available to characterize the portion of the original sample lost to follow-up. Relatedly, information about long-term psychological outcomes is scantly available. Most studies have been restricted to follow-up periods of one year or less, complicating efforts to understand the persistence of affective impairment in the years post-ICU discharge. Finally, identification of significant symptoms of depression is overwhelmingly limited to screening instruments, and 'clinical significance' has been defined variously by research using different criterion guidelines.

Assessment and identification

The clinical syndromes included in the family of mood disorders are characterized by affective, cognitive, and somatic disturbances. The significant overlap between physiological symptoms of depression and an organic condition that may be associated with critical care can complicate the accurate diagnoses of a mood disorder in this population. Physiological symptoms of a major depressive episode (i.e. changes in sleep patterns, psychomotor agitation or retardation, fatigue or loss of energy, significant changes in weight, and changes in appetite) are readily observable criteria that can also be associated with a variety of medical conditions. In the context of current diagnostic and classification systems, particular care should be taken to make an accurate differential diagnoses between a depressive disorder and Mood Disorder Due to a General Medical Condition. In making this distinction, the clinician seeks to establish that the 'mood disturbance is aetiologically related to the general medical condition through a physiological mechanism (DSM-IV-TR [5])'.

In samples of critically-ill patients and survivors of ICU admissions, a thorough assessment is required to distinguish between mood disturbances that are physiological consequents of a general medical condition and depressive disorders that are *secondary to* a major illness or injury (e.g. secondary to physical limitations, social isolation/stigma, hopelessness related to prognosis, lost productivity, etc.). As indicated by the DSM [5], it is often instructive in the process of making a differential diagnosis to compare the course of the mood disturbance with that of the illness and to identify any patient factors not often associated with the common course of specific depressive disorders (e.g. typical age of onset, gender, etc.). The obvious implication of a misdiagnosis is the application of a psychological intervention when, in fact, the depressive mood symptoms are physiologically related to a medical syndrome; in this instance, medical remediation of the underlying organic condition is the primary course of treatment.

Optimally, such distinctions can be made by clinical interviews conducted by mental health professionals integrated into recovery/rehabilitation programs. Formal interviews—such as the Structured Clinical Interview for DSM-IV [5] (SCID)—provide the framework for a thorough investigation of clinical symptoms and facilitate differential diagnoses, however, they can often require one to two hours of a patient's and clinician's time. If a thorough interview is not possible, due to time constraints or patient comfort, there are several screening instruments that have demonstrated good reliability and criterion validity. These include the Beck Depression Inventory-II (BDI-II), the Brief Symptom Inventory-30 (BSI-30), the Center for Epidemiological Studies Depression Scale (CES-D), Geriatric Depression Scale (GDS), the Hamilton Rating Scale for Depression (HRSD), and the Hospital Anxiety and Depression Scale (HADS). Each of these instruments allows clinicians to assess various affective, cognitive, and somatic aspects of depressive symptoms. These instruments provide a cross-sectional assessment of current or recent mood functioning; however, more thorough questioning may be necessary to determine the course of the mood disturbance in order to diagnose a specific clinical syndrome. Furthermore, these instruments may not fully assess the differential impact of physical limitations versus psychological disturbances on social and occupational functioning.

Risk factors

Risk factors related to post-ICU depression are commonly grouped into (1) pre-injury/illness psychosocial variables, (2) ICU treatment/illness variables, and (3) post-ICU/recovery variables (e.g. Davydow, et al. [1]). Two reviews—Davydow and colleagues' [1] systematic review and Jackson and colleagues' [3] overview—represent important efforts to identify these risk factors, and have been supported by a small collection of empirical studies published between 2009 and 2012 [6–9].

The background characteristics that patients 'bring with them' to the ICU are often difficult to assess, given that measuring pre-morbid psychological or physical functioning requires retrospective collection of data from patients or their surrogates. Even so, Davydow et al. [1] found evidence to suggest that depressed mood and poor physical functioning in the month preceding ICU admission predicted symptoms of depression at follow-up and post-discharge. Inconsistent findings related to gender have been reported, however, when an effect has been observed, female gender is more predictive of depression than male gender. In addition to premorbid depression and anxiety, Jackson et al. [3] cited evidence supporting higher body mass indices as a predictor of post-ICU depression. Finally, Tøien et al. [8] reported that being unemployed pre-ICU admission predicted depression at 12-month follow-up.

Several ICU-treatment variables have been associated with post-ICU affective impairment. In their review, Jackson et al. [3] reported evidence that longer ICU stays and longer duration of mechanical ventilation were associated with depression; Adhikari, et al. [8] reported similar findings among ARDS patients, showing that these two variables predicted higher BDI-II scores at follow-up. Jackson et al. [3] also identified studies implicating the number of days on sedatives, mean ICU benzodiazepine dosage, and maximum organ failure scores as predictors of affective dysfunction. Notably, in their systematic review, Davydow et al. [1] concluded that ICU length of stay and the duration of sedation had no appreciable impact on depression post-discharge. Furthermore, patient subjective perception of the ICU experience appears to play a role. Rattray et al. [7] reported that patient recall of frightening experiences in the ICU at discharge predicted higher rates of depression, as did poor recall for the ICU experience and dissatisfaction with quality of care. Finally, Kiekkas et al. [6], in a review of psychological distress and delusional memories following critical care, cited evidence supporting a link between delusional memories of the ICU and higher rates of post-discharge depression.

Davydow et al. [1], presented several findings related to post-ICU predictors of depression. An obvious finding that enjoys consistent report is that post-ICU indicators of psychological dysfunction are associated with other comorbid conditions and dysfunction at subsequent follow-ups. For instance, post-ICU symptoms of anxiety and post-traumatic stress are associated with cross-sectional elevated rates of depression. In one of the few long-term follow-up studies, Adhikari et al. [9], showed that elevated symptoms of depression among ARDS patients at 2-year follow-up predicted elevated (and relatively stable) rates of depression at 5-year follow-up; they also noted that slower recovery of organ functioning was predictive of depression. As reviewed by Davydown et al. [1], Weinert and Meller [10] found that poorer physical functioning also played a role. Specifically, a decline in physical function between two and six months post-discharge predicted higher rates of depression at six months; however, a decline in functioning between discharge and two months did not. Finally, Jackson et al. [11], reported that cognitive impairment at 6 months post-discharge was significantly associated with higher symptoms of depression (see Box 383.1).

Early intervention

Although there is growing urgency to provide services targeting early emergence of psychological disturbances during ICU treatment and post-discharge, few empirically supported programs have been developed specifically for this population. Peris et al. [12] developed an ICU programme based on the participation of clinical psychologists in intra-ICU treatment. Psychologists and trained staff offered a variety of services to patients at bedside and to family members involved in the patient's care. Bedside, clinical psychologists were involved in providing psychoeducational services, promoting stress management and coping strategies, and counselling; on average, patients had five or six encounters with psychology staff. Psychologists were also involved in supporting family

Box 383.1 Risk factors having moderate to strong associations with post-ICU depressive symptoms

Strong support

- Use of anti-depressant medications pre-injury/illness.
- Retrospective report of depressed mood pre-ICU admission.
- Poor physical functioning prior to ICU admission.
- Mean benzodiazepine dosage during ICU treatment.
- Cognitive impairment at discharged and follow-ups.
- Recall of stressful memories or nightmares from ICU experience.
- Symptoms of other psychiatric disorders (e.g. anxiety) at discharge and follow-up.
- Quality of physical and mental health post-ICU.

Moderate/inconsistent support

- Female gender.
- Unemployment status pre-injury/illness.
- Longer length of hospital stay.
- Longer duration of mechanical ventilation.
- ICU treatment specialty (e.g. medical versus trauma ICU).
- Daily sedative interruption.
- Satisfaction with hospital care/treatment.
- Changes in physical functioning post-discharge.

members' decision-making processes and their bedside interactions with patients. Patients who were admitted subsequent to the implementation of this service evidenced less negative psychological outcomes 12 months post-discharge than did patients admitted prior to the implementation of this service. Patients participating in the clinical psychologist intervention showed lower rates of depression (6.5 versus 12.8%), anxiety (8.9 versus 17.4%), and symptoms of post-traumatic stress (21.1 versus 57%); these patients also endorsed significantly higher subjective ratings of quality of life than the control group. Notably, the annual cost associated with the Clinical Psychology Service at Careggi Florence University Hospital (Florence, Italy) is €30,000.

Beyond psychological interventions delivered during critical care, Jones et al. [13], demonstrated the potential of psychological services integrated into rehabilitation and recovery programs. In a multi-site, randomized control trial involving patients admitted to ICUs, Jones et al. [13] tested the benefit associated with a rehabilitation program to promote positive physical and psychological outcomes after critical illness. All patients were visited on units, had three follow-up telephone calls, and were offered clinic appointments at 8 and 24 weeks post-discharge. Patients in the intervention group were provided a rehabilitation manual to self-implement during the at-home recovery. The manual detailed a 6-week rehabilitation package that targeted psychological, psychosocial, and physical problems. Patients who used the rehabilitation manual evidenced significantly improved physical functioning at 8 and 24 weeks post-discharge as compared with the control group. Although not statistically significant, the intervention group also evidenced lower rates of depression (12 versus 25%).

These promising results emphasize the importance of involving psychology services or allied disciplines in ICU treatment and post-discharge recovery. What is particularly encouraging about these results is evidence to suggest that post-ICU mood or affective disorders are tractable and that they might be influenced by relatively low-key interventions such as a self-guided rehabilitation program manual. Given the potential for symptoms of depression to interfere with patient adherence to recovery care or rehabilitation programmes, early intervention programmes like these may prove beneficial to facilitating physical recovery and minimizing the costs associated with rehabilitation and delayed return to productivity.

Future research

The risks and benefits associated with administering antidepressant medications during and post-ICU care are important areas for future research. In his review of treatments for psychiatric conditions developing after critical care, Weinert [14] cited inconsistent evidence supporting the safety and efficacy of administering antidepressants to ICU survivors. Weinert also reviewed evidenced from allied disciplines (i.e. from biopsychology studies) suggesting that psychopharmacological interventions administered in the ICU could protect neural pathways and other brain structures often implicated in the development of post-ICU depression. Given the potential for antidepressants to facilitate faster recovery and increased participation in rehabilitation, Weinert's call for new research focused on confirming results from previous clinical trials is renewed here.

Beyond the effectiveness of psychopharmacological interventions, models for the effective delivery of rehabilitation/recovery services more generally should be the focus of new research efforts. One candidate system that has enjoyed recent critical review [15,16] is post-ICU follow-up clinics. These clinics, where they do exist, may provide services such as primary care, physical and/or cognitive rehabilitation, and psychological treatment. In their 2006 survey of ICU follow-up clinics in the UK, Griffiths et al. [17] found that 'clinical psychology' was the discipline with which these clinics most frequently had prenegotiated referral arrangements. Given the identified need for psychological services, evaluations of critical care follow-up clinic programmes should focus on the effective ways that mental health professionals may be incorporated in such interdisciplinary treatment teams. In addition to identifying the long-term needs of ICU survivors, these clinics could provide an appropriate context to establish empirical support for the differences between affective disorders in this population versus other physically ill or injured patients.

PART 21.3

Out-of-hospital support after critical illness

CHAPTER 384

Long-term weaning centres in critical care

Jeremy M. Kahn

Key points

- Successful liberation from prolonged mechanical ventilation requires an inter-disciplinary care team and consistent application of evidence based practice.
- Dedicated weaning centres may facilitate liberation of mechanical ventilation by concentrating this expertise in a low acuity environment.
- The evidence that weaning centres improve outcomes is limited, but available data suggest that they may provide equivalent care to intensive care units (ICU) at a lower cost.
- The availability of weaning centres may have unintended spillover effects to acute care hospitals that influence how they manage patients with chronic critical illness (CCI).
- Future research should determine which types of patients will most benefit from admission to a dedicated weaning centre and how to organize and manage these facilities to best improve outcomes.

The role of care setting in ventilator weaning

Acute respiratory failure requiring invasive mechanical ventilation is one of the most common reasons for intensive care unit (ICU) admission [1]. Common causes of acute respiratory failure include pneumonia, congestive heart failure, acute exacerbations of chronic respiratory disease, and post-operative respiratory insufficiency. In addition to treating the underlying illness causing respiratory failure, ICU practitioners must consider the use of key evidence-based practices that might facilitate weaning from mechanical ventilation, including daily spontaneous breathing trials, avoidance of continuous intravenous sedation, and early mobilization of the ventilated patient [2]. Liberation becomes even more complex in the subset of patients requiring prolonged mechanical ventilation. Additional considerations in these patients include the timing of tracheostomy, the use of a protocolized approach to liberation, and, in patients with very poor prognoses, decisions surrounding potentially placing limits on the use of life-sustaining therapy [3].

Weaning patients in this manner, especially those patients requiring prolonged mechanical ventilation, requires extensive expertise about pulmonary physiology, an experienced interdisciplinary care team and a rigorous, often protocolized approach to discontinuing ventilator support [4,5]. Historically this care was provided solely in the ICU of an acute care hospital. However, given the complexity of the process, it is increasingly being provided in dedicated weaning centres [6]. Dedicated weaning centres differ from acute care ICUs in they primarily admit patients directly from acute care hospitals and typically admit only longer term ventilated patients, allowing them to focus on the special needs of this population. Thus, dedicated weaning centres offer a novel and potentially beneficial care setting for these unique and high-risk patients.

Types of weaning centres

There are two major types of dedicated weaning centres: long-term acute care hospitals (LTACHs) that provide care to many types of patients with chronic critical illness (CCI) including those without ventilator dependence, and hospitals that only care for patients receiving prolonged mechanical ventilation.

Long-term acute care hospitals

The major type of dedicated weaning centre in the United States is specialized hospitals that care for a variety of patients with CCI. Called LTACHs, these hospitals are governed by special regulations set forth by the United States Centers for Medicare & Medicaid Services. LTACHs are defined not by the types of patients they care for, but by their average length of stay, which by rule must exceed 25 days. This means that they not only provided dedicated weaning services to patients receiving prolonged mechanical ventilation, but also provide other types of acute care for patients who are sick enough to be hospitalized, but do not require all the services of an acute care hospital [7].

LTACHs are generally smaller than most general acute care hospitals, with fewer beds and fewer annual admissions [8]. This lower case load allow LTACHs to focus on more holistic aspects of care, including the nutritional, rehabilitation, and social planning needs of this population. Many if not all of the patients admitted to an LTACH for ventilator weaning have already undergone tracheostomy and placement of a feeding tube [9]. LTACHs vary in their ability to respond to severe physiological decomposition, which can happen during the weaning process. Some LTACHs have ICUs on site, while others have to transfer these patients back to an acute care hospital.

LTACHs are among the fastest growing segments of health care in the US, and the number of ICU patients in the US transferred to LTACs is steadily increasing over time [6]. This increase is due

in part to the increase in patients requiring prolonged mechanical ventilation as a result of increased survival in mechanical ventilation and an aging of the population. Yet it is also due to the expansion of the numbers of LTACHs—per case hospital payment and generous reimbursement creates financial incentives for transfer to LTACHs that support the expansion of this model of care.

Dedicated weaning centres

The other type of weaning centre is a hospital that provides nothing, but ventilator care to patients requiring prolonged mechanical ventilation. This is the model that predominates outside the United States, with well-known weaning centres existing in Germany, the United Kingdom, Italy, and other countries [10-12]. Similar to LTACHs, these weaning centres are often small, but they still possess the resources to care for patients requiring mechanical ventilation over the long term. Generally these facilities specialize not only in post-ICU rehabilitation and ventilator weaning, but also chronic respiratory failure, sleep disordered breathing and neuromuscular disease. These conditions are analogous to post-ICU recovery in that they require clinicians with expertise in the respiratory system and a multidisciplinary approach to care. An important characteristic of these hospitals is that there are relatively few of them compared to the demand, and admission is limited to the small number of patients who most clearly might benefit from their care.

Effectiveness of weaning centre care

Conceptual rationale for benefit

Dedicated weaning centres exist in part because of a strong conceptual rationale for their superiority in chronic ventilator weaning, both in the clinical domain and the economic domain (Table 384.1). In the clinical domain, perhaps the most compelling rationale stems from the volume-outcome relationship in health care—the notion that with greater clinical experience in complex disease comes better outcomes [13]. It stands to reason that hospitals that care for a large number of patients with prolonged mechanical ventilation would be more facile at liberating them from mechanical ventilation. Other potential reasons underlying a clinical benefit include greater use of interdisciplinary care teams, greater use of protocols for chronic weaning and greater continuity of care, with the same providers present day after day, instead of switching frequently as in a traditional ICU. Additionally, dedicated weaning centres admit primarily low acuity patients, meaning that in theory there are fewer emergencies to distract providers from the task of ventilator weaning.

There is also reason to suspect that dedicated weaning centres can provide less costly care for patients receiving prolonged mechanical ventilation. Dedicate weaning facilities need less resources overall compared to traditional acute care hospitals, meaning that they can operate at lower fixed costs and are therefore less costly on a per-patient and per-day basis. Additionally, to the degree that they facilitate weaning they may shorten the duration of ICU stay and overall acute care stay, saving money in the short term. Finally, by providing a place for chronically critically ill patients to convalesce outside of the hospital, they may prevent costly re-admissions to acute care.

Conceptual rationale for harm

Just as there are theoretical reasons why dedicated weaning facilities may lead to improved outcomes and lower costs, there are reasons why they may lead to worse outcomes and higher costs (Table 384.2). Dedicated weaning facilities may increase mortality and prolong ventilator weaning by fragmenting the cost of care across two or more hospitals, leading to communication failures and clinical fumbles. Also, because dedicated weaning facilities admit many long-stay patients with impaired immunity, the patients may be exposed to more highly-resistant organisms leading to severe hospital-acquired infections [14]. Moreover, transfers to dedicated weaning facilities typically involve an interhospital transfer, which can involve risks, although most studies suggest that the risk is relatively low [15].

Regarding costs, dedicated weaning facilities might increase costs by resulting in an overall increase in the acute care length of stay. To the degree that dedicated weaning facilities increase survival, they may increase costs through the added cost of survivorship, albeit to a degree that society may accept on a cost-utility basis. Finally, depending on the reimbursement scheme dedicated weaning facilities could be quite costly to payers such as governments and health insurers, even if they are cost saving from the hospital or patient perspective.

Existing evidence

Mortality for patients with prolonged mechanical ventilation is extremely high, with most studies estimating approximately 50% one-year survival [16]. Currently there are few studies comparing

Table 384.1 Theoretical reasons underlying a clinical and economic benefit associated with dedicated weaning centres

Domain	Factor
Clinical benefit	◆ Greater clinical experience ◆ Fewer handoffs within the hospital ◆ Lower overall severity of illness ◆ Improve use of weaning protocols
Financial benefit	◆ Shorter hospital length of stay ◆ Decreased weaning duration ◆ Lower fixed costs ◆ Fewer readmissions

Table 384.2 Theoretical reasons underlying a clinical and economic harm associated with dedicated weaning centres

Domain	Factor
Clinical harm	◆ Lower intensity staffing ◆ Fragmentation of the episode of acute care ◆ Disrupted communication ◆ Risks of interhospital transfer
Financial harm	◆ Increased overall length of stay ◆ Improved survival ◆ High costs to payers ◆ Opportunity costs for families having to travel to regional hospitals

costs of care and outcomes of patients receiving care in a dedicated weaning centre compared to the alternative of continued care in the ICU of a traditional acute care hospital. A single-centre study performed in the United States found that of 2,134 ICU patients evaluated for transfer to an LTACH, median survival was longer in the LTACH group, but 6-month survival was not different [17]. Daily costs were much lower in the LTACH compared to the ICU, although total costs were not directly compared between groups. This early evaluation indicates that transfer to LTACH does not impact long-term patient survival, but might actually prolong the dying process, which could be interpreted as harm. It also suggests that if LTACH days are substituted for ICU days then total health care costs can be reduced by transferring patients to LTACHs.

A more recent study evaluated 234,799 patients receiving prolonged mechanical ventilation in 2,609 acute care hospitals in the US [18]. A total of 20.6% of patients were transferred to an LTACH. Using a sophisticated technique to control for severity of illness and the indication bias associated with the decision to transfer, the authors found that there was no difference in one year survival between the two groups, similar to the previous study. However, six month costs were lower for patients transferred to LTACHs than for patients who remained in an ICU, primarily driven by a reduction in re-admissions to acute care hospitals and skilled nursing facilities.

Together, these studies suggest that chronic weaning facilities do not worsen survival for patients requiring prolonged mechanical ventilation, though nor do they improve it. They may reduce costs by offering equivalent services at a lower daily cost. Neither study investigated other important outcomes besides survival and costs. Potentially important outcomes include speed of liberation from mechanical ventilation, patient and family satisfaction and health related quality of life. Future research should examine the impact of weaning centre care on these other domains.

Indirect effects

Weaning centres may have important effects for the health system that are independent of their effects on the patients for which they actually provide care. It is important to consider these indirect effects when evaluating the role of dedicated weaning centres in the health system. Dedicated weaning centres provide a place for chronically ventilated patients to receive care outside of the ICU. This frees up ICU beds, which are a scarce resource in many health care systems, for other uses. Ultimately this may lead to fewer unplanned discharges and admission delays, which could improve outcomes for ICU patients [19,20]. At the same time, freeing up ICU beds may induce a tolerance for CCI that may paradoxically increase overall health care utilization. With no hospitals to transfer patients dependent on mechanical ventilation, physicians may be more inclined to limit life-sustaining therapy. However, with weaning centre beds as an option, physicians may be inclined to avoid these difficult discussions and simply transfer the patient. In the US, rules governing LTACHs prohibit them from admitting patients with no chance of recovery, however there are few data to gauge the effectiveness of these rules.

Conclusion and future directions

Although dedicated ventilator weaning hospitals have existed for decades, our understanding of them is still in its infancy. In many ways they operate in parallel to acute care ICUs, providing similar services, but at potentially reduced costs, and in a potentially more patient centred way. Paradoxically, with the increasing focus on rehabilitation and early mobilization in critical care, acute care ICUs may come to look more like dedicated weaning centres over time.

Several key aspects of weaning centres are still unknown and should be the subject of future research. First, research is needed into the types of patients that most benefit from transfer to these hospitals, the optimal timing of transfer, and how that timing integrates with the timing of tracheostomy. Furthermore, research is needed into the organizational characteristics of weaning facilities that are associated with improved outcome. Just as acute care ICUs benefit from care protocols for weaning and intensivist physician staffing, there may be organizational factors that benefit patients in dedicated weaning facilities. Finally, we need empiric research into the indirect effects of dedicated weaning facilities, which should provide more insight into the optimal role they play in the health system.

As we wait for this research, clinicians who care for patients in dedicated weaning centres and ICU clinicians who refer patients to dedicated weaning centres, should be aware of all these issues. At a minimum, clinicians should discuss the implications of prolonged ventilator care to ensure that patients and their families have appropriate expectations about their outcomes. Dedicated weaning centres will certainly be part of critical care for many years to come, but their utilization should be part of an informed decision about the goals of care and not a default decision in an extremely high-risk, high-cost patient population.

CHAPTER 385

The ICU survivor clinic

Priya Das and Carl Waldmann

Key points

- Continuity of care by intensivists enables early diagnosis and management of intensive care unit (ICU) problems.
- Specialist reassurance and advice can ease psychological recovery.
- The clinic service evolves to meet the needs of patients.
- Follow-up acts as service evaluation for the ICU care given to patients.
- It is has a fundamental role in assessing long-term outcomes.

Introduction

Critical illness leaves patients at risk of long-term physical and psychological problems. Leaving intensive care unit (ICU) is just the start of their long recovery process, and there are considerable effects on patient morbidity and mortality. Implementation of an ICU follow-up service has enabled provision of support following hospital discharge and manage sequelae effectively.

In 1989 the Kings Fund report [1] highlighted that morbidity, as well as mortality should be considered following intensive care: 'there is more to life than measuring death'. The National Audit Commission (Critical to Success) [2] and the National Expert Group (Comprehensive Critical Care) [3] have since echoed the need to focus on quality of life post-discharge. Globally, ICU patients require the highest level of support, both medical and financial, amongst all hospital patients. The average daily cost per patient in an ICU was estimated by Edbrooke et al. to be £1000; six times greater than that of an average ward patient [4]. The benefits of this large investment made during intensive care are only sustained when continued support is in place following discharge. All other specialties review patients following admissions and intensive care should be no different.

Post-ICU care is developing an evidence base and becoming an area of research in its own right. The concept is established in the UK and Australia, and is an area of interest in the United States. Indeed since 2009 the concept of the implementation of multidisciplinary post-ICU care has been officially advised [5] and the number of follow-up services is continuing to grow around the world.

Provision of an outpatient follow-up clinic supports key objectives. Through meeting patients regularly timely diagnoses of problems are made, and appropriate referrals can be made to other specialties, including the Traumatic Stress Counselling service.

Management plans and treatment decisions are frequently amended as a result of reviewing the patient during clinic consultations. Intensivists also use this opportunity to see the impact critical illness has had on patients and family members alike.

The follow-up clinic enables quality assurance of the critical care provided to both patients and relatives.

The format of the follow-up clinic

Follow-up in the UK is non-standardized, with each hospital deciding how to run their own service. The Royal Berkshire Hospital in the UK implemented outpatient clinics in 1993, which run two to four times a month, and all ICU survivors are invited to attend. Family attendance and participation at the clinic is also encouraged too.

30-minute appointments are offered at 2, 6, and 12 months following hospital discharge, by a team consisting of intensivists, experienced ICU nurses, and specialist follow-up nurses.

The service endeavours to meet patients' needs, as opportunities to make extra clinic appointments are given and patients are encouraged to revisit the ICU and meet the staff who cared for them during their illness. In addition, investigations are also organized during the clinic to monitor clinical progress.

Recently, the clinic has received referrals not only from other hospitals where no ICU follow-up exists, but also from local primary care doctors and distant health authorities too.

The annual cost of running the service is £36,000, which accounts for <1% of the annual ICU budget. In the United States funding plays a key role in providing the service, as follow-up clinic budgets are not always included in the main ICU budget. A typical breakdown of costs is shown in Table 385.1.

Outcomes after intensive care

The concept of health-related quality of life (HRQL) recognizes that both physical and emotional factors contribute to a patient's wellbeing. It remains a core principle of both the follow-up clinic as well as in the patient's community rehabilitation phase

Whilst clinical, biochemical, and radiological tests assess the extent of physical sequelae, quality of life tools address the impact of critical illness on patients. Box 385.1 illustrates that several factors can contribute to the HRQL.

The perceived quality of life (PQOL) tool is a self-administered or interviewer-administered instrument, which consists of 20 items. Alongside being quick to complete, when repeated during successive clinic appointments they may indicate less obvious and multifactorial struggles patients are experiencing.

Commonly used quality of life tools are shown in Table 385.2.

Table 385.1 Breakdown of costs

Component	Cost (£)
Nursing	21,000
Medical	7,000
Administration	6,000
Laboratory tests and X-rays	2,000
Total	36,000

Box 385.1 Case one

An elderly gentleman had a long ICU stay and had lost a significant amount of lean body mass. Despite investigations including lung function tests being normal, at home he did could not complete daily tasks. He felt frail, fatigued, and subsequently lost his confidence to perform household activities.

Table 385.2 Quality of life tool examples

Subjective	Description
PQOL	Perceived quality of life [15]
HAD	Hospital anxiety and depression [16]
NHP	Nottingham Health Profile [17]
EuroQol	'European' tool [18]
SF 36	36-item short-form survey [19]
Objective	
QALY	Quality of life tool [20]
Employment status	—

Data from various sources (see references).

Problems after intensive care

Alongside the more established sequelae, less obvious symptoms which affect patients include:

- Taste loss.
- Anorexia.
- Nail ridging.
- Hair loss.
- Muscle weakness.

Added distress may be caused as some may think they are developing a new condition. The trauma of going through the critical illness can further complicate a patient's emotional recovery, which in turn can profoundly impede the rehabilitation process. The clinic can be seen as a convenient place to provide specialist explanations and reassurance from intensivists, who know to anticipate these issues, and can address specific worries and misconceptions sympathetically.

Tracheostomy follow-up

Less noticeable abnormalities such as swallowing difficulties may go unreported. Percutaneous tracheostomies may interfere with the swallowing function when *in-situ*, but in the long run the stoma itself is associated with low morbidity [6]. Late complications include tethering of the skin to the trachea.

The follow-up service is a convenient point in time to review previously tracheostomized patients and organize surgical referrals when needed. In Reading, UK this group of patients undergo routine MRI scans to exclude tracheal stenosis. Some patients with unsightly scars or severe tethering can easily be managed by offering a small procedure under Local Anaesthesia in ENT outpatients.

Sexual dysfunction

Reluctance to have sexual intimacy is an embarrassing symptom for most people to admit. Among ICU survivors even fewer will report it in the context of having gone through a recent critical illness.

One study of 127 patients revealed its incidence to be as high as 44% [7], so the clinic can be a timely place to identify the symptom and organize outpatient referrals to an Andrology clinic for men and Gynaecology clinic for women. The study also demonstrated that had the intensivist team not asked specifically about the symptom, no other health professional would have recognized it in the 1 year study period.

Psychological effects

Some degree of memory loss of the ICU stay is anticipated, with 70% patients being unable to describe what has happened when prompted at the clinic visit, including even those who did not receive sedation on the unit. Those patients who were emergency admissions to the unit are especially prone to psychological sequelae. Although short term problems are anticipated, consequences occurring many years later have also been identified. In 2004 Kapfhammer et al. demonstrated that 11 out of 46 ARDS survivors had developed a post-traumatic stress disorder (PTSD) diagnosis during interviews conducted around 8 years later, highlighting the need for ongoing monitoring [8].

ICU diaries

During appointments patients can also receive a diary of the events of their ICU stay. It uses simple English and holds factual descriptions, which help to fill gaps in the patients' memories about their ICU stay, and contextualize any disjointed flashbacks.

Box 385.2 illustrates this.

From reading the ICU Diary and talking through her experience with the follow-up team she was able to contextualize the memory, and discovered she had suffered a sudden period of desaturation. Patients have fed back that 'the diary and appointment helped to piece the time and events together'.

Box 385.3 demonstrates the wider benefits of the diary, particularly that it helps loved ones and other people understand and appreciate what an ICU survivor has been through.

A study of 12 European ICUs (n = 352) demonstrated that the provision of ICU diaries at 1 month follow-up reduced the risk of new-onset PTSD compared to the usual 3 month follow-up (5 versus 13%, P = 0.02) [9].

Box 385.2 Case two

An ICU patient recalled a time where she could suddenly hear loud noises and see flashing lights on the machine next to her. She thought she was dying and became very distressed.

Box 385.3 Case three

A young lady, 17 years old, survived meningitis and when she returned to school she looked physically well, but the teachers became frustrated because she was struggling to learn simple concepts, and her friends were upset because she did not socialize as much. She was given eight copies of her diary, which she distributed to the teachers and her friends. Subsequently, she felt that this was the first time those around her had understood what she had been through. Teachers even gave her an extra 30 minutes during her GCSE exams.

Delirium

Delirium can affect up to 80% of ICU patients, with some going on to suffer long-term nightmares and delusions. Jones et al. demonstrated that ICU survivors with delusional memories of their admission are prone to PTSD and panic symptoms 8 weeks post discharge. The lack of factual recall was identified as a predictor of developing these problems [10].

The use of validated delirium scores, such as CAM-ICU and IS DSC [11], that are calculated during an ICU admission will help recognize delirium in ICU patients. If these patients are appropriately managed it is hoped that severe psychological sequelae including cognitive decline can be prevented.

Effects on family

During appointments patients can talk openly about problems they encounter during rehabilitation. Family members are also encouraged to speak about the admission and how they feel the rehabilitation is progressing. The experience of watching a loved one go through a critical illness has significant effects on family members; a study highlighted that spouses are particularly prone to depression and anxiety whilst their loved one is in intensive care, which commonly continues after ICU discharge when the patient recovers in the community.

Other resources used during follow-up

DIPEx (www.dipex.org) is an online database which provides personal accounts of survivors' experiences with critical illness. Patients have highlighted it as being beneficial, and the ICU subsection includes diary entries and video clips of patients' ongoing recovery. A section is also available for carers and relatives to record their memories.

Discovery interviews are an evidence-based technique that enables patients and their loved ones to tell the story of their illness. It uses a framework to guide the person through key parts of their experience; an approach that has allowed a better understanding about patient needs, the recovery process and general wellbeing.

Conclusion

Estimated mortality in ICU has been quoted as 16%, and hospital mortality (including ICU and general ward) as 24% (ICNARC CMP 2010–2011) [12]. For the surviving patients, leaving Intensive care is the start of a long recovery process. The follow-up clinic serves as a means of addressing some of the long-term issues faced by patients during their recovery. It provides a needs assessment for each individual patient and acts as a safety net. The design of the service is evolving to meet patient needs, be they physical or psychological problems, or functional difficulties they face at home.

The clinic's potential continues to emerge, and in the future it may act as a standard for measuring quality of care in ICU patients. Important benefits are shown in Fig. 385.1

Intensive care follow-up is not common practice yet, in 2006 a study reviewed 266 ICUs in the UK, and found that 44 ran clinics (55%). It showed that marked differences existed in the format and service offered by follow-up clinics at that time, with 56 clinics (77%) only reviewing patients who had been treated on the ICU for at least 3 days duration. Nearly half of the follow-up clinics (39 clinics, 49%) have established access to at least one other outpatient service [13]. Around the world key limiting factors which have been identified in provision of follow-up include funding and health personnel (resource) allocation towards the service. In 2009 the PRaCTICaL study concluded that the nurse led follow-up clinic did not provide significant benefits [14].

As the evidence base for this area of research builds, it is hoped that in the near future a larger study of multidisciplinary post intensive care follow-up clinics will be conducted.

CHAPTER 386

Rehabilitation from critical illness after hospital discharge

Laura Vincent and Carl Waldmann

Key points

- Management of patients throughout the critical care pathway should be reviewed in order to maximize rehabilitation potential.
- Rehabilitation should be initiated early in the ICU care pathway.
- NICE guidance recommends that rehabilitation after ICU is no longer optional and should be mandated for all.
- Validated, reproducible and sensitive assessment tools are required to recruit appropriate patients to rehabilitation schemes and to monitor their progress.
- We await evidenced-based recommendations for the type, timing, and duration of rehabilitation after hospital discharge.

Introduction

More than 110,000 patients are admitted to Intensive Care each year in the UK [1], the majority of whom survive to hospital discharge. Historically, surviving an Intensive Care admission was considered a successful outcome. We now understand that this is just the beginning of a long, hard road to recovery.

A breadth of physical, psychological, and cognitive problems are experienced by patients after discharge from Intensive Care, resulting in a markedly and persistently reduced Health Related Quality of Life (HRQL) [2]. These problems dramatically impede a patient's functional recovery and cause great distress, as patients struggle to contextualize their residual deficits, within their understanding of their critical illness.

In addition to the personal impact on intensive care unit (ICU) survivors, there is unquestionable strain on relatives, carers, and society in general [3]. Families face physical and financial pressures assuming the role of informal care givers, and emotional stress, particularly dealing with the frustrated patient who feels lacking in autonomy. With prolonged recovery, the socio-economic impact of critical illness is considerable. Making huge investments in Intensive Care therapy is of less value, if appropriate support is not continued through the rehabilitation phase.

The optimization of the morbidity and HRQL after critical illness, have now become key therapeutic objectives.

The introduction of structured ICU follow-up clinics allows the multisystem sequelae of critical illness to be identified early and appropriate referrals to be made in a timely fashion, thus preventing the development of more chronic disabilities.

The additional provision of structured rehabilitation programmes, can aid patients' recovery towards their previous functional level.

The National Institute of Clinical Excellence (NICE) have advocated a post-ICU rehabilitation pathway [4]. This guideline represents progress, by officially acknowledging the need for rehabilitation after critical illness, and provides a framework for the implementation of such a programme.

Comprehensive rehabilitation after ICU incorporates rigorous psychological assessment and therapy in addition to physical regimes, but this is beyond the scope of this chapter.

ICU acquired weakness

There is growing appreciation of the profound skeletal muscle weakness experienced commonly by ICU survivors. This ICU acquired weakness (ICU-AW) has been linked to multiple independent risk factors, and it develops through complex and inter-related mechanisms [5].

ICU-AW results in increased duration of mechanical ventilation, length of ICU and hospital stay, and reduced physical function and HRQL. ICU-AW is therefore a huge obstacle in the functional recovery of critically ill patients. Many patients need at least a year to regain full mobility [6,7] and adopt a self-preservative approach to life.

Accordingly, in addition to post-ICU rehabilitation strategies, there is now a focus on preventing ICU-AW, right from the beginning of the critical illness pathway. This topic is detailed in a separate chapter.

Exercise rehabilitation

Rehabilitation programmes for specific diseases, such as heart attack, stroke, and respiratory disease, are well established and have shown dramatic benefits, yet ICU rehabilitation strategies are not widely implemented [8] and there is considerable variation in the extent and delivery of these services [9].

In 2009, NICE introduced the long awaited guideline: Rehabilitation after Critical Illness [4]. This advocates individualized structured rehabilitation at each stage of a patients' recovery, starting early in the critical care admission and continuing until three months post-discharge. It recommends a cycle of functional and clinical assessments, to identify at risk patients, determine rehabilitation goals, and facilitate the construction of a

patient-specific programme. They emphasize a multi-disciplinary approach, involving health care professionals with appropriate expertise, comprehensive handover between care providers, and detailed written documentation. Unfortunately, whilst providing a structure for the approach to rehabilitation, due to a dearth of supporting literature, the guideline cannot recommend any validated physical assessment tools to identify patients most likely to benefit, or any specific details of evidenced based rehabilitation regimes. It is therefore not applicable as a transferrable tool currently.

Rehabilitation after hospital discharge

The continuation of rehabilitation into the post-hospital phase of recovery from critical illness is inconsistent and non-standardized.

The clinical effectiveness of rehabilitation programmes for UK adult critical care patients, initiated after discharge from critical care, was demonstrated in a randomized controlled trial, investigating the use of a six-week self-help rehabilitation manual [8]. 126 patients were recruited 1 week after ICU discharge and randomized to receive 'usual' follow-up care, or an additional six week rehabilitation package. This consisted of a manual, addressing physical, psychological, and social issues, and included a self-directed exercise program. Patients received three weekly telephone calls and completed a rehabilitation diary.

At 2 and 6 months physical recovery was significantly greater in the rehabilitation group ($P < 0.006$). Psychological recovery was less affected, with a lower rate of depression at 8 weeks after ICU discharge in the intervention group that did not quite reach significance ($P < 0.066$), and no appreciable difference in anxiety. Studies have since been undertaken, to explore the impact of a rehabilitation program further, particularly looking at the timing of the programme and the effect on HRQL [10, 11].

Nature of exercise prescription

Evidence for the specific detail of exercise rehabilitation programmes after hospital discharge is limited and not comparable.

By removing some of the personal responsibility from patients, supervised group exercise sessions may maximize the results of activities and minimize patient anxiety. However, this is not a feasible approach for all patients, who may live far from the hospital, or be discouraged by the 'peer-pressure' of a class environment [12].

Unsupervised home exercise programmes depend on the patient's self-motivation to engage with the programme. They must understand the activities and have clear objectives and indicators of progress. This approach necessitates a focus on patient education and empowerment in their recovery.

Aerobic activity has been utilized in several studies. Patients are advised to undertake a specific cardiovascular endurance activity, at an intensity level determined by the results of initial assessments. Patients are instructed to work towards physiological markers such as 'modified Borg scores' (a subjective assessment of level of dyspnoea) and heart rate; indicators which can also be used to measure individual progress [12].

Strength training is incorporated into some programmes, where the maximum amount of weight a patient can lift over a set number of repetitions is assessed, and a prescription of target repetitions and weights is made, with subsequent adjustment based on progress.

In a non-controlled prospective study of 38 ICU survivors, McWilliams et al. [13] enrolled patients in a 6-week rehabilitation programme, comprising one supervised and two unsupervised exercise sessions each week. They demonstrated significant improvements in 6-minute walk test and Intermittent Shuttle Walk Test ($P < 0.001$) and in anxiety and depression scores ($P < 0.001$). Unfortunately, the lack of a control group limits the interpretation of this result. The positive effect of the intervention needs to be compared with the expected natural course of recovery, over the same time period.

Elliott et al. [11] performed a multicentre randomized controlled trial of the impact of an 8-week, graded, personalized, home-based endurance and strength training programme. This involved trainer visits, phone calls, and an exercise manual. Both groups demonstrated improved function at 8 and 26 weeks, but there was no significant difference between the groups. This may reflect a missed cohort of patients, who would have benefited most from the intervention, and outcome measures that were not assessed for, which may have been more sensitive to the intervention.

Timing of post-hospital rehabilitation programme

It is clear from available evidence that rehabilitation commencing as early as the ICU phase of critical illness has marked outcome benefit. It is logical therefore that rehabilitation commenced as soon as possible after hospital discharge is likely to be more effective.

There is wide variation between studies with regards to the timing of initiation of post-hospital rehabilitation. Elliott et al. commenced their intervention at one week post-hospital discharge, whereas McWilliams et al. had a delay of up to 3 weeks in initiating therapy [11,13]. Such a delay may reduce the impact of an intervention, as there may already be significant natural recovery prior to the onset of therapy.

In order to recommend evidence-based standards for the timing of a post-hospital rehabilitation pathway, further research is required.

Assessment of patients

Screening and assessment tools are essential components of successful ICU rehabilitation, to identify those patients who should be targeted and to monitor improvements in ICU-AW and functional capacity. This allows the programme to be tailored to the specific needs of individuals and adjusted with progress.

There is an ongoing drive to develop safe, objective clinical assessment tools, which are reproducible, encompass all aspects of physical recovery, and sensitive enough to demonstrate a significant response to rehabilitation [14].

NICE could not provide any evidence for validated screening or assessment tools for the adult general ICU population. One 'low quality' research paper included in the NICE literature review [15] used the Rivermead Mobility Index (RMI) assessment in the neurorehabilitation population. Whilst the RMI showed good validity and reliability in this patient group, its efficacy has not been demonstrated in the general ICU population.

A simple test of muscle strength in clinical use outside the ICU environment, is the Medical Research Council (MRC) sum score. This has significant limitations in critically ill patients who are often sedated or uncomfortable, may have cognitive dysfunction and may be connected to invasive monitoring lines—factors that may preclude their full compliance. It is difficult to maintain complete objectivity and isolated muscle group strength does not translate directly to functional capabilities.

A number of critical care specific assessment tools are being developed which are more appropriate to the general ICU population.

The Physical Function ICU Test (PFIT) tool, developed by Skinner et al. [16], is reliable and responsive to physical progress, but uses mainly cardiovascular assessments and does not address all components of physical function. There was a small sample size and it is unlikely that the exercises would be achievable in early critical illness.

The Chelsea Critical Care Physical Assessment Tool (CPAx) has been recently published [17]. It is a numerical and pictorial scoring system consisting of 10 domains of physical morbidity, including respiratory function. Each component is graded on a Guttman scale from 0–5, such that the maximum score is 50. The scores are displayed on a radial chart, and provide a realistic and holistic representation of functional capability, which can be repeated to show trends. It has good inter-rater reliability and ongoing research suggests predictive validity for hospital outcome.

Conclusion

Exercise rehabilitation has been shown to enhance the functional recovery of critically ill patients and can no longer be considered as an afterthought in the critical illness treatment pathway. Rehabilitation should be incorporated routinely into clinical practice, to optimize the quality of life of ICU survivors. Available guidelines provide a framework for implementation of rehabilitation from ICU admission through to post-hospital discharge care. The challenges lie in identifying those patients likely to benefit from such an intervention and in devising a personalized and validated rehabilitation programme.

SECTION 22

End-of-life care

PART 22.1

Withdrawing and withholding treatment

CHAPTER 387

Ethical decision making in withdrawing and withholding treatment

Margaret Isaac and Jared Randall Curtis

Key points

- The process of intensive care resource allocation and practices around withholding and withdrawing life support vary by physician, hospital, region, and country.
- Shared decision-making is the recommended default approach to medical decision-making, though there is cultural geographic and individual variability in physician attitudes and patient/family preferences toward shared decision-making.
- Surrogate decision-making is difficult, with decisions being shaped by many factors including family members' preferences and patients' values.
- Communication with patients and families regarding complex medical decisions and shared decision-making can be enhanced with specific approaches and techniques.
- Previously completed advance directives can help inform decision-making when patients lose decisional capacity in the ICU.

Introduction

Intensive care units (ICUs) are the centre of some of the highest technology, and most advanced care that medicine has to offer and have the potential to offer life-saving treatment to critically-ill patients. Death preceded by ICU care occurs in approximately 20% of patients in the US [1], creating an imperative for critical care physicians and staff to thoughtfully and ethically address end-of-life issues. Particularly in settings in which resources are limited, an ethical approach to resource allocation must be advanced, both in considering if patients are sick enough to warrant critical care services, and, at the other end of the spectrum, determining when patients are too sick to benefit from this type of care. A variety of models for decision-making exist, and many professional medical societies advocate for a shared decision-making approach. However, patients and their surrogate decision-makers are widely variable in their preferences for decision control, so their role and the role of the treating physician is best approached on an individualized basis. Similarly, the literature on communication in the ICU setting describes key features associated with increased family satisfaction, though physicians are best served to use these as general guidelines, tailoring their specific approach to the individual patient and family. Other challenges in physician-patient/surrogate communication include cross-cultural communication and working with interpreters, implementation of wishes expressed in advance directives and discussing resuscitation preferences.

Resource allocation

Critical care provision requires utilization and mobilization of many resources—resources not universally available across all regions and countries. Even within urban centres in the developed world, there is significant variability in the availability of ICU beds. Although the number of ICU beds does not correlate with societal health expenditures within the developed world, it does correlate significantly with mortality [2]. The manner in which finite resources are allocated varies significantly within the US and across other countries. The process by which these resources are allocated raises specific ethical considerations—both in terms of who is deemed sick enough to warrant critical care, and who is too sick to benefit. Principles of resource allocation outlined by the American Thoracic Society highlight the following [3]:

- Each individual's life is valuable and equally so.
- Respect for patient autonomy, as represented by informed consent, is a central tenet for providing health care, including ICU care.
- Enhancement of the patient's welfare, by providing resources that meet an individual's medical needs and that the patient regards as beneficial, is the primary duty of health care providers.
- ICU care, when medically appropriate, is an essential component of a basic package of health care services that should be available for all.
- The duty of health care providers to benefit an individual patient has limits when doing so unfairly compromises the availability of resources needed by others.

Withholding and withdrawing of life support

Most patients who die in the ICU do so after having life-sustaining treatments withheld or withdrawn [4]. Though many medical

ethicists and medical societies, including the American Thoracic Society and the American Medical Association view withholding and withdrawal of life-sustaining treatments to be ethically equivalent, this view is not universally shared. The degree to which these treatments are withdrawn and the process by which these decisions are made varies significantly by country, shaped in part by cultural and religious differences. In a large study that included seven different geographic regions throughout the world, 36% of in-hospital deaths followed withdrawal or withholding of life-sustaining treatments [5]. In a study comparing regional practice variability in Europe, rates of withdrawal of life-sustaining treatments were over two times as high in northern Europe (47%) as in southern Europe (18%) [4].

Physicians' actions are shaped by their own cultural and religious beliefs and individual clinician characteristics affect decisions to limit life-sustaining treatments. Specifically, religious affiliation impacts physicians' decisions to either withdraw or withhold these treatments—with decisions to withhold treatment being more common among Jewish, Greek Orthodox, and Muslim physicians in Europe, and decisions to withdraw treatment being more common among Protestant, Catholic, and unaffiliated physicians [6]. Time from ICU admission to limitation of these treatments also varied with physicians' religious affiliations. Overall religiosity among Jewish physicians is inversely related to willingness to withdraw life-sustaining treatments. In a survey of US physicians, black physicians were far more likely than white physicians to personally want treatments such as CPR, mechanical ventilation, and artificial feeding when given hypothetical scenarios of living with severe brain damage or in a persistent vegetative state, though the majority of all physicians surveyed did not desire such treatments.

Use of intensive care services during terminal hospitalizations varies in different regions and countries, but in most parts of the developed world, intensive care is increasingly being used at the end-of-life among older individuals [7]. Therefore, given the aging of populations in the developed world, increasing attention must be paid towards thoughtful advance care planning, health care utilization, and optimal end-of-life care in the ICU setting.

Decision making

Models of decision making

Many models and frameworks of medical decision-making have been developed, encompassing a spectrum from maximal patient autonomy to a more traditional parentalist approach. At the patient autonomy end of the spectrum, informed decision-making (or the 'informed choice' model) describes a process in which patients are informed about health care treatments and their alternatives and then independently choose from these options. On the other hand, parentalism describes a relationship in which physician is guardian, providing information to steer a patient towards a decision that the physician considers preferable. This model, the traditional one used in the intensive care setting, assumes that 'physician knows best' by virtue of their training and experience and will act in the best interest of the patient. This is still commonly used in certain countries as the default approach, and is used universally in the setting of emergency care, in which consent cannot be explicitly obtained and is often considered implied. In between these extremes is shared decision-making. Shared decision-making involves:

- Involvement of both patient and physician in the medical decision-making process.
- Sharing of information between patient (about personal values and goals) and physician (about prognosis and specifics of medical treatment options).
- Discussion of treatment preferences and evaluation of understanding.
- Consensus between both parties on the treatment to be implemented.

Geographic and cultural variability

Although shared decision-making was endorsed as the preferred default model for medical decision-making in the ICU by an international group of critical care societies in 2003, significant variability in decision-making processes exists across practice sites, countries, and cultures. Patients and families themselves express varying preferences regarding the locus of decision control, with many expressing preference for a shared decision-making model [8], but significant percentages desiring either more autonomy, or a more directive approach on the part of physicians [9]. In short, there is tremendous variability amongst family members regarding their desired level of participation in medical decision-making, so clinicians are best served by assessing this on an individualized basis and adapting their approach to the preferences of the family member as well as the circumstances of the patient. In Europe and in Israel, for example, a parentalist approach is more common than in the US. The ETHICUS study, evaluating differences in end-of-life care in ICUs across European countries and Israel, found that a minority of end-of-life decisions were discussed with family. The authors speculated that this mainly reflected situations in which further medical intervention was thought by physicians to be unwarranted. Geographic differences in sharing of prognostic data with patients exist as well—with only a minority of Japanese physicians and patients agreeing that a patient should be informed of an incurable cancer diagnosis before their family, and a majority of US physicians and patients agreeing with such a statement. Other studies as well have supported the finding that particular ethnic groups (Asians and Latinos, specifically) support a more family-centred approach to medical decision-making than other groups. These studies again suggest the need for an individualized, tailored approach specific to each clinical situation, taking into account geographic location, family dynamics, prognosis, and cultural factors.

Surrogate decision-making

Because most patients receiving end-of-life care in the ICU either lack decisional capacity or the ability to communicate, clinicians often turn to surrogate decision-makers for assistance with medical decision-making. Laws regarding designation of a proxy decision-maker, in the absence of a patient-selected surrogate, vary widely by country [10]. Many physicians expect that surrogates will utilize substituted judgment when making decisions on behalf of the patient (i.e. 'What would the patient say about their preferences if they were able to talk to us right now?'). However, some patients express a preference for surrogates to abide by best interest standard when participating in decision-making. Data suggest that, in practice, proxies actually rely on many factors including substituted judgement and the bests interests of the patient, as well their own values and best interests. Multiple studies from a variety of countries have shown that surrogate accuracy in describing the

Box 387.1 VALUE mnemonic

- **A:** Acknowledge emotion.
- **L:** Listen.
- **U:** Understand the patient as a person.
- **E:** Elicit questions.

wishes of patients is often poor. However, the accuracy of substituted judgments has been positively associated with patients having spoken with their surrogate in advance about care preferences.

The job of a surrogate decision-maker can come at a cost: in one study, over half of surrogate decision-makers suffered symptoms of learned helplessness, characterized by reduced motivation, difficulty in determining causality, and depression. Multiple studies have found an increased risk of psychological symptoms for family members and surrogate decision-makers of patients who died in an ICU—including depression, anxiety, panic disorder, post-traumatic stress symptoms, and complicated grief [11–13].

Because effective surrogate decision-making can be very difficult for many family members and many patients have not expressed clear treatment preferences prior to critical illness, ICU clinicians are frequently in the position of helping family members identify patients' values, exploring how those values might lead to specific treatment preferences, and interpreting how the preferences inform specific treatment decisions that need to be made. ICU clinicians can help family members with this process by asking directed questions about the patient's values and goals and the aspects of life most important to the patient.

Communication

Communication with an interdisciplinary team

Critical care provision relies on the skills and coordination of various staff and specialists. Interdisciplinary communication around end-of-life care in the ICU significantly augments the quality of care that is provided, though is variable across practice sites and countries. Interdisciplinary communication is valued by terminally ill patients and their families [14]. Caring for dying patients, withdrawing life support, and conflict among clinicians are all independently associated with burnout among nursing staff as well [15]. Burnout among critical care physicians is lower among those who maintain positive working relationships with nursing staff, and higher in individuals who experience conflict with colleagues and staff [16], highlighting the need to enhance interdisciplinary collaboration to provide a sustainable work environment for all ICU staff.

Communication with patients and families

Skilled communication is one of the core tools of any physician addressing end-of-life care. While every medical case, patient, and family, are different, several principles can help guide clinicians in leading family conferences:

- Families of critically-ill patients are more satisfied when physicians spend more time listening and less time talking [17].
- Families benefit from explicit reassurance that patients will not suffer, from statements of support for the medical decisions they have made, and from statements that they and the patient will not be abandoned [18].
- Family satisfaction increases when physicians express empathy explicitly.

A randomized controlled trial from France found that use of a specific communication strategy (see Box 387.1) and a bereavement brochure led to lower rates of post-traumatic stress symptoms, anxiety, and depression among surviving family members [19]. Notably, the conferences implementing this standardized

Table 387.1 Approach for effective family conferences in the ICU

Stage	Components to consider
Preparation	◆ Conduct conference early within the ICU stay ◆ Find a quiet, private space for the conference [12], with chairs for all participants ◆ Hold a 'pre-conference' with participating clinicians to ensure common goals and messages
Conducting the conference	◆ Speak less, listen more [18] ◆ Use empathic language [19,20] to acknowledge family emotions ◆ Explicitly acknowledge the difficulty of having an ill loved one, and of surrogate decision-making ◆ Discuss patient values, hopes, fears, and treatment preferences ◆ Remind surrogate decision-makers of their role in invoking substituted judgment ◆ Assure families that all attempts will be made to prevent patient suffering ◆ Make explicit statements about non-abandonment of the patient and family [19] ◆ Provide support for decisions made by family [19]
Closing the conference	◆ Ask the family to summarize what they understand from the discussion and what further questions they have ◆ Summarize next steps and a follow-up plan

Data from various sources (see references).

approach also were longer in duration, had a higher proportion of family speech, and a higher proportion of nurse speech, though it is not clear which of these factors was causative.

The multi-disciplinary ICU family conference is a key component of high quality care for critically-ill patients and their families.

Addressing spirituality

Spiritual concerns on the part of patients and/or their surrogates are prominent at the end of life, and physicians often feel ill-equipped to address these issues. Family satisfaction and feelings of support increase when spiritual needs are discussed with clinicians and addressed by spiritual care providers.

Cross-cultural communication and working with interpreters

Communication across cultures and languages can create additional barriers in communication and can lead to miscommunication and misunderstandings. In an observational study of family conferences utilizing a professional medical interpreter, alterations (including additions, omissions, substitutions, and editorializations) occurred over 50% of the time, with three-quarters of the alterations thought to have clinically significant impact, the vast majority of those being negative [20]. Interpreted conferences have been found to be shorter in length, and contain fewer physician statements of family support than non-interpreted conferences. Best practices include:

- Briefing and debriefing with interpreter before and after family conferences.
- Clarifying the interpreter's role as strict interpreter or cultural broker.
- Introduction of interpreter and their role to the patient/surrogate(s).
- Triangular seating arrangement for patient/surrogate(s), interpreter, and clinician.
- Eye contact with patient/surrogate(s), addressing patient/surrogate(s) in the first-person.
- Speaking slowly and ensuring only one person is speaking at at time.
- Request for direct and complete translation from the interpreter.
- Explicit identification of misunderstandings by the interpreter.

Specific communication challenges—health care directives and advance care planning

Advance care planning and completion of health care directives/living wills have been promoted by many as a mechanism to allow better understanding of patients' care preferences and values. These are rarely completed in the critical care setting, but occasionally, a pre-existing advance directive helps to shape and frame discussions with surrogate decision-makers. An extensive literature demonstrates the poor performance of health care directives—pointing to their inadequacy in realistically identifying the types of medical decisions that are most salient at the end of life, and failing to capture the evolution in preferences that often occur over the course of a complex illness. However, advance directives are associated with higher surrogate ratings of quality of dying and with lower burden on surrogates.

Recent studies suggest that communication about end-of-life care among patients with cancer is associated with increased quality of life and reduction in the use of intensive life-sustaining treatments and reduced health care costs at the end of life. A randomized trial targeting hospitalized patients over age 80 showed that advance care planning was associated with improved quality of life and reduced ICU use at the end of life as well as reduced psychological symptoms among family members. These studies suggest promise for advance care planning to improve quality of life and quality of care while simultaneously reducing intensive care use at the end of life.

Specific communication challenges—discussing resuscitation preferences

Resuscitation preferences are commonly addressed in discussions with patients and families in the critical care setting and these discussions present unique challenges to clinicians. Patient preferences, followed by short-term prognosis, are the biggest factor in determining Do Not Attempt Resuscitation (DNAR) status in the ICU setting. Studies have shown that patients routinely overestimate their survival post-resuscitation and these overestimates may be associated with consumption of television medical dramas, which themselves have historically portrayed unrealistically high in-hospital CPR survival rates. Knowledge of actual CPR survival rates has been shown to affect patient preferences. Patients who choose to be full code are more likely to think of resuscitation abstractly as a means to restore life, and DNAR status as a sign of inferior care while patients who opt for DNAR status are more likely to think of resuscitation in terms of suffering and futility, and see DNAR orders as a means towards a natural death. With this in mind, several core messages can help clinicians communicate with patients and surrogates about resuscitation:

- Emphasizing that resuscitation occurs in the setting of patient death, rather than resorting to euphemistic language, such as 'restarting the heart'.
- Describing the alternative to resuscitation, namely, natural death with comfort-focused care.
- When appropriate, using CPR survival data to help patients understand their probability of surviving resuscitation.

Conclusion

In summary, critical care services, while potentially life-saving, are increasingly utilized at the end of life, particularly for older patients. Utilization of these intensive resources can cause stress and distress for critically-ill patients and their families and requires careful consideration on the part of clinicians. Though shared decision-making has been endorsed as a preferred approach, patients and their surrogate decision-makers have variable preferences with regard to their desired level of involvement in medical decision-making, and this is best evaluated on an individual basis. Effective communication, both outside of the ICU through, for example, advance care planning, and inside the ICU, such as during family conferences, can benefit patients, their families, clinicians, and health care systems as a whole.

CHAPTER 388

Management of the dying patient

Judith E. Nelson and Aluko A. Hope

Key points

- Limitation of life-supporting therapies in anticipation of death has become common in Intensive Care Units (ICUs) around the world.
- Like other clinical procedures performed by intensive care clinicians, life support limitation should be approached with careful attention to relevant evidence, standards of quality, and involvement of the interdisciplinary ICU team.
- ICU clinicians should avoid use of phrases like 'withdrawal of care' and 'nothing more we can do', but instead emphasize their ability to achieve the patient's values, control patient distress, and provide family support.
- A decision to withhold any life-sustaining therapy should prompt a critical review of the rationale for continuing other such therapies.
- Knowledge of underlying principles and best practices for limitation of life support, together with skills for clear and empathic communication, are core competencies for intensive care clinicians.

Introduction

The withdrawal or withholding of life-supporting therapies in anticipation of death has become common in ICUs around the world [1]. Most ICU deaths in the US involve life support limitation [2]. In other parts of the world, the proportion of deaths following withdrawal or withholding of life support ranges from about one-quarter to two-thirds, depending on the region [3]. Thus, knowledge and skill related to limitation of life support, including processes of communication, decision-making, and implementation, are essential for delivery of high-quality intensive care. In this chapter, we synthesize existing relevant evidence and provide recommendations based on the best available data for approaching this important area of critical care practice.

Legal and ethical frameworks

In the US and many other countries, withholding (refraining from starting a treatment) and withdrawal (stopping a treatment that is already underway) of life supporting therapy are both acceptable, legally and ethically [4]. Thus, when prognosis is uncertain, a time-limited trial of life support may be initiated without an irrevocable commitment to continued treatment. In practice, clinicians as well as patients and families often find withdrawing a treatment more emotionally difficult than withholding. Intensive care treatment is not withdrawn in some countries [1]. Key ethical and legal principles related to US practice are summarized in Box 388.1.

Advance directives allow the patient to specify preferences regarding specific life-sustaining therapies (a living will), and/or to authorize a surrogate to make medical decisions if the patient becomes incapacitated (a health care proxy or durable power of attorney for health care). When the patient lacks decision-making capacity, the right to refuse life-sustaining treatment is extended to a surrogate appointed by the patient or designated by applicable law. Standards for life-support limitation by surrogates vary from state to state in the US, as does the legal hierarchy of individuals who serve as surrogate decision-makers in the absence of a designation by the patient. Wherever they practice, intensive care clinicians must be familiar with the applicable local provisions.

In the US, a growing number of states have established templates that allow written directives to be translated into medical orders that are accessible across multiple venues in the health care system; The 'POLST' (Physician Orders for Life Sustaining Treatment) [5] is one example. A pre-printed, checklist order form addressing specific life-sustaining treatments provides the basis for discussion by the clinician with the patient or the surrogate. The completed form operationalizes the patient's preferences as medical orders, which can be changed or updated at any time.

Communication and decision-making

Since some patients and families may choose to continue intensive care therapies primarily out of fear that limitation will inevitably be accompanied by patient suffering, it is important for clinicians to provide assurance that the patient's comfort can and will be maintained. Families are more satisfied when assured that the patient undergoing life support limitation will not suffer or be abandoned prior to death. ICU clinicians should avoid use of phrases like 'withdrawal of care' and 'nothing more we can do', but instead emphasize their ability to achieve the patient's values, control patient distress, and provide continuing patient and family support.

Physicians frequently miss opportunities to acknowledge and address emotions experienced by patients and families facing life-threatening illness [6]. Incorporation of empathic statements in clinician communication, which helps to modulate emotions and to enhance trust in clinicians, is supported by expert opinion and

Box 388.1 Key ethical and legal principles for limitation of life-supporting treatment

- Based on the principle of autonomy and the patient's right to refuse any therapy, limitation of life support is ethically and legally justified.
- Withholding (refraining from starting a treatment) and withdrawal (stopping a treatment that is already underway) of therapy are ethically and legally equivalent, although families and clinicians may perceive them differently in practice.
- When a patient lacks decision-making capacity, their right to refuse life-sustaining treatment is extended to a surrogate appointed by the patient or designated by applicable law.
- When there is evidence of the patient's values and preferences, surrogate decisions should use 'substituted judgment', i.e. what the patient (having capacity) would decide under the circumstances.
- If the patient's wishes are unknown, decisions are to be made in the 'best interests' of the patient, promoting the patient's overall well-being by weighing the benefits and burdens of intensive care therapies.
- In controlling patient symptoms, clinicians may intervene in ways that may hasten the patient's death as a foreseeable but unintended effect when the intent is to relieve patient suffering ('doctrine of double effect').

empirical data [6]. The intensivist needs skills for listening as well as delivering information about the patient's condition and prognosis. The family's proportion of speaking time in an ICU meeting with clinicians is related to family satisfaction [7]. Recommendations have been provided for approaching patients and family members who prefer continuation of life-supporting treatments based on the belief that a miracle will occur [8], and those who insist on 'everything' despite a clinician's view that the treatments will not have meaningful benefit.

Critical care guidelines endorse a shared decision-making model in which both the patient or family and the physician play an active role [9], but there is a wide continuum of preferred roles among patients and families, and varying roles for clinicians across different countries, regions, and cultures [1]. In general, it is appropriate for clinicians, after investigating the patient's values and preferences, to offer a recommendation reflecting best medical judgment. Besides fulfilling a professional responsibility, the clinician's recommendation may help to address the stress, guilt, doubt, and fear that plague many surrogates making major treatment decisions for others. Some ICUs distribute printed informational materials such as a brochure to families to help them prepare for surrogate decision-making.

Decisions about the limitation of life support often give rise to conflict [10]. In a large, multinational survey, conflicts (between nurses and physicians, among nurses, and between staff and relatives) were reported by over 70% of responding clinicians, with end-of-life care representing a major source of discord and attendant job strain [10]. Clinicians' decisions to limit life sustaining treatments are influenced by diverse factors apart from patients' wishes, including such provider-level factors such as number of years since completing training, specialty, experience working in ICUs, gender, cultural background, and religious beliefs [11]. For a variety of reasons that are thought to include an exaggerated sense of personal responsibility for the patient's outcome and a perceived 'covenantal bond' to continue life-sustaining treatment [12], surgeons may be less willing to accept withdrawal of intensive care therapies after surgery. Recognition of diverse influences including nonclinical and idiosyncratic factors is valuable for prioritizing attention to patient-focused concerns and for promoting consensus among the patient, family, and multiple members of the health care team.

When conflicts arise over the use of life support, a process oriented approach informed by the most common reasons for conflicts may facilitate consensus [13]. The intensive care clinician should always first explore the family's current understanding of what has happened and what is expected. After describing the medical situation as perceived by the clinical team, the intensivist can then address other potential sources of conflict. These include discordant perceptions of appropriate roles (e.g. the family feels obligated to pursue every treatment to extend life, while the physician feels responsible to limit treatments thought to be futile and the nurse to protect the patient's dignity and comfort during the dying process); distrust of the team based on past experiences or cultural factors; and strong emotions such as grief or fear. Exploration of spiritual beliefs may also be important. Experts have recommended a 'differential diagnosis' approach to conflict over decisions to limit treatment [13]. Strategies for promoting consensus are summarized in Box 388.2.

Life-supporting treatments

Mechanical ventilation is the form of life support that is most frequently withheld or withdrawn in anticipation of death in the ICU.

Box 388.2 Strategies for promoting consensus in decision-making about limitation of life support

- Distribute printed information that describes a family meeting and guides the family on how to prepare.
- Coordinate the approach among all members of the clinical team.
- Elicit the family's understanding of what has happened and what is expected.
- Clarify the medical situation as perceived by the clinical team.
- Attend to family emotions (e.g. grief, fear, guilt) through empathic communication.
- Investigate other potential sources of conflict, such as role clash, distrust, spiritual beliefs.
- Allow the family to speak and ask questions.
- Focus attention on the patient's values, goals and preference.
- Provide reassurance about symptom control and non-abandonment.
- Offer a professional recommendation to a receptive family.
- Validate the family's intentions and their approach to decision-making.
- Support the family's decision while optimizing patient comfort and dignity.

Life-sustaining therapy may also include vasopressor medications, renal replacement, transfusions, antibiotics, tube feeding, intravenous hydration, and other modalities without which the patient's death would be expected [14]. Although ethically equivalent, limitation of individual treatments tends to be sequential rather than simultaneous, and withdrawal of mechanical ventilation usually occurs as a late event [15]. Although withdrawal of artificial nutrition rarely causes discomfort for seriously ill patients, nutrition is often limited only as a last step, likely because of the symbolic importance of food for many families.

An observational study of 14 hospitals in one metropolitan area in the Northwest US found that withdrawal of all life-sustaining interventions occurred over more than 1 day for nearly half of the patients [15]. Among long stay patients, a longer duration of the process of withdrawal was associated in this study with greater family satisfaction with care [15]. 'Stuttering withdrawal', however, is not considered optimal by most expert guidelines. Guidelines suggest that a decision to withhold one life-sustaining therapy should prompt a critical review of the rationale for continuing all other therapies [14]. Ongoing phlebotomy and imaging should be reconsidered and all medications should be re-evaluated. Deactivation of a pacemaker or automatic implantable cardiac defibrillator should also be addressed. A Task Force of the Society of Critical Care Medicine has provided a conceptual framework and recommendations for the use of non-invasive ventilation in patients who have foregone endotracheal intubation and invasive ventilation, emphasizing clarity about care goals and weighing of therapeutic benefits and burdens [16].

Life support limitation: a clinical procedure

Like other clinical procedures, limitation of life support requires expertize, careful preparation, and consistent implementation in accordance with the best available evidence, appropriate documentation, interdisciplinary collaboration, and ongoing evaluation. Inexperienced clinicians should not perform this procedure independently until they have demonstrated their competence in a supervised setting. Ideally, an attending physician and an experienced nurse with specific relevant training will both play an active role. Input from all team members should be invited in formulating and implementing the final plan.

Preparing the patient and family

Most patients and families do not know what to expect, fear the unknown, and take comfort from a straightforward, sensitive, description of common scenarios after limitation of life support. A key point for clinicians to communicate, however, is that a degree of uncertainty is inherent with respect to the patient's responses—a small minority of patients will survive to hospital discharge after life support limitation. For non-survivors, the duration of the dying process is variable. Broad estimates based on the patient's clinical condition (for example, minutes to hours or hours to days) can be cautiously offered.

The family should be reassured that the clinical team will respond immediately and effectively to any patient distress. Since families (and even some clinicians) may not understand acceptable approaches to symptom control at the end of life, it is helpful to review the basic principles. The doctrine of double effect provides justification for the use of opiates and sedatives at any dose needed to maintain the comfort of the patient, even if the clinician sees a potential for drug-related respiratory depression or hypotension [14]. Clinicians may wish to address timing and setting along with other aspects of the process of forgoing life support. A family may have reasons to delay implementation—for example, to give an out-of-town relative time to make a final visit, or to allow arrangements for a funeral that by religious law must occur quickly after death. Conversely, rapid withdrawal of life support may be requested by a family that finds it more painful to postpone an inevitable outcome. The clinical team should endeavour to accommodate the family's preferred schedule. Consideration may be given to transfer of the patient to a more private and peaceful setting, such as a Palliative Care Unit or a private room on a regular hospital ward with arrangements for close monitoring of symptoms. When a patient and family have developed important relationships with the critical care team, symptom needs are expected to require intensive nursing, or continuity of care would be compromised by transfer, the ICU may be the optimal place for withdrawal of life sustaining therapies. Efforts to optimize the environment might then include closing curtains, liberalizing family visits, and removing all tubes, lines, and drains that are not necessary for the patient's comfort. Electronic monitoring should be discontinued so that alarms do not disturb the patient or family and attention remains focused on the patient rather than on irrelevant technology. Expert recommendations suggest a specific conversation with family and staff about the rationale for removing monitors in order to alleviate anxiety.

Families should feel they have the option, but not an obligation to be with the patient during or after discontinuation of treatments or at the time of the patient's death. A non-judgmental, open-ended approach by the clinician, with reassurance that the patient will be continuously attended by staff, will allow the family to express true preferences and help relieve guilt or other concerns for those who decide to leave. For families who plan to stay, a description of the procedure and expected patient responses should be offered. The family can be prepared for the possibility of noise from respiratory secretions, a range of breathing patterns (fast, slow, deep, shallow), snoring, muscle twitching, and progressive slowing of heart rate, and lowering of blood pressure. Most families welcome an inquiry about religious or spiritual traditions they may wish to observe, and an offer of pastoral care. The family may also value the opportunity to speak with a social worker and/or an organ donation coordinator.

Methods of withdrawing mechanical ventilation from an endotracheally-intubated patient

No comparative evidence identifies the optimal strategy for separating a patient from the ventilator. Some clinicians withdraw ventilator and endotracheal tube in one step. Others maintain the artificial airway to protect against obstruction and permit access for suctioning. Another approach involves incremental reduction of oxygen and ventilatory support over a relatively short period (e.g. 10–30 minutes), followed by complete withdrawal of the ventilator. The last strategy allows for titration of medications to address symptoms during the period of final 'weaning'.

Symptom control

Approaches to symptom control can be broadly categorized as 'pre-emptive' (i.e. the patient is medicated with opiates and/

or sedatives before withdrawing life support) and 'reactive' (i.e. medications are given if patient distress is actually observed). Pre-emptive treatment might be given when the patient's death is expected imminently after withdrawal and the patient is either already in distress or such distress is anticipated. Although the use of general anaesthesia ('pre-emptive high doses of opioids and sedatives for anaesthesia or at least deep sedation to assure comfort') has been proposed for the 'potentially conscious and imminently dying patient', this strategy may be appropriate only when consistent with the patient's values and when the risk of distress is sufficiently high to justify the risk of hastening the patient's death. For the patient with a reasonable prospect of surviving after separation from the ventilator, treatment would be deferred unless and until the patient manifested signs of (or self-reported) distress. There is no reason to medicate a patient who is brain dead. All other patients undergoing withdrawal of life support must be carefully assessed for distressing symptoms throughout the process [18]. Tools are available for behavioural assessment of pain and dyspnoea [19]. Ample doses of opiates and sedatives (as infusions and boluses), along with sufficient staff, should be immediately available at the bedside. Dosing is limited only by the principle of proportionality (i.e. treatment should be proportional to the patient's symptoms). Documentation in the medical record by both physicians and nurses should clearly reflect this relationship. Expert recommendations are available to guide management of symptoms including pain, dyspnoea, and delirium for critically-ill patients at the end of life [14].

Noisy breathing, with unpleasant, gurgling sounds, often occurs during the dying process, causing distress for some families and ICU staff. Pharmacologic approaches include glycopyrronium bromide, hyoscine (scopolamine), atropine, and octreotide. Since glycopyrronium bromide does not cross the blood brain barrier, there is reason to believe it can reduce pharyngeal and tracheobronchial secretions with less risk of central effects than hyoscine or atropine. Non-pharmacologic interventions, such as repositioning and gentle suctioning, may also be helpful for some patients.

Neuromuscular blocking agents should never be introduced when the ventilator is withdrawn [14]. For patients who have already received such a medication, withdrawal of mechanical ventilation should be deferred until neuromuscular function is restored. If neuromuscular blockade cannot be reversed without an unacceptable delay, it may be appropriate to proceed, with close attention to physiologic signs of distress and liberal use of comfort medications.

The ICU nurse and withdrawal of life support

The ICU nurse is involved more directly and frequently with the patient undergoing limitation of life support, and with the patient's family, than any other clinician. In a U.S. national survey, two-thirds of nurse respondents experienced emotional difficulty with the process of limiting life support, but more than 60% reported that physicians did not usually provide emotional support, for which they looked instead to their colleagues and even to patients' families [19]. The presence of a physician during this process is an important form of support both for nurses and families. Ideally, this presence continues during the post-mortem care, which is often a lonely and psychologically difficult part of the nurse's work. Reducing the nurse-patient ratio to 1-to-1 during withdrawal of life support, and providing the primary nurse at least a brief period of respite after a patient's death, are among strategies to improve the practice environment and patient care. The End-of-Life Nursing Education Consortium (ELNEC) project [20] provides specialized training and extensive curricular materials in palliative and end-of-life care including limitation of life support for nurses.

Conclusion

Increasing sophistication and application of life-supporting technologies have been accompanied by a growing need for expertise in limiting their use when burdens exceed potential benefits for critically-ill patients. Like other clinical procedures performed by intensive care clinicians, withholding and withdrawing life support should be approached with careful attention to relevant evidence, standards of quality, and involvement of the interdisciplinary ICU team. Knowledge of underlying principles and best practices for limitation of life support, together with skills for clear and empathic communication, are core competencies for intensive care clinicians.

PART 22.2

Management of the potential organ donor

CHAPTER 389

Beating heart organ donation

Martin Smith

Key points

- Donation after brain death provides an opportunity to maximize the number and condition of organs for transplantation, and currently the only reliable source of donor hearts.
- Brain death is associated with haemodynamic instability and other physiological changes that can jeopardize donor organ function.
- Aggressive donor management increases the number of potential donors who become actual donors, increases the total number of organs transplanted per donor, and improves transplantation outcomes.
- Optimization of haemodynamic variables is the cornerstone of donor management.
- Hormone replacement remains controversial and should only be used in unstable donors requiring large doses of vasopressors, or in those with poor ventricular function.

Introduction

Transplantation is the optimal treatment of end-stage dysfunction of many organs and can be life-saving. The principal factor restricting access to transplantation is the availability of suitable donor organs; there is an ever widening gap between the rising demands for transplantation and a diminishing supply of organs. Although living donation and donation after circulatory death are important and increasing sources of organs for transplantation, it is donation after brain death (DBD) that remains the most important. In DBD there is the opportunity to maximize the number and condition of potentially transplantable organs and also to provide a reliable source of hearts for transplantation.

The process of donation

Organ donor management begins with timely identification of potential donors, including those with a severe neurological injury that is likely to progress to brain death. Although adequate time must be allowed for the proper confirmation of brain death, unnecessary delays should be avoided because the incidence of systemic complications that jeopardise transplantable organ function increases progressively with time. Once brain death has been confirmed there should be a uniform request for consent for donation undertaken in conjunction with a representative from the local organ donation/procurement organization.

Following the confirmation of brain death there is a change in emphasis of care. Brain protective strategies that have previously been aimed at preserving residual brain function are replaced by physiological support designed to optimize organ function for subsequent transplantation. If a patient wishes to become an organ donor, it is the duty of the intensive care team to fulfil this wish by providing organs in the optimum condition. The management of the potential organ donor is thus the beginning of the management of up to seven potential recipients (Table 389.1).

Physiological changes after brain death

Brain death is associated with profound physiological changes that can jeopardize transplantable organ function (Table 389.2).

Cardiovascular changes

Intractable increases in intracranial pressure (ICP), usually following catastrophic neurological injury, may lead to brain ischaemia, cerebral herniation, and brain death. As ICP increases, brainstem ischaemia progresses in a rostral-caudal direction with typical clinical correlates. Cerebral ischaemia precipitates vagal activation resulting in bradycardia and hypotension. Pontine ischaemia produces a mixed vagal and sympathetic activation, and the classic Cushing response characterized by bradycardia and hypertension. Finally, ischaemia of the medulla results in a massive autonomic sympathetic surge in a last ditch attempt to maintain cerebral perfusion [1]. This sympathetic storm, which lasts between one and six hours, increases heart rate, blood pressure, cardiac output, and systemic vascular resistance, and leads to central redistribution of blood volume, increased cardiac afterload, and splanchnic ischaemia [2]. It is also associated with widespread myocardial damage characterized by mitochondrial swelling, myocytolysis, and necrosis in up to 25% of donor hearts. Myocardial dysfunction, demonstrated by echocardiography, occurs in approximately 40% of brain dead donors [3].

Following the onset of brain death, the period of intense autonomic activity is followed by loss of sympathetic tone, profound vasodilatation and capillary leakage. The resulting hypotension and hypovolaemia is compounded by central diabetes insipidus and causes donor organ hypoperfusion if untreated.

ECG abnormalities are common after brain death and include ST segment and T wave changes, atrial and ventricular arrhythmias, and conduction abnormalities. They are multifactorial in origin reflecting loss of vagal tone, sympathetic over activity, myocardial ischaemia, blood gas and electrolyte abnormalities, as well as the effects of drug therapy.

Respiratory changes

The cardiovascular changes associated with the sympathetic storm lead to increases in pulmonary hydrostatic pressure, capillary

Table 389.1 Physiological goals during donor management

System	Variable	Target range
Cardiovascular	Heart rate	60–120/min
	Systolic blood pressure	>100 mmHg
	Mean blood pressure	>70 mmHg
	Cardiac index	2.4 L/min/m^2
Ventilation	Tidal volume	8–10 mL/kg
	Positive end expiratory pressure	5 cmH_20 (15 cmH_20 during recruitment manoeuvres)
	Peak airway pressure	<30 cmH_2O
Arterial blood gases	pH	7.35–7.45
	PaO_2	>10.5 kPa
	$PaCO_2$	4.7–6.0 kPa
	SpO_2	≥95%
Electrolytes	Sodium	130–150 mmol/L
	Potassium, calcium, magnesium, phosphate	Normal range
	Glucose	4–8 mmol/L
Urine output		0.5–3 mL/kg/hour
Haemoglobin		>10.0 g/dL

endothelial damage, and the risk of pulmonary oedema. Pulmonary damage is aggravated by the profound inflammatory response associated with brain death [4].

Endocrine and metabolic changes

Brain death is associated with hypothalamic and pituitary dysfunction or failure characterized by a classic endocrinopathy and thermoregulatory impairment. In particular, there are decreases in circulating tri-iodothyronine (T3), cortisol, and anti-diuretic hormone (ADH) which may contribute to cardiovascular deterioration [2]. The changes in anterior pituitary function are variable because pituitary blood flow may be preserved to some extent after brain death. Reduction in circulating T3 concentration occurs in 60–80% of brain dead donors, but only a few (around 15%) have very low levels [5]. This has been implicated in the deterioration of myocardial function because of a shift to anaerobic metabolism. Posterior pituitary failure is almost ubiquitous and leads to reduced levels of ADH and diabetes insipidus in 90% of brain dead donors. This results in hypovolaemia, hypernatraemia and hyperosmolality if untreated. Blood cortisol levels are also low and associated with impairment of donor stress responses. Hyperglycaemia is common because of decreased insulin concentrations and the development of insulin resistance. Hypothalamic failure causes loss of temperature control; early hyperpyrexia is followed by hypothermia because of reduction in metabolic rate and muscle activity, and peripheral vasodilatation.

Table 389.2 Complications of brainstem death

Complication	Reported range of complication
Hypothermia	100% (unless active rewarmed)
Hypotension requiring vasopressors	80–90%
Diabetes insipidus	50–80%
Coagulopathy	30–55%
Myocardial dysfunction	25–40%
Cardiac arrhythmias	25–35%
Pulmonary oedema	15–20%
Hyperglycaemia	70–75%
Acidosis	60–70%

Inflammatory response

Brain injury and brain death result in a profound neuro-inflammatory response. This leads to a systemic inflammatory response that can cause or aggravate established non-neurological organ dysfunction [4].

Coagulopathy

Release of tissue thromboplastin from ischaemic brain may lead to disseminated intravascular coagulation. Other factors that contribute to the high incidence of coagulopathy in brain dead organ donors include massive transfusion, hypothermia, acidosis, and dilution of coagulation factors during fluid resuscitation.

Monitoring the organ donor

Optimum donor management requires invasive monitoring and management of cardiorespiratory variables. Continuous ECG, SpO_2, direct arterial blood pressure, core-peripheral temperature gradient, and hourly urine output and arterial blood gases are monitored routinely. Central venous pressure measurement is a poor guide to fluid resuscitation after brain death, and cardiac output monitoring using pulse contour analysis or transpulmonary thermodilution is increasingly employed. Echocardiography is required to assess ventricular function in potential heart donors, and sequential assessment is a useful guide to fluid resuscitation. A pulmonary artery catheter should be inserted in those with cardiovascular instability and is invariably required for the assessment of cardiac function in potential heart donors [6].

Resuscitation and maintenance of the organ donor

Aggressive donor management is crucial for several reasons. First, it facilitates donor somatic survival between confirmation of brain death and organ retrieval. This period can be prolonged because of the time required for the consent process, donor screening, identification and preparation of recipients, and mobilization of the retrieval team. Secondly, it maintains donor organs in the best possible condition and thereby improves the functionality of transplanted organs and the quality of life of the recipient. Minimizing on-going ischaemia reperfusion injury in donor organs by maintenance of haemodynamic stability is crucial in this regard. Standardized donor management results in an increase in the number of potential donors who become actual donors, an increase in total organs transplanted per donor, and improved

post-transplantation outcomes [7]. Historically, it has been estimated that up to 25% of organ donors are lost because of poor donor management [8].

Cardiovascular support

Optimization of haemodynamic variables is the cornerstone of donor management, but is not straightforward because of the multiple contributors to cardiovascular instability after brain death. These include hypovolaemia secondary to osmotic diuretics used to treat intracranial hypertension, diabetes insipidus, hyperglycaemia-induced osmotic diuresis, and brain-death related cardiac dysfunction and peripheral vasodilation [1].

Treatment of the autonomic storm with a short acting β-adrenergic receptor blocker is associated with a reduced risk of myocardial damage and increased probability of subsequent heart transplantation [9]. However, this treatment must be provided before brain death has been declared and therefore raises considerable ethical issues. The subsequent combination of myocardial depression, loss of peripheral vascular tone, arrhythmias and hypovolaemia leads to hypotension requiring support in 90% of donors. It is vital for organ preservation that adequate perfusion pressures are maintained and a mean arterial pressure >70 mmHg should be the goal. Fluid resuscitation is the initial treatment, but there is no evidence to support the preferential use of crystalloid or colloid. Although renal graft function benefits from a more aggressive fluid regime, euvolaemia is the goal if thoracic organs are to be donated because excessive fluid loading is associated with a decreased likelihood of lung transplantation [5]. However, lung protective strategies using relatively modest fluid replacement do not adversely affect post-transplant renal function if donor haemodynamic variables are monitored and managed appropriately [10]. Blood and other blood products should be administered as indicated.

If blood pressure cannot be maintained despite adequate fluid resuscitation, dopamine and other catecholamines, such as adrenaline, should be considered [11]. As well as the cardiovascular benefits, the anti-inflammatory actions of catecholamines offer some degree of organ preservation [12]. In patients with low systemic vascular resistance, noradrenaline may be used as a short term measure to maintain arterial pressure during fluid resuscitation. Prolonged and high-dose administration of noradrenaline or adrenaline may worsen neurogenic myocardial injury and transplanted heart dysfunction [13]. Vasopressin (0.5–1.0 milliunits/kg/h) may reduce catecholamine requirements without impairing graft function and the American College of Cardiology and Canadian guidelines recommended vasopressin as the first-line vasopressor for donor resuscitation [6,14]. Regional wall motion abnormalities and poor left ventricular ejection fraction are the most common reasons that donor hearts are deemed unsuitable. However, neurogenic cardiac injury can be reversible [15] and optimization of cardiac function may convert marginal to actual donors.

Cardiac function can be adversely affected by the hormonal changes associated with brain death and hormone replacement has been recommended.

Respiratory support

The lungs are one of the most difficult organs to preserve after brain death and are transplanted from only 15–25% of donors [14]. There are high rates of pulmonary damage before and after brain death including aspiration or ventilator acquired pneumonia, neurogenic pulmonary oedema, systemic inflammation, ventilator-induced pulmonary injury (barotrauma), and over-zealous fluid resuscitation. Lung-protective strategies, including low tidal volumes, minimizing airway pressure, avoiding high inspired oxygen fractions and fluid overload, and recruitment manoeuvres (particularly after the apnoea test) increase the number of eligible and transplanted lungs [16].

Hormone support

Early studies of three-hormone replacement, including thyroid hormone, steroid and vasopressin, reported catecholamine sparing effects, conversion of marginal to actual donors, improved short-term graft function, and increased numbers of transplanted hearts [17,18], but subsequent randomized trials have not confirmed these benefits [19]. Thus, three-hormone replacement remains controversial and, pending larger studies, should only be considered in unstable donors requiring large doses of vasopressors or in those with an ejection fraction less than 40% [20,6].

Some guidelines recommend thyroid hormone replacement only if cardiac function is impaired, whereas others advocate universal application [11]. The improvement in cardiac function and haemodynamic stability associated with thyroid hormone replacement in some studies might reflect the positive inotropic properties of thyroid hormone in the setting of the sick euthyroid syndrome rather than the effects of replacement therapy per se. There is little evidence to support the role of endogenous steroid supplementation as a routine part of donor management, although there has been recent interest in the administration of methylprednisolone to moderate the inflammatory response to brain death [5,11]. The initial treatment of diabetes insipidus is aimed at correcting hypovolaemia and hypernatraemia by the administration of hypotonic intravenous fluids or water via a nasogastric tube. If urine output continues greater than 3–4 mL/kg/hour, continuous vasopressin infusion or intermittent desmopressin, which is specific for the V_2-vasopressin receptor and has predominantly antidiuretic effects, should be administered [6].

Other support

Poor glucose control affects recipient renal and pancreatic function. Hyperglycaemia usually responds to standard insulin regimens, but in the presence of severe insulin resistance, substantial doses of insulin may be required to maintain plasma glucose in the required range (4–8 mmol/L) [6].

Blood-product replacement should be aimed at providing adequate oxygen delivery and correction of coagulopathy. There is no evidence to guide the red cell transfusion threshold in brain dead donors, but maintaining a haemoglobin level > 10.0 g/dL (or haematocrit > 30%) has been recommended [20].

The loss of hypothalamic thermoregulation, combined with profound vasodilatation and an inability to shiver, results in a poikilothermic donor. Adverse effects of hypothermia include cardiac dysfunction, arrhythmias, coagulopathy, and cold-induced diuresis. The core temperature should be maintained greater than 35°C by warmed fluids, humidified inspired gases, and convective warming blankets.

General ICU management

General ICU measures should be continued during the period of donor management, although unnecessary drugs should be discontinued. Feeding or a glucose source should be maintained and

electrolytes abnormalities corrected. Mechanical methods of thromboprophylaxis should be continued up to, and during, organ retrieval.

CHAPTER 390

Non-heart-beating organ donation

Mohamed Y. Rady and Ari R. Joffe

Key points

- The transplantation community endorses non-heart-beating organ donation (NHBD) to increase the supply of transplantable organs.
- Controlled NHBD occurs after withdrawal of life-support followed within 1–2 hours by cardiac arrest.
- Uncontrolled NHBD occurs after failed cardiopulmonary resuscitation (CPR) in an unexpected cardiac arrest.
- Controversial fundamental assumptions in NHBD include: the meaning of the 'irreversibility' of death, unacknowledged conflicting interests during EOL decisions, and perimortem donor interventions that may cause harm.
- Clinicians must understand NHBD ethical issues in order to obtain informed consent.

Introduction

The 2 types of non-heart-beating organ donation (NHBD) (controlled and uncontrolled) can increase the supply of transplantable organs at end of life (EOL) [1]. We describe the medical steps and ethical challenges of NHBD in the intensive care unit (ICU).

Controlled NHBD

Several medical conditions qualify for controlled NHBD:

- Acute traumatic and non-traumatic brain/spinal cord injuries.
- Neuromuscular or pulmonary diseases.
- Circulatory support with durable mechanical devices [2,3].

There is no lower or upper age limit, but most donors are <75 years. Donors have transplantable organs (e.g. liver, kidneys, heart, and/or lungs) and are dependent on circulatory and/or ventilatory life-support. There are several steps involved [2,4]. First, a decision is made to discontinue life-support based on either patient's expressed wishes or the best-interest standard. Secondly, consent is obtained from prior donor registration or surrogates. Thirdly, withdrawal of life-support in the ICU or operating room is co-ordinated with the surgical procurement team. Mechanical asystole determining absent circulation (AC) must ensue within 2 hours from treatment withdrawal to minimize donor warm ischaemia time; otherwise, NHBD is aborted. Fourthly, death is declared after AC and a mandatory 'no-touch' period. AC is confirmed electrocardiographically or by absent arterial pulse manually or through indwelling catheters. The no-touch period between the onset of AC and surgical procurement varies from 75 seconds to 10 minutes [5]. Finally, in situ perfusion with cold preservative fluid halts warm ischaemic injury of transplantable organs. This is facilitated through either antemortem cannulation of femoral vessels and administering heparin and phentolamine to enable rapid flushing of blood from organs after AC, or a super-rapid recovery laparotomy/median sternotomy, direct cannulation and perfusion of the abdominal aorta and decompression of the inferior vena cava, followed by en-bloc removal of viscera [6].

Controlled NHBD is ethically justified by expert-panel opinions [2,4]. First, clinicians decide to withdraw life-support independent of NHBD, thus avoiding conflicting interests in EOL decision-making [1]. Secondly, informed consent is obtained. Third, antemortem interventions are compatible with the double-effect principle because they are intended for preserving organs and the unavoidable risk of donor harm is foreseen but unintended. Fourth, the short no-touch period after AC is compliant with the 'accepted medical standards' in the Uniform Determination of Death Act [7]. AC of 65 seconds is postulated as permanent cessation of circulation because autoresuscitation (spontaneous return of circulation) is unlikely without prior cardiopulmonary resuscitation (CPR), and no attempts are made to restart circulation by CPR because of the do-not-resuscitate decision [7].

Uncontrolled NHBD

Uncontrolled NHBD follows unexpected cardiac arrest: in-hospital, out-of-hospital, and/or after determining brain death [8,9]. Death is declared after 30 minutes of unsuccessful CPR by confirming absent arterial pulse, usually followed by a 'hands-off period' of up to 5 minutes. Then CPR is resumed or continued until extracorporeal membrane oxygenation (ECMO) is initiated. ECMO maintains systemic circulation with oxygenated blood and preserves transplantable organs. A balloon catheter may be inflated in the thoracic aorta to prevent perfusing cerebral and coronary circulation and resuscitating donors on ECMO [6,10]. ECMO allows time for consent and coordinating surgical procurement. Uncontrolled NHBD is said to be justified ethically because:

- Decisions to stop CPR are independent of NHBD.
- AC is permanent when death is pronounced.
- ECMO is intended to preserve NHBD opportunity.
- Informed consent is obtained before procurement.

Ethical challenges in NHBD

Unresolved ethical challenges threaten the acceptability of NHBD among the general public and medical community. These challenges are not limited to harm from ignoring quality EOL indicators or transplanting marginal quality allografts [3]. The most serious challenges in NHBD originate from controversial fundamental assumptions [1].

Reversibility of death in NHBD

Death is an irreversible biological/ontological state and separates the dying process from the disintegration process. The dying process may be interrupted or reversed by resuscitation; however, death cannot be reversed and is irreversible [11]. Death is defined philosophically as an 'irreversible state of loss of the integrative unity of the organism as a whole'[1]; the organism cannot resist the disintegration entailed by entropy [12]. If NHBD is non-compliant with the irreversibility of death, then donating organs is the proximate cause of death. A weak construal of 'irreversible' is invoked in donors, i.e. the state of AC will not be reversed, and therefore is 'permanent' [1]. Replacing the objective standard of irreversibility (cannot be reversed) with a subjective notion of permanence (will not be reversed) is incompatible with the death concept [10]. As Marquis explains:

> 'Suppose that Joe has a heart attack and his circulatory function stops. Fred, a physician standing next to Joe, refuses to perform CPR on Joe because Joe is a rival . . . Suppose that CPR would have been successful, but because it was not performed, cessation of Joe's circulatory function was permanent. Was Fred's refusal to act wrong? Not if we understand the irreversible cessation of circulatory function as equivalent to the permanent cessation of circulatory function . . . On that understanding, Joe was dead as soon as he collapsed, and Fred's failure to perform resuscitation was not wrong, for he had no obligation to resuscitate a corpse'[13].

Another implication of the 'permanence' construal of 'irreversible' is that 'two patients in exactly the same physiologic state would be considered dead or alive depending on whether resuscitation will be attempted' [1], even though 'death is a state of a body'[13].

Acceptable medical standards

There is only one state of death, with 2 proposed diagnostic tests: confirming irreversible cessation of either whole brain (including brainstem) functions, or circulatory and respiratory functions [12]. Irreversible cessation of whole brain function has not occurred in NHBD, since CPR survivors can regain critical brain functions after 10 minutes of AC. Historical reports claim that no-touch periods >2 minutes after AC are unnecessary (Table 390.1) [1,14,15]. However, autoresuscitation is reported from a few seconds to 33 minutes after terminating CPR, including after monitored electrical asystole for 3–7 minutes with ($n = 3$) or without ($n = 6$) an arterial line [1]. Some early autoresuscitation cases are explained by discontinuing positive pressure ventilation and relieving dynamic lung hyperinflation, and/or delayed cardiac delivery of vasoactive drugs. However, most cases of autoresuscitation are late (after several minutes) and unexplained [1]. Physicians declare death in practice by confirming AC without a waiting period. The declaration is validated retrospectively after passage of time confirming the 'irreversibility' [1]. This retrospective validation is impossible in NHBD, making it imperative to define the no-touch period after AC with scientific certainty.

Prognostication in uncontrolled NHBD

Reinstituting CPR and/or ECMO after declaring death 'retroactively negates' the death diagnosis in uncontrolled NHBD [7]. The concern is: the patient is dead using a weak 'construal' of 'irreversible'; however, the dead donor is resuscitated with CPR (and/or ECMO), the exact intervention that was ethically disallowed to justify the weak construal of 'irreversible'[1]. Initiating ECMO after >1 hour of CPR can resuscitate >40% of cardiac arrest patients with good neurological outcomes [16]. Similarly, some NHBD donors are resuscitated and organ procurement is aborted [17].

Conflict of interests

NHBD should be independent of EOL decisions [1]. EOL decisions can be subjective because of inaccurate prognostication of survival and future quality-of-life [18,19]. Subconscious biases can

Table 390.1 Clarification of the controversies surrounding the interpretation of 'the irreversibility of death' in non-heart-beating donors

Absent circulation is irreversible at 2–10 minutes	Absent circulation is not irreversible at 2–10 minutes
Permanent is a reasonable 'construal' of irreversible	The ordinary meaning of irreversible is 'not capable of being reversed.' Permanent is not a 'construal' of irreversible at all
There is a moral/legal obligation not to resuscitate	Irreversible is not a moral/legal concept. The obligation not to resuscitate is due to the patient being alive. Death is a state of a body, and those in exact states cannot be both dead and alive
There is no difference in outcome by waiting for irreversibility	This admits that permanence is a prognosis of death, not a diagnosis of death. The donor is dying
Autoresuscitation does not occur after 65 seconds of absent circulation	This is based on inadequate data ($n = 5$), and tries to explain away the Lazarus phenomenon*
Autoresuscitation does not occur at 2 minutes ($n = 12$ donors) [14] or 5 minutes ($n = 73$ donors) [15] after mechanical asystole	The studies report historical cases of successful NHBD donors with short observation timelines and small sample sizes. The effects of antemortem interventions and surgical procurement influence the scientific reliability and are susceptible to the confounding effect of 'self-fulfilling prophecy'
Permanence accords with accepted medical standards	This mischaracterizes accepted medical standards. In the usual circumstances, the consequence of a mistaken diagnosis of death does not result in immediate organ removal
Brain death is not required to diagnose death	The intent of the law is that there is only one death per person. Donors are not brain dead

*Five studies published between 1912 and 1970 that reported on 108 heterogeneous patients aged 9 months to 87 years with incomplete definition or standardization of selection criteria, monitoring methods, or observation timelines. Only five cases had electrocardiogram monitoring continued >2 minutes after loss of cardiac activity.

have potent and pervasive influence on the complex psychology of medical decision-making [1]. Unrecognized conflicting interests can exist if clinicians know of the NHBD option in advance of EOL decision-making. Clinicians are aware of transplantation benefit in end-organ failures, patients on transplant waiting lists, and the institutional academic/financial prestige from transplantation [1]. Conflicting interests may have consequences including premature withdrawal of medical care in salvageable patients.

Clinicians associated with transplantation should not obtain NHBD consent [1]. Some Spanish clinicians assume two conflicting roles: intensivists caring for critically-ill patients and procurement coordinators consenting for donation [20]. Many institutions permit clinicians to have simultaneous conflicting roles: caring for the terminally ill, discussing EOL and life-support withdrawal, managing donors, and caring for critically ill recipients before and/or after transplantation [1].

The US team-huddle programmes embed procurement coordinators with hospital staff [1,10]. Team-huddle programs enable surveillance for donors, early antemortem interventions for optimizing organ perfusion and protection, and overcoming familial barriers to donation consent [1]. Team-huddling of intensivists with procurement professionals can create conflicting interests [1].

Antemortem interventions and the double-effect principle

Antemortem interventions benefit the recipient and not the donor. It is arguable whether a donor can consent to non-beneficial interventions that are potentially hastening/causing death [1]. Administering heparin and phentolamine can be harmful because of haemorrhage and hypotension. Vascular cannulation is an invasive procedure requiring anaesthesia. With heparin, four factors should be fulfilled to apply the double-effect principle:

> [the] action (giving heparin) must be intrinsically good (done to obtain functional organs); the bad effect (death) may be foreseen but the agent must only intend the good effect; the bad effect must not be a means to the good effect; and the good effect must be proportional to (compensate for, or outweigh) the bad effect. [One must consider] whether the bad effect (death) is not intended, whether the bad effect (death) is not a means to the good effect (obtaining functional organs), and whether the good effect (obtaining functional organs) is proportional to the bad effect (death) [1].

Potential NHBD donors that survive >2 hours can suffer additional EOL distress from antemortem interventions and failed NHBD.

Conclusion

NHBD can increase the supply of transplantable organs at the EOL. Unresolved ethical challenges threaten the acceptability of NHBD. Intensivists should be familiar with the ethical challenges in order to make an informed decision on their participation and to obtain informed consent from donors.

PART 22.3

Post-mortem diagnosis

CHAPTER 391

Post-mortem examination in the ICU

Eva Tejerina and Andrés Esteban

Key points

- Post-mortem examination should be seen as a reliable method to improve quality of medical care by monitoring diagnostic accuracy and treatment of the critically ill patients.
- Despite technological improvements in medicine, percentage of missed diagnosed had not changed over time, and some diseases remain particularly challenging to identify.
- Autopsy remains the essential verification of the clinical diagnosis in critically ill patients, and provides a 'gold standard' to assess the accuracy of diagnostic tests.
- Autopsy findings also offer relevant information for the advance of medical knowledge and the description of new disease entities.
- Post-mortem examination rates have fallen worldwide during the past decades. So, it should encourage clinicians to remember the value of the autopsy.

Introduction

Autopsy has long been regarded as a valuable and reliable tool for quality control in medical practice. It may facilitate new discoveries about pathogenesis and therapy, give feed-back for clinical research protocols, provide epidemiological information, monitor public health, and serve to console and reassure grieving families. The autopsy also provides an excellent basis for teaching students the fundamentals of anatomy and the manifestations of disease. It provides important information on the effects of newer drugs on normal and on diseased tissues and is a source of relevant data for detecting and evaluating emerging diseases. The prestigious 'Case Records of the Massachusetts General Hospital' in the *New England Journal of Medicine* is a good example of the value of the autopsy as an educational tool. For decades it continued to publish, on a weekly basis, enigmas solved by autopsy findings.

Although autopsy remains a fundamental element of quality assurance in critical care medicine, post-mortem examination rates have fallen worldwide during the past decades [1–3]. A variety of factors has been attributed to this decrease: fear of potential legal repercussions, the time-consuming task of autopsies for the pathology departments, reluctance of families to give permission for the procedure, or exclusion of minimum mandatory autopsy rates as one of the accreditation criteria for hospitals. However, despite concerns that relatives will be unwilling to give permission for a post-mortem examination, a study in an ICU in a Spanish hospital has reported that if they are approached sensitively up to 43% of relatives may agree [4]. It has been suggested that how, and by whom, the family is approached are important factors in whether consent is obtained. Other reasons have also been attributed to the decline in autopsy rates, including the availability of new and more effective technologies for diagnostic procedures, particularly in terms of imaging techniques. In intensive care medicine, clinicians may be reluctant to perform post-mortem examinations in patients who have been intensively investigated and treated. Also, an autopsy may be performed more frequently if the diagnosis is not considered to be completely clear.

An autopsy rate of 25% is the minimal considered adequate for an accurate quality assurance of clinical diagnostic performance, whereas the rate considered optimum is of 35% [5]. A high autopsy rate requires that intensive care staff be persuaded of the importance of autopsies as part of the teaching and quality assurance programmes. It is also necessary to count on the Pathology Department collaboration. It is of paramount importance that the hospital administration assigns the autopsy cost to the teaching and quality assurance budget. Furthermore, in order for an autopsy to be an educational tool, the information that is obtained must be relayed to the primary caregivers in a timely fashion. Formal teaching sessions with reviews of autopsy and an individual discussion of each particular case must be regularly scheduled [6,7].

Diagnostic errors and quality assurance

A correct diagnosis is a complex interaction of cognitive skills and technical procedures in conditions of uncertainty. Confirmation of clinical diagnosis by necropsy strengthens clinical cognition because it can eliminate uncertainty about diagnosis in most cases. In addition, unexpected findings at autopsy contribute to the increasing pool of medical knowledge, which may lead to better patient care.

Traditionally, unexpected autopsy findings have been categorized as Class I or major discrepancies and Class II or minor discrepancies, using the Goldman criteria [1]. Class I error was an autopsy findings for which an accurate premortem diagnosis would have altered therapy and survival. And, Class II diagnostic error was defined as an unsuspected diagnosis related to death, but it would not, however, have changed immediate management for any of the following reasons: the patient was already receiving appropriate therapy even though the diagnosis was not known; effective

therapy was not available; or the patient refused further investigations or treatment. Several studies have shown that major discrepancies are frequent, and in 5–40% of all hospitalized patients, and in 7–32% of adult intensive care patients a treatable condition that might have altered outcome, had it been recognized, is identified at post-mortem examination [2,3,8–12]. These differences in discrepancy rates among studies may be explained by different populations and also by differences in the indications for autopsy. Studies from hospitals in which autopsies are predominantly performed in complicated cases may be expected to show higher discrepancy rates. On the other hand, it is likely that unexpected autopsy findings in cases with apparently well-established diagnoses are actually the most interesting ones.

Despite technological improvements in medicine, percentage of missed diagnosed had not changed over time, although the spectrum of diseases identified at autopsy has evolved [1,13]. Some diseases remain particularly challenging to identify, despite advanced medical technology, improved diagnostic tests and techniques, and increased clinical awareness. Events such as missed infections, thromboembolic disease and myocardial infarction remain very prevalent and often unrecognized conditions [1,2,8], emphasizing the importance of maintaining a high index of suspicion for these diagnoses in the critically ill. The intensive care unit patient, exposed to a wide spectrum of invasive procedures and indwelling medical devices, is placed at a higher risk to develop nosocomial infections coupled with more virulent and resistant strains of infectious agents. Critically ill patients are also frequently colonized with pathogens, leading to difficulties of separating colonization from active infection. It provides an immense challenge to the ICU care team to accurately and quickly establish the source of infection. Indeed, infectious diagnoses compromise the majority of missed causes of death in the various autopsy studies [2,3,9–11], especially when reporting cases from the ICU setting.

Other possible explanation for the stability of these rates is increased selection by clinicians. A selection bias due to the hypothesis that only families with concerns about management or outcome gave consent or, alternatively, that caregivers were more persistent when they perceived a need for post-mortem examination. It might also have influenced the incidence of discrepancies. With progressively fewer autopsies performed over time, clinical selection for diagnostically challenging cases might offset true gains in diagnostic accuracy. However, more recently, some authors [13] noted that the frequency of major discrepancies significantly decreased over time.

Recently, a prospective study of all consecutive autopsies performed on patients who died in the ICU between January 1982 and December 2007 was conducted [14]. Of 2857 deaths during the study period, autopsies were performed in 866 patients (30.3%). Autopsy reports were available in 834 patients, of whom 63 (7.5%) had class I errors and 95 (11.4%) had type II errors. The most frequently missed diagnoses were pulmonary embolism, pneumonia, secondary peritonitis, invasive aspergillosis, endocarditis, and myocardial infarction (Table 391.1). The autopsy did not determine the cause of death in 22 patients (2.6%). Our rate of diagnostic discrepancy remained relatively constant over time (Fig. 391.1), and the conditions leading to discrepancies have slightly changed, with pneumonia showing a decline in diagnostic accuracy in the last years.

The high-risk, critically-ill population is exposed to sophisticated trauma and critical care management and procedures, coupled with invasive and immunocompromising technology. Subsequently, the terminal diagnosis and cause of death may differ considerably from the initial disease state that prompted the ICU admission. It might be expected that the longer a patient stays in an ICU, the more likely the clinical and autopsy diagnoses would agree. Other authors have suggested that diagnostic accuracy may decrease with increasing hospital time due to the failure of doctors to recognize new problems in patients who are already being treated for other diseases [2,11]. However, most studies found no statistically significant correlation between the length of stay in the ICU or hospital and the discrepancy rate [3,8].

The persisting discordance between clinical and autopsy diagnoses is also an argument for continuing to perform autopsies, and reinforces the importance of the post-mortem examination in detecting otherwise unexpected diagnoses. The autopsy has historically helped define how cases that previously appeared atypical could more commonly be recognized antemortem. Repeated detection of certain missed diagnoses may result in the recognition that some patterns of presentation are more typical than previously appreciated.

Technically adequate autopsies fail to establish the cause of death in 1–5% of cases [15]. Despite an expert histopathological examination, there remain a proportion of adult deaths for which no definite cause of death can be found. This could be explained either

Table 391.1 Major discrepancies found at post-mortem examination of 834 patients who died in the ICU

Diagnosis	Number
Infectious disorders	
Pneumonia	23
Secondary peritonitis	12
Invasive aspergillosis	8
Pulmonary tuberculosis	3
Intra-abdominal abscess	3
Mediastinitis	2
Meningoencephalitis	2
Cardiovascular disorders	
Endocarditis	8
Myocardial infarction	8
Aortic dissection	3
Cardiac tamponade	2
Pulmonary disorders	
Pulmonary embolism	24
Aspiration pneumonitis	2
Gastrointestinal disorders	
Gastrointestinal haemorrhage	7
Mesenteric ischaemia	6
Acute pancreatitis	5
Oncologic disorders	
Lymphangitis carcinomatosa	3
Lung cancer	2
Other	4

because post-mortem examinations of adults who were apparently healthy, but died suddenly and unexpectedly sometimes reveal no morphological abnormalities or because different pathologies coexisted in a patient, which could be responsible for death. Even in these cases, autopsy may help to exclude some suspected conditions as the cause of death.

Standard for accuracy

Autopsy remains the essential verification of the clinical diagnosis in critically ill patients, and provides a 'gold standard' to assess the accuracy of diagnostic tests. Specifically, pulmonary pathology represents a major diagnostic challenge because of the low yield of clinical criteria and because pulmonary infiltrates may be due to different processes that affect patients receiving mechanical ventilation.

Several studies have reported a noticeable rate of missed diagnoses of pneumonia [2,9,14], illustrating the difficulty in establishing this diagnosis in ventilated patients. Clinical criteria used to define pneumonia have included radiographic appearance of a new or progressive pulmonary density, fever, leucocytosis, or purulent tracheal aspirates. Patients receiving mechanical ventilation, however, frequently develop other conditions that either obscure these findings or give rise to a similar clinical picture. Alternative diagnosis that may mimic ventilator-associated pneumonia includes alveolar oedema, either cardiogenic or non-cardiogenic, alveolar haemorrhage, atelectasis, pulmonary infarction, and the fibroproliferative phase of ARDS. Post-mortem lung histologic studies of patients receiving mechanical ventilation have found clinical parameters and antemortem chest radiographs present a high inaccuracy rate in predicting ventilator-associated pneumonia. Our group analysed in a recent study [16] 253 deaths and found that 142 (56%) patients had pneumonia diagnosed by histological criteria. In comparison with autopsy findings, antemortem clinical diagnosis of pneumonia had a sensitivity of 64.8% and a specificity of 36%, applying as diagnostic criteria the presence of chest radiograph infiltrates and two of three clinical criteria (leukocytosis, fever, purulent respiratory secretions). If the diagnostic criteria for pneumonia were more strict (chest radiograph infiltrates and all of the clinical criteria), the sensitivity was 91% and the specificity 15.5%.

Other entities such as acute respiratory distress syndrome (ARDS) show similar diagnostic difficulties in patients with mechanical ventilation. Our group had also published a study [17] comparing clinical diagnostic criteria for ARDS with autopsy findings in 382 patients, of whom 127 (33%) met the clinical criteria, and 112 (29%) had diffuse alveolar damage. In all patients, the sensitivity of the clinical definition was 75% and the specificity was 84%. In this series, the accuracy of the clinical definition for ARDS was only moderate.

Impact of the autopsy on clinical performance and future research

Information gained from the routine use of post-mortem examinations in ICU may allow the development of strategies for the early detection of diagnoses. Possibly, some patients could have been managed more appropriately, by analysing preventability of deaths, iatrogenic lesions caused by therapeutic measures, or assigning blame to human or system errors.

However, no intervention study has directly addressed the impact of autopsy findings on clinical practice or performance improvement. Given the absence of any studies, the current literature provides no direct evidence for or against an impact of post-mortem findings on clinical performance at the level of individual practitioners or institutions. This does not invalidate the potential role of the autopsy in relation to clinical practice or performance improvement, but instead reveals an important gap in the literature.

Furthermore, maintaining a high autopsy rate and merging accurate hospital discharge data and autopsy data are effective ways to improve the accuracy of survival estimates and mortality prediction models, and to estimate mortality attributable to diagnostic failures.

Autopsy findings also offer relevant information for the advance of medical knowledge and the description of new disease entities. As an example, a recent pandemic was originated by a novel influenza A (H1N1) virus, and severe cases were characterized by ARDS, shock, and acute kidney injury. Lung histopathological changes in fatal cases showed signs of diffuse alveolar damage, necrotizing bronchiolitis, and occasional alveolar haemorrhage [18]. And, kidney pathological changes are consistent with acute tubular necrosis and persistence of viral infection despite antiviral treatment [19].

The health care system as a whole can thus benefit enormously from autopsy data, by, substantially enhancing the accuracy of vital statistics, which play important roles in research, funding, and other policy decisions. Future research opportunities include characterizing the factors leading to errors in clinical diagnosis, establishing optimal means of using autopsy data in performance improvement strategies, exploring different mechanisms for encouraging autopsies, and testing the efficiency of these improvements with new correlations between clinical and autopsy diagnoses.

Ongoing controversy

An ongoing controversy raises the question whether autopsy is still needed as a tool to monitor diagnostic accuracy in ICUs, and therefore, there is an urgent need to reverse the decline in the rate of post-mortem examinations.

Some arguments against the continuation of performing autopsies are cost containment, progress in diagnostic procedures, lack of time and interest by both pathologists and clinicians, and persisting distrust of families. It has been suggested [20] that, in the future, autopsies should be performed at regional autopsy centres, staffed by pathologists specially trained in autopsy, where autopsies could be performed safely and where the information obtained from autopsy materials could be used more effectively. It should be coupled with a distribution mechanism for decentralized autopsy resource, whose materials could be used for the detection and analysis of emerging diseases, the identification of public health or epidemiological issues, outcome analysis, quality improvement investigations, and possibly for human tissue studies. Undoubtedly, this model has important limitations mainly related to the transfer of the corpse, which is time-consuming, may affect the family consent to practice the post-mortem examination, and make communication difficult between clinicians and pathologists.

By contrast, it can be argued that the autopsy offers relevant information for teaching and for the advancement of medical knowledge. The description of new disease entities continue to be based upon autopsy findings. It is also an important source of relevant data to assess the effect of surgical interventions or other novel therapeutics. Furthermore, the autopsy provides information unavailable by any other method, and should be considered in every patient who dies in the ICU.

Conclusion

During the past few decades, autopsy rates have decreased worldwide. However, significant discrepancies are found between clinical diagnoses before death and post-mortem findings, despite advances in diagnostic technology. This reinforces the importance of the post-mortem examination in detecting otherwise unexpected diagnoses, even in patients under the close investigation and scrutiny that follows ICU admission. It should encourage clinicians to remember the value of the autopsy as a reliable tool in assuring and improving the quality of medical care by monitoring diagnostic accuracy and treatment of the ICU patient.
