The ventilatory control system is centered in the brain stem and consists of an intrinsic ventilator pattern generator with three types of inputs [5]. One input is a series of afferent nerves from mechanoreceptors in the lung and chest wall. These sense respiratory system stretch, irritants, and ventilatory muscle loads. A second set of inputs arise from central and peripheral chemo receptors sensing pH, PCO_2, and PO_2. A final input involves cortical signals designed to modulate the respiratory pattern for voluntary activities. The purpose of the control system is to provide an adequate level of ventilation to effect CO_2 and O_2 transport, while minimizing the mechanical loads on the ventilatory muscles. The normal resting ventilatory pattern of 10–12 breaths/min, tidal volumes of 5–7 mL/kg, and inspiratory:expiratory timing of 1:2–1:3 is a consequence of this control system strategy [6].

This system can be compromised with any central nervous system (CNS) injury, but especially those that affect brain stem function. In addition to CNS injury, general anaesthesia and a variety of drugs, especially sedatives and opioid analgesics can also affect this function. At its extreme, ventilatory controller failure results in a respiratory arrest. Damage to efferent nerves, primarily the phrenic nerve, will compromise the controller's ability to provide adequate inspiratory muscle stimulation.

Although some CNS injuries can produce inappropriate hyperventilation, the consequence of most diseases/drugs affecting the ventilatory control system is usually inadequate ventilation resulting in a respiratory acidosis (hypercarbic respiratory failure). The pH threshold from a respiratory acidosis that requires intervening with mechanical ventilatory support depends on the clinical situation. In the absence of significant cardiac dysrhythmias, pressor-dependent hypotension, or elevated intracranial pressure, pH values as low as 7.15 (or perhaps lower) have been shown in clinical trials to not cause harm [7]. However, the initiation of mechanical ventilatory support for hypoventilation and respiratory acidosis from CNS causes is usually driven by the clinical judgment that the ventilatory drive is unreliable for maintaining a safe level of ventilation for an extended period.

If mechanical ventilation is required for an impaired ventilatory controller, the mechanical ventilation strategy must assure that an adequate minute ventilation is delivered. This often requires clinician set ventilator breath rates, and either set tidal volumes or pressure targeted feedback mechanisms to assure adequate tidal volumes. Alarm systems that are properly set are critical.

Abnormal ventilatory control systems may also create inappropriate flow demands and breath timing patterns. These can be especially challenging to clinicians trying to minimize sedation while providing assisted breaths that can synchronize with these patient demands [8].

Demand/capability imbalances

The mechanical loads on the ventilatory muscles are primarily those imposed by the minute ventilation demands, airway resistance, and the compliance/elastance of the respiratory system [9]. Minute ventilation demands are driven by metabolic demands (i.e. oxygen consumption (VO_2) and carbon dioxide production (VCO_2)) and the amount of minute ventilation that is wasted (dead space ventilation or VD). Airway resistance is due to both patient airway geometry and the artificial airway properties. Compliance/elastance properties are driven by both parenchymal lung abnormalities, as well as chest wall abnormalities (e.g. tight surgical bandages, abdominal compartment syndrome, anasarca, ascites, and obesity). Imposed loads from the ventilator itself (artificial airway resistance and patient ventilator dys-synchrony) can also exist [10]. The presence of intrinsic positive end expiratory pressure (PEEP) can add to inspiratory muscle loads required to initiate a breath.

The capability of the patient's ventilatory system is composed of the inspiratory muscle's strength and endurance properties. These can be affected by metabolic abnormalities, systemic inflammation, nutritional factors, electrolyte factors, and drugs. The resting position of the diaphragm is particularly important as it is the major muscle of inspiration. If the diaphragm is flattened from lung hyperinflation, bullous disease and/or intrinsic PEEP, inspiratory muscle capabilities are greatly diminished.

Ventilatory muscle failure and resulting inadequate ventilation occurs when the demands outstrip the capabilities (Fig. 91.1). Clinically, this is often manifest initially by rapid-shallow breathing (a muscle 'protective' response driven by the ventilatory control center) [11]. As overloaded muscles continue to work, muscle damage occurs, hypoventilation worsens, and a respiratory acidosis develops (hypercarbic respiratory failure). At its extreme, ventilatory muscle failure produces a respiratory arrest.

Because gas exchange may be adequate in the face of progressive ventilatory muscle overload for a prolonged period, the clinical decision to initiate mechanical ventilatory support for demand/capability imbalances is best driven by mechanical assessments. Importantly, this is not so much by an assessment of mechanical loads (e.g. work of breathing or pressure time product which may be elevated several fold in patients requiring mechanical ventilation), but rather by an assessment of muscle load tolerance. Conceptually, this can be expressed using a transdiaphragmatic pressure referenced to muscle strength to calculate a pressure time index (PTI) (12):

$$PTI = (P_{Dtidal} / P_{D\,max}) \times (T_i / T_{tot}) \qquad \text{[eqn 1]}$$

where P_{Dtidal} is the transdiaphragmatic pressure change during inspiration, P_{Dmax} is the maximal voluntary transdiaphragmatic pressure, and T_i/T_{tot} is the fraction of the ventilator cycle spent in inspiration. A PTI value greater than 0.15 is associated with impending inspiratory muscle failure.

Clinically, load intolerance is associated with diaphoresis, accessory muscle use, abdominal paradox, inability to speak short phrases, and tachycardia [11,13,14]. The decision to institute mechanical ventilation in this setting is usually based on clinical judgment that load intolerance is becoming life threatening. Objective measurements or laboratory values can support the decision to initiate mechanical ventilatory support under these circumstances but these rarely provide definitive information that would override the clinical assessment.

Mechanical ventilation strategies in the setting of demand/capability imbalances focus on both improving muscle capabilities and reducing muscle loads. This involves proper unloading of ventilatory muscles with positive pressure breaths. Support strategies,

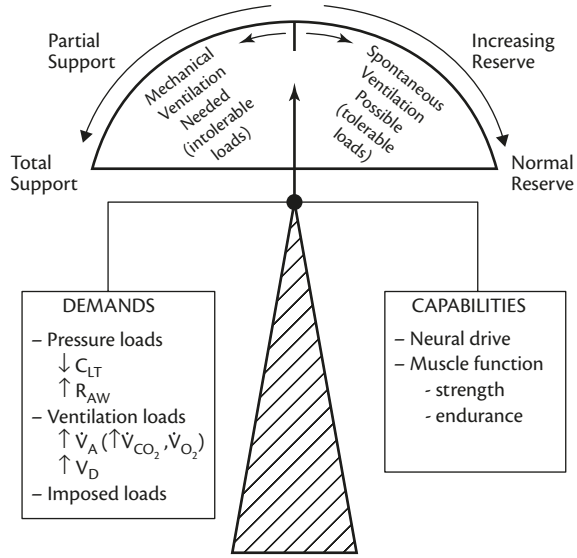

Fig. 91.1 Conceptual relationship between ventilatory muscle demands (left side of balance) and capabilities (right side of balance). As demands overwhelm capabilities, the balance shifts to the left and indications for mechanical ventilatory support increases.

however, must not totally unload ventilatory muscles as this can produce muscle atrophy [15]. In practice, this means a mechanical ventilation strategy focused on patient-triggered assisted modes of ventilation titrated to comfort. This requires skill in assuring appropriate triggering of breaths (including the use of circuit PEEP in the setting of intrinsic PEEP), proper flow synchrony such that ventilator flow matches patient demand, and proper breath cycling to coincide with neural cycling [8,10]. It also requires the proper setting of the respiratory rate and I:E ratio to assure adequate lung emptying is occurring, and intrinsic PEEP is minimized. Importantly, placement of an endotracheal tube is not always required for this support. In patients with load/capability imbalances, but with good airway protection capabilities, non-invasive (mask) ventilation may avoid endotracheal intubation, most notably in the COPD population with an acute exacerbation.

Maintaining alveolar patency

Many lung diseases affecting lung parenchyma can cause alveoli to flood and/or collapse. Inhalation injuries, infections, systemic inflammation (e.g. sepsis, pancreatitis), blunt chest trauma, aspiration, congestive heart failure, and fluid overload all can contribute. The predominant clinical manifestation of loss of alveolar patency is ventilation perfusion mismatching, producing shunts and hypoxaemia (hypoxaemic respiratory failure). If severe enough, the resulting compliance/elastance loads from alveolar instability can also contribute to ventilatory muscles overload and hypercarbic respiratory failure.

Provided that other components of oxygen delivery (i.e. cardiac output and haemoglobin concentration) and tissue oxygen extraction are adequate, arterial PO_2 values above 55 mmHg are generally adequate to assure tissue oxygen delivery. Clinical clues that oxygen delivery is inadequate and in need of therapy include altered mental status, cardiac dysrhythmias, and other organ dysfunction. Objective data suggesting impaired tissue oxygenation includes the development of a metabolic (lactic) acidosis.

Support of patients with compromised alveolar function involves the judicious use of PEEP to stabilize alveoli along with administration of supplemental oxygen [16]. If a tolerable load/capability balance exists (e.g. patients with some forms of cardiogenic pulmonary oedema), continuous positive airway pressure (CPAP), through either a mask or an endotracheal tube, may be all that is required to accomplish this. However, concomitant ventilatory support is often as needed as well. Under these conditions it is important to remember that PEEP is a two-edged sword. While, on one hand, the expiratory pressure can help maintain alveolar patency during exhalation, it will add to the total interthoracic pressure and could increase the risk of overdistention injury, especially when coupled with an excessive tidal volume [16–18]. Balancing PEEP and FIO_2 to provide proper oxygenation in the setting of alveolar injury is clearly a major clinical challenge and, as described elsewhere in this book, various imaging, mechanical, and gas exchange methodologies have been proposed.

Support for an artificial airway

Airway function can be compromised from a variety of different disease states [19]. CNS abnormalities (e.g. CNS injury, tumours, drugs) can result in a failure to maintain appropriate muscle tone for airway patency, and loss of cough and/or other airway defence reflexes. Clinical consequences can include the inability to ventilate due to airway compromise and aspiration of posterior pharyngeal material. Airway function can also be compromised by structural injuries to the pharynx, larynx, and major airways.

Clinically, loss of airway patency is manifest by a high work of breathing, inadequate ventilation, and sometimes stridor. Inadequate airway protection is manifest by weak or absent cough (especially when being suctioned), a need for frequent suctioning (e.g. more than every 2 hours), and clinical aspiration [19].

Although a mask system with constant positive airway pressure can often alleviate airway compromise from some structural abnormalities (e.g. obstructive sleep apnoea), compromised airway function, and/or inability to protect the airway often requires placement of an artificial airway (endotracheal tube or tracheostomy). In a large survey of over 5000 patients receiving mechanical ventilation [4], 89% had an oral tracheal tube, 4% had a nasal tracheal tube, and 4.9% had a facial mask. A tracheostomy was present in 2% of the patients. Interestingly, 85 patients with COPD received non-invasive ventilation (NIV) in this survey of whom 22% subsequently required tracheal intubation. One-hundred-and-forty-eight patients with other forms of respiratory failure received NIV and 36.5% subsequently required tracheal intubation.

Unless a need for positive pressure ventilation is required many patients can tolerate an artificial airway for isolated airway issues reasonably well (especially a tracheostomy). However, endotracheal tubes in particular can impose a significant resistive load on inspiratory muscles, especially if narrow (i.e. less than 7 mm internal diameter) and/or partially occluded with secretions [20]. Endotracheal tubes can also be uncomfortable, and require sedation and/or analgesics to assure tolerance. Under these conditions, some mechanically-ventilatory support may be needed to allow patients to tolerate the artificial airway. Often this is a low level of pressure, targeted ventilation (e.g. inspiratory pressure support of 5–10 cmH_2O) with optional back-up rates and PEEP. Some devices offer an automatic tube or airway compensation feedback mechanism that delivers inspiratory pressure support in a pattern designed to specifically unload the calculated resistance loads of the artificial airway. While theoretically appealing, this feedback capability has not as yet been shown to improve clinical outcomes.

Conclusion

Mechanical ventilation is a commonly-used modality in ICUs worldwide. Conceptually, mechanical ventilation is indicated when the patient's ability to ventilate the lung and/or effect gas transport across the alveolar capillary interface is compromised to a point that harm is imminent. In practice, this means addressing one or more of three fundamental pathophysiological processes—loss of proper ventilatory control, ventilatory muscle demand–capability imbalances, and/or loss of alveolar patency. A fourth general indication involves providing a positive pressure assistance to allow tolerance of an artificial airway in the patient unable to maintain a patent, protected airway.

Although some hard and fast thresholds for initiating mechanical ventilation exist (e.g. respiratory arrest, refractory hypoxaemia, severe acidosis from ventilatory muscle failure, inability to protect the airway), the decision to initiate mechanical ventilation usually involves an integrated assessment of the patient. This assessment should include mental status, airway protection capabilities, ventilatory muscle load tolerance, spontaneous ventilatory pattern,

and signs of organ dysfunction from either acidosis, and/or hypoxaemia. This involves a high level of clinical expertise. Providing mechanical ventilatory assistance can be life sustaining; however, it is associated with significant risk and must be applied only when indications justify the risk.

CHAPTER 92

Design and function of mechanical ventilators

Robert L. Chatburn and Eduardo Mireles-Cabodevila

Key points

- A mode of ventilation is a predefined pattern of interaction between the ventilator and the patient.
- There are nearly 300 commercial names for modes of ventilation and no standardized vocabulary nor classification system. There is a great need to distinguish modes based on tags (classifications) instead of names.
- A taxonomy or hierarchical classification system suitable for comparing modes can be based on 10 fundamental concepts described in this chapter.
- The taxonomy based on these concepts allows description of modes in terms of control variable, breath sequence, and targeting schemes.
- Once modes can be classified, their ability to serve the goals of ventilation can be compared and matched appropriately to patient needs. This is analogous to the way drugs are prescribed.

Introduction to ventilator design

A mechanical ventilator is an automatic machine designed to provide all or part of the work required to move gas in and out of the lungs. There is a huge variety of ventilator designs, but no standardized classification system. To understand such a vast subject in such a small chapter requires that we depart from the traditional approach of describing schematics and specific design components (e.g. drive mechanisms, valves, pneumatic circuits, etc.) [1]. Indeed, the internal operations of modern ventilators are largely unknowable and unimportant to most clinicians. What distinguishes ventilators is their range of technological capabilities, expressed mainly by the 'modes of ventilation' they offer. There are nearly 300 commercial names for modes of ventilation and no standardized vocabulary nor classification system. To address this problem, we use a simple taxonomy which is based on the fundamental concepts of pulmonary physiology and ventilator design [2–4]. What follows is a description of this approach. These concepts build on one another to yield a practical taxonomy that may be used to simplify the task of comparing and contrasting the features of ventilators, and ultimately, to select the most appropriate mode for a given clinical situation. This didactic approach is informed by over 30 years of experience teaching mechanical ventilation and the data from an international survey [4]. After describing these 10 concepts, we demonstrate how the resulting taxonomy can be used to guide the selection of modes.

Defining a breath

The most basic function of a ventilator is to deliver a breath. A breath is defined in operational terms using a graph of flow versus time (Fig. 92.1). A breath is defined as one cycle of inspiratory flow followed by a matching expiratory flow, yielding approximately the same volumes. These flows are paired by size, not necessarily by timing. For example, in Airway Pressure Release Ventilation there is a large inspiration (transition from low pressure to high pressure) possibly followed by a few small inspirations and expirations, followed finally by a large expiration (transition from high pressure to low pressure). These inspirations and expirations represent several small spontaneous breaths superimposed on one large mandatory breath. In contrast, during high frequency oscillatory ventilation, small mandatory breaths are superimposed on larger spontaneous breaths.

Ventilators shape the flow waveform using a wide variety of physical systems comprised of a source of high pressure gas (e.g. a compressor), flow control valves, and electronic control systems. A detailed description of these components is beyond the scope of this chapter. However, a generalized schematic of a ventilator is shown in Fig. 92.2. The two most important valves are shown in Fig. 92.3. They are similar in design in that an electronic signal adjusts the position of the actuator such that the orifice diameter changes and thus controls the flow through the valve [5]. They work in synchrony, meaning that during inspiration the output flow control valve opens and the exhalation valve closes, forcing gas into the lungs. During expiration, the output flow control valve closes and the exhalation valve opens, allowing gas to flow from the lungs to the atmosphere. In the case of the output flow control valve, the input source is at high pressure (e.g. 10–20 psi) and the output is adjusted by the targeting scheme software to achieve a desired waveform for either inspiratory flow or inspiratory pressure. In contrast, the exhalation valve operates at patient circuit pressures (<1 psi) and generally controls the end expiratory pressure level, rather than the expiratory flow waveform.

Assisting a breath

The definition of a ventilator implies assistance with the patient's work of breathing. Work is a function of pressure and volume;

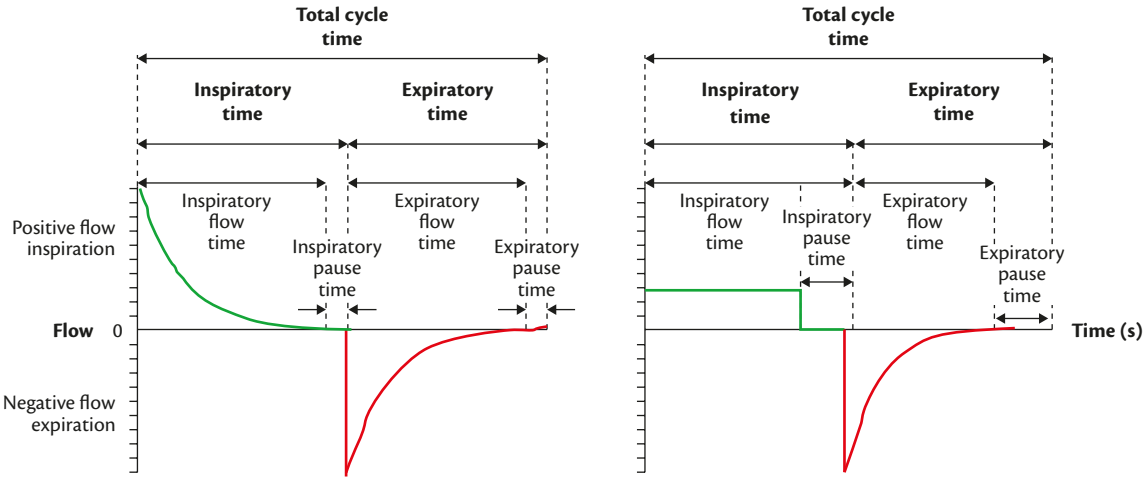

Fig. 92.1 A breath is defined as one cycle of inspiratory flow followed by a matching expiratory flow. (Left) Pressure control ventilation. (Right) Volume control ventilation.

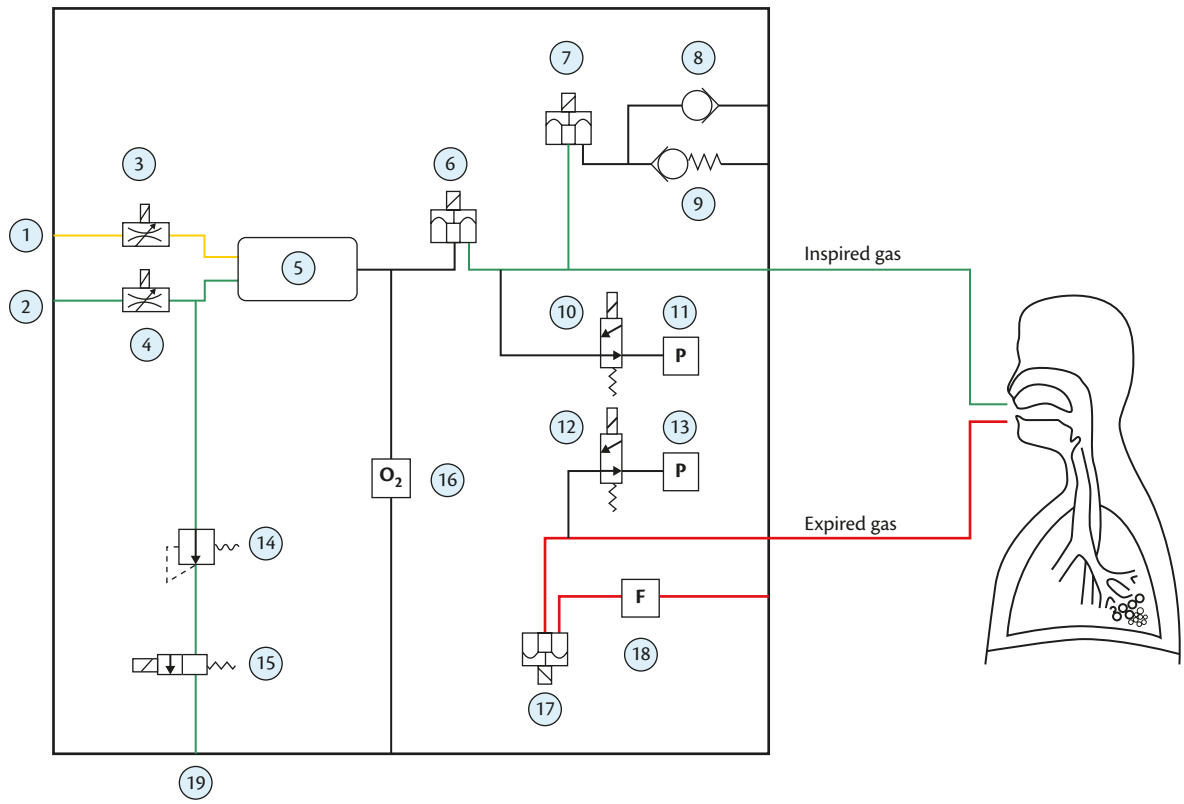

Fig. 92.2 Simplified schematic of a modern intensive care ventilator. High pressure gas enters the ventilator through the gas inlet connections for oxygen and air (1,2). Mixing takes place in a reservoir (5) and is controlled by two valves (3,4). Oxygen content is monitored by an oxygen sensor (16). Inspiratory flow from the reservoir is controlled by a separate inspiratory flow control valve (6). On the inspiratory circuit there is a safety valve (7) and two non-return valves (8,9). In normal operation the safety valve is closed so that inspiratory flow is supplied to the patient's lungs. When the safety valve is open, spontaneous inspiration of atmospheric air is possible through the emergency breathing valve (8). The emergency exhalation valve (9) provides a second channel for expiration when the exhalation valve (17) is blocked. Also on the inspiratory circuit are an inspiratory pressure (P) sensor (11) and a pressure sensor calibration valve (10). The exhalation circuit consists of the exhalation valve (17), expiratory pressure sensor (13) with its calibration valve (12), and an expiratory flow (F) sensor (18). The exhalation valve is a proportional valve and is used to adjust the pressure in the patient circuit. Conversion of mass flow to volume (barometric temperature and pressure saturated, BTPS) requires knowledge of ambient pressure, measured by another pressure sensor. Pressure in the patient circuit is measured with two independent pressure sensors (11,13). Oxygen flow to the nebulizer port (19) is controlled by a pressure regulator (14) and a solenoid valve (15).

either the patient's inspiratory muscles or the ventilator generates an increase in the pressure difference across the lungs (which we will refer to simply as inspiratory pressure; a detailed discussion of the subject is provided in a recent textbook [6]) so that their volume increases during inspiration. In terms of ventilator graphic displays, an assisted inspiration can be recognized as one for which airway pressure rises above baseline (positive end expiratory pressure) during inspiratory flow. On the other hand, if airway pressure drops below baseline pressure during inspiration, the patient is doing some work on the ventilator and the breath is 'loaded', rather than assisted. Some loading is unavoidable for several reasons—ventilators cannot control airway pressure perfectly so pressure always drops a little with patient inspiratory effort, some pressure drop may be necessary for triggering a breath, and the presence of electrical/mechanical delays between sensing a patient effort and the start of inspiratory flow [7].

Assistance with volume control versus pressure control

A ventilator provides assistance either by manipulating inspiratory pressure (called **pressure control**) or by manipulating inspiratory flow (called **volume control**). To understand this, we employ a mathematical model of patient-ventilator interaction known as the equation of motion for the respiratory system[8]:

$$P(t) = EV(t) + R\dot{V}(t) \qquad \text{[eqn 1]}$$

where $P(t)$ is inspiratory pressure generated by the ventilator as a function of time (t), E is respiratory-system elastance, $V(t)$ is volume as a function of time, R is respiratory-system resistance, and $\dot{V}(t)$ is flow as a function of time. This is a simplified version that assumes a passive respiratory system; otherwise patient inspiratory effort is represented as muscle pressure, $Pmus(t)$, on the left side of the equation. The equation indicates that the ventilator can either control the left side of the equation (pressure control, implying preset inspiratory pressure, either as a specific target value or in proportion to patient effort) or the right side (volume control, implying preset tidal volume and inspiratory flow). With pressure control, for a given pressure waveform, the inspired volume and flow are functions of elastance, resistance, and time. In contrast, with volume control, for a given flow waveform, inspiratory pressure is a function of elastance, resistance, and time. Idealized waveforms for volume and pressure control are shown in Fig. 92.4.

For completeness, we mention the case where neither pressure nor volume are controlled and the only preset values are inspiratory and expiratory times. This case is called **time control** and while rare, does exist in the modes called High Frequency Oscillatory Ventilation and Intrapulmonary Percussive Ventilation.

Starting and stopping inspiration

To assist a breath, the ventilator must know when to start and stop the inspiratory time (see Fig. 92.1). It does this by monitoring one or more variables and taking action when a preset threshold value is met. Starting inspiration is called **triggering**. Common trigger variables include time, airway pressure or flow change and the electrical signal from the diaphragm. Stopping inspiration is called **cycling**. Common cycle variables are the same as for triggering. The amount that the trigger or cycle variables must change before triggering or cycling occurs is called trigger or cycle **sensitivity**.

Machine versus patient triggering and cycling

Machine triggering or cycling is the initiation or termination of inspiratory flow, independent of the patient determined components of the equation of motion, i.e. *Pmus* (effort), elastance, or resistance. Common examples of machine trigger variables are preset frequency and minimum minute ventilation. Common examples of machine cycling variables are preset inspiratory

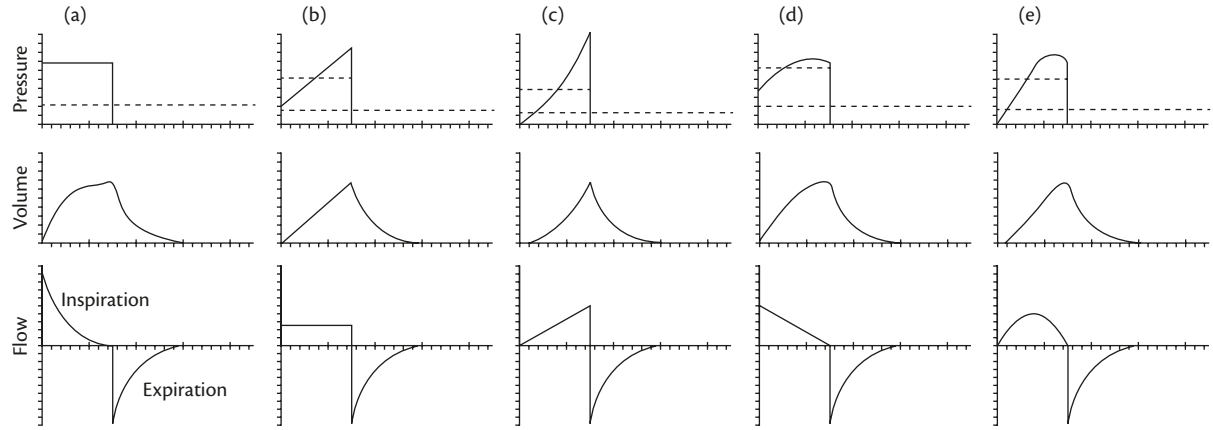

Fig. 92.4 Idealized ventilator output waveforms. (a) Pressure-controlled inspiration with a rectangular pressure waveform. (b) Volume-controlled inspiration with a rectangular flow waveform. (c) Volume-controlled inspiration with an ascending-ramp flow waveform. (d) Volume-controlled inspiration with a descending-ramp flow waveform. (e) Volume-controlled inspiration with a sinusoidal flow waveform. The short dashed lines represent mean inspiratory pressure, and the long dashed lines represent mean pressure for the complete respiratory cycle (i.e. mean airway pressure). Note that mean inspiratory pressure is the same as the pressure limit in (A). These waveforms were created as follows: (1) defining the control waveform using a mathematical equation (e.g. an ascending-ramp flow waveform is specified as flow = constant × time); (2) specifying the tidal volume for flow- and volume-control waveforms; (3) specifying the resistance and compliance; (4) substituting the preceding information into the equation of motion for the respiratory system; and (5) using a computer to solve the equation for the unknown variables and plotting the results against time.

Courtesy of Mandu Press Ltd., Cleveland Heights, Ohio.

time and tidal volume. Patient triggering or cycling is the initiation or termination inspiratory flow based on one of the patient determined components of the equation of motion, i.e. *Pmus*, elastance, or resistance. Common examples of patient trigger variables are airway pressure drop below baseline and inspiratory flow due to patient effort. Common examples of cycling variables are peak inspiratory pressure and percentage of peak inspiratory flow. A detailed description of trigger and cycle variables has been presented elsewhere [9].

Mandatory versus spontaneous breaths

A **spontaneous** breath is one for which the patient **both** initiates and terminates inspiration, independent of machine settings, e.g. inspiratory time. Thus, the patient both triggers and cycles inspiration. If the machine triggers or cycles inspiration, the breath is defined as **mandatory**.

Breath sequences

There are only two classes of breaths—mandatory and spontaneous—which can be combined in only three basic sequences. If every breath is spontaneous, we call the sequence continuous spontaneous ventilation (CSV). If spontaneous breaths may exist between mandatory breaths (whether or not they actually happen) we call the sequence intermittent mandatory ventilation (IMV). Finally, if spontaneous breaths are not permitted between mandatory breaths, we call the sequence continuous mandatory ventilation (CMV).

Ventilatory patterns

Combining the concepts of control variable and breath sequence, we can construct a simple means for classifying modes of ventilation. With two main control variables and three possible breath sequences, there are only five basic ventilatory patterns: volume control continuous mandatory ventilation (VC-CMV), volume control intermittent mandatory ventilation (VC-IMV), pressure control continuous mandatory ventilation (PC-CMV), pressure control intermittent mandatory ventilation (PC-IMV), and pressure control continuous spontaneous ventilation (PC-CSV). Volume control continuous spontaneous ventilation (VC-CSV) is not valid because presetting the tidal volume implies machine cycling, which makes spontaneous breaths impossible.

Again, for completeness we note the rare case of time control intermittent mandatory ventilation (TC-IMV) is a ventilatory pattern that describes High Frequency Oscillatory Ventilation and Intrapulmonary Percussive Ventilation.

Targeting schemes

Ventilatory patterns can be used to sort the large number of mode names into just a few categories. This is very useful for many purposes, but when it becomes necessary to distinguish among modes within the same category, we need to consider the underlying feedback control or targeting schemes used to create the mode. We define a targeting scheme as a model of the relationship between operator inputs and ventilator outputs to achieve a specific ventilatory pattern. Targeting schemes are being developed all the time, but currently, there are only seven that are used for most commercially available ventilators [10]. These targeting schemes are described in Table 92.1.

A taxonomy for modes of ventilation

A **mode of ventilation** may be generally defined a predetermined pattern of interaction between the ventilator and the patient [3]. Referring to a mode using the name coined by the manufacturer has become problematic with the proliferation of new modes. The solution is a hierarchical classification system, a taxonomy that allows us to describe and compare modes at any level of detail. The previous

Table 92.1 Explanation of how targeting schemes transform operator inputs into ventilator outputs

Name	Description	Advantage	Disadvantage	Example mode name	Ventilator	Manufacturer
Set-point	The operator sets all parameters of the pressure waveform (pressure control modes) or volume and flow waveforms (volume control modes)	Simplicity	Changing patient condition may make settings inappropriate	Volume Control Continuous Mandatory Ventilation	Evita Infinity 500	Dräger
Dual	The ventilator can automatically switch between volume control and pressure control during a single inspiration	Can adjust to changing patient condition and assure either a preset tidal volume or peak inspiratory pressure, whichever is deemed most important	May be complicated to set correctly and may need constant readjustment if not automatically controlled by the ventilator	Volume Control	Servo-i	Maquet
Servo	The output of the ventilator (pressure/volume/flow) automatically follows a varying input	Support by the ventilator is proportional to inspiratory effort	Requires estimates of artificial airway and/or respiratory system mechanical properties	Proportional Assist Ventilation Plus	PB 840	Covidien
Adaptive	The ventilator automatically sets target(s) between breaths in response to varying patient conditions	Can maintain stable tidal volume delivery with pressure control for changing lung mechanics or patient inspiratory effort	Automatic adjustment may be inappropriate if algorithm assumptions are violated or they do not match physiology	Pressure Regulated Volume Control	Servo-i	Maquet
Bio-variable	The ventilator automatically adjusts the inspiratory pressure or tidal volume randomly	Simulates the variability observed during normal breathing	Manually set range of variability may be inappropriate to achieve goals	Variable Pressure Support	Evita Infinity 500	Dräger
Optimal	The ventilator automatically adjusts the targets of the ventilatory pattern to either minimize or maximize some overall performance characteristic (e.g. work rate of breathing)	Can adjust to changing lung mechanics or patient inspiratory effort	Automatic adjustment may be inappropriate if algorithm assumptions are violated or they do not match physiology	Adaptive Support Ventilation	G5	Hamilton Medical
Intelligent	Targeting scheme that uses artificial intelligence programs such as fuzzy logic, rule based expert systems, and artificial neural networks	Can adjust to changing lung mechanics or patient inspiratory effort	Automatic adjustment may be inappropriate if algorithm assumptions are violated or they do not match physiology	IntelliVent ASV	G5	Hamilton Medical

nine theoretical constructs support a practical taxonomy to achieve these goals [11–16]. The taxonomy has four levels as follows:

1. Control variable (pressure or volume).
   A. Breath sequence (CMV, IMV, or CSV).
      i. Primary breath targeting scheme.
         a. Secondary breath targeting scheme (only for IMV).

In CMV and CSV there is only one type of breath; mandatory for CMV and spontaneous for CSV. We refer to those breaths as primary breaths when specifying their targeting schemes. For IMV we will consider mandatory breaths primary and spontaneous breaths secondary. An example of how this taxonomy can be used to compare the modes of two common intensive care ventilators is shown in Table 92.2. This table illustrates two very important points. First, modes that are essentially the same or very similar are given very

Table 92.2 Classification of mode names on two common intensive care ventilators

different names by manufacturers and, secondly, because of this, modes are most practically compared using their **tags** (taxonomic attribute groupings), rather than by their **names** or ad hoc pseudo-classifications (e.g., VC-CMV is often referred to as 'assist/control' in the adult literature, but it means PC-CMV in the paediatric literature).

breath sequence. Table 92.1 provides the information necessary for identifying targeting schemes.

Comparing modes

The previous section provides a means for identifying modes. This is useful to clinicians, educators, researchers, and manufacturers alike. However, clinicians are faced with the task of not only identifying modes, but comparing them and selecting the one that best serves the needs of the patient. Yet, trying to compare modes by simply reading the operator's manuals is impractical. We propose an approach that first identifies the general goals of patient care and then matches them to specific technological capabilities of the available modes [14]. First, we assert that there are only three main goals of mechanical ventilation, safety (optimizing both gas exchange, and the risk of ventilator associated lung injury Fig. 92.7), comfort (optimizing synchrony between patient and ventilator Fig. 92.8), and liberation (optimizing the duration of mechanical ventilation Fig. 92.9) [10]. Next we realize that these general goals and their specific objectives lead naturally to clinical aims for individual patients. Once the patient's needs are assessed, treatment options in terms of mechanical ventilation modes can be identified using the general technical capabilities of ventilators and design features of specific modes.

In Table 92.3, we have identified the technological capabilities of currently available targeting schemes (Table 92.1) and grouped them according to the three goals of ventilation. Then we have listed the mode names from Table 92.2 and noted which

technological capabilities they offer. Note that some columns have no check marks because they represent capabilities of modes on other ventilators.

Conclusion

In this chapter we introduce a new approach to understanding the design and function of mechanical ventilators. These devices have become so complex that a formal classification system (taxonomy) is required to compare and contrast treatment options. We have shown how such a taxonomy can be constructed from 10 fundamental maxims of ventilator design. Finally, we have demonstrated how a formal description of ventilator technology can be used to match specific patient needs identified from clinical assessment to particular mode capabilities. This approach highlights the requirement for a thorough patient evaluation, identification of the goals of care and an understanding of ventilator technology.

CHAPTER 93

Setting rate, volume, and time in ventilatory support

Charles M. Oliver and S. Ramani Moonesinghe

Key points

- Ventilator rate, volume, and time parameters are interrelated directly, mechanically, and physiologically.
- The physiological consequences of mechanical ventilation and risks of ventilator-induced trauma may be exacerbated by lung pathology.
- Programming of parameters should be considered within the context of an individualized ventilation strategy to achieve adequate gas exchange, while minimizing attendant risks of mechanical ventilation.
- Recommended strategies should be modified within accepted limits to mitigate disease-specific risks.
- Parameters should subsequently be titrated against blood gas- and ventilator-derived targets and other clinical variables.

Introduction

While mechanical ventilation (MV) remains a cornerstone of critical care practice, understanding of its optimal usage continues to evolve. Striving for proposed physiological ideals has given way to strategies targeting more modest PaO_2, $PaCO_2$, and pH values, thereby reducing risks of volutrauma, barotrauma, atelectrauma, and bio-trauma, which may exacerbate or perpetuate lung injury [1,2].

Interactions between intrinsic pulmonary physiomechanics, pathological processes, and the effects of positive pressure ventilation are complex. Programming of ventilator parameters must therefore be considered within the context of an individualized ventilation strategy in order to achieve gas exchange targets, while minimizing the attendant risks of MV.

Rate, volume, and time

Rate, volume, and time parameters are interrelated directly, physiologically, and mechanically.

Minute ventilation ($\tilde{V}_{min}$) is the gas flow per minute, which is calculated as the product of the inspiratory volume, or tidal volume (V_T) and the ventilatory rate. V_T and rate are readily amenable to manipulation, and may be titrated to biochemical and physiological targets in MV.

Programming of absolute duration of inspiratory and expiratory phases of ventilation, and their ratio is necessarily limited by ventilatory rate. Furthermore, setting inspiratory time in volume-targeted modes may limit the magnitude of delivered gas flow and result in excessive system pressures. Disease-specific factors must be considered when setting expiratory time.

MV may be broadly classified as mandatory, assisted, or a combination. Rate, volume, and time values must be selected in mandatory modes, although this may be performed automatically. Spontaneous inspiration is augmented to a target pressure or volume in assisted modes and a back-up rate may be set to provide additional ventilator-delivered breaths. The duration of inspiration and expiration may be programmed in both mandatory and assisted modes.

Rate

In conventional mandatory ventilation a rate of 10–20 breaths/min will usually provide a $\tilde{V}_{min}$ sufficient to create and maintain favourable partial pressure gradients across alveolar membranes. Higher rates may be indicated in certain disease states and are routinely selected for children, infants, and neonates. Rates in excess of three times the physiological range are used in high frequency ventilation, and lower rates may be programmed for ventilator weaning and in individuals susceptible to gas-trapping.

Provided V_T remains constant, increasing ventilatory rate will increase alveolar ventilation, which may be beneficial. However, in addition to its additive role in ventilator-induced lung injury (VILI) [3], increasing ventilatory rate limits inspiratory and expiratory times, which may worsen gas exchange and predispose to complications in susceptible individuals as discussed in 'Targets in Pathophysiological States'.

Volume

Of the generated inspiratory volume (V_T), a proportion is unavailable for gas exchange. This 'dead space' volume comprises physiological (conducting airways and alveoli at which no gas exchange occurs) and apparatus dead space. While the former is relatively fixed, the latter should be minimized to optimize ventilatory efficiency. The flow of fresh gas ($\tilde{V}_A$) available for exchange in the alveolar compartment is therefore the product of ventilatory rate and what remains of V_T once dead space volume is accounted for:

$$\tilde{V}_A = r.\left[V_T - \left(V_D + V_{APP}\right)\right] \quad \text{[eqn 1]}$$

where $\tilde{V}_A$ is alveolar ventilation, r is rate, V_T is tidal volume, V_D is physiological dead space volume, and V_{APP}, apparatus dead space volume.

Provided alveolar perfusion matches ventilation, oxygenation and CO_2 elimination may be improved by increasing alveolar ventilation relative to dead space ventilation. It should, however, be noted that simply increasing rate will lead to a proportionally greater increase in dead space ventilation relative to $\tilde{V}_A$.

Tidal volume may be increased in positive pressure ventilation (PPV) by increasing generated inspiratory pressure with due attention to rate and time variables; however, the volume delivered is also dependent upon system compliance. Pathological processes resulting in differential regional compliance may cause asymmetrical distribution of gas flow and pressure inequalities in affected individuals. Such changes predispose to dynamic hyperinflation, over-distension of alveoli in more compliant lung units and exaggeration of physiological gas flow:perfusion ($\tilde{V}_A$:Q) mismatching.

Evidence of the potential harm caused by exposure to MV comes from studies of the pathogenesis of VILI and the acute respiratory distress syndrome (ARDS). While the aetiology of ARDS is likely to involve synergy between pulmonary insult and MV in predisposed individuals [4,5], VILI may develop in previously normal lungs in as little as 6hours [4,6,7]. Demonstrated associations include exposure to high end-inspiratory lung volumes (volutrauma) [8], shear stress resulting from cyclical inflation and deflation of differently compliant lung units (atelectrauma), and large transpulmonary pressure gradients [9].

Data from ARDS trials suggest that limitation of V_T to 4–8 mL/kg ideal body weight (IBW) [10,11] and limitation of plateau pressure (a surrogate for transpulmonary pressure) to less than 30–35 cmH_2O [10] may decrease early morbidity and mortality in affected individuals. However, due to increasing evidence of the potentially deleterious effects of high inflationary pressures and inspiratory volumes, such lung protective strategies are increasingly being adopted in the management of patients with previously normal lungs [12]. Targets include V_T 6–8 mL/kg IBW [13,14] and limitation of plateau pressure (P_{PLAT}) to 30 cmH_2O [12].

As can be seen from eqn 1, the limitation of V_T and P_{PLAT} without compensatory increase in rate may result in hypercapnoea in poorly compliant lungs. It may therefore be necessary to accept supraphysiological $PaCO_2$ or institute an alternative means of CO_2 removal.

Additional strategies to aid improved ventilation include the manipulation of time, rate, and mode variables to limit airway pressures and improve flow distribution, titration of positive end expiratory pressure (PEEP) to limit atelectrauma [15] and shunt, patient repositioning, and pharmacological agents.

Time variables

Time variables, which may be individually programmed or automatically determined include duration of inspiration and expiration and their ratio (I:E ratio). These variables are interdependent and limited by ventilatory rate; furthermore, their manipulation may predispose to complications.

To permit theoretical modelling, groups of alveoli and their terminal airways possessing similar mechanical characteristics are termed 'lung units'. The time required to fully inflate or deflate such units is determined by both compliance and resistance to flow, the product of which, the time constant (τ), determines the speed with which alveolar and proximal airway pressures reach equilibrium.

Many disease processes affect lung tissue mechanics and thus inspiratory (τ_i) and expiratory (τ_e) time constants, but because such changes are rarely homogenous, regional flow pattern variations occur. Lung units with low τ_i tend to fill quickly with a subsequent distribution of flow to more distensible units with greater resistance. PPV may therefore cause over-distension of compliant units and subsequent collapse of compressed units in a variety of pathologies, predisposing to complications and exaggerating $\tilde{V}_A$:Q mismatching.

Time variables may be controlled in both mandatory and assisted modes of ventilation; however, it is imperative to ensure synchrony with spontaneous effort to reduce distress, work of breathing, and breath stacking. Time variables must therefore be considered both individually and as components of an individualized strategy.

Inspiratory time

Inspiratory time (t_i) is the duration over which pressure is applied in PPV to deliver V_T and is typically set at 1 second when respiratory rate is 20 breaths/minute. Any increase in t_i occurs at the expense of expiratory time (t_e), unless rate is reduced to compensate.

Increasing t_i may improve oxygenation by permitting equilibration of pressure between differently compliant lung regions, increasing mean airway pressures, and preventing atelectasis. Reducing t_i predisposes to the complications of increased flow and system pressures in volume-controlled modes [8].

Expiratory time

Expiratory time (t_e) is typically set at 2 seconds when rate is 20 breaths/minute, and may only be maintained or increased at the expense of t_i at higher rates.

Pressures generated in PPV may be sufficient to overcome increased airway resistance and distend alveoli, but exhalation is passive and diminished if tissue elasticity is reduced. Conditions in which highly compliant alveoli empty into bronchioles with increased resistance to flow, such as chronic obstructive pulmonary disease (COPD), therefore require a longer t_e to permit lung unit emptying. If t_e is insufficient to permit emptying prior to inspiratory cycling, gas trapping and the generation of intrinsic PEEP ($PEEP_i$) may occur, with both respiratory and haemodynamic consequences.

I:E ratio

This is usually set at 1:1 to 1:2, but ratios of 1:2 to 1:4 may be required to prevent dynamic hyperinflation in severe airflow limitation. Awake patients may be more comfortable with shorter inspiratory times and high inspiratory flow rates.

Inverse ratio ventilation (IRV), in which t_i exceeds t_e, may be employed if adequate oxygenation cannot be achieved by increasing PEEP. It is thought that increased mean airway pressures and improved filling of lung units with high τ_i are responsible for its effects. Caution should be exercised in using IRV in patients with airflow limitation to avoid generation of $PEEP_i$.

Proposed benefits of IRV include:

- Reduced shunt due to prevention and resolution of atelectasis.
- Increased efficiency of CO_2 elimination due to delayed lung unit emptying.
- Lower V_T and transpulmonary pressures due to reduced $\tilde{V}_{min}$.

Suggested strategy

- Following a thorough clinical assessment, consider first whether lung physiomechanics are likely to be normal.

Table 93.1 Targets in the absence of overt pulmonary pathology

Rate	10–20 breaths/min
V_T	6–8 mL/kg IBW
I:E	1:2
P_{PLAT}	<30 cmH_2O

- Targets in the absence of overt pulmonary pathology are shown in Table 93.1.
- Adjust parameters in response to clinical examination, blood gas analysis, and monitoring. Recruitment manoeuvres may be required, particularly if a period of hypoventilation precedes institution of MV.

PaO_2 may be optimized by adjusting $\tilde{V}_{min}$, I:E ratio, PEEP, and FIO_2. Normocapnoea should not be pursued at the expense of exceeding pressure limits, unless there is urgent indication to do so. Development of a respiratory acidosis (pH < 7.25) should prompt reconsideration of pathology, mode of ventilation, and alternative methods of CO_2 removal.

Targets in pathophysiological states

Modify the parameters shown in the previous section considering predominant manifestations of pulmonary disease.

Airflow limitation

Narrowing of medium- and small-calibre airways significantly increases resistance to gas flow, disrupting regional and global pressure-flow relationships, and variably increasing time constants. Injudicious PPV programming in such individuals may result in volume redistribution, alveolar over-distension, and ventilator trauma.

Dynamic hyperinflation due to insufficient t_e and unfavourable I:E ratios exacerbates $\tilde{V}_A$/Q mismatching, and further increases the risk of trauma. $PEEP_i$ estimation may be necessary to avoid acute deterioration.

Restrictive lung disease

In the absence of significant airflow limitation, low compliance results in reduced τ. Affected lung units fill quickly, with rapid gas flow redistribution, $\tilde{V}_A$/Q mismatching and over-distension of relatively unaffected units. Attention to volume and pressure settings may mitigate risk of trauma in such individuals.

Emphysema

The characteristic destruction of lung parenchyma and diminishment of elastic recoil results in markedly increased compliance of affected tissue. Because tissue damage is patchy, with changes characteristic of causative agents and disease processes, affected units are slow to open and prone to over-distension. A low rate with long t_i and t_e should be set to permit filling and emptying of slower units, and P_{PLAT} limited to prevent trauma.

COPD

Because emphysematous changes co-exist with airflow limitation in COPD, both τ_i and τ_e may be significantly prolonged. A low rate and prolonged expiratory phase (I:E ratio 1:2.5 or 3.0) may allow for slow changes in airway flows and prevent gas trapping. Airway pressures must be limited to prevent over-distention and the potential for rupture of bullae.

ARDS

ARDS is characterized by absolute volume loss with decreased total system compliance [16], but pathological changes are not evenly distributed and even targeting tidal volumes of 6–8 mL/kg may over-distend aerated lung units and exacerbate shunt through compression atelectasis.

Optimal ventilatory strategies in ALI and ARDS remain the subject of debate, with some advocating bedside quantification of injured and healthy lung volumes in order to permit individualization of V_T targets and the limitation of regional distending pressures [17]. The weight of evidence supports limitation of V_T to 4–8 mL/kg IBW [10,11] and plateau pressure to less than 30–35 cmH_2O [10] as the least deleterious strategy.

CHAPTER 94

Respiratory support with positive end-expiratory pressure

Ignacio Martin-Loeches and Antonio Artigas

Key points

- Positive end-expiratory pressure (PEEP) is usually one of the first ventilator settings chosen when mechanical ventilation (MV) is initiated.
- A sufficient level of PEEP is necessary to prevent alveolar derecruitment, without developing alveolar overdistension, dead space ventilation, and hypotension.
- The ideal level of PEEP is that which prevents derecruitment of the majority of alveoli, while causing minimal overdistension.
- The level of PEEP should be individualized and higher PEEP might be used in the more severe end of the spectrum of patients (acute respiratory distress syndrome) with improved survival.
- A survival benefit for higher levels of PEEP has not been yet reported for any patient under MV but a higher PaO_2/FiO_2 ratio seems to be better in the higher PEEP group.

Introduction

Positive end-expiratory pressure (PEEP) is the pressure present in the airway (alveolar pressure) above atmospheric pressure that exists at the end of expiration. The term PEEP is defined in two particular settings. Extrinsic PEEP (PEEP applied by a ventilator) and intrinsic PEEP (PEEP caused by a non-complete exhalation that causes progressive air trapping). Applied (Extrinsic) PEEP—is usually one of the first ventilator settings chosen when mechanical ventilation (MV) is initiated. The application of PEEP has two primary purposes:

- To increase lung volume in patients who have acute lung restriction in order to improve arterial oxygenation by recruiting or stabilizing alveolar units, and to protect the alveoli against injury during phasic opening and closing of atelectatic units that produces hypoxaemia;
- To reduce the effort required for patients to trigger the ventilator or breathe spontaneously in the presence of dynamic hyperinflation and auto-PEEP.

It is important to consider that lung recruitment occurs during inspiration and PEEP is applied during expiration in order to maintain the alveolar units opened.

Physiological effects of PEEP

Applying PEEP increases alveolar pressure and alveolar volume. The increased lung volume increases the surface area by reopening and stabilizing collapsed or unstable alveoli. PEEP therapy can be effective when used in patients with a diffuse lung disease with a decrease in functional residual capacity (FRC). FRC is determined by primarily the elastic characteristics of the lung and chest wall, and in pulmonary diseases, such as ARDS, reduced because of the collapse of the unstable alveoli. Opening the alveoli with positive pressure improves the ventilation–perfusion match. After the shunt effect is modified to a ventilation–perfusion mismatch with PEEP (unoxygenated blood returning to the left side of the heart), lowered concentrations of oxygen can be used to maintain an adequate PaO_2. PEEP therapy may also be effective in improving lung compliance [1].

Lung protection ventilation is an established strategy of management to reduce and avoid ventilator induced lung injury and mortality. Levels of PEEP have been traditionally used from 5 to 12 cmH_2O; however, higher levels of PEEP have also been proposed and updated in order to keep alveoli open, without the cyclical opening and closing of lung units (atelectrauma). Several studies have evaluated the effect of modest versus high levels of PEEP in patients with and acute respiratory distress syndrome (ARDS) [2]. A survival benefit for higher levels of PEEP has not been yet reported for any patient under MV, but a higher PaO_2/FiO_2 ratio seems to be better in the higher PEEP group. In addition, higher levels of PEEP have been associated with improved survival (about 10%) among the subgroup of patients with ARDS.

How to set the PEEP

The ideal level of PEEP is often difficult to set but in general is that which the majority of lung units are set in order to maximize gas exchange and minimize over-distension. The main goal is to titrate the optimal level of PEEP defined as the level of PEEP that allows the lowest FiO_2 with an adequate level of oxygenation and avoiding complications induced by the level of PEEP. The National Heart, Lung, and Blood Institute ARDS Clinical Trials Network have proposed to set individualized PEEP using a table that correlates the level of FiO_2 and PEEP based on the oxygenation (Table 94.1) [3]. Titrating PEEP according to the ARDS Net PEEP-FiO_2 ladder is strongly recommended. The benefit of PEEP might depend on the

potential for alveolar recruitment. If the potential of recruitment is low, an increase in PEEP will not result in a beneficial effect on oxygenation with an accompanying higher risk for ventilator-induced lung injury, increased dead space that might potentially result in redistribution of pulmonary blood flow to non-ventilated regions of the lungs. If the increase of PEEP improves alveolar recruitment, the strain (distribution of pressure) might be reduced.

The potential for recruitment can be identified by the use of a 'PEEP trial'. In a 'PEEP trial', the PEEP is progressively increased. Ideally, only one variable—the amount of PEEP—is altered during the trial, with V_T, fraction of inspired oxygen (FiO_2), body position, and other factors that might affect oxygenation unchanged. An assessment for both favourable and adverse PEEP effects should be made at each level as PEEP increased. As the condition of the patient may change over time, to determine the effects of PEEP most clearly the intervals at each level must be kept short. When the increase of PEEP is associated with an improvement of PaO_2 and compliance and a decrease of PCO_2, an alveolar recruitment is expected. Conversely, if the alveolar recruitment is not achieved, there is a minimal improvement of oxygenation by an increase in dead space. The PEEP trial should be performed in a systematic manner whenever feasible [4].

It has been hypothesized that the level of PEEP can be determined by identifying pressure–volume (P–V) curve inflection points. Acquiring a dynamic curve presents the key to the curve's bedside application. The lower inflection point (LIP) on the total respiratory system P–V curve is widely used to set PEEP in patients with acute respiratory failure (ARF) on the assumption that LIP represents alveolar recruitment However, it is becoming widely accepted that the upper inflection point (UIP) of the deflation limb of the P–V curve represents the point of optimal PEEP (Fig. 94.1). New methods used to identify optimal PEEP, including computed tomography (CT), transthoracic lung ultrasound (LUS) and active compliance measurements, are currently being investigated. Using CT, it is possible to assess the pulmonary distribution of the increase in gas volume resulting from tidal ventilation and PEEP and to separate PEEP-induced lung overdistension from alveolar recruitment. In the mid-1990s, Gattinoni et al. [5] measured PEEP-induced alveolar recruitment on a single junta-diaphragmatic CT section by quantifying the decrease in non-aerated lung parenchyma characterized by CT attenuations ranging between −100 and +100 Hounsfield units (HU). In spite of the reference method for assessing PEEP-induced lung recruitment is lung CT, it is an important source of radiation, requires

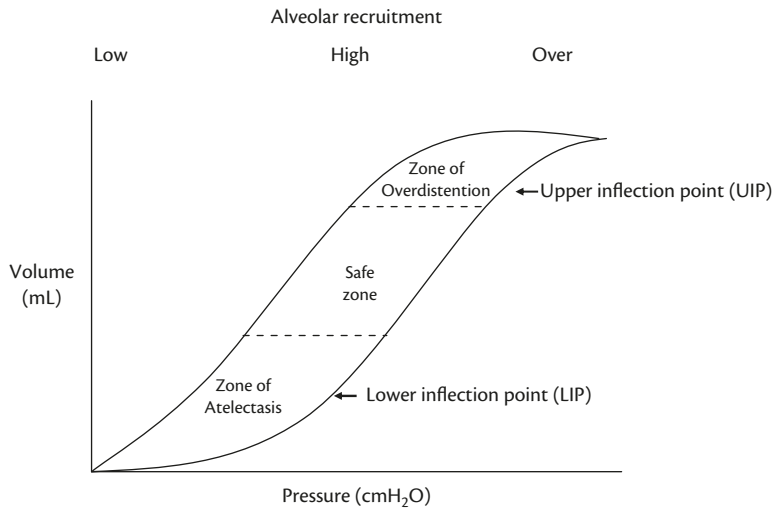

Fig. 94.1 The hysteresis of the pressure–volume curve of the lung. On inflation limb lungs need higher pressures to inflate than on deflation. On deflation limb, the higher lung volume can be maintained on lower pressure. Thus, once the lung is open it is more compliant. At the lower inflection point the lung opens up, compliance improves, and at the upper inflection point optimal lung volume is achieved. At over inflation, compliance decreases and lung injury occurs. The upper inflection point of the deflation limb of the P–V curve represents the point of optimal PEEP.

transporting an often unstable and hypoxaemic patient outside the ICU with a time-consuming analysis of data. Other considerations such as the stress index and the measurement of oesophageal pressure have been recently proposed to assess the level of PEEP to avoid overdistension.

Finally, some considerations on how to set the PEEP should be taken into account in patients with acute respiratory failure (ARF) due to acute exacerbation of chronic obstructive pulmonary disease (COPD). The application of low levels of PEEP can result useful in order to reduce the magnitude of the inspiratory effort during assisted MV (or pressure support) and weaning, and therefore intrinsic PEEP. The application of PEEP in COPD patients requires close monitoring of the end-expiratory lung volume by inspection of flow/volume curves during application of increasing levels of PEEP. The presence of dynamic hyperinflation and expiratory flow limitation can be suspected based on the shape of the expiratory limb of the flow/volume curve (Fig. 94.1).

Haemodynamic effects of PEEP

Based on a better understanding of heart and lung interactions, lung overdistension (with the consequent effect on the pulmonary circulation and thus on the right ventricle) might be present with the application of excessive tension and deformation of the lung tissues (Table 94.2). These effects are determined in part by the stress (transpulmonary pressure) and strain (ratio tidal volume and FRC) applied to about 480 million of alveoli and 30,000 cycles/days. The vast majority of the studies that found an inverse relationship between high levels of PEEP and RV function were conducted before the studies that proposed to limit the tidal volume in the patients with ARDS and therefore these patients were ventilated with tidal volumes higher than 10 mL/kg ideal body weight.

As end-expiratory, end-inspiratory, and mean airway pressures are all increased in the presence of PEEP, PEEP induces an increase in the intrathoracic pressure with several hemodynamic effects [6]. Despite extensive investigation, the effect of PEEP on human cardiac physiology is complex, unpredictable, and has not been totally defined. It may also elevate mean systemic pressure (PMS), the static circulatory filling pressure that is the upstream pressure for venous return. A PEEP level of less than 10 cmH_2O rarely causes haemodynamic problems in the absence of intravascular volume depletion. The cardiodepressant effects of PEEP are often minimized with judicious intravascular volume support or cardiac inotropic support. Although peak pressure is related to the development of barotrauma, arterial hypotension is related to the mean airway pressure that may decrease venous return to the heart or decrease right ventricular function.

Except from the failing ventricle, PEEP usually decreases cardiac output. It is important to understand certain aspects of cardiac physiology to appreciate the effect of PEEP in cardiac output. Cardiac output is the product of heart rate and left ventricular stroke volume. In most pathophysiological states, stroke volume is the major determinant of cardiac output, while heart rate changes reflexively in response to changes in stroke volume. Stroke volume is influenced by four major factors:

- Diastolic ventricular filling, termed preload.
- Ventricular distensibility or compliance.
- Ventricular contractility.
- Ventricular afterload.

Preload and ventricular distensibility influence stroke volume by their effects on the heart during diastole, while contractility and afterload influence stroke volume during systole. At least three factors probably contribute to the decrease in cardiac output produced by PEEP decreased venous return (right ventricular filling), increased right ventricular afterload (regional or generalized lung overdistention can also stretch pulmonary vessels, which reduces their calibre and increases pulmonary vascular resistance) and decreased left ventricular distensibility (Fig. 94.2).

Decreasing PEEP

If PEEP is reduced prematurely, some alveoli may remain sufficiently unstable to collapse, which worsens oxygenation. If this happens, PEEP higher than the previous baseline level may be required to reopen the collapsed alveoli and, conceivably, the patient's requirement for MV may be unnecessarily prolonged.

Bacterial effects

The alveolar opening achieved with PEEP is likely to be responsible for this reduction in pneumonia risk, although the precise mechanism is unknown. PEEP is protective against pulmonary micro-aspiration by a protective counterbalance pressure. Various experimental studies have confirmed lower bacterial growth and a lower incidence of bacteraemia with strategies to maintain alveolar opening and reduce atelectasis after intratracheal instillation of bacteria into bronchial tree. The early application of PEEP in the non-hypoxaemic ventilated patients would stabilize the alveoli and can contribute to reducing the bacterial burden, and therefore the incidence of early-onset VAP.

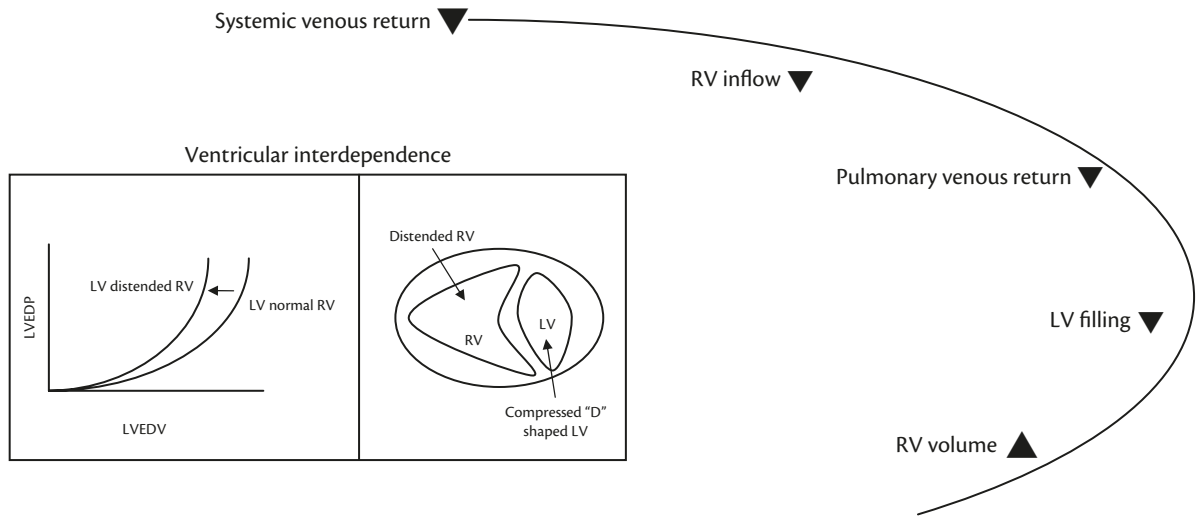

Fig. 94.2 Effect of positive end-expiratory pressure (PEEP) on left ventricular (LV) filling. See text.
Abbreviation: LVEDV, left ventricular end-systolic volume.

Hormonal effects

PEEP induces a rapid and intense antidiuresis with fall in fractional excretion of sodium (FE Na^+), whereas negative pressure breathing is associated with increased urinary flow. As discussed before, PEEP has haemodynamic effects, but also leads to indirect cardiovascular reflex activation or deactivation of high and low pressure baroreflexes, and to vasoactive hormonal release of antidiuretic hormone (ADH), renin, and norepinephrine.

Contraindications

There are no absolute contraindications to applied PEEP. However, applied PEEP can have adverse consequences (especially at high levels) and should be used cautiously in patients with unilateral lung disease, obstructive lung disease (without the presence of expiratory flow limitation), elevated peak and mean airway pressures, bronchopleural fistulae, hypovolaemia, elevated intracranial pressure, and pulmonary embolism (PEEP can worsen hypoxaemia in pulmonary embolism when adjacent unobstructed pulmonary vessels become compressed).

Complications

A classic paradigm of MV is that the systemic hypotension induced ventilation failure to produce the right ventricle (RV), and that this associated with high pressure and mainly with the use of PEEP. This paradigm comes from classical studies in which objective a progressive elevation of PEEP is associated with a progressive increase in central venous pressure and a fall in blood pressure. Thus, in clinical practice, it is common to have episodes of hypotension in a mechanically-ventilated patient. Between the responses are initial therapeutic volume expansion, initiation, or dose increase of inotropic agents, the reduction in the dose of sedatives and also the descent PEEP level with the intention of reducing the pressure intrathoracic. The possibility of right ventricular failure due to pulmonary hypertension, with a drop in systemic blood pressure related to the elevation of PEEP, is mainly produced in many situations with other conditions, such as hypovolaemia, the appearance of comorbid conditions that decrease the compliance lung (increased intra-abdominal pressure, restrictive lung disease, presence of auto-PEEP or pneumothorax) and the inappropriate use of appropriate modes of ventilation.

Another important point when PEEP is applied is the possibility to produce barotrauma. Pulmonary barotrauma is lung injury that results from the hyperinflation of alveoli past the rupture point. The most severe form is the development of pneumothorax, pneumomediastinum and subcutaneous emphysema.

CHAPTER 95

Volume-controlled mechanical ventilation

Kristy A. Bauman and Robert C. Hyzy

Key points

- Volume-controlled modes of mechanical ventilation guarantee flow and tidal volume, while airway pressures are variable.
- In volume-controlled modes, the clinician sets the flow pattern, flow rate, trigger sensitivity, tidal volume, respiratory rate, positive end-expiratory pressure (PEEP), and fraction of inspired oxygen (FIO_2).
- Patient ventilator synchrony can be enhanced by setting appropriate trigger sensitivity and inspiratory flow rate.
- I:E ratio is adjusted to improve oxygenation, avoid air trapping and enhance patient comfort.
- Low tidal volume ventilation in conjunction with plateau pressure limitation should be employed in patients with acute respiratory distress syndrome (ARDS).

Introduction

The goal of mechanical ventilation is to achieve adequate gas exchange, while minimizing haemodynamic compromise and ventilator-associated lung injury (VALI). There are a vast and ever increasing number of ventilator modes and settings to choose from. After endotracheal intubation, the first choice facing the clinician is between two basic modes of mechanical ventilation—pressure- and volume-controlled. In pressure control mode, peak inspiratory pressure is selected and tidal volumes are variable. In volume control mode, tidal volume is guaranteed at the expense of variable airway pressures. Volume-controlled ventilation, (also termed volume-cycled or volume-limited) can be delivered via several modes including controlled mechanical ventilation (CMV), assist control (AC) and synchronized intermittent mandatory ventilation (SIMV).

Ventilator settings for volume-controlled ventilation

Mode

In controlled mechanical ventilation, the minute ventilation (V_E) is determined by the set respiratory rate and tidal volume. This mode is used in patients with no spontaneous effort such as those in comatose states or pharmacologically paralysed. The ventilator does not respond to spontaneous breaths or changes in flow requirements. During AC ventilation, the clinician sets the minimum V_E as well, although the patient can increase V_E by triggering additional breaths. With each additional breath, the full preset tidal volume is delivered. Therefore, if a patient has a respiratory rate twice that of the preset frequency, the V_E will be effectively doubled. In SIMV mode, the mandatory ventilator breaths are synchronized with the patients' inspiratory effort. Additional inspiratory efforts either receive no additional ventilator assistance or pressure support may augment these breaths. With the exception of mandatory ventilator breaths, the tidal volume delivered is highly variable.

Controlled mechanical ventilation and AC volume-controlled modes control the tidal volume of each breath and provide most of the work of breathing. In patients who are critically ill, where control of ventilation and minimizing respiratory muscle oxygen consumption are paramount, controlled mechanical ventilation and AC may be the preferred modes. SIMV can provide partial or full ventilator support, ostensibly offering improved patient–ventilator synchrony and preservation of respiratory muscle strength [1]. AC and SIMV are the most commonly used modes of volume-controlled ventilation in medical and surgical intensive care units [2]. There are little data available regarding the benefits of one volume-controlled mode over another. In a multicentre observational study of ventilated critically-ill patients, there was no significant difference in clinical outcomes between those receiving AC ventilation versus those receiving SIMV with pressure support [3].

With volume-controlled modes, the clinician must set the flow pattern, flow rate, trigger sensitivity, tidal volume, respiratory rate, positive end-expiratory pressure (PEEP), and fraction of inspired oxygen (FIO_2).

Most mechanical ventilators currently available offer a pressure limited form of mechanical ventilation where the tidal volume is assured. The term utilized for this modality varies according to the designation created by the company. Although comparative studies are lacking the putative advantage of these modalities is to ensure an adequate tidal breath, while utilizing a pressure mode, which may afford greater patient-ventilator synchrony.

Flow pattern and flow rate

While the term volume-controlled ventilation is commonly used, the ventilator actually is controlling the inspiratory flow. Each breath terminates after delivery of the set tidal volume unless a pressure limit is exceeded. Flow can be delivered either in a constant pattern or a decelerating pattern. (Fig. 95.1) A constant flow pattern

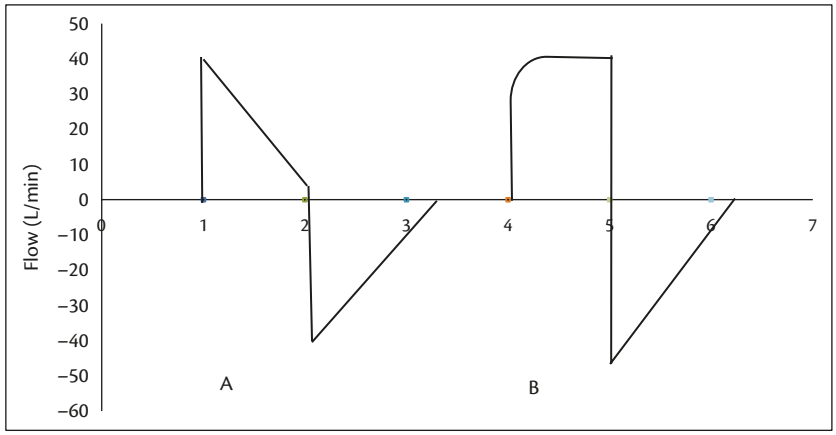

Fig. 95.1 Decelerating flow pattern (A). Constant flow pattern (B).
Adapted from Hess DR and Kacmarek RM. *Essentials of Mechanical Ventilation*, 2nd edn, Copyright 2002, with permission from McGraw-Hill Education.

provides nearly constant gas flow during the inspiratory cycle. It is often called a rectangular or square wave pattern. Tidal volume is delivered to the lungs equally throughout the entire inspiratory time (Ti). The airway pressure increases linearly with time.

The decelerating flow pattern is also termed a descending ramp flow pattern. Inspiratory flow is greatest at the beginning of inspiration and decreases throughout the inspiratory cycle. Most of the tidal volume is delivered early during inspiration and unless the flow rate is increased, the inspiratory time is lengthened with descending ramp flow. Peak inspiratory pressure is higher with constant flow and mean airway pressure is higher with descending ramp flow. An advantage of descending ramp flow is that the longer Ti can enhance alveolar gas distribution, improving oxygenation and ventilation. When switching between constant and descending ramp flow the ventilator must adjust either the peak flow rate or the Ti to maintain the set tidal volume.

In a spontaneously breathing individual, expiration is passive and expiratory time is longer than inspiratory time. Thus, the inspiratory to expiratory (I:E) ratio is less than 1. In patients receiving mechanical ventilation inspiratory time is a function of tidal volume and inspiratory flow. In mechanically-ventilated patients with airways obstruction and air trapping, dynamic hyperinflation can be avoided by shortening the inspiratory time. This may be accomplished on a breath-by-breath basis either by decreasing tidal volume, increasing the flow rate of gas administered, or by decreasing the number of breaths administered per minute.

The I:E ratio during volume-controlled ventilation be deliberately lengthened with important physiological effects. A longer inspiratory time increases mean airway pressure, increases intrathoracic pressure, can decrease cardiac output, particularly if hypovolaemia is present, increases oxygenation in patients with acute respiratory distress syndrome (ARDS), and can lead to air trapping [4].

Inverse ratio ventilation (IRV) can be used as a strategy to improve oxygenation in ARDS. IRV implies a prolonged inspiratory time with an I:E ratios exceeding 1:1. IRV is commonly employed with pressure-controlled ventilation, but can also be performed in volume-controlled ventilation through the use of a low flow rate or the administration of an inspiratory pause on every breath. While, in general, studies have demonstrated that it improves oxygenation, IRV has not been shown to improve clinical outcomes such as mortality or duration of mechanical ventilation. IRV is uncomfortable and often requires high levels of sedation or pharmacologic paralysis [5].

Triggering mechanism and sensitivity

In AC mode, the patient is able to trigger the ventilator to provide breaths. These breaths can be pressure- or flow-triggered. Pressure-triggered breaths are delivered when the patient exerts a specified negative-pressure deflection below the level of set PEEP or auto-PEEP, when present. Flow triggering occurs when the machine senses a decrease in flow of a set magnitude during exhalation. Triggering mechanism and sensitivity significantly influence inspiratory work of breathing and patient ventilator synchrony. Ineffective triggering is a form of ventilator asynchrony. As a result, triggering sensitivity should be set at the lowest required value that does not lead to auto-cycling or 'breath stacking'. Conversely, the sensitivity should not be set at such a value above which the patient has to overcome a significant amount of ventilator circuit or airways resistance to trigger a breath. This results in increased work of breathing and discomfort.

For example, a patient with significant air trapping due to obstructive airways disease may develop a significant amount of auto or intrinsic PEEP. If the trigger sensitivity is set at –2 cmH_2O and intrinsic PEEP is 10 cmH_2O, the patient will have to exert a negative-pressure deflection of –12 cmH_2O to trigger a breath. This can be recognized easily at the bedside as the patient will have obvious attempts to inhale with no ventilator breath delivered. The flow rate also is an important factor in work of breathing. The inspiratory flow rate should be set high enough in order to complete inhalation before the patient begins to exhale. Exhalation against a closed exhalation valve is distressing to a patient and best avoided. In general, the average flow rate should be four times the minute ventilation to avoid discomfort.

Tidal volume

Tidal volume should be set with individual pulmonary mechanics and physiology in mind. Present practice suggests tidal volumes in the range of 6–8 mL/kg ideal body weight are appropriate for most clinical circumstances. In order to avoid VALI, ideally plateau pressures should not be in excess of 30 cmH_2O, lower if possible, as

this is a continuous, not a threshold variable. In individuals with normal lungs, tidal volumes such as 10 mL/kg of ideal body weight are generally well-tolerated without generating high airway or plateau pressures. Nevertheless, clinicians should be cognizant of the fact that tidal volumes in excess of 700 mL have been associated with an increased risk of ARDS in post-operative patients with normal lungs. Persons with history of lung resection and pulmonary fibrosis typically can tolerate tidal volumes of 4–8 mL/kg. In ARDS, volume-controlled ventilation with tidal volumes of 6 mL/kg are recommended based upon the ARDS Network study demonstrating a 22% reduction in mortality in those receiving a low tidal volume strategy [6]. Low tidal volumes of less than 6 mL/kg may result in atelectasis; however, this can be offset by increases in PEEP. In controlled mechanical ventilation or AC modes the delivered tidal volume should be equivalent to exhaled tidal volume. Exceptions are the presence of an endotracheal tube cuff leak and pneumothorax with bronchopleural fistula.

Respiratory rate

The back-up respiratory rate should be chosen in order to satisfy the desired minute ventilation based upon pH and PCO_2 goals. In AC mode, however, if the patient triggers each breath, the set back-up rate may have no effect upon V_E. Ideally, the back-up rate is 2–4 breaths below the respiratory rate in patients receiving AC, permitting patients to determine their own minute ventilation and PCO_2.

PEEP and FIO_2

At initiation of mechanical ventilation, in most cases an FIO_2 of 1.0 and PEEP of 5 cmH_2O are recommended. These variables can be adjusted based upon patient condition and physiological goals. FIO_2 is later decreased in order to maintain an arterial saturation of at least 88% on arterial blood gas or 92% on pulse oximetry, allowing for the imprecision of the latter device.

Clinical uses

Volume-controlled ventilation is the most commonly used mode in inpatient settings. The major advantage is the delivery of a constant tidal volume, thus minute ventilation is assured. The peak inspiratory pressure will vary based upon compliance and resistance of the respiratory system. The vast majority of patients undergoing mechanical ventilation can be successfully and safely managed using conventional volume-controlled mechanical ventilation. There are no absolute indications for resorting to pressure-controlled modes, including in the initial management of patients with ARDS, where a low tidal volume strategy via volume-controlled ventilation has a proven mortality benefit. In the limited available studies comparing volume-controlled to pressure-controlled ventilation in persons with hypoxic respiratory failure, there have to date been no differences in clinically important variables, such as mortality.

Limitations

A major limitation of volume-controlled ventilation is that the flow pattern is fixed and will not change with changing demands of the patient. This increases the risk for patient-ventilator dys-synchrony. Pressure modes typically do allow for varied flow depending upon patient demand and may be preferred for this reason. Additional, in poorly compliant, stiff lungs, airway pressures during volume-controlled ventilation may be excessive leading to concern for ventilator-associated lung injury. In these instances, pressure-controlled ventilation may be advantageous.

CHAPTER 96

Pressure-controlled mechanical ventilation

Thomas Muders and Christian Putensen

Key points

- Pressure-controlled, time-cycled ventilation (PCV) enables the physician to keep airway pressures under strict limits in order to minimize the risk for ventilator-associated lung injury in patients with acute respiratory distress syndrome.
- During PCV inspiratory and expiratory pressures, and cycle times have to be chosen by the physician. These presets, as well as respiratory system mechanics determine (decelerating) inspiratory gas flow, tidal volume, and intrinsic positive end-expiratory pressure ($PEEP_i$).
- To avoid a harmful rise in tidal volume with improvement in respiratory system mechanics, continuous display, and tight monitoring of tidal volume is mandatory during PCV.
- When compared with flow-controlled, time-cycled ('volume-controlled') ventilation, PCV reduces peak airway pressure, while mean airway, and mean alveolar pressures and gas exchange improve. However, no consistent data exist, showing PCV to improve patient outcome.
- Airway pressure release ventilation (APRV) allows superimposed and unrestricted spontaneous breathing and, thereby, improves haemodynamics and gas exchange, whereas need for sedation, vasopressors and inotropic agents and duration of ventilator support decreases.

Introduction

Today's lung protective ventilatory strategies reduce tidal volume (V_T) to 6 mL/kg ideal body (iBW) [1] and limit airway pressures [1] to minimize risk for ventilator associated lung injury (VALI) and to improve outcome in patients with acute respiratory distress syndrome (ARDS).

In contrast to flow-controlled, time-cycled ventilation (= 'volume-controlled', VCV) using a squared flow control, during pressure-controlled (preset), time-cycled ventilation (PCV) a preset square-wave pressure is applied to the airway. PCV results in a decelerating inspiratory gas flow holding the alveoli inflated for a preset period of time. In this chapter, we try to point out the principle and special characteristics, and physiological effects of pressure-controlled, time-cycled, continuous mandatory mechanical ventilation (PC-CMV), a prototype of PCV. Furthermore, we will discuss important variants of PCV, such as assisted PCV (PC-A/C), pressure-controlled inverse-ratio ventilation (PC-IRV) and pressure-controlled airway pressure release ventilation (PC-APRV).

Principle characteristics of PCV

PCV results in a square-wave pressure to the airway and a decelerating inspiratory gas flow holding the alveoli inflated for a preset period of time (Fig 96.1). Flow will initially enter the lung rapidly to reach the preset airway pressure as quickly as possible. As the open and fast-filling alveoli fill, and their pressure reaches equilibrium with the preset pressure, flow will decelerate, whereas slow compartments continue to fill with gas. The ventilator will constantly adjust gas flow so that inspiratory pressure is maintained during the entire set inspiratory time. Flow will continue until the preset pressure reaches equilibrium with alveolar pressure throughout all lung units, which is indicated by the flow pattern decelerating to zero [2]. During expiration, pressure is released abruptly, and the lung will passively deflate against the set PEEP level. V_T depends mainly on respiratory compliance and resistance, and the difference between the preset pressure levels [2].

Input parameters of PCV

During PCV principally, inspiratory and expiratory pressures, and cycle times have to be chosen by the physician, but the way to determine these parameters depends on the ventilator.

Expiratory and inspiratory airway pressures

Apart from external positive end-expiratory pressure ($PEEP_e$) driving pressure (positive inspiratory pressure, PIP) as pressure increment above $PEEP_e$ or absolute inspiratory pressure (P_{INSP}) can be set (Fig. 1).

Ventilator rate, and expiratory and inspiratory time

Furthermore, ventilator rate (VR) and fractional inspiratory time (duty cycle, T_{INSP}/T_{TOT}) or VR, and inspiratory-to-expiratory ratio (I:E) has to be chosen. Alternatively, expiratory (T_{EXP}) and inspiratory (T_{INSP}) times can be set directly (Fig. 96.1).

Output parameters of PCV

Global and regional respiratory system mechanics (compliance and resistance) affect alveolar pressure (P_A), intrinsic PEEP ($PEEP_i$), inspiratory gas flow, V_T, total minute and alveolar ventilation, resulting from preset airway pressures and cycle times.

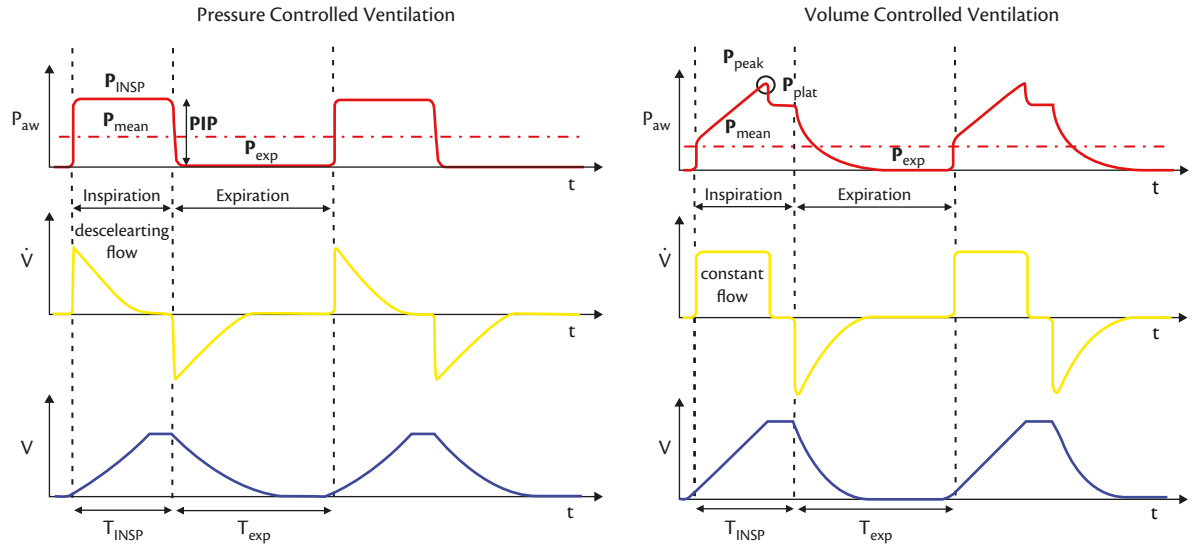

Fig. 96.1 Time (t) courses of airway pressure (P_{aw}), flow ($\dot{V}$), and volume (V) during pressure-controlled (PCV) (left) and volume-controlled (VCV) (right) mechanical ventilation.

P_{INSP}, inspiratory pressure; P_{exp}, expiratory pressure; P_{mean}, mean airway pressure; PIP, positive inspiratory pressure (= driving pressure); P_{peak}, Peak inspiratory pressure; P_{plat}, plateau pressure; T_{INSP}, inspiratory time; T_{exp}, expiratory time. See text for details.

Inspiratory flow

Depending on the respective ventilator, the abruptness of rise to peak flow can be modulated by setting slope or inspiratory rise-time. Rampant rise in flow might create some pressure overshoot that does not lead to elevated peak alveolar pressure and may not be associated with harm to the lung [3]. In contrast, longer rise-times creating a shallow increase to peak flow might be associated with a slow ramp of inspiratory pressure and have been reported to cause a delayed filling of the lung [4].

Mean airway pressure

Due to the squared waveform of the airway pressure during PCV, mean airway pressure ($\overline{P}_{aw}$, that is the is the integral of P_{aw} over time divided by duration of a single breath (T_{TOT}) can easily be calculated as

$$\overline{P}_{aw} = (PEEP_e \times T_{EXP} + P_{INSP} \times T_{INSP}) / T_{TOT} \quad \text{[eqn 1]}$$

Thus, during PCV changes in $\overline{P}_{aw}$ can directly be predicted from variations in preset airway pressures or cycle times. $\overline{P}_{aw}$ increases with increasing $PEEP_e$, P_{INSP} or I:E, whereas it decreases with decreasing $PEEP_e$, P_{INSP} or I:E (Fig 96.1). In contrast, changes in frequency maintaining I:E constant do not affect $\overline{P}_{aw}$.

Alveolar pressure

During PCV P_A can never exceed preset P_{INSP}. Mean alveolar pressure ($\overline{P}_A$) is closely related to mean airway pressure ($\overline{P}_{aw}$) and affected by minute ventilation (V_E) and inspiratory (R_I) and expiratory (R_E) resistances [3]:

$$\overline{P}_A = \overline{P}_{aw} + V_E \times (R_E - R_I) \quad \text{[eqn 2]}$$

If inspiratory and expiratory resistances are similar, changes in VR do not relevantly influence $\overline{P}_{aw}$. When R_E exceeds R_I, $\overline{P}_{aw}$ relevantly underestimates $\overline{P}_A$, and increments in VR may cause a noteless increase in $\overline{P}_A$. This phenomenon is pronounced when V_E is high and common in chronic obstructive lung diseases [3]. Peak P_A equilibrates to P_{aw} at end-inspiration when a sufficient inspiratory time is provided. With increasing VR and/or decreasing T_{INSP} peak, P_A falls below P_{INSP}, whereas end-expiratory P_A rises above $PEEP_e$ with increasing VR and/or decreasing T_{EXP} [3] creating $PEEP_i$ (Fig 96.2).

Intrinsic PEEP

$PEEP_i$ occurs when regional or total expiration remains incomplete within the T_{EXP} available leading to dynamic hyperinflation [5]. This dynamic phenomenon depends on a complex function of the respiratory mechanics and the input parameters of PCV [6].

$PEEP_i$ can be increased either by higher driving pressure (resulting in higher V_T during PCV), higher I:E ratio or higher VR (both shortening T_{EXP}). As described previously and in Fig. 96.2, changes in P_A are mainly affected by differences between R_I and R_E. Thus, increasing I:E ratio might elevate $PEEP_i$ up to maximal airway pressure, whereas pure increases in VR will reduce peak P_A and increase $PEEP_i$ [3].

Furthermore, higher respiratory time constants increase $PEEP_i$ for the same input parameters [5]. As the time constant (t) is equal to resistance (R) × compliance (C), high time constants are caused by high airway R and/or C, which may occur on a regional basis, e.g. in slow compartments, as well as for the whole respiratory system [7]. It is important to note that elevation in airway resistance also can be caused by the design of the ventilator circuit (e.g. narrow tubes, slow PEEP valves) [7].

In inhomogeneous lungs different $PEEP_i$ may occur [8] and mainly the slower compartments will profit from $PEEP_i$ in terms of alveolar recruitment, whereas fast compartments might be overinflated (Fig 96.2).

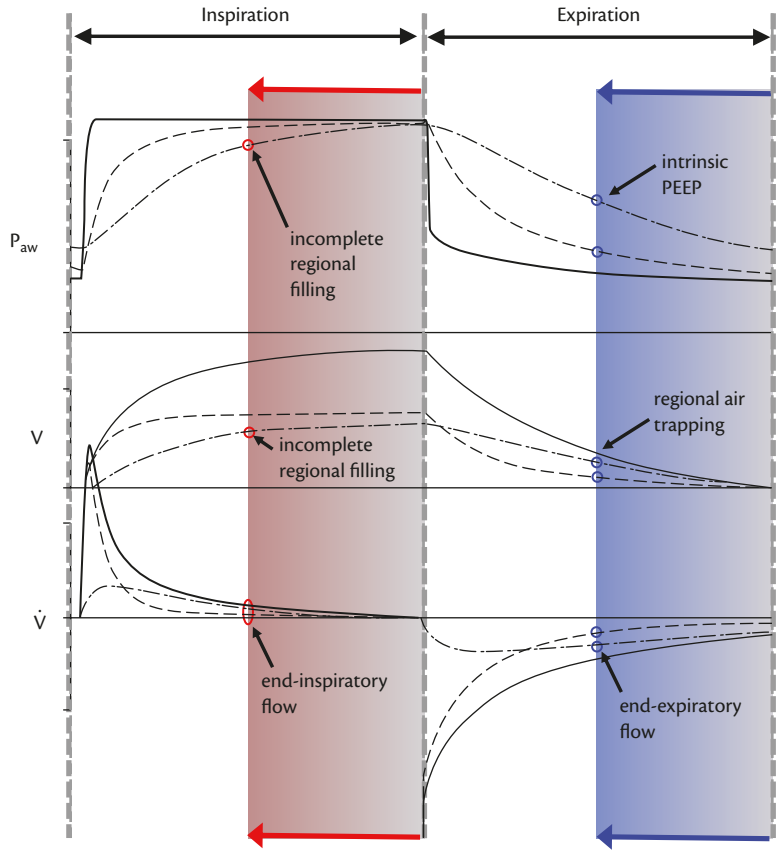

Fig. 96.2 Time courses of airway pressure (P_{aw}), volume (V), and flow ($\dot{V}$) during pressure controlled ventilation. Shortening inspiration (red arrow and area) can cause incomplete regional filling and persisting end-inspiratory flow. Shortening expiration (blue arrow and area) can cause intrinsic PEEP, regional air trapping, and persisting end-expiratory flow. See text for detailed influence of I:E ratio, inverse ratio, and respiratory frequency.

Tidal volume

In contrast to VCV, which ensures a preset V_T, during PCV V_T mainly depends on the difference between the preset pressure levels, VR or cycle times, and respiratory compliance and resistance. To enable a nearly-complete lung inflation T_{INSP} should be longer than three times the time constants of the respiratory system, leading to a minimal T_{INSP} of 1.0–1.5 s in healthy intubated adults. In obstructive patients, this time can rise to 2–4 s, whereas in patients suffering from ARDS, lung can be inflated within 0.8–1 s due to reduction in lung compliance [3]. Furthermore, incomplete lung emptying will decrease V_T. Therefore, T_{EXP} should be longer than three expiratory time constants. Hence, incomplete lung filling will occur with VR above 25–30 breaths/min. Generally, during PCV increasing I:E ratio mainly increases $PEEP_i$, whereas reductions in VR cause reduced peak P_A and increased $PEEP_i$, and thereby further decrease effective driving pressure. Thus, V_T is more affected by changes in VR than by altered I:E ratio (Fig 96.2).

At this point it is important to note, that V_T will change with changes in lung mechanics. When the lung is recovering over time and lung compliance improves, V_T will rise and may relevantly exceed the limits of lung protective ventilation. In this situation, inspiratory pressure has to be reduced to keep V_T below 6 mL/kg iBW. Therefore, respiratory mechanics and V_T have to be carefully monitored during PCV.

Alveolar and minute ventilation

As long as complete lung filling and emptying is ensured, increasing VR will improve total minute and alveolar ventilation, and thereby CO_2 elimination. At higher VR and decreases in T_{INSP}, peak P_A will not equilibrate to preset inspiratory pressure causing incomplete filling of slow lung compartments and a decline in V_T. As a consequence, functional dead space to tidal volume ratio will increase, and CO_2 elimination will be impaired by decreased alveolar ventilation. In clinical practice, with a fixed non-inverse I:E ratio, VR can be increased to improve CO_2 elimination until V_T decreases by 25–30%. A further increase in VR will be counterproductive due to increased dead space, even when V_E increases [3].

Physiological effects of PCV

The effects of using PCV when compared with VCV, while keeping all other parameters (VR, I:E ratio, PEEP and plateau pressure) constant can be summarized as follows.

Airway and alveolar pressures

During PCV decelerating flow reduces peak P_{aw}, but increases mean P_{aw} [9]. Homogeneity of regional peak P_A distribution within the lung is improved with PCV, reducing exposure of more diseased lung units to high pressures.

Ventilation distribution and pulmonary gas exchange

PCV seems to favour ventilation of slow lung units due to fast gas flow during early inspiration. As a consequence, $PaCO_2$ falls, since dead space ventilation is decreased, whereas arterial oxygenation is slightly improved [9]. However, clinical relevance of PCV-related advantages remains debatable.

Cardiovascular effects

The application of positive pressure ventilation generates an increase in airway and, therefore, in intrathoracic pressure, which in turn reduces venous return to the heart. This produces a reduction in right- and left-ventricular filling, and results in decreased stroke volume, cardiac output, and oxygen delivery [10]. For comparable mean airway pressures no differences in haemodynamic impairment were seen between PCV and VCV. Since influence of changes in ventilator settings on $\overline{P}_{aw}$ is more predictable with PCV, haemodynamic impairment should also be more predictable.

Ventilator-associated lung injury

Regional lung strain calculated from computed tomography scans is comparable between PCV and VCV [11]. Although, experimental data suggest PCV to reduce VALI, no consistent results have been seen with respect to reduced barotrauma or improved outcome in patients [12].

Variants of PCV

Assisted PCV

Assisted PCV (PC-A/C) enables the patient to trigger the ventilator and in opposite to pressure-support ventilation (PSV) time and not flow determines the cycle off. Compared with PSV, a risk of prolongation of T_{INSP} by not reaching the default expiratory triggering threshold (e.g. mask leaking, severe obstruction), and resulting insufficient drop in inspiratory flow is lower under assisted PCV [3]. Therefore, T_{INSP} must be adjusted to match the patient's spontaneous T_{INSP}, usually 0.6–1.2 seconds [13]. This gives more security for the patients, but also avoids freedom of ventilation pattern (restraining, for instance, the possibility of a spontaneous sigh and potentially increasing discomfort) [13].

With assisted PCV, breaths are triggered either by the patient's effort or by elapsed expiratory time, guaranteeing lower central apnoeas and sleep fragmentation. When compared with assisted VCV (flow-controlled, volume-cycled), assisted PCV results in lower peak P_{aw} and reduced workload [3].

Pressure-controlled inverse ratio ventilation

In healthy patients breathing for themselves, the ratio of the time spent in inspiration to that in expiration is about 1:2. Therefore, traditionally, the I:E ratio has been usually set at 1:2 or 1:1.5 to approximate the normal physiology. In inverse ratio ventilation (IRV) the T_{INSP} is prolonged (I:E ratio is inversed), thereby increasing $\overline{P}_{aw}$ and allowing the use of lower P_{aw} limits. This alternative ventilation strategy was initially developed to treat infants and adopted for adult patients with ARDS the early 1980s to improve severe hypoxaemia [8]. IRV can be delivered using pressure controlled, time-cycled ventilation (PC-IRV) [9] or flow-controlled ('volume-controlled'), time-cycled ventilation (VC-IRV) [8].

Principle of PC-IRV

The effects of changes in T_{INSP} and I:E ratio on P_{aw} and P_A can be summarized thus: the elongation of inspiratory time increases $\overline{P}_{aw}$, enables equilibration of peak P_A to preset P_{INSP}, and causes full lung inflation of even slow lung compartments. Shortening T_{EXP} leads to incomplete lung emptying and causes an increase in $PEEP_i$ [8,9]. Both mechanisms increase $\overline{P}_A$ and

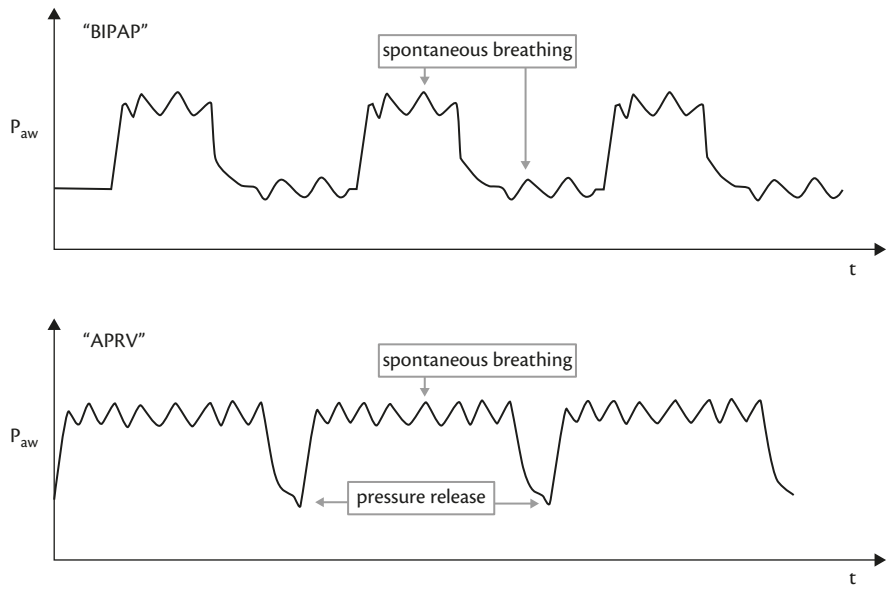

Fig. 96.3 Time courses of airway pressure (P_{aw}) biphasic-positive-airway-pressure (BIPAP) airway-pressure-release-ventilation (APRV). Both modes similarly provide a time-cycled switch between two different airway pressures and allow unrestricted spontaneous breathing at any time point and pressure. In the absence of spontaneous breathing BIPAP and APRV are equal to PCV. See text for details.

thereby transpulmonary pressure that is the driving force to recruit non-aerated alveoli and to prevent alveolar recollapse during expiration. This reduces intrapulmonary shunting and improves arterial oxygenation. Therefore, during IRV elevation in $\overline{P}_{aw}$ is a major determinant of improved oxygenation [5,14].

Physiological effects of PC-IRV

When compared with conventional mechanical ventilation using an increased $PEEP_e$ to reach the same magnitude of $PEEP_{TOT}$ as that produced intrinsically by IRV ($PEEP_{TOT} = PEEP_e + PEEP_i$), IRV had no advantage [15]. Furthermore, CT observations in experimentally-induced lung injury showed no improvement in lung aeration, but demonstrated that during IRV the upper, already well-aerated lung regions become even more aerated, whereas poorly- or non-aerated lung units localized in the dependent lung regions are less aerated when compared with conventional mechanical ventilation with essentially the same mean airway pressure and extrinsic/intrinsic PEEP [16].

A major problem during IRV is that $PEEP_i$ changes, due to altered respiratory mechanics for example, may not be immediately clinically evident. A remaining terminal flow at the end of the expiration indicates that a certain $PEEP_i$ exists, but it does not quantify the amount [8]. Therefore, careful monitoring and continuous display of V_T and expiratory flow has to be recommended during PC-IRV.

Limitation of PC-IRV

The long T_{INSP} of usually makes IRV incompatible with spontaneous breathing, and respiratory depressants or muscle relaxants must be administered to assure patient acceptance. Deep sedation sufficient to suppress respiratory efforts is known to cause significant cardiovascular depression [17]. Incompatibility with spontaneous breathing is a major limitation of IRV.

Airway pressure release ventilation (APRV)

APRV incorporates the characteristics of PCV, PC-IRV, spontaneous breathing, and partial ventilatory support into one technique with potentially widespread applicability. Based on the clinical and experimental data, APRV is indicated in patients with ARDS, and atelectasis after major surgery.

Principles of APRV

APRV provides a squared pressure pattern identical to PCV by time-cycled switches between two pressure levels in a high flow or demand valve continuous positive airway pressure (CPAP) circuit, while allowing unrestricted and unsupported spontaneous breathing in any phase of the ventilator cycle (Fig 96.3) [17,18].

The degree of ventilator support with APRV is determined by the duration of the two CPAP levels and the mechanically delivered V_T [17,18]. V_T depends mainly on respiratory compliance and the

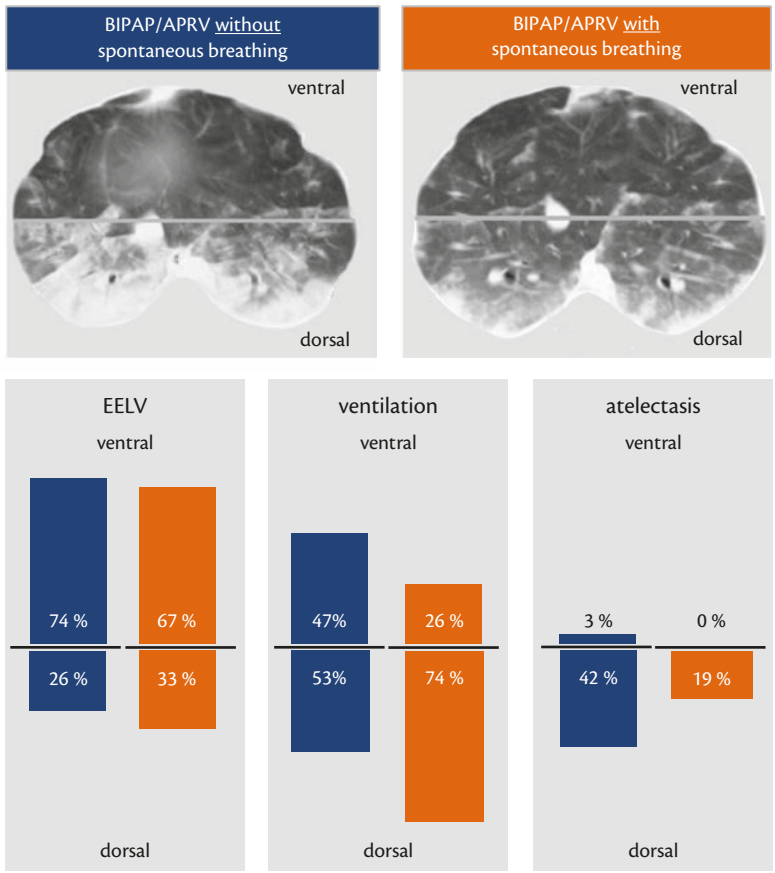

Fig. 96.4 Densitometric analysis of computed tomography scans (pig, experimental lung injury) during BIPAP/APRV with (orange) and without (blue) spontaneous breathing. Spontaneous breathing increase end-expiratory lung volume, decreases atelectasis and redistributed regional ventilation into dependent lung regions.
Data from Wrigge H et al., 'Spontaneous breathing with airway pressure release ventilation favors ventilation in dependent lung regions and counters cyclic alveolar collapse in oleic-acid-induced lung injury: a randomized controlled computed tomography trial', *Critical Care*, 2005, **9**(6), pp. R780–9.

difference between the CPAP levels. By design, changes in ventilatory demand do not alter the level of mechanical support during APRV. When spontaneous breathing is absent, APRV is not different from conventional PCV [17,18].

Synonyms used for APRV are biphasic positive airway pressure (BIPAP) [17] and bi-level airway pressure (Bilevel). BIPAP is identical to APRV except that no restriction is imposed on the duration of the low CPAP-level (release pressure) [17,18]. Based on the initial description, APRV keeps the duration of the low CPAP-level (release time) at 1.5 seconds or less (Fig 96.3).

Physiological effects of superimposed spontaneous breathing during APRV

As known from CT scans in patients with ARDS, alveolar collapse is primarily localized in the dependent lung regions (Fig 96.4), which correlates with intrapulmonary shunting and accounts entirely for the observed hypoxaemia [19]. If the diaphragm is relaxed, it will be moved by the weight of the abdominal cavity and intra-abdominal pressure towards the cranium. During spontaneous breathing, the posterior muscular sections of the diaphragm moves more than the anterior tendon plate [17]. Thereby, transpulmonary pressure will be increased especially in dependent lung regions. Periodic reduction of intrathoracic pressure, achieved by maintaining spontaneous breathing, promotes venous return to the heart and right- and left-ventricular filling and improves outflow from the right ventricle (the major determinant of pulmonary vascular resistance), thereby increasing cardiac output and oxygen delivery [17].

In clinical and experimental studies spontaneous breathing with APRV in is associated with recruitment of atelectasis and increased end-expiratory lung volume (Fig 96.4) [20], improved ventilation of dependent lung areas, and thereby improved ventilation–perfusion matching, a rise in cardiac output, oxygenation and oxygen delivery [17], whereas oxygen consumption remains unchanged despite the work of spontaneous breathing. Furthermore, tidal recruitment (cyclic collapse) that might be a major contributor to VALI is reduced [20] . Renal, intestinal, and cerebral perfusion have been shown to be increased [17].

When allowing spontaneous breathing, lower levels of sedation are possible. Less sedation helps in reducing the doses of vasopressor and inotropic agents, while maintaining cardiovascular function in a stable condition, and reducing the duration of ventilator support [17].

Limitations for APRV

In patients with left ventricular dysfunction, switching abruptly from controlled to supported ventilation with a simultaneous reduction in airway pressure might cause further decompensation due to augmentation right ventricular preload and increase in left ventricular afterload. Provided that satisfactory CPAP levels are applied, maintaining spontaneous breathing during APRV should not be a disadvantage and is not per se contraindicated in patients with ventricular dysfunction.

In concept, APRV does not provide breath-to-breath assistance of spontaneous inspiration. Thus, APRV is not expected to be an advantage in difficult-to-wean patients.

Because lower levels of sedation are used to allow spontaneous breathing, APRV should not be used in patients who require deep sedation for management of their underlying disease (e.g. cerebral oedema with increased intracranial pressure).

CHAPTER 97

Pressure support ventilation

Hérnan Aguirre-Bermeo and Jordi Mancebo

Key points

- Pressure support ventilation (PSV) is an assisted ventilatory mode that is patient-triggered, pressure-limited, and flow cycled. During PSV, airway pressure is maintained nearly constant during the entire inspiration.
- PSV allows the patient to maintain a certain degree of control over respiratory rate and tidal volume.
- The main use of the modality is in withdrawal from mechanical ventilation because it unloads respiratory muscles and allows a gradual reduction of support until extubation.
- If not properly used (usually due to excessive levels of support), this modality generates high and abnormal tidal volumes, and wasted inspiratory efforts.
- The closed-loop modality could have important clinical implications in withdrawal of mechanical ventilation in specific groups of patients. It appears to be as good as usual care performed by experts and skilled teams.

Definition

Pressure support ventilation (PSV) is an assisted ventilatory mode that is patient-triggered (by pressure, airflow, or both), pressure-limited, and flow cycled. In this modality, the airway pressure is maintained almost constant during the entire inspiration. The ventilator provides assistance when the patient makes a breathing effort, and then, when inspiratory flow reaches a certain threshold level, cycling to exhalation occurs. The use of PSV is common in all intensive care units (ICUs), and it is the most commonly used method to wean patients from mechanical ventilation [1].

Mode characteristics

Trigger

In PSV, the clinician decides whether to use pressure or flow triggers to initiate ventilatory assist. The recommended pressure and flow triggers are, respectively, from –0.5 to –2.0 cmH_2O, and from 1 to 2 L/min [2].

Several studies have compared the use of pressure versus flow triggers, without finding any significant differences between the triggers. However, Aslanian et al. [2] found that the flow trigger was more effective in reducing breathing effort when used in PSV versus volume-controlled modality. In patients with intrinsic positive end-expiratory pressure ($PEEP_i$), the flow trigger can decrease inspiratory effort; moreover, low levels of external positive end-expiratory pressure (PEEP) are recommended to compensate for this $PEEP_i$, the dynamic flow limitation and for decrease the work of breathing [3].

Flow delivery

Once the ventilator is triggered, the machine provides an inspiratory flow (via a servo regulatory mechanism) to maintain the preset level of airway pressure (pressure support setting) nearly constant throughout the inspiration. The velocity of pressurization, which depends on the shape of the inspiratory flow waveform, is the time required for the ventilator to reach the pressure support setting at the onset of inspiration (rise time). Different pressurization rates have a profound effect on effort. Low pressurization rates produce a high inspiratory muscle effort, while high pressurization rates lower inspiratory muscle effort [4]. Visual inspection of the ventilator waveforms may be used to guide this setting. Tidal volume depends on the preset level of pressure support, the inspiratory effort of the patient, the cycling-off threshold level, and the mechanical characteristics (resistance and compliance) of the patient's respiratory system.

Cycling of expiration

During PSV, cycling from inspiration to expiration is triggered when the inspiratory airflow reaches a certain threshold value. The threshold value coincides, theoretically, with the end of inspiratory muscle effort. This flow value could be a percentage of peak flow (i.e. 25% of peak flow) or a fixed level (i.e. 5 L/min). The latest generation of ventilators allow the physician to set this flow threshold value [5]. Modification of the cycling-off criteria can influence inspiratory effort and patient–ventilator synchrony. In patients with chronic obstructive pulmonary disease (COPD), setting the cycling-off at higher percentages of peak inspiratory flow can improve patient–ventilator synchrony and reduce inspiratory muscle effort [6]. Thille et al. [7] have described a similar phenomenon in COPD and non-COPD patients. Tracings obtained during pressure support ventilation are shown in Fig. 97.1.

Physiological effects

Breathing pattern and respiratory effort

PSV allows the patient to retain control over the respiratory rate and tidal volume, a process referred to as physiological ventilation. PSV induces changes in the breathing pattern that affect tidal volume and respiratory rate, without, however, inducing major changes in minute ventilation. As a result, in most patients, tidal volume rises and the ventilator respiratory rate decreases as the

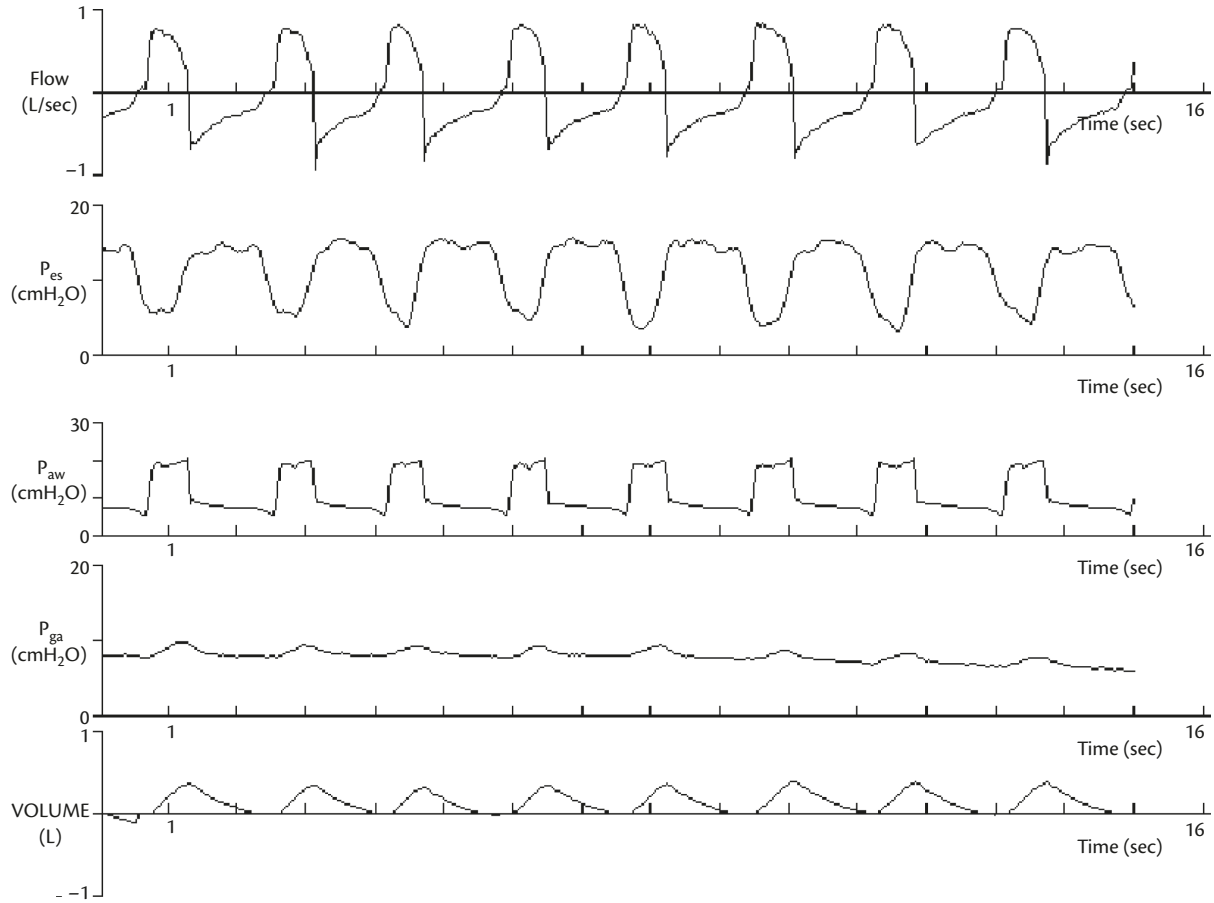

Fig. 97.1 From top to bottom: tracings of airflow (flow), oesophageal pressure (P_{es}), airway pressure (P_{aw}), gastric pressure (P_{ga}), and tidal volume (Volume) recorded in a patient breathing in PSV mode.

level of support is increased. Inappropriate low levels of support can generate low tidal volumes and a high respiratory rate, resulting in patient discomfort and hypercapnia; on the other hand, excessive levels of support may produce hyperinflation, the appearance of wasted inspiratory efforts, respiratory alkalosis, and even periods of apnoea.

Patient ventilator synchrony during PSV

Asynchronies can be present in all ventilator modalities and inappropriate ventilator settings can aggravate the frequency and severity of these asynchronies.

The patient–ventilatory synchrony achieved with PSV is good because it is able to recognize the beginning and the end of each spontaneous effort. However, asynchronies occur during PSV. Often, but not always, these asynchronies during PSV can be detected at the bedside by examining ventilator waveforms.

Thille et al. [8] found that assisted control modalities are associated with a higher prevalence of asynchronies compared with PSV. In their study, the most common asynchronies were ineffective triggering and double-triggering.

A study by Leung et al. [9] showed that high levels of support (above 60–70% of full support) generated wasted inspiratory efforts. A more recent study [7] found that the frequency of asynchronies can be decreased by lowering pressure-support levels.

Clinical usefulness and applications

Withdrawal of mechanical ventilation

In the process of withdrawal of mechanical ventilation, the support level should be reduced as quickly as the patient's clinical tolerance will permit. This reduction, therefore, must be made on an individual basis. The support levels are usually lowered by one or two steps per day (between 2 and 4 cmH_2O per step). A spontaneous breathing trial (SBT) should be conducted as soon as the physician suspects that weaning may be possible and the patient appears to be ready to breathe without ventilatory assistance. This trial can be performed by disconnecting the patient from the ventilator and attaching a T-piece to the endotracheal tube or, alternatively, the SBT can be performed by administering low levels of PSV with or without PEEP. Esteban et al. [10] showed that both methods (pressure support or a T-piece) are suitable for successful discontinuation of ventilator support. However, a recent study by Cabello and colleagues [11], showed that, in difficult to wean patients (those who had failed at least one SBT), the use of pressure support and PEEP modifies the breathing pattern, inspiratory muscle effort, and cardiovascular response when compared with the T-piece trial. In fact, of the 100% of difficult to wean patients who failed a T-piece trial, 79 and 57%, respectively, successfully completed subsequent PSV with PEEP and PSV without PEEP trials. For these reasons, it

is still unclear as to which SBT is best to predict successful extubation, and therefore weaning strategies must be individualized.

Initial suggested settings

As occurs in other ventilation modalities, all PSV settings must be adjusted individually in each patient. However, we can provide some suggestions for the initial PSV settings. These settings should be checked several times during the day and/or whenever the patient requires an adjustment.

First, the pressurization rate should be fast (short rise time), and the support level should be adjusted to produce a respiratory rate of approximately 25–30 breaths/min depending on the patient's comfort. Cycling off should be approximately 25% of peak inspiratory flow (a higher percentage is recommended in COPD patients). The FIO_2 and PEEP must be adjusted according to gas exchange and $PEEP_i$.

Closed-loop modality

A closed-loop, knowledge-based system has been designed to help in withdrawal from mechanical ventilation. The system continuously analyses physiological data (respiratory rate, tidal volume, and end-tidal CO_2 level) and adapts the level of pressure support to keep the patient within a 'comfort zone'. This comfort zone is defined as a respiratory rate that can vary freely from 15 to 30 breaths/min (up to 34 breaths in patients with neurological disease). The tidal volume should be above a minimum threshold and an end-tidal CO_2 level below a maximum threshold [12]. The level of pressure support is periodically adapted by the system in steps of 2–4 cmH_2O. The system automatically tries to reduce the pressure level to a minimal value, at which time a 'spontaneous breathing trial' with the minimal low-pressure support is performed by the system. Upon successful completion of this trial, a message on the screen recommends separation from the ventilator.

Lellouche et al. [12], showed that this system reduces the duration of mechanical ventilation and ICU stay compared with the usual intensive care weaning procedures. However, two recent studies have failed to fully confirm these results [13,14]. Rose et al. [13] reported that the automated system did not reduce weaning time in their study, in contrast to the positive findings of Lellouche and colleagues. However, this may be due to differences between the two studies, particularly in terms of patient severity, duration of ventilation, the patient–nurse ratio, and in ICU staffing levels. The study performed by Schadler et al. [14] also had several difference with the Lellouche et al. study. One important difference is that the Schadler study was performed in post-operative patients with nursing and medical staff who were skilled in the management of mechanical ventilation. The authors found that overall weaning times did not differ significantly between the control group and the experimental group, with the exception of a subgroup of 132 patients who had undergone cardiac surgery (24 hours in closed-loop versus 35 hours in control group, $p = 0.035$). Given the findings published to date, we can conclude that this closed-loop modality performs at least as well as experienced medical staff in weaning patients from mechanical ventilation.

CHAPTER 98

High-frequency ventilation and oscillation

Mireia Cuartero and Niall D. Ferguson

Key points

- High-frequency oscillatory ventilation (HFOV) is a ventilatory mode that delivers pressure oscillations around a relatively constant mean airway pressure.
- Resultant tidal volumes with HFOV are very small—often smaller than the anatomic dead space—but adequate ventilation is achieved through a number of mechanisms generally related to enhanced mixing of gas within the lung.
- HFOV has been widely studied and adopted in the neonatal intensive care unit (ICU), where it may help reduce the incidence of chronic lung disease; it is also commonly used in the paediatric setting.
- In adults with acute respiratory distress syndrome (ARDS), HFOV is often effective in improving oxygenation among patients failing conventional ventilation.
- Despite being theoretically ideal for preventing ventilator-induced lung injury, recent trials indicate that HFOV does not reduce mortality in patients with moderate–severe ARDS.

Introduction

High-frequency oscillatory ventilation (HFOV) is a ventilation mode that achieves adequate alveolar ventilation despite using very low tidal volumes (V_T), at or below the dead space volume (V_D) (approximately 1–2 mL/kg), at frequencies significantly above normal physiological values (more than 3 breaths/second) [1]. Theoretically, it presents some advantages in its ability to apply a lung protective ventilation strategy and thereby avoid ventilator-induced lung injury (VILI) [2,3].

The modern history of HFOV began in 1971 when Jonzon presented a study about the circulatory effects of high-frequency ventilation [4]. The next year, Lunkenheimer et al. described the use of a ventilator based on an electromagnetic vibrator at very high respiratory frequencies (40 Hz) to clear CO_2 [5]. Previously, there had also been some studies reported in animal models. However, through his work in animals and neonates in the late 1970s and 1980s, A. C. Bryan is considered to be the father and developer of HFOV as it is currently known [6,7]. HFOV was initially introduced in the neonatal ICU, where it has been the subject of many randomized controlled trials (RCTs) [8], and it was also widely adopted in the paediatric intensive care unit (ICU). More recently, HFOV made the transition to adult critical care beginning in the late 1990s when technical improvements allowed for the oscillation of those weighing more than 35 kg. Since then, there have been many series and case reports of this ventilatory mode in adults failing conventional ventilation, and a few randomized trials in patients with acute respiratory distress syndrome (ARDS).

HFOV is one of a family of ventilatory modes termed high-frequency ventilation (HFV), and is the only one we will discuss in any detail here. Other members of this family include high frequency jet ventilation (HFJV) and high-frequency percussive ventilation (HFPV). Their differences are based on the manner of generating the high frequency—by an oscillating membrane with HFO, by jet catheter in HFJV, and with flow interruption in HFPV—and also by their ranges in frequency (2–15 Hz), on the type of wave (triangular or sinusoidal), the inspiratory–expiratory ratio (I:E) (constant or adjustable), and the type of expiration (active or passive) (Table 98.1).

Physiological effects of HFOV

The HFOV ventilator (see Fig. 98.1) is an oscillator with a diaphragm located in the inspiratory circuit. The ventilator pressurizes the patient circuit by means of a continuous flow of gas (bias flow) and a control valve allows modulation of the mean airway pressure (mP_{aw}). The gas is actively pushed in and pulled out of the patient by diaphragm, which oscillates according to an electrically-driven magnet or by bi-directional blower, depending on the model. The amplitude of displacement of the diaphragm can be modified by adjusting the power, which generates a peak-to-peak pressure gradient, displayed as ΔP on the more commonly-used SensorMedics 3100B oscillator. The oscillation frequency on this ventilator can be adjusted to between 180 and 900 cycles/min (3–15 Hz), although in adults frequencies between 5 and 10 Hz are most commonly used. The amplitude displacement of the diaphragm, the oscillation frequency, and the characteristics of the airway and respiratory system compliance determines the amplitude of the oscillations (or pressure difference ΔP) around the mean airway pressure (mP_{aw}).

During HFOV there is relative decoupling of oxygenation and ventilation. Oxygen is generally directly dependent on FIO_2 and mP_{aw}. Ventilation meanwhile, is directly proportional to power (ΔP) and inversely proportional to the applied frequency. CO_2 elimination is proportional to the frequency and the square of the tidal volume ($Vco_2 \alpha = f \times V_T^2$). Unlike conventional ventilation, where tidal volume (V_T) is relatively independent of respiratory

Table 98.1 Main characteristics of the different types of HFV

Type of HFV	Mechanism	Hz (breaths/min)	Exhalation	Pros	Cons
HFJV	Additional flow through a small-bore catheter placed within the endotracheal tube (Coanda effect)	1.7–2.5 (100–150)	Passive	Very efficient for removing CO_2	Risk of dynamic hyperinflation Unpredictable V_T Tracheobronchial injury
HFPV	HFV + conventional pressure-control breathing pattern	3.4–15 (200–900)	Passive	Improve secretion clearance	Much less studied
HFOV	Pressure oscillations around a mP_{aw}, resulting in very small V_T	3–15 (180–900)	Active	Decoupling of ventilation (depending on V_T and Hz) and oxygenation (depending on mP_{aw}).	Air leak syndrome Right heart failure Pneumothorax

HFJV, high frequency jet ventilation; HFPV, high-frequency percussive ventilation; HFOV, high-frequency oscillatory ventilation.

rate, during HFOV increasing frequency reduces inspiratory time and can have a strong influence on the resultant tidal volume, thus reductions in frequency usually lower $PaCO_2$. The V_T produced is often less than the volume of the anatomical dead space and is determined by the ΔP, the frequency, the airway resistance (mainly by endotracheal tube size), and respiratory system compliance. Even though the ΔP measured in the ventilator circuit can be as high as 90 cmH_2O, the transmission of this pressure to the alveoli is significantly attenuated, and is dependent on the diameter of endotracheal tube, the oscillation frequency, the resistance of the airway, and respiratory system compliance.

Because tidal volumes with HFOV are often lower than dead space volumes, the mechanisms of gas-transport mechanisms are complex and multiple (see Fig. 98.2) [9,10]. Adequate ventilation is achieved through the following phenomena:

- **Direct alveolar ventilation**: despite a very small V_T proximal alveoli may still be ventilated directly by bulk convection (the usual method of gas transport within the lung).
- **Turbulence in the large airways**: causing enhanced mixing.
- **Asymmetric velocity profiles**: due to the rapidly alternating high velocities of gas in the airway, a summation vector is created with a parabolic shape of penetration greater into the centre of the air than in the periphery. This leads to fresh gas entering through the middle of the airway, while expired gas tracks up the outside of the airway.

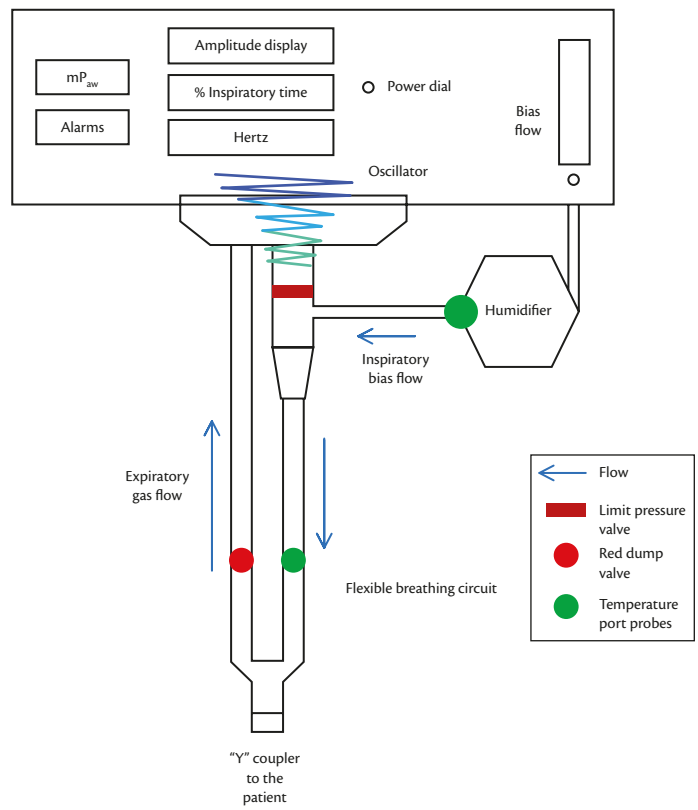

Fig. 98.1 Scheme of the HFOV circuit.

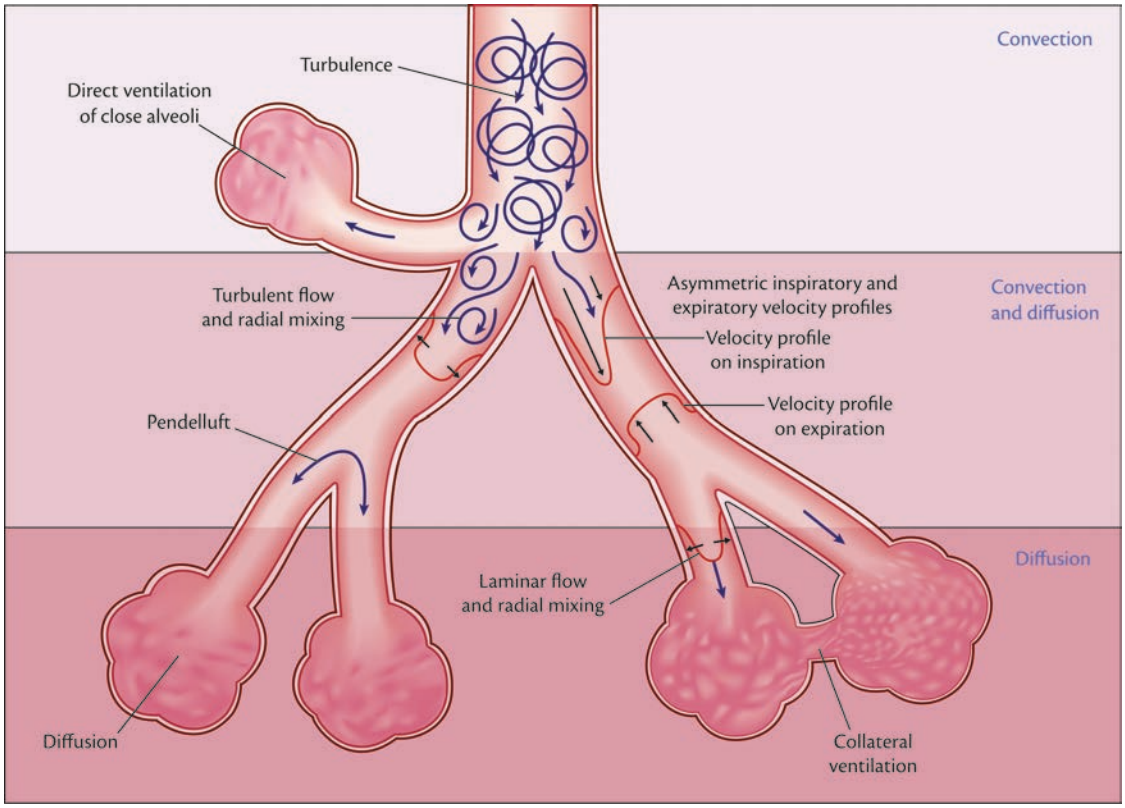

Fig. 98.2 Gas transport mechanisms.

- **Pendulum movement of air between alveolar units (pendelluft)**: this is the exchange of gas between adjacent lung units with differing time constants, due to the asymmetries in airflow impedances.
- **Increased dispersion**: this refers to the molecular dispersion of gas in the airway increases the sinusoidal deformation and radial forces at gas diffusion movements caused by the turbulence produced in the bronchial branches (Taylor dispersion).
- *Molecular diffusion*: displacement of the molecular gas from areas of higher to lower concentration. CO_2 has a higher diffusion constant than O_2.

The key action of HFOV is the constant maintenance of the mP_{aw}, in contrast to conventional modes, where even if the numerical value of mP_{aw} is similar, airway pressure varies greatly over the course of the respiratory cycle. The relatively constant mP_{aw} decreases the resistance to gas movement, facilitating and promoting the gas-transport phenomena described in the bulleted list previous to this paragraph. Moreover, the active recruitment of non-functional alveoli may be accomplished in a few hours, thanks to the constant high mean airway pressure.

Clinical implications

In 1980s Bryan and colleagues developed several physiological studies, which set the basis for our current knowledge of HFOV [7]. There have been several experimental animal studies to apply this mode to prevent VILI. Most of them, even when compared to 'protective' conventional ventilation, showed an improvement in pulmonary injury severity scores, in gas exchange and a decrease of some inflammatory markers (TNF, IL-1B, IL-6, IL-8, IL10, and TGF). Many case series were reported as a first clinical approach since that moment on.

From 1990s up to now, HFV has become standard practice in neonatal and paediatric ICU's in the treatment of newborns with respiratory distress syndrome. A recent meta-analysis [11], however, and the latest Cochrane review [12] comparing HFOV with conventional ventilation in preterm infants do raise some doubts about the real effectiveness of HFOV in the neonatal population. The 15 RCTs included in the Cochrane review showed no clear benefit with HFOV when their results were pooled. In those studies there are data suggesting some reduction in the rate of chronic lung disease (CLD) with HFOV, but that was not consistent across all them. Moreover, the introduction of HFOV into neonatal ICU's coincided with the simultaneous introduction of surfactant in the treatment of newborns with respiratory distress of prematurity. There is strong evidence that surfactant has led to a decreased mortality and morbidity, so a confounding effect cannot be ruled out. Therefore, further trials on elective HFOV in infants at higher risk of CLD could be conducted, although the feasibility of such trials may be questioned given the widespread adoption of HFOV in the neonatal and paediatric setting.

In adults, the first studies were set as a rescue therapy for patients with severe ARDS who were 'failing' conventional ventilation. Fort

et al. published the first of those case series, which suggested an improvement in oxygenation with HFOV [13]. Later on, Mehta and others showed similar results in subsequent case series [14]—HFOV appeared to be safe and effective in improving oxygenation in these extremely severe ARDS patients.

During the late 1990s several small RCT set out to explore those promising results further. The largest of these [15] randomized 148 patients with ARDS to either conventional mechanical ventilation (MV) with a V_T target of 6–10 mL/kg actual body weight, or to HFOV. There was no significant difference between groups in the primary outcome measure of survival without need for mechanical ventilation at 30 days. There was, however, an improvement in oxygenation and a non-significant trend towards lower mortality at 30 days with HFOV compared with the conventional MV (37 versus 52%, $P = 0.102$). Ten years later, however, it was clear that this and other trials were confounded by both small sample sizes and outdated control ventilation strategies. Thus, despite a meta-analysis showing a significant reduction in mortality [11], calls went out for larger trials comparing HFOV with lung-protective conventional ventilation in adults with ARDS. These trials were conceived on the premise that HFOV could be theoretically ideal for preventing VILI, based on the very small tidal volumes delivered, and the minimal swings in alveolar airway pressure, which might allow one to use higher pressures to recruit the atelectatic lung, while simultaneously avoiding tidal overdistention [16,17].

Recently, two large multicentre RCTs have been published, which shed light on the effects of HFOV on all-cause mortality. Both the Oscillation for ARDS (OSCAR; $n = 795$) trial [18] and the Oscillation for ARDS Treated Early (OSCILLATE; $n = 548$) trial [19] recruited patients with moderate–severe ARDS and assigned them to relatively early support with HFOV versus protective conventional MV (with V_T target 6 mL/kg and in the case of OSCILLATE, higher positive end-expiratory pressure). In contrast to prior studies, both of these trials found no evidence of improved survival in patients assigned to HFOV. Indeed, the OSCILLATE trial was stopped early because of concerns of a significantly higher mortality rate in the HFOV group (47 versus 35%).

Complications

HFOV, like any ventilatory mode, has related potential complications. None of the reported RCTs or case series, however, suggested any specific and clear complications at a higher rate than might be expected with conventional ventilation. The specific reasons for the higher mortality seen in the OSCILLATE trial remain uncertain, but among the postulated explanations are:

- Haemodynamic consequences related to higher airway pressures and sedation levels.
- Increased barotrauma and paradoxical increase in VILI.
- Increased sedation use.
- Chance alone.

A known complication of HFOV (and of conventional ventilation) is barotrauma, with the occurrence of air leak being reported in up to 25% of patients in some case series of rescue therapy. This ARDS population, however, is at higher risk of developing pneumothorax. The two recent large trials did not show statistically significant differences in barotrauma, although in OSCILLATE barotrauma rates did trend higher in the HFOV group.

Secondly, because the bias flow rate is insufficient to meet ventilatory demands, adults on HFOV usually requires larger doses of sedation and sometimes paralysis in order to blunt or eliminate their respiratory efforts, something that is often not the case in paediatric and neonatal populations. Transient muscle relaxation is often recommended during the initiation of HFOV, during recruitment manoeuvres and, in some specific conditions, such as air leak syndromes and severe hypoxaemia. In fact, a moderate amount of spontaneous breathing does not usually interfere with gas exchange during HFOV; changes in the mP_{aw} of plus or minus 5 cmH_2O can often be allowed. Moreover, although the use of neuromuscular paralysis and sedation are related with an overall increased mortality in the overall ICU population, they may improve survival when used in short-term and early stages of ARDS.

Another potential complication is the obstruction of the airway due to the lack of clearance of secretions. This effect is uncommon, and can be reduced by means of adequate humidification [13,19]. Nevertheless a sudden increase in $PaCO_2$ or unexplained increase in ΔP on the ventilator should be investigated with bronchoscopy to rule out endotracheal tube obstruction.

Finally, as with any kind of positive pressure ventilation, HFOV increases intrathoracic pressure, reducing venous return and even may potentially promote right heart failure, perhaps because of the constant mean airway pressure to which the right ventricle is exposed [15,20]. However, the presence of acute cor pulmonale is usually reversible in patients who recover from ARDS and does not increase long-term mortality.

Conclusion

HFOV produces effective exchange of CO_2 and O_2 with lower peak pressures at the alveolar level and a higher mean airway pressure. Indeed, applying a stable mP_{aw} produces minimal variations in pressures and ventilation volumes, keeping the lung volume above functional residual capacity largely constant. Therefore, HFOV is an interesting ventilatory modality, which has the potential to minimize ventilator-induced lung injury, at least in theory.

HFOV has become an established lung-protective modality in neonatal and paediatric intensive care, although further studies to support an improvement of mortality and morbidity could be conducted. In adults recent publications do not support the routine use of HFOV in patients with moderate-severe ARDS as there was no signal for benefit and even a suggestion of harm from one trial. While these findings do not necessarily apply to patients with severe hypoxaemia failing conventional ventilation, they do increase uncertainty about the role of HFOV even in these patients. In carefully selected patients who respond to lung recruitment, HFOV may still have a role in severe ARDS, but only after conventional ventilation settings have been optimized and after prone positioning has been considered.

CHAPTER 99

Prone positioning in the ICU

Paolo Taccone and Davide Chiumello

Key points

- Prone positioning optimizes lung recruitment and ventilation–perfusion matching, resulting in an improvement of gas exchange in 70–80% of acute respiratory distress syndrome (ARDS) patients. For this effect, patients with profound life-threatening hypoxaemia may be treated with prone positioning as a rescue manoeuvre.
- Independently from gas exchange, prone positioning may exert a protective role against ventilator-induced lung injury, reducing the unphysiological stress and strain to which the lung parenchyma is exposed during mechanical ventilation.
- The current clinical evidences support the use of prone position in the most severe form of ARDS (e.g. PaO_2/FiO_2 < 150 mmHg, need of high plateau pressure and high positive end-expiratory pressure (PEEP) level, diffuse pulmonary infiltrates), while it should be avoided in less severe patients for its potential adverse effects.
- Optimal dose of prone positioning is still undetermined. Based on the physiological rationale, we currently suggest to apply prone positioning as long as possible (e.g. >18–20 hours daily), until the resolution of the acute phase of ARDS.
- While prone positioning does not required any special equipment to be performed, it may significantly increase the risks of potentially life-threatening complications. Therefore, we recommend that prone positioning should be performed with great care by experienced personnel.

Introduction

Prone positioning (also known as 'proning', 'prone manoeuvre', or 'prone ventilation') refers to mechanical ventilation with patients positioned in prone position in contrast of standard supine (flat or semi-recumbent) position. The use of the prone positioning was proposed over 30 years ago as a means to improve arterial oxygenation in patients with acute respiratory distress syndrome (ARDS) [1]. Since then, extensive physiological research has been conducted to explore the possible mechanisms underlying the observed improvement in gas exchange, which involve changes in the distribution of both ventilation and pulmonary blood flow. Furthermore, it has been shown that, independently of gas exchange, prone positioning may reduce the harm of mechanical ventilation [2,3], which is known to adversely impact patient survival. In this chapter, we will summarize the physiological effect of prone positioning, as well as the clinical evidences supporting its use to reduce mortality in patients with ARDS [4,5].

Physiological effects of prone positioning

The effects of prone positioning on gas exchange results from a redistribution of lung ventilation and pulmonary perfusion. Indeed, in any body position, regional lung ventilation and pulmonary blood flow are influenced by the gravitational field of the earth. When we apply prone positioning to a patients, we reverse the vector of this gravitational force, with major consequences on inflation and perfusion distribution. As a secondary and less relevant effect, prone positioning also promotes postural drainage of secretions from the tracheobronchial tree, possibly ameliorating regional lung ventilation.

Distribution of ventilation

The distribution of alveolar lung inflation is different in prone and supine position [6]. In a normal subject lying flat in supine position, the pleural pressure, that is the determinant of alveolar dimension, results greater in the dorsal posterior region that in the non-dependent sternal region, mainly because of the hydrostatic pressure imposed by the weight of the lung tissue. Therefore, the non-dependent alveoli, located near the sternum, are more inflated than the dependent one in the dorsal region (see Fig. 99.1). In patients with ARDS, this inflation heterogeneity is exaggerated by the dramatic increase in lung weight due to the widespread inflammatory lung oedema. In this condition, the increase in pleural pressure gradient leads to an over inflation of the non-dependent region and a compression atelectasis of the dependent region. When the patient is turned in prone position, the inflation gradient is reversed, and the regional alveolar size is greater in dorsal regions and lower in ventral regions. Once again, the dependent lung regions (ventral) are collapsed [7]. Of note, in prone position the pleural pressure gradient is significantly decreased compared with supine position, resulting in a more homogeneous distribution of alveolar inflation (see Fig. 99.1). Accordingly, a reduced amount of collapsed lung parenchyma (i.e. more lung recruitment) and decreased alveolar over inflation is observed with prone positioning.

Another phenomenon has been recently emphasized to contribute to the redistribution of lung inflation during prone positioning, which is related to the position of the heart in the thorax. Indeed, while in supine position the cardiac mass has a direct compressive effect on the posterior regions of the lung (particularly the left lower lobe), in prone position the lungs are relieved from the heart weight [87], as this lies directly on the sternum. This effect may be particularly pronounced in patient with cardiomegaly.

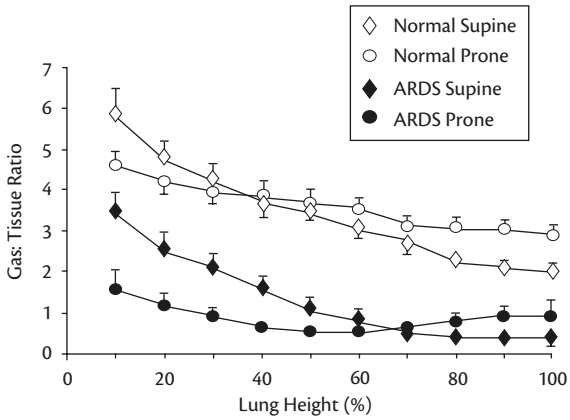

Fig. 99.1 Lung inflation (expressed as gas/tissue ratio measured by CT scan) for each lung section along the ventrodorsal axis (on the *x*-axis, level 0 represents the most non-dependent lung section, while *level 10* represents the most dependent one). Data have been collected on healthy subjects (open symbols) and ARDS patients (closed symbols). The degree of alveolar inflation reflected by the gas/tissue ratio is that observed in the supine (square symbols) and prone position (dot symbols), respectively.

Distribution of perfusion

In normal subject, pulmonary blood flow progressively increases from the non-dependent to the dependent region of the lung, following gravitational distribution. In ARDS patients, factors other than gravity influence regional distribution of lung perfusion force, as hypoxic pulmonary vasoconstriction and extrinsic compression of the vessel by mechanical ventilation. Experimental studies have confirmed that in supine position ARDS leads to a high shunt fraction in the dorsal region (i.e. high perfusion and poor aeration). Interestingly, when the prone position is applied, perfusion distribution is less gravity-dependent than in the supine position, and a substantial fraction of pulmonary perfusion is maintained in the dorsal region. As this phenomenon is coupled to a recruitment of the dorsal region with prone position, the reopened alveoli continues to receive the majority of blood flow, resulting in a shunt reduction and a better matched ventilation/perfusion ratio [9].

Prone positioning and clinical outcome

Effect on oxygenation

Based on the results of many observational studies, as well as randomized controlled trials (RCTs), there is wide agreement that prone positioning increases arterial oxygen tension in most of the patients with ARDS. However, the degree of the response was variable, ranging from great improvement, to no change, and even a significant deterioration in a small fraction of patients. Among patients whose oxygenation improves, this improvement is usually progressive while in the prone position, showing a time-dependent effect. Furthermore, when returning to a supine position after a period in a prone position, some patients maintain an oxygenation benefit for hours, while other rapidly return to their basal supine oxygenation. Finally, the effect of prone positioning may change over the course of ARDS, usually decreasing in its benefit when lung pathology progresses from the oedematous phase to the fibrotic phase (i.e. after 7–10 days).

In conclusion, the short- and long-term oxygenation response while in the prone position are highly variable, probably because the individual response is strictly dependent on patients' underlying pathophysiological status. Notably, while several clinical variables have been investigated as possible predictors of this response, none of them have shown sufficient accuracy to be considered reliable at the bedside.

Effect on mortality

In the past, it has been suggested that prone positioning improves oxygenation, but in recent years there has been a progressive recognition that the prone position may decrease the stress and strain to which the lung parenchyma is exposed during mechanical ventilation [2,3]. Therefore, the possible survival advantage of prone positioning should be independent of oxygenation changes, which were constantly demonstrated to be uncorrelated with outcome, but it may be related to a decrease in the danger associated with mechanical ventilation (ventilator induced lung injury).

To date, five high-quality RCTs have addressed whether prone positioning might decrease the mortality of adult patients with ARDS:

- **The Prone-Supine study group** [10], enrolled 304 patients presenting with acute lung injury (ALI) or ARDS. This study investigates prone positioning applied for a mean of 7 hours daily, for a maximal period of 10 days (mean 4.7 days of treatment). Other relevant co-treatment, as mechanical ventilation settings were not protocolized. Although no effect on 6-month mortality was found in the overall study population, a post hoc analysis showed a trend towards reduced short-term mortality in the subgroup of patients which presented the most severe form of ARDS.
- **The Guerin et al. study** [11]: consisted of a larger population of 802 patients with hypoxaemic acute respiratory failure from various aetiologies (only about half of them fulfilled the ALI/ARDS criteria). The treatment protocol was 9 hours of prone positioning per day, applied until clinical criteria of improvement were matched (mean 4.1 days of treatment). No effect on primary outcome was found, and prone positioning was associated with a significant increase in adverse events.
- **The Mancebo et al. study** [12]: randomized 136 ARDS with diffuse radiologic pulmonary infiltrates. This study investigates a prolonged prone positioning strategy (mean 17 hours daily for 10.1 days of treatment), and included a lung protective mechanical ventilation protocol in both study arms. The findings of the study were negative, but there was a not statistically significant trend in intensive care unit (ICU) mortality reduction of about 15% in the treatment arm.
- **The Prone-Supine study II** [13]: enrolled 342 ARDS patients, using a prolonged prone positioning protocol (mean 18 hours daily for 8.3 days of treatment) and a protocolized protective mechanical ventilation strategy. Based on the result of the previous studies, patients were stratified at enrolment according to the severity of their hypoxaemia (severe hypoxaemia defined as PaO_2/FiO_2 ratio below 100). No significant effect on mortality was found in the overall population, while a trend in 6-month mortality reduction of about 10% was demonstrated in the most severely hypoxaemic patients.
- **The PROSEVA study** [14]: randomized 466 severe ARDS patients with a PaO_2/FiO_2 ratio lower than 150 with a positive end expiratory

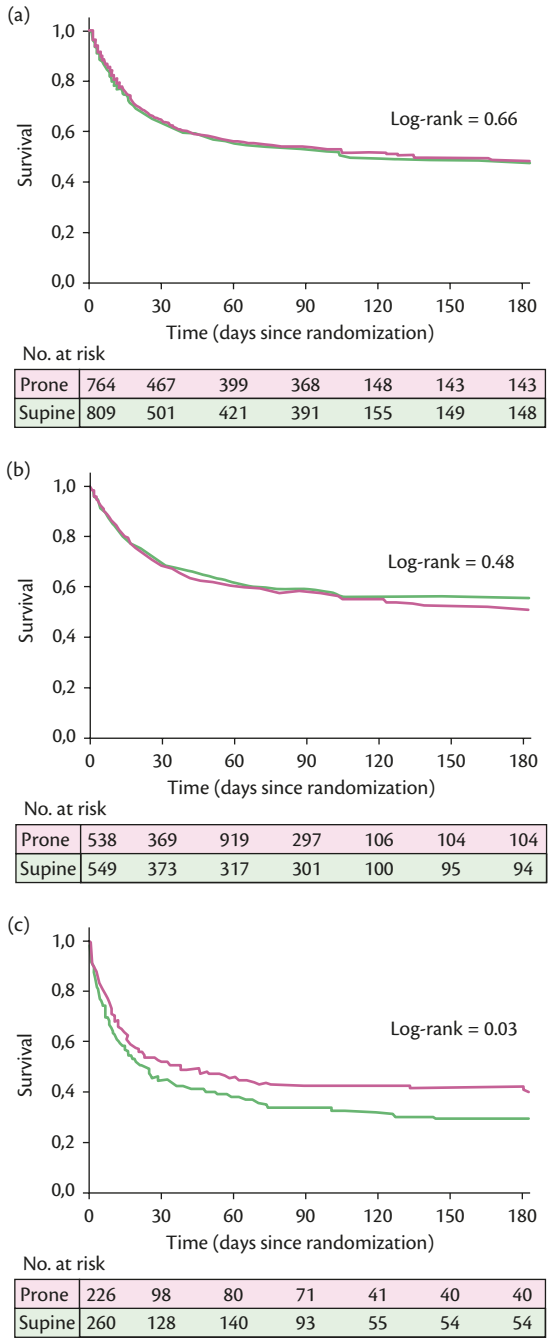

Fig. 99.2 Kaplan–Meier estimates of survival rates of the prone (solid line) and supine (dashed line) patients from a patient-level meta-analysis of the four largest RCTs investigating the effects of prone positioning on mortality [10–13]: (a) entire ARF population, (b) moderately hypoxaemic patients (PaO_2/FiO_2 100–200 mmHg at baseline, and (c) severely hypoxaemic patients (i.e. PaO_2/FiO_2 < 100 mmHg.

pressure (PEEP) higher than 5 cmH_2O to prone positioning for at least 16 hours or to supine position. The 28-day mortality rate was 16% in the Prone group compared with 32.8% in the supine group ($P < 0.001$). Patients were ventilated in the prone position for 73% of the 22.334 patient hours from the enrolment to the last session.

Notably, all these trials have different potential methodological bias, such as inadequate patient selection, underpowered population, possible suboptimal treatment strategy, and lack of standardization for relevant co-treatment (e.g. protective low tidal volume ventilation). However, the last trial published finally showed a definitive evidence supporting that prone positioning has a beneficial effect on survival in the most severely ill patients. Accordingly, two patients-level meta-analyses with different inclusion criteria were conducted in collaboration with trialists of the first four trials [4,5], aiming to study the interaction between the severity of hypoxaemia and the response to prone positioning. Both studies confirmed a survival advantage of prone positioning of about 10% in the most severely hypoxemic patients, with no significant heterogeneity among trials [5]. On the contrary, no effect was observed in patients with less severe hypoxaemia, discouraging the routine use of prone positioning in this subgroup of patients (see Fig. 99.2).

The hypothesis that prone positioning may be more effective in the most severe patients has a strong pathophysiological rationale. Indeed, these patients have been extensively demonstrated to present greater amount of pulmonary oedema, more widespread alveolar collapse and greater lung recruitability [18], and prone positioning exert its lung-protective effect mainly recruiting the collapsed regions of the lung.

Other outcomes

Prone positioning has been hypothesized to reduce the incidence of ventilator-associated pneumonia through improved reduction of secretion. Although some encouraging positive results, most trials evaluating VAP as an outcome were flawed by major limitations, and this finding should be taken cautiously [5].

Application of prone positioning

Patients selection

We believe that available clinical and preclinical data support the use of prone positioning in the management of patients with the most severe form of ARDS. In contrast, given the potentially harmful effects, prone positioning should not be routinely used in patients with less severe ARDS [4,5].

A practical question facing the physician at the bedside is which level of hypoxaemia should be used to identify ARDS patients that may possible benefit from prone positioning. Some RCT investigators proposed a threshold of PaO_2/FiO_2 ratio below 100 mmHg (with a PEEP higher that 5 cmH_2O) [10,13], others 150 mmHg [14]. However, although the PaO_2/FiO_2 ratio is correlated to the severity of the disease process, it is also highly dependent to other confounding factors (e.g. ventilatory strategy, PEEP response, haemodynamic status, fluid balance, etc.), and its reliability and reproducibility as a single indication criterion for prone treatment is questionable. Therefore, we currently suggest that clinicians should evaluate ARDS severity using a PaO_2/FiO_2 threshold (e.g. below 150) preferentially in conjunction with other markers of severity, as the direct/indirect evidence of high recruitability of the lungs (e.g. diffuse infiltrates at CXR or CT imaging), a severe impairment of respiratory mechanics (e.g. high plateau pressure), and a rapidly progressive deterioration of gas exchange unresponsive to conventional ventilation. Furthermore, a lack of oxygenation improvement should not be used as an absolute criterion to discontinue prone positioning. Indeed, as oxygenation response may depends to phenomenon unrelated to lung recruitment (as pulmonary blood flow

diversion) [19], it is not a reliable marker of lung protection during prone positioning.

There are very few absolute contraindications to prone positioning, as spinal instability and unmonitored increased intracranial pressure. Other conditions should be identify as relative contraindication, as open abdominal wounds, multiple trauma with unstabilized fracture, pregnancy, severe haemodynamic instability, and high dependency on airway and vascular access (e.g. extracorporeal membrane oxygenation support).

Positioning and timing of treatment

Prone positioning does not required any special equipment, and it can be safely performed manually by 3–5 specifically-trained health care personnel. Recently, some commercially-available beds have been specifically developed to perform the turning manoeuvre and/or maintain the positioning, but the reduction of workload and the possible advantage of procedure standardization must be weighed against the costs of these rather pricy devices.

In our clinical practice we start prone positioning as soon as the patients is diagnosed as having a severe form of ARDS. It is usual to wait a few hours to allow initial stabilization and perform any diagnostic procedures needed, but if the patient presents with an urgent life-threatening hypoxaemia, which is unresponsive to a highly-supporting mechanical ventilation (e.g. PaO_2 < 55 mmHg with PEEP > 20 cmH_2O and FIO_2 100%), prone positioning should be immediately assumed as a rescue manoeuvre.

The optimal daily duration of prone positioning is still unknown [5]. The final RCTs [12,13] applied a longer time of prone positioning compared with early trials [10,11] (i.e. 17–18 versus 7–9 hours/day), and the PROSEVA study, which used a prolonged prone position clearly showed a significant reduction in mortality [14].

Furthermore, the optimal timing and weaning criteria from prone positioning remain undetermined. Some trials suggested a shorter 'acute phase' protocol [10,11,14], while others prolonged the application of the treatment until the final phases of weaning from mechanical ventilation [12,13]. In the absence of certain information, based on the physiological rationale and clinical data available, currently suggested that a daily prone position be applied for as long as possible (e.g. >18–20 hours daily), until the resolution of the acute phase of ARDS (i.e. <7 days).

Finally, ventilation of patients in the prone positioning according to a lung-protective ventilation strategy is strongly recommended. Moreover, the use of prone positioning has been proposed in association to other non-conventional treatments [14,20] (e.g. inhaled nitric oxide, high-frequency oscillatory ventilation, extracorporeal membrane oxygenation), but the benefit of these combinations remained unpredictable and their use needs to be limited to selected patients in highly specialized centres.

Adverse events

Several side effects have been associated to the use of prone positioning, with some between-report differences in actual occurrence and incidence [10–14]. Some complications of prone positioning are reported as uncommon, but they may be dramatic and potentially life-threatening, especially in severely unstable patients (e.g. inadvertent extubation, displacement of thoracotomy tubes or extracorporeal membrane oxygenation access, major arrhythmias). Other less severe and more common adverse events include the displacement of vascular accesses, need for increased sedation or muscle relaxants, airway obstruction, transient desaturation, hypotension or increased use of vasopressor, and vomiting. Furthermore, dependent facial oedema, pressure ulcers, and some rare cases of nerve compression or retinal damage may occur, and they must be prevented or minimized by careful positioning and the use of adequate soft-padding.

Of note, one of the RCT published a demonstrated a significant increase in the rate of adverse events associated to a prolonged strategy of prone positioning [13]. However, we believe these increased risks may be partially explained by the increased frequency of turning manoeuvres required by the study protocol (i.e., every 4 hours). Therefore, we currently suggest reducing the number of turning as low as possible.

Conclusion

In conclusion, in order to minimize the potential risks, we suggest that prone positioning should be applied only by specifically-trained personnel with adequate experience in its use. A high level of attention of ICU staff is mandatory, especially during the turning manoeuvre, with maximal effort to prevent, or promptly recognize and correct, any possible major complication.

CHAPTER 100

Failure to ventilate in critical illness

Vito Fanelli and V. Marco Ranieri

Key points

- During assisted ventilation, patient and ventilator pumps share the work of breathing, avoiding both respiratory muscle atrophy and fatigue.
- Deterioration of patient/ventilator interplay causes asynchrony, which is associated with prolonged mechanical ventilation, and longer intensive care unit and hospital length of stay.
- Depending on the phase of the respiratory cycle, there are three types of asynchrony—asynchrony during the triggering phase; asynchrony during delivery of inspiratory flow; asynchrony during the cycling phase from inspiration to expiration.
- Bedside analysis of flow and airways pressure traces allows recognizing patient–ventilator asynchrony. Altered mental status, discomfort, activation of accessory inspiratory and expiratory muscles, tachycardia, and hypertension are all signs associated with patient ventilator asynchrony.
- Continuous adjustment of sedation, ventilator trigger, flow rate, and criteria of cycling from inspiration to expiration allow to minimize asynchronies.

Introduction

Mechanical ventilation is a life-saving therapy that is effective in reducing the work required to breathe and improves alveolar ventilation. Since its first description in 1952 during the polio epidemic, mechanical ventilation has become common practice for many physicians, and its technology has improved to provide better care for critically-ill patients [1].

In the most severe forms of acute respiratory failure, the use of deep sedation and neuromuscular blocking agents dictate the adoption of controlled mechanical ventilation. The medical practitioner sets ventilator parameters with the aim of reducing oxygen consumption, improving gas exchange and oxygen availability in the whole organism.

In less severe forms of respiratory failure or during the resolution phase of the disease that has imposed the use of mechanical ventilation, assisted controlled ventilation allows patients to contribute to work of breathing, thus avoiding deep sedation, muscle atrophy, and long-term dependency from the ventilator.

The most robust model that helps to understand the complex interaction between patient and ventilator during respiratory failure is the equation of motion that states [2]:

$$P_{mus} + P_{aw} = V'^{*}R = V_T^{*}E + PEEP_i \qquad \text{[eqn 1]}$$

where P_{mus} is the pressure developed by inspiratory muscles, P_{aw} is the pressure applied to respiratory system by the ventilator, V′ is the inspiratory flow, *R* is the airways resistance, V_T is the tidal volume, E is the elastance of the respiratory system and $PEEP_i$ is the intrinsic PEEP. Based on this equation, respiratory failure occurs when there is an imbalance between the inspiratory muscle generating force and the inspiratory load through its resistance, elastic, and $PEEP_i$ components. Therefore, mechanical ventilation restores the balance, helping respiratory muscle to overcome inspiratory load. In particular, during controlled mechanical ventilation, the contribution of inspiratory muscles (P_{mus}) is negligible, and the ventilator generates pressure (P_{aw}) to overcome the elastic (E) and resistive forces (*R*) of the respiratory system. This generates flow (V′) and changes in volumes (V_T). On the other hand, during assisted ventilation, both the inspiratory muscles and the ventilator pump work together to share the work required to overcome resistance and elastic loads, and the threshold pressure of $PEEP_i$. Any deterioration of this complex interplay causes patient–ventilator asynchrony, which exposes the patient to the risk of failure to ventilate, meaning no rest for their muscles and deterioration of gas exchange. The aim of this current chapter is to define the most common examples of asynchronies between patients and the ventilator, explaining physiopathological mechanisms and common solutions at the bedside. It is noteworthy that around 25% of intensive care unit (ICU) patients experiences asynchrony with the ventilator and those who are failing to ventilate because of asynchrony are exposed to many risks, including prolonged mechanical ventilation [3,4], longer ICU, and hospital length of stay [4].

Ideally, at the same moment when inspiratory muscles are contracting, patients should receive enough assistance from the ventilator to satisfy their ventilation needs and rest their muscles. This is until the switch from inspiration to expiration takes place. For this to happen, it is necessary that the ventilator promptly recognizes the inspiratory effort without delay, through an efficient trigger. Moreover, the machine should provide enough flow for the needs of the patient by matching the patient's neural inspiratory time with that of the ventilator. Toward this end, it is easily understood that

the perfect synchrony between patient and ventilator is a goal to achieve by the physician assessing the patient's ventilator demands [3]. Necessary interventions to improve patient–ventilator interaction can be made by a bedside analysis of flow and airway pressure traces that are displayed on the ventilator's screen [5].

There are three types of asynchrony:

- Asynchrony during the triggering phase.
- Asynchrony during delivery of inspiratory flow.
- Asynchrony during the cycling phase from inspiration to expiration.

This classification takes into account the phase of the respiratory cycle in which the asynchrony occurs [5].

Asynchrony between the patient's ventilatory drive and ventilator's trigger

Asynchrony during the triggering phase occurs when there is a discrepancy between the patient's ventilatory drive and the ventilator's trigger activation (Table 100.1). Inspiratory effort required to activate the trigger is an important part of the inspiratory effort [6]. Newer ventilators are equipped with pressure triggers that are as efficient as the flow triggers in terms of the time that elapses between effort and opening of the inspiratory valve. To date, due to the sensitivity of the trigger systems on newer ventilators, there is a greater risk of AutoTrigger than in their low-sensitivity counterparts. In fact, simple cardiac oscillations, movement of the condensate within the systems of the tubes or air leaks within the system, can activate the trigger [7]. The risk is that breaths, which are delivered by the ventilator without inspiratory effort, may lead to dynamic hyperinflation of the respiratory system, especially in heavily-sedated patients. Consequently, this removes every positive effect of assisted ventilation in terms of respiratory muscle activity. AutoTrigger may be recognized as a breath delivered by the ventilator that is not preceded by a drop in airway pressure as a consequence of inspiratory effort. In this case, it is important to verify the sensitivity of the trigger itself and adjust the level of sedation, such that the patient is not too deep [8].

Ideally, the patient's inspiratory effort should coincide with the 'breath' delivered by the ventilator. The algorithms of the most recent ventilators are based on indirect measurements of the patient's inspiratory time, such as flow or airway pressure signals. In fact, assuming the electrical activity of the diaphragm as the most useful measure to determine the beginning of the patient's neural inspiratory time, several studies have shown that the inspiratory time identified by the activity of the diaphragm differs significantly from that identified by the analysis of flow, oesophageal pressure and trans-diaphragmatic pressure [9]. The direct consequence of this discrepancy is that patient–ventilator asynchronies may be generated and they are essentially of two types–trigger delay and ineffective triggering (Table 100.1). Trigger delay is defined as a delay between the patient's inspiratory time (or the so-called neural trigger) and the breath delivered by the ventilator. The trigger delay can be caused mainly by a depressed respiratory drive [10,11] or by an increase in the elastic load caused by high levels of intrinsic PEEP ($PEEP_i$) [9,12]. In five ICU patients, Parthasarathy showed a significant delay between the beginning of inspiratory effort of the patient, measured by the electrical activity of the crural diaphragm, and the beginning of inspiratory flow [9]. Moreover, in this small cohort of patients, a correlation between the trigger delay and the level of $PEEP_i$ was noted. As a consequence, $PEEP_i$ represents a threshold that must be overcome before inspiratory flow could be delivered. It is important to note that in COPD patients with high levels of $PEEP_i$, the increase of the inspiratory effort required to match the value of $PEEP_i$ may have negative haemodynamic consequences. For example, an important inspiratory effort equal to an oesophageal pressure of –15 cmH_2O, in the presence of a value of $PEEP_i$ equal to 20 cmH_2O, leads to a significant increase in cardiac venous return and displacement of the interventricular septum with an altered diastolic filling of left ventricle [13]. The application of an external PEEP value, equal to about 80% of the value of $PEEP_i$, reduces inspiratory effort and improves haemodynamics [13].

Finally, an excessive elastic load may generate the second type of asynchrony—ineffective triggering. Ineffective triggering is defined as a reduction in oesophageal pressure of more than 1 cmH_2O that is not able to open the inspiratory valve, or has not achieved an increase of inspiratory flow >100 mL/sec [10]. At the bedside, ineffective triggering has been shown to represent nearly 90% of patient–ventilator asynchrony events [4] and it can be identified through the analysis of flow traces displayed on the mechanical ventilator. The start of this trigger is indicated by the point at which the expiratory flow decreases suddenly during expiration, altering its normal morphology and reaching the zero line. The time elapsed between this point and the point at which the airway pressure begins to rise is the 'triggering delay'. If a breath delivered by the mechanical ventilator does not follow this abrupt reduction in expiratory flow, ineffective triggering occurs (Table 100.1). Ineffective triggering is caused by high levels of ventilator assistance in either pressure-support or assisted-controlled ventilation [10]. It has been demonstrated that the amount of ineffective triggering is proportional to the level of assistance by the ventilator [10]; in fact, increasing the level of assistance reduces the work of breathing and the degree of dyspnoea, but also increases the number of ineffective triggering. It is important to note how breaths before ineffective triggering are characterized by larger tidal volumes, shorter expiratory time, and higher values of $PEEP_i$ [10,14]. Consequently, the increase in the elastic load due to the $PEEP_i$ threshold may be an important risk factor for ineffective triggering [10,12,14]. Of note, ineffective triggering has been associated with poor outcome, highlighting the need to recognize asynchrony and promptly correct it. In a cohort of 60 ICU patients under mechanical ventilation within 24 hours, those who showed ineffective triggering breaths were more that 10% of total breaths in 10 minutes of observation had poorer outcomes as demonstrated by longer duration of mechanical ventilation, fewer ventilator-free days and a lower likelihood of home discharge [4].

Many attempts have been made to reduce the time delay between a patient's inspiratory time and flow delivered by the ventilator. In this respect, synchrony during the triggering phase has been improved significantly with the neutrally-adjusted ventilatory assist (NAVA) ventilation mode [15]. In fact, with this method of assisted ventilation, the signal recognized by the ventilator to deliver the inspiratory flow is very close to the patient neural time and it uses neural electromyography activity of the diaphragm [15]. In this case, therefore, the trigger will not consist of changes in pressure or flow signals that are greatly influenced by the extent of respiratory elastic load. During NAVA, the level of assistance is proportional to every millivolt of electrical activity of the diaphragm, and the

Table 100.1 Different types of patient–ventilator asynchrony, in relation to the phase of the respiratory cycle in which are realized possible causes and remedies to implement

Type of asynchrony	Phase of respiratory cycle	Aetiology	Diagnosis	Solution
Asynchrony during triggering phase: ◆ Autotrigger. ◆ Trigger delay. ◆ Ineffective triggering.	Inspiration	**Autotrigger:** High trigger sensitivity; cardiac oscillations; movement of condense into tubing system; air leaks. **Trigger delay:** Depressed respiratory drive; over-assistance by the ventilator; increased elastic load ($PEEP_i$). **Ineffective triggering:** Depressed respiratory drive; over-assistance by the ventilator; Increased elastic load ($PEEP_i$).	**Autotrigger:** Lack of decrease in the airway pressure tracing at the beginning of inspiration. **Trigger delay:** Time delay between the abrupt decrease of expiratory flow (with distortion of morphology) until it reaches zero line and the beginning of airway pressure increase **Ineffective triggering:** Time delay between the abrupt decrease of expiratory flow (with distortion of morphology) until it reaches zero line and the beginning of airway pressure increase.	**Autotrigger:** Check trigger sensitivity; reduce the level of sedation; correct underlying respiratory alkalosis. **Trigger delay:** Reduce the level of sedation; reduce the level of assistance by the ventilator; minimize $PEEP_i$, essentially increasing expiratory time. **Ineffective triggering:** Reduce the level of sedation; reduce the level of assistance by the ventilator; minimize $PEEP_i$, essentially increasing expiratory time.
Asynchrony during the delivery of inspiratory flow: ◆ Rate of increase in airway pressure. ◆ Inspiratory flow.	Inspiration	Higher or lower rate of increase in airway pressure. Higher or lower inspiratory flow.	**Rate of increase in airway pressure:** Lower rate of increase in airway pressure is associated with increased work of breathing and patient's discomfort. **Inspiratory flow:** Higher inspiratory flow is associated with a decrease of inspiratory time and an increase of respiratory rate.	**Rate of increase in airway pressure:** Optimize the rate of increase in airway pressure to reduce dyspnoea and to avoid short inspiratory time, especially in patients with long time constant of respiratory system. **Inspiratory flow:** Titrate the inspiratory flow to patient's ventilation needs avoiding the miss concept that higher inspiratory flow reduces tachypnoea.
Asynchrony during the cycling phase from inspiration to expiration.	Expiration	Patient's neural inspiration lasts longer than ventilator inspiratory time. Patient's neural inspiration lasts less than ventilator inspiratory time.	Longer neural inspiration 'Double triggering', two breaths delivered by the ventilator for each inspiratory effort: the asynchronous breath lasts less the breath before. Shorter neural inspiration. Activation of expiratory muscle during ventilator inspiratory time. Consequently, it's possible to observe a sudden increase in the airway pressure at the end of inspiration.	Longer neural inspiration. Change the expiratory trigger in order to increase the duration of inspiration. This means the expiration begins after higher percentage of flow decay. Shorter neural inspiration. Change the expiratory trigger in order to decrease the duration of inspiration. This means the expiration begins after lower percentage of flow decay.

inspiration ends when the peak value of electrical activity of the diaphragm decreases to a fixed percentage. In this way, the level of assistance is proportional to the electrical activity of the diaphragm, leaving part of the work of breathing to the patient; it terminates when the diaphragm is relaxed and the electrical activity is decreased [16].

Asynchrony between the patient's ventilatory requirements and flow delivered by the ventilator

Good patient–ventilator synchrony is achieved even when the mean inspiratory flow is adjusted to the patient's ventilator requirements. In fact, flow asynchrony has been related to the increase in the speed of airway pressurization, the patient's ventilator drive, and the ventilator's performance [17]. Both airway pressurization rates that are too slow or too fast may produce discomfort for the patient [18] (Table 100.1). A slow rate of airway pressurization may not reduce the patient's dyspnoea and, indeed, increases the work of breathing, especially in the presence of impaired respiratory mechanics as in COPD or in patients with restrictive diseases [17]. In 11 COPD patients under assisted ventilation, the same inspiratory pressure was applied with a different rate of airway pressure increasing, ranging from 0.1 to 1.5 seconds. In this cohort of patients, Bonmarchand showed that progressively slower rates of airway pressure increasing were associated with an increased work of breathing, while respiratory rate, tidal volume, and $PEEP_i$ remained unchanged [17].

Asynchrony between inspiratory time of the patient and cycling of ventilator from inspiration to expiration

In ideal conditions, the patient's end of inspiration should coincide with the opening of the exhalation valve of the ventilator in order to allow passive expiration. In a controlled mode, cycling of the ventilator from inspiration to expiration is determined by the amount of inspiratory flow and the respiratory rate. On the contrary, in assisted ventilation mode, the algorithm of the ventilator must recognize the end of inspiration. In the pressure-support ventilation, cycling of the ventilator from inspiration to expiration occurs as a consequence of exponential decay of the inspiratory flow; in fact, the expiratory valve opens when the flow is reduced to a threshold value, usually expressed as 30% of peak flow. However, this criterion presents some issues [12], since the patient's inspiration may be shorter or longer than the time to deliver a given flow by the ventilator (Table 100.1). For example, if the flow delivered by the ventilator ends before the end of the patient's neural inspiration, an asynchrony may take place—the so-called 'double triggering' in which two breaths are delivered by the ventilator for a single inspiratory effort. This asynchrony is easily identifiable because the asynchronous breath is shorter than the preceding breath. In fact, the asynchronous breath begins at a higher volume of elastic equilibrium. It is possible to manipulate the expiratory trigger in modern ventilators by changing the decrease percentage of flow, which determines the cycling from inspiration to expiration. Therefore, manipulation of the expiratory trigger in order to increase the duration of inspiration avoids double triggering asynchrony (see Table 100.1).

In contrast, in patients with high values of time constants of the respiratory system, as in COPD patients, the mechanical ventilator may continue to deliver flow, even after the end of a patient's neural inspiration [19]. The time constant (τ) indicates the time necessary for the respiratory system to reach the volume of elastic equilibrium, and it is proportional to the value of airway resistance and compliance of the respiratory system according to the following formula:

$$\tau = R\,\mathrm{cmH_2O/L/sec} * C\,\mathrm{L/cmH_2O} \qquad \text{[eqn 2]}$$

where R indicates the value of airway resistance and C indicates the value of respiratory system compliance.

In COPD patients, the time constant of the respiratory system may be increased due to high values of expiratory resistance and compliance because of dynamic hyperinflation and/or expiratory flow limitation. Therefore, the longer time necessary for the flow to fall at threshold value determines that the inspiratory time of the ventilator to deliver flow is longer than the neural inspiration of the patient, causing asynchrony. In COPD patients with high constants equal to 0.54 and ventilated with a pressure support of 20 cmH_2O, a clear asynchrony has been shown consisting of activation of expiratory muscles during inspiratory flow delivered by the ventilator [20]. Consequently, this expiratory asynchrony is characterized by the sudden increase in airway pressure at the end of inspiration caused by activation of expiratory muscles. This asynchrony may be avoided by manipulating the expiratory trigger in order to reduce the ventilator's inspiratory time (see Table 100.1).

Conclusion

Optimization of patient–ventilator interactions can only be achieved through a continuous adjustment of ventilator trigger, flow rate, and criteria of cycling from inspiration to expiration. These fine adjustments imply an interpretation of ventilator waveforms as flow and airway pressure. Nevertheless, it is mandatory to observe patients at the bedside, looking for signs of asynchrony, such as altered mental status, discomfort, activation of accessory inspiratory and expiratory muscles, tachycardia, and hypertension.

CHAPTER 101

Ventilator trauma in the critically ill

Marcelo Amato and Andreas Wolfgang Reske

Key points

- Ventilator trauma refers to complications of mechanical ventilation that have an impact on morbidity and mortality.
- Two major forms of ventilator trauma may be distinguished, an acute form related to rupture of airspaces causing air leak syndrome and a subacute form causing protracted inflammatory responses.
- The most relevant consequence of airspace rupture is tension pneumothorax, which requires emergency intervention to prevent respiratory or haemodynamic collapse.
- Subacute ventilator trauma results from cyclic sublethal cell injury during mechanical ventilation and triggers intense, potentially self-perpetuating inflammatory responses.
- A marker-variable to monitor the risk of subacute ventilator trauma is driving-pressure. Because it is closely related to lung compliance and thus to the size of the lung compartment that remains functional, driving-pressure can aid in identifying disproportionate combinations of tidal volumes and lung compliance.

Introduction

Two major forms of ventilator trauma, occurring as complications of mechanical ventilation, can be conceptualized. The first form is the occurrence of extra-alveolar gas, also called gross barotrauma or air leak syndromes. Most air leak syndromes, such as pneumothorax or subcutaneous emphysema, cause acute problems. In contrast, the second form of ventilator trauma represents a subacute problem that can be easily obscured by complex critical illness. Except for extreme conditions found in experimental models, subacute ventilator trauma often causes protracted lung inflammation, fibrosis, and deterioration of lung function, contributing to systemic inflammation and organ failure. Clinical distinction of the two forms of ventilator trauma is not always straightforward. For example, gross barotrauma may cause venous gas embolism, leading to pulmonary hypertension, inflammation, and deterioration of gas exchange, ultimately mimicking the clinical picture of the subacute form. The recognition that subacute ventilator trauma may impair prognosis and increase mortality in mechanically-ventilated patients was one of most important discoveries of the last decades, and directly affected our daily practice of mechanical ventilation.

Gross barotrauma

Extra-alveolar gas usually escapes through ruptured alveoli or terminal airways at the junction with the vascular sheaths, due to large pressure gradients between intra-alveolar and interstitial spaces. Large pressure-gradients between these two regions are created not only during positive-pressure ventilation, but also during strong spontaneous efforts when very negative interstitial pressures are created. Gas accumulation in the pulmonary interstitium is called pulmonary interstitial emphysema. Gas may migrate through the interstitium, either peripherally, forming subpleural cysts, or centrally reaching the hilum and mediastinum. Pressurized mediastinal or subpleural gas collections can rupture and cause pneumothorax. Many pneumothoraces occurring during positive-pressure ventilation are under tension, necessitating prompt intervention to prevent respiratory or haemodynamic collapse. Gas can also spread along fascial planes to the neck, thorax, or abdomen, and cause subcutaneous emphysema or pneumoperitoneum.

The current incidence of gross barotrauma during a prolonged course of mechanical ventilation is below 10%, much lower than the figures reported before the advent of lung-protective mechanical ventilation. Although gross barotrauma is rarely the cause of death, its occurrence indicates severe underlying lung pathology, and is statistically correlated with increased morbidity and longer intensive care unit (ICU) stay. Common risk conditions for gross barotrauma are acute respiratory distress syndrome (ARDS), pneumonia, aspiration, and air trapping due to obstructive airway diseases. Such conditions are commonly associated with global airspace overstretching, as in asthma, or with localized overstretching, as in ARDS, where few lung regions remaining aerated (the '**baby lung**') must accommodate unevenly distributed tidal volumes [1].

Interestingly, gross barotrauma has not been necessarily associated with high positive end-expiratory pressure (PEEP), except for old studies using large tidal-volumes. In recent clinical studies limiting airway plateau-pressures below 35 cmH_2O, no clear association between high airway pressures and barotrauma could be detected.

Ventilator-induced lung injury

The subacute form of ventilator trauma, named 'ventilator-induced lung injury' (VILI) in experimental studies or, more conservatively (when the relative contributions of mechanical ventilation and

underlying disease are less clear), 'ventilator-associated lung injury' is histologically indistinguishable from the diffuse alveolar damage associated with ARDS. In lung samples from experimental animals and patients, light microscopy revealed alveolar haemorrhage, neutrophil infiltration, hyaline membranes, intra-alveolar and interstitial oedema, increased septum thickness, airspace collapse, and proliferation of macrophages and type II pneumocytes. Within terminal airways, alterations such as intraluminal inflammation, epithelial denudation, and necrosis have been described. Later, in a more chronic phase, alterations include bronchopulmonary dysplasia, cysts (dilated airways), airway remodelling, and fibroproliferation. Electron microscopy further reveals endothelial/epithelial abnormalities and tears, disruptions of the basement membrane, formation of intracapillary blebs, and an abnormal surfactant layer.

A key feature of mechanically-ventilated lungs, whether normal (during anaesthesia ventilation) or diseased, is the presence of non-aerated and unstable regions due to atelectasis, oedema or consolidation. Besides representing the disease itself, loss of aeration has been proposed as a central biophysical promoter of VILI. It was shown that, in the same lung, unstable lung regions were injured by VILI, whereas stable regions were not. The classical concept of mechanical interdependence suggests that pressures acting locally in non-uniformly expanded lungs at the boundaries between the atelectasis and aerated lung may be a multiple of the apparent transpulmonary pressure [2].

Synergistically with but also independent from non-uniform lung aeration, cyclic airspace overstretching, alveolar instability (due to surfactant dysfunction or negative transpulmonary pressures, for instance), and lung inflammation, have all been reported to precipitate or contribute to VILI. The sequelae of these mechanisms and the resulting intensity of VILI seem to depend on the intensity and duration of ventilation and are not restricted to mandatory ventilation. Among the physical mechanisms of VILI is the detachment of epithelial and endothelial cells from basement membranes and rupture of cellular and/or cytoskeletal structures. In addition to physical injury, a generalized pulmonary inflammatory response can cause and maintain VILI. Pulmonary inflammation involves neutrophil accumulation and activation in the pulmonary capillaries, the interstitial, and the alveolar spaces, and potentiates the destabilization of the alveolar–capillary barrier. The consequences are the development and dispersion of oedema, loss and inactivation of surfactant, loss of integrity of the alveolar compartment, and the transfer of bacteria and inflammatory mediators into the systemic circulation [3].

Accordingly, inflammatory cytokine concentrations (e.g. TNF-α, interleukin-(IL)-1β, IL-6, or IL-8) in broncho-alveolar lavage fluid or serum are associated with more injurious ventilation and with higher morbidity or mortality. Among the mechanisms by which cellular and subcellular pulmonary structures can sense injurious mechanical stimuli, and trigger and maintain local and systemic inflammatory or reparative responses are transformation of strain into (bio)chemical signals (mechanotransduction), stress failure of cytoskeletal structures (necrosis), and impairment of the alveolar barrier (decompartimentalization). These mechanisms can be activated also by unilateral injury or even without ultrastructural damage [3].

Several of the afore-mentioned pathomechanisms have the potential to become self-perpetuating. Proteinaceous oedema, for example, increases the lung weight and inactivates surfactant, which aggravates collapse of the dependent lung regions, worsens the non-uniformity of lung aeration and amplifies the negative effects of mechanical interdependence. The latter in turn alters vascular transmural pressures, promotes the development and distribution of lung oedema, and impairs ventilation-to-perfusion matching. Surfactant depletion and dysfunction, as another example, creates negative perivascular pressures, which together with altered alveolar–capillary barrier permeability, promote the development of oedema.

Seminal studies observed that adding PEEP to injurious mechanical ventilation attenuates VILI and may interrupt the viscious cycle described in the previous paragraph. The generalized readout of such experiments is that PEEP attenuates VILI when the end-inspiratory volume or plateau pressures are maintained unchanged [4,5]. To explain such beneficial effects, many facets of the application of PEEP need to be considered. First, adding PEEP to mechanical ventilation with unchanged plateau pressure reduces the amplitude of both pressure and cyclic (over)stretching. Applying PEEP to a non-uniformly expanded lung reduces the amount of non-aerated lung units, stabilizes unstable lung units, and reduces both non-uniformity and oedema.

Effects on remote organs

The clinical consequences of VILI are not limited to the lung. Injurious ventilation can have deleterious systemic effects. Accordingly, the most common cause of death in ARDS patients is not intractable hypoxaemia, but a systemic inflammatory response syndrome and multiple organ dysfunction. Interactions between local pulmonary, systemic and distal organ inflammation may help explaining the decreases in serum levels of inflammatory cytokines, associated with decreased morbidity and mortality observed in recent trials of lung-protective mechanical ventilation [6].

Barotrauma versus volutrauma

After the recognition of subacute ventilator trauma unrelated to air leaks, it was proposed to replace the old term *barotrauma* (i.e. pressure-induced trauma) by **volutrauma** (volume-induced trauma). The rationale for this new terminology came from two remarkable observations:

- Chest strapping, by significantly decreasing chest-wall compliance, minimized VILI despite the application of very high positive airway pressures.
- Negative pressure ventilation, by cyclic application of vacuum around the chest wall, could produce severe VILI—despite atmospheric airway pressure.

Tidal volumes generated in the first experiment were small, but very high in the second experiment. Thus, injury was not solely related to high airway pressures—it only occurred when high tidal volumes were concomitantly generated [4].

Although representing an improvement, the term **volutrauma** was later shown to be also imprecise. It became evident that high tidal volumes are not always injurious. Conversely, in lungs with gross collapse and low tidal-compliance, VILI can occur despite 'protective' tidal volumes (as low as 4 mL/kg). To better estimate injury risks, it was later proposed that tidal volumes should be individualized according to both the potential size of the whole lung (normalized by height or ideal body weight), but also according to

the size of the functional lung compartment (spared from disease) that accommodates the tidal volume. This reduced functional lung volume in ARDS patients has been termed the **baby lung** [1]. The lung areas within the **baby lung** that are spared from collapse, are particularly exposed to VILI because they are exposed to significantly increased mechanical work. Since shunt makes gas exchange less efficient, the spared zones have to achieve the whole ventilation task. Studies using positron emission tomography have shown that the most inflamed areas in injured, mechanically-ventilated lungs are the ones receiving the highest ventilation, and not the silent, non-aerated regions.

Stress, strain and cyclic lung stress

Trying to circumvent the main limitations of the terms **barotrauma** and **volutrauma**, the engineering terms **stress** and **strain** were recently proposed for defining risk-constellations for VILI.

Stress represents an evolution of **barotrauma**. Risk is now defined in proportion to transpulmonary pressures (airway minus pleural pressure) and it becomes possible to explain the attenuation of VILI by chest strapping. It is also possible to explain the pronounced VILI associated with negative pressure or vigorous spontaneous ventilation—strongly negative pleural pressures may generate high transpulmonary pressures even against atmospheric airway pressure.

Conversely, **strain** represents an evolution of **volutrauma** and risk is now defined in proportion to resting lung volume. **Strain** equals the ratio between end-inspiratory lung volume and functional residual capacity (when central airways are submitted to atmospheric pressure). Thus, it can be explained why even small tidal volumes can be injurious in patients with gross lung collapse—the resting lung volume (the denominator) decreases and **strain** becomes high.

One main limitation of the **stress/strain** approach is its physical reductionism: it assumes that **stress** on the structure can be estimated as a quasi-linear function of **strain**. In fact, a complex structure like the lung, composed of different cell types attached to a network of extracellular matrix, elastic and collagen fibres, reacts to physical deformation in a markedly non-linear manner. For instance, the response of pneumocytes to surface deformations depends on their repair capabilities. There is a clear threshold, beyond which further **strain** causes cell wounds and uncontrolled transmembrane ion traffic. The lung has a very large reserve of alveolar surface, which is folded during resting conditions. Therefore, the delicate lung surface will be stressed only when unfolding is no longer possible. Below this threshold, prolonged large variations in surface area (i.e. during a marathon race) are tolerated without significant injury. Assuming that this non-linearity is constitutive for lung function, the interchangeable use of **strain/stress** becomes troublesome. The assessment of **stress** requires oesophageal pressure measurement as a surrogate of pleural pressure, which is rarely reliable in supine patients with massive atelectasis. Proper **strain** calculation requires whole-lung computed tomography and many approximations for the calculus of recruitment and true 'surface deformation' (as opposed to surface unfolding). In conclusion, the actual **stress** will hardly be represented by in vivo **strain** measurements, especially when considering measurement errors at the bedside.

Another limitation of the **stress/strain** engineering perspective is the omission of consideration of the 'pace of deformation'—vital cells easily adapt to sustained deformations by the neoformation of cell membranes, but they rarely survive rapid, large changes of alveolar surface area. It has been shown that **strain** preconditioning helps cells to stand a subsequent large deformation [3]. Translated to a larger scale, increasing end-expiratory volumes by application of PEEP may have preconditioning effects protecting against injury by high inspiratory lung volumes (**strain**). This would be another explanation for protective effects of PEEP.

Bedside estimate of cyclic lung stress

Based on the principles exposed previously, absolute end-inspiratory thresholds should be de-emphasized for assessing the risk of VILI. Cyclic deformation-thresholds should be proposed instead. Variables indicating cyclic **stress** variations (pressure swings) applied to the lung tissue seem preferable to markers of area/volume deformation, since the latter are difficult to assess at the bedside. Transpulmonary pressures should be included in the consideration of ventilator settings: increased pleural pressures might counterbalance **stress**, while negative pleural pressures may amplify stress.

A marker-variable fulfilling most of the aforementioned characteristics is **driving-pressure** [7]. During controlled mechanical ventilation, **driving-pressure** is the difference between end-inspiratory and end-expiratory pressures, both measured during the brief pauses while flow is zero. It represents the total cyclic pressure gradient applied across the respiratory system for elastic expansion of lung plus chest wall. Thus, part of the total **driving-pressure** applied to the respiratory system is counteracted by chest wall elastance, which means that cyclic lung stress would be better represented by isolated measurements of transpulmonary pressure. Nevertheless, the simplification of using **driving-pressure** as a marker-variable is convenient because it renders estimation of pleural pressure unnecessary and it is also reasonable because lung elastance during acute diseases is typically 5–10 times higher than chest wall elastance [7]. Therefore, the majority (80–90%) of **driving-pressure** is indeed applied to the lung. Moreover, obesity and intra-abdominal hypertension usually cause positive offsets in pleural pressures, but rarely increase chest-wall elastance, which is relatively constant among patients.

Assuming that **driving-pressure** mirrors cyclic changes in transpulmonary pressure shows why this variable has the best predictive power for VILI in experimental and human studies, and outperforms simple measurements of plateau pressure or tidal volume [7]. Moreover, **driving-pressure** can be calculated as the ratio between tidal volume and compliance. Because the size of the **baby lung** is positively correlated to compliance, **driving-pressure** will indirectly account for the size of the **baby lung**—for a given tidal volume [1].

For application of **driving-pressure** as a surrogate of cyclic **stress**, a **driving-pressure** threshold would aid in limiting cyclic deformation and VILI. Obviously, no well-established threshold can yet be proposed. However, in all recent trials testing lung-protective ventilation strategies, reduction of **driving-pressure** (usually to below 15 cmH_2O) was associated with reduced morbidity and mortality [7]. This **driving-pressure** threshold is also supported by millions of patients who undergo uncomplicated anaesthesia ventilation, where **driving-pressure** is commonly below 15 cmH_2O.

The **driving-pressure** concept can also be applied in the presence of spontaneous breathing efforts when some reasonable assumptions are made. If the respiratory system compliance can be

measured during a preceding period of controlled ventilation, the tidal volume during subsequent assisted spontaneous efforts allows estimation of the total **driving-pressure** applied to the system by ventilator and inspiratory muscles. Using this approach, potentially injurious combinations of compliance and tidal volume can be identified. For instance, a tidal volume of 500 mL measured during low levels (e.g. 5 cmH_2O) of pressure support, together with a recent compliance measurement of 20 mL/cmH_2O, indicates that a very high total **driving-pressure** of 25 cmH_2O is applied, deserving the same concern as if it was observed during controlled ventilation.

Conclusion

Still today, acute and subacute ventilator trauma cause significant extra-morbidity and -mortality in mechanically-ventilated patients. The traditional concepts of barotrauma and volutrauma evolved to more sophisticated considerations about physical stress and strain applied to the delicate lung tissue. By representing integrated information about cyclic lung stress and specific responses of the lung tissue, **driving-pressure** can work as a marker-variable to predict the risks of VILI at the bedside.

PART 4.7

Weaning ventilatory support

CHAPTER 102

Assessment and technique of weaning

Martin J. Tobin

Key points

- Several studies suggest that most patients weaned successfully could have tolerated the weaning attempts had they been initiated a day or more earlier. Such data emphasize the need for the early use of screening tests.
- A screening test should have a high sensitivity. The ratio of respiratory frequency to tidal volume (f/V_T) has been evaluated in more than 25 studies—its average sensitivity is 0.89.
- Weaning involves undertaking three diagnostic tests in sequence, measurement of predictors, a weaning trial, and a trial of extubation.
- Of the techniques used for a weaning trial, IMV has been repeatedly shown to be inferior to the use of T-tube trials or pressure support.
- Six randomized trials have evaluated the usefulness of protocols in the management of weaning. Three revealed no benefit, two had major methodological problems, leaving only one supporting the use of protocols.

Introduction

Although mechanical ventilation is often lifesaving, the high risk of complications makes it imperative to disconnect patients from the ventilator at the earliest possible time [1]. This process is usually referred to as weaning, an unfortunate term because the word means a gradual reduction in a process [2]. Most patients move quite abruptly from a period of high-level support to unassisted breathing.

The timing of this process is critical. Several randomized controlled trials (RCTs) have revealed most patients who received mechanical ventilation for a week or longer were able to tolerate ventilator discontinuation on the first day that weaning-predictor tests were measured [3,4]. Many of these patients may have tolerated extubation a day or so earlier.

Many physicians view weaning predictors as something to perform at the point they think a patient might be able to tolerate disconnection from the ventilator. However, weaning predictors have the greatest potential for enhancing clinical management if performed at a time when physicians have considerable doubt as to whether or not a patient is ready for ventilator disconnection.

One of the main sources of weaning delay is the failure to **think** the patient just **might** come off the ventilator. Psychological research suggests much of this delay in ventilator weaning results from clinicians being overconfident in their intuition that a patient is not ready for a weaning trial [2]. Another source of error is the failure to pay close attention to pretest probability, i.e. failure to recognize the importance of Bayesian principles in clinical-decision making.

Assessment of patient readiness for weaning

By alerting physicians to a patient's readiness to tolerate unassisted ventilation—hours or days before he or she would otherwise order a spontaneous breathing trial—weaning-predictor tests circumvent the cognitive errors inherent in clinical decision-making [2].

Weaning-predictor tests function solely as a screening test. The goal of a screening test is not to miss anybody with the condition under consideration. It should have a low false-negative rate and a higher false-positive rate is acceptable [5]. An ideal screening test has a high sensitivity [2,5].

Weaning uses three diagnostic tests in sequence—measurement of predictors, a weaning trial, and a trial of extubation [2]. The sequential nature of the testing leads to particular problems in studies undertaken to investigate the reliability of a predictor test. One is spectrum bias where a new study population contains fewer (or more) sick patients than the population in which a diagnostic test was originally developed [5,6]. A second is test-referral bias, where the results of a test under evaluation are used to select patients for a reference-standard test, e.g. passing a weaning trial that leads to extubation [5,6]. A third factor is base-rate fallacy [6,7]. Consider a diagnostic test for a disease that has a false-positive rate of 5% and false-negative rate of 0%, and the incidence of the disorder (under consideration) is 1 per 1000 persons. A randomly selected person undergoes diagnostic testing. The result comes back positive. What is the chance this person has the disease? Most physicians answer 95%. The correct answer is 1.96% [7]. Physicians who answer 95% are failing to take into account the pretest probability of the disorder. Thus, they fall into the trap of base-rate fallacy.

Pretest probability is the estimate of the likelihood of a particular condition (weaning outcome) before a diagnostic test is undertaken [2]. Post-test probability (typically expressed as positive- or negative-predictive value) is the new likelihood after the test results are obtained. A good diagnostic test achieves a marked increase (or decrease) in the post-test probability (over pretest probability) (Fig. 102.1). For every test the change between

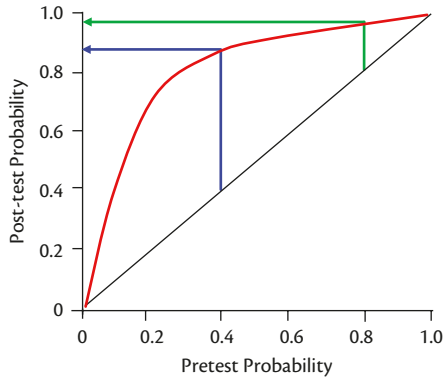

Fig. 102.1 Relationship between pre- and post-test probability for a good weaning-predictor test, sensitivity of 0.9 and specificity of 0.9, is characterized by the red curve. If pretest probability of weaning success is 0.40, Bayes' theorem dictates that a positive result on the weaning-predictor test will yield a post-test probability of 0.86. If pretest probability is 0.80, post-test probability will be 0.97. The increase between pretest and post-test probability in the second instance (21%, 0.17/.80) is only a fraction of that in the first instance (115%, 0.46/0.40) despite the sensitivity and specificity being identical. Thus, a high pretest probability markedly decreases the apparent reliability of a weaning-predictor test.

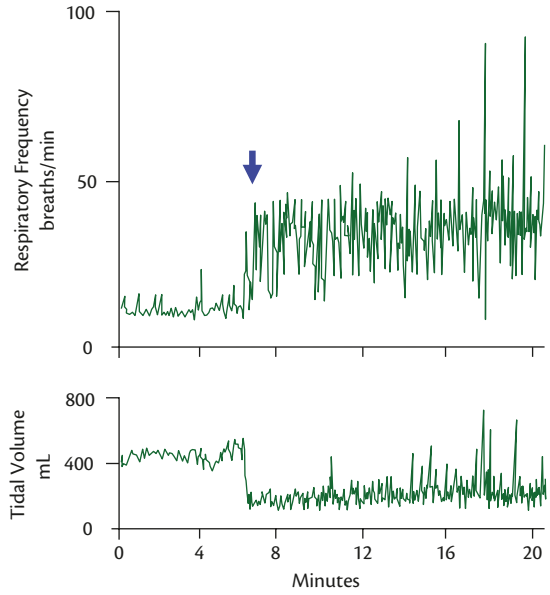

Fig. 102.2 A time-series, breath-by-breath plot of respiratory frequency and tidal volume in a patient who failed a weaning trial. The arrow indicates the point of resuming spontaneous breathing. Rapid, shallow breathing developed almost immediately after discontinuation of the ventilator.

pre- and post-test probability is determined by Bayes' theorem [6]. Three factors determine the magnitude of the pre- to post-test change—sensitivity, specificity, and pre-test probability. Sensitivity and specificity are commonly assumed to remain constant for a test. In truth, test-referral bias, a common occurrence in studies of weaning tests, leads to major changes in sensitivity and specificity [5]. Likewise, major changes in pre-test probability arise as a consequence of spectrum bias [5].

Frequency-to-tidal volume ratio

Weaning-failure involves several different physiological abnormalities [8]. The combination of a low tidal volume and elevated respiratory frequency is recognized as the physiological hallmark of weaning failure (Fig. 102.2) [9]. Patients who fail a weaning trial typically demonstrate rapid shallow breathing in the first few minutes after they are disconnected from the ventilator [10] quantified as the ratio of respiratory frequency to tidal volume (f/V^T) [11]. The higher the f/V_T, the more severe the rapid, shallow breathing and the greater the likelihood of unsuccessful weaning. An f/V_T of 100 best discriminates between successful and unsuccessful attempts at weaning [11]. The measurement should be obtained during spontaneous breathing because measurements of f/V_T in the presence of pressure support or CPAP will result in inaccurate predictions of weaning outcome [2].

The initial evaluation of f/V_T was reported in 1991 [11]. Since then, this test has been evaluated in more than 25 studies. Sensitivity ranges from 0.35 to 1 [6]. Specificity ranges from 0 to 0.89 [6]. At first glance, this wide scatter suggests that f/V_T is an unreliable predictor of weaning outcome. This was also the viewpoint of an Evidence-Based Medicine Task Force that undertook a meta-analysis of the studies [12,13]. The Task Force, however, failed to take account of test-referral bias and spectrum bias [2,5]. When data from the studies (included in the meta-analysis) were compared with the test characteristics in the original 1991 report, taking into account Bayesian pretest probability, the weighted Pearson correlation coefficient was 0.86 ($P < 0.0001$) for positive-predictive value and 0.82 ($P < 0.0001$) for negative-predictive value (Figs. 102.3 and 102.4) [6]. The average sensitivity in all of the studies on f/V_T was 0.89, and 85% of the studies reveal sensitivities higher than 0.90 [6]. This sensitivity compares well with commonly used diagnostic tests [2].

Diagnostic screening requires a simple test performed at a time when pre-test probability is low (less than 50%) [2]. A screening test should be cheap, easy to perform, pose minimal risk to patients, and provide a quick answer. A spontaneous breathing trial that involves 30–120 minutes of monitored performance is the antithesis of a screening test.

Techniques of weaning

When a screening test is positive, the clinician proceeds to a confirmatory test [5]. The goal of a positive result on a confirmatory test is to rule in a condition, i.e. the likelihood of a patient tolerating a trial of extubation is high. An ideal confirmatory test has a low rate of false-positive results (i.e. a high specificity) [5]. Unfortunately, the specificity of a spontaneous breathing trial is not known. Indeed, its specificity will never be known because its determination would require an unethical experiment—extubating all patients who fail a weaning trial and counting how many require reintubation [2].

T-tube trials

During a T-tube trial, the patient is completely disconnected from the ventilator and required to breathe spontaneously, while receiving an enriched supply of oxygen through a T-tube circuit. If the

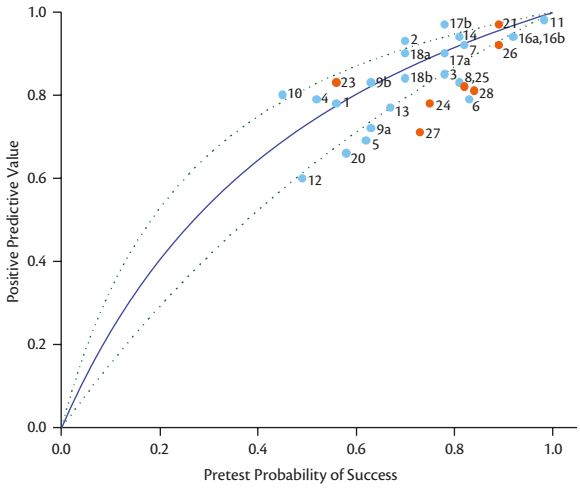

Fig. 102.3 Positive-predictive value (post-test probability of successful outcome) for f/V_T plotted against pretest probability of successful outcome. Studies included in EBM Task Force meta-analysis are indicated by blue symbols; additional studies are indicated by red symbols. The curve is based on the sensitivity and specificity originally reported by Yang and Tobin[2411] and Bayes' formula for 0.01-unit increments in pretest probability between 0.00 and 1.00.[226] The lines represent the upper and lower 95% confidence intervals for the predicted relationship of the positive predictive values against pretest probability. The observed positive-predictive value in each study (indicated a separate number) is plotted against the pretest probability of weaning success (prevalence of successful outcome).

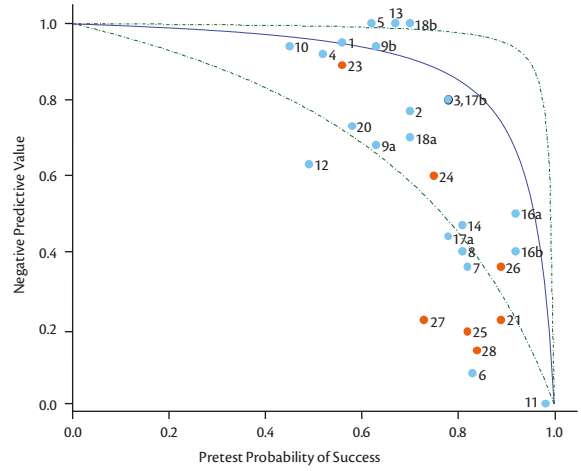

Fig. 102.4 Negative-predictive value (post-test probability of unsuccessful outcome) for f/V_T. The curve, its 95% confidence intervals, and placement of a study on the plot are described in the legend of Fig. 102.3. The observed negative-predictive value in each study (indicated a separate number) is plotted against the pretest probability of weaning success (prevalence of successful outcome).

trial is successful, the patient is extubated. If the trial is unsuccessful, the patient is typically given at least 24 hours of respiratory muscle rest with full ventilator support before another T-tube trial is performed [2].

Intermittent mandatory ventilation

Intermittent mandatory ventilation (IMV) was the most popular method of weaning for many years [14]. With IMV, the mandatory rate from the ventilator is reduced in steps of 1–3 breaths per minute, and an arterial blood gas is obtained about 30 minutes after each rate change. Titrating the number of ventilator-supported breaths in accordance with the results of arterial blood gases provides no information regarding a patient's work of breathing (which may be excessive) [9].

Pressure support

When pressure support is used for weaning, the level of pressure is reduced gradually (decrements of 3–6 cm H_2O) and titrated on the basis of the patient's respiratory frequency [3]. When the patient tolerates a minimal level of pressure support, he or she is extubated. What exactly constitutes a 'minimal level of pressure support' has never been defined [9].

Comparison of weaning methods

Two RCTs revealed weaning time was three times longer with IMV than with the use of T-tube trials [3,4]. In a study involving patients with respiratory difficulties on attempted weaning, T-tube trials halved the weaning time compared with pressure support [4]. In another study, the weaning time was similar with the two methods [3]. Performing trials of spontaneous breathing once a day is as effective as performing such trials several times a day, but much simpler [4]. In patients not expecting to pose any particular difficulty with weaning, a half-hour trial of spontaneous breathing is as effective as a 2-hour trial [15]. In a recent study of patients requiring prolonged mechanical ventilation, the rate of successful weaning was more than 40% higher with trials involving unassisted breathing through a tracheostomy than with pressure support [16].

Weaning by protocol versus usual care

Six RCTs compared the use of protocols with usual care in the management of weaning [2]. Three found protocolized weaning was without benefit. Data from two of the other studies, although sometimes viewed as evidence of the benefit of protocolized weaning, contain internal validity problems of such magnitude that the data cannot be accepted as supportive. This leaves only one of the six studies supportive of the use of protocols [2].

In a RCT to determine whether the inclusion of f/V_T in a weaning protocol influenced weaning time Tanios et al. [17] found weaning duration was longer in the f/V_T protocol group than in the non-protocol group. In this study, patients who had a f/V_T of 105 or less progressed to a weaning trial, whereas patients with a f/V_T of 106 or higher were returned to the ventilator. When conducting research, this is exactly how a protocol must be specified and followed. No flexibility is permitted. However, it is not clinically realistic to slavishly comply with a protocol that decides an entire day of ventilator management on a one-unit difference in a single measurement of f/V_T. Rather, customizing knowledge of each patient outperforms the inflexible application of a protocol.

Extubation

Decisions about weaning and decisions about extubation are commonly combined [18]. When a patient tolerates a weaning trial without distress, a clinician feels reasonably confident that the patient will be able to sustain spontaneous ventilation after extubation. Before removing the endotracheal tube, however, the clinician must also judge whether or not the patient will be able to maintain a patent upper airway after extubation.

Of patients who are expected to tolerate extubation without difficulty, approximately 10–20% fail and require reintubation [3,4]. Mortality among patients who require re-intubation is more than six times higher than patients who can tolerate extubation [15]. The reason for the higher mortality is unknown. It might be related to the development of new problems after extubation or to complications associated with reinsertion of a new tube. A more likely explanation is that the need for re-intubation reflects greater severity of the underlying illness [18].

Many find it convenient to extubate a patient once he or she can breathe comfortably on a pressure support of about 7 cmH_2O and PEEP 5 cmH_2O based on the belief that such 'minimal ventilator settings' are simply overcoming the resistance engendered by an endotracheal tube [19]. This ignores the inflammation and oedema that develops in the upper airways after an endotracheal tube has been in place for a day or more. On removal of the tube, the mucosal swelling produces an increase in upper airway resistance. Straus et al. [20] demonstrated the respiratory work dissipated against the supraglottic airway after extubation is almost identical to the work dissipated against an endotracheal tube before extubation. Thus, applying any level of pressure support causes underestimation of the respiratory resistance a patient will encounter after extubation. The addition of a small amount of pressure support produces surprisingly large reductions in inspiratory work in ventilated patients: 5 cmH_2O decreases inspiratory work by 31–38% and 10 cmH_2O decreases work by 46–60% [19]. Independently, addition of 5 cmH_2O of PEEP can decrease work of breathing by as much as 40% in ventilated patients [19]. In the case of a patient who might experience cardiorespiratory difficulties after extubation, it is sensible to ensure that the patient is able to breathe comfortably for about 30 minutes in the complete absence of pressure support or PEEP before removal of the endotracheal tube.

Conclusion

In conclusion, to minimize the likelihood of either delayed weaning or premature extubation, a two-step diagnostic strategy is recommended—measurement of weaning predictors followed by a weaning trial. Because each step constitutes a diagnostic test, clinicians must be mindful of the scientific principles of diagnostic testing when interpreting the information generated by each step. The critical step is to contemplate the possibility that a patient **just might** be able to tolerate weaning. Such diagnostic triggering is assisted through use of a screening test, which is the rationale for measurement of weaning-predictor tests. Importantly, one should not postpone this first step by waiting for a more complex diagnostic test, such as a T-tube trial. Because of the many complex facets of pulmonary pathophysiology that impinge on ventilator disconnection, weaning requires individualized care at a high level of sophistication.

CHAPTER 103

Weaning failure in critical illness

Annalisa Carlucci and Paolo Navalesi

Key points

- Weaning failure is defined as either unsuccessfull mechanical ventilation discontinuation or extubation failure.
- Both are associated with increased morbidity and mortality.
- An impaired balance between respiratory muscles force and respiratory system impedance (load) is the main cause of weaning failure. Weak cough and increased upper airway resistances are also implicated in the aetiology of extubation failure.
- A systematic approach to assess readiness by means of a spontaneous breathing trial is crucial to reduce the risk of extubation failure.
- In selected cases, non-invasive ventilation and intensive physiotherapy may facilitate discontinuation of mechanical ventilation and avert extubation failure.

Definition and outcome

Weaning failure has been defined as either failure to discontinue mechanical ventilation or a need for re-intubation within 48–72 hours after extubation (extubation failure) [1].

The former is generally assessed as an inability to breath spontaneously through an endotracheal tube for a relatively short period of time, commonly 30–120 minutes, the so-called spontaneous breathing trial (SBT) [1]. SBT failure is predominantly consequent to an excessive load for the capacity of the respiratory muscles [1].

Extubation failure encompasses a more complex phenomenon. On the one hand, it can be consequent to the incapacity to maintain the spontaneous unassisted breathing after removal of the endotracheal tube, suggesting an increase of the load imposed on the respiratory muscles after extubation. On the other hand, it can be due to the inability to maintain patent the upper airway without necessarily requiring mechanical ventilation or to incapacity to adequately clear secretions [1].

Both discontinuation and extubation failure constitute major clinical and economic burdens. Failure to discontinue mechanical ventilation is associated with increased morbidity and mortality. In particular, patients who require more than 7 days of mechanical ventilation after the first attempt of withdrawal are characterized by a high rate of death [2]. Extubation failure is also associated with an increased risk of death, ranging between 40 and 50% [3], which is correlated with the aetiology of extubation failure and the delay in re-intubation [4]. A high incidence of pneumonia and clinical deterioration before re-intubation are considered to play a predominant role in worsening outcome [1–3]. Table 103.1 summarizes the major causes of weaning failure.

Epidemiology

The time for weaning accounts for 40–50% of the total duration of mechanical ventilation, depending on the reason for initiating mechanical ventilation [1]. In a recent observational multicentre study including 2714 intubated patients who met criteria for weaning readiness, 45% failed at least one attempt. Of these patients, 39% were extubated within 7 days (difficult weaning) and 6% after 7 days (prolonged weaning) after the first attempt [2].

Extubation failure is reported to be as high as 15–18% of planned extubations; about one-third of extubation failures occurs within the first 12 hours and approximately two-thirds within the first 24 hours [1,4].

Causes of failure of mechanical ventilation discontinuation

Readiness for discontinuation of mechanical ventilation is commonly assessed, when overall clinical stability is achieved, which implies that all the acute problems are overcome, the patient is haemodynamically stable, a high FiO_2 is not required, positive end-expiratory pressure (PEEP) values not exceeding 5 cmH_2O are used, and comfortable breathing and adequate gas exchange are obtained with no or minimal (7–8 cmH_2O) inspiratory support [1].

Discontinuation failure may depend on a multiplicity of factors and is often consequent to more than one single cause. Irrespective of the underlying disorder leading to the need for mechanical ventilation, the most common mechanism is an unfavourable balance between the force generating capacity of the respiratory muscles and the load they must face [1,5]. Any treatment able to reduce the load and/or to augment muscle force may favour discontinuation success [5]. A highly unfavourable unbalance between force and load represents the most common cause of early SBT failure, which is sometimes unpredictable when the patient receives even a minimal assistance. Indeed, an inspiratory support as low as 5 cmH_2O can reduce the respiratory work by nearly 40% [6].

Failure can occur later in the course of the trial. Sometimes an inspiratory load that is tolerable at the beginning of the trial increases throughout the SBT. In a series of chronic obstructive pulmonary disease (COPD) patients undergoing SBT, Jubran et al. found that that airway resistance significantly increased throughout the trial (from 9 ± 2 cmH_2O to 15 ± 2 cmH_2O) within 45 minutes in the patients who failed, while it did not vary in those who succeeded [7]. The increase in pulmonary resistance in the course of

Table 103.1 Causes of weaning failure

the SBT may suggest a mechanism related to the cardio-pulmonary interaction [7]. In fact, a remarkable increase of the inspiratory negative intrathoracic pressure swings leads to a rise in both cardiac preload (i.e. venous return) and afterload (i.e. left ventricular transmural pressure), which may cause pulmonary congestion and oedema of the bronchial wall, and consequently worsens pulmonary mechanics and increases the magnitude of the load imposed on the respiratory muscles. Thus, an unrecognized or latent cardiac dysfunction can become evident when interrupting the ventilator support to resume spontaneous breathing [1].

A critical reduction of the force-generating capacity of the respiratory muscles may also lead to a failure to discontinue mechanical ventilation. This is quite common in mechanically-ventilated patients with neuromuscular diseases. Besides, the respiratory muscles can be weakened because of ICU-acquired critical illness neuromyopathy (CINM), which may occur as a complication of sepsis and multiple organ failure, hyperglycaemia and in patients receiving neuromuscular blocking agents for days, aminoglycosides, and/or steroids [8]. Also, diaphragm disuse atrophy complicates the clinical course of patients undergoing controlled mechanical ventilation. After 5–6 days of controlled mechanical ventilation the force-generating capacity of the diaphragm was found to be reduced by two-third [9]. This was associated with histobiochemical signs of diaphragmatic injury and atrophy, with a significant correlation between duration of mechanical ventilation and magnitude of diaphragmatic injury [9]. A physiological study performed on patients who had received prolonged mechanical ventilation showed that the recovery from inspiratory muscle weakness is a major determinant of 'late' weaning success [10]. A poor nutritional status may also play a role in decreasing muscle force [1]. Finally, in patients with lung hyperinflation because of diseases causing prolonged expiratory time constant and/or expiratory flow limitation, such as asthma and COPD, the force-generating capacity of the diaphragm is reduced because the muscle fibres, though well-functioning, are already shortened at end expiration [11].

Cerebral dysfunctions affecting the level of consciousness [12] or determining psychological or psychiatric disorders, such as ICU-acquired delirium and depression may contribute to discontinuation failure [1].

Causes of extubation failure

Any of the causes of discontinuation failure may also be implicated in the pathogenesis of extubation failure. This holds especially true whenever readiness for discontinuation of mechanical ventilation is not systematically tested with a SBT [6,12].

In some cases, after removal of the endotracheal tube, the inspiratory load may rise up consequent to an increase in upper airway resistance due to laryngeal inflammation and oedema. However, a physiological study showed that the work of breathing necessary to overcome supraglottic airway resistance soon after extubation is on average rather close to that formerly imposed by the endotracheal tube [13]. In patients with prolonged intubation complications leading to tracheal obstruction, such as tracheal stenosis, granuloma, and tracheomalacia may also cause extubation failure [14].

In patients successfully completing SBT, weak cough and the inability to clear secretions may afterwards cause extubation failure not predicted by the conventional parameters used to assess readiness for discontinuation of mechanical ventilation [1]. In a prospective study on 115 patients who passed the SBT and were ready to be extubated, a peak expiratory flow during glotic-free cough ≤60 L/min was associated with a five-fold increase in extubation failures [15].

Preventing strategies

Although conventionally considered as a specific period of the time spent on mechanical ventilation, the process of weaning should start as soon as mechanical ventilation is instituted and include any intervention aimed at facilitating resumption of spontaneous breathing through the native airway. If, on the one hand, discontinuation of mechanical ventilation and extubation should be considered as soon as possible to avoid the consequences of unnecessary prolonged intubation, on the other hand, because of their detrimental consequences, both discontinuation and extubation failures must be prevented.

The methodology used to assess readiness for withdrawal of mechanical ventilation and extubation is crucial. A systematic approach to determine readiness utilizing standardized meaningful physiological and clinical criteria may improve weaning and extubation outcome [12]. Assessing readiness by means of the SBT represents a cornerstone of this process. Anyhow, the wide variability of the methods used to perform the SBT, i.e. T-piece trial, minimal levels of CPAP and low values of inspiratory support, may affect the SBT outcome [2].

Based on the aforementioned experimental data, although never proved by clinical studies, a rapid switch from controlled to assisted modes of mechanical ventilation should in principle reduce the risk of diaphragm atrophy and injury. The ventilator settings are also important. Unnecessarily high levels of mechanical support may

result in excessively low patient's respiratory drive and effort, which is associated with poor patient-ventilator interaction and increased risk of prolonged mechanical ventilation [16]. Avoiding excessive sedation can also improve the outcome of weaning [17].

In some patients with underlying chronic respiratory disorders intubated for treatment of severe hypercapnic acute on chronic respiratory failure, an early extubation followed by immediate application of non-invasive ventilation (NIV) may help to speed up the process of discontinuation, while reducing the risk of developing ventilator associated pneumonia [18].

NIV can be also successfully used to decrease the re-intubation rate in patients at increased risk of extubation failure, such as those with underlying chronic or cardiac disorders, prior weaning failure, and numerous comorbidities [19]. In particular, in patients who develop hypercapnia during the SBT, prophylactic application of NIV at extubation reduces the rate of re-intubation and mortality [20].

In patients at risk of developing extubation failure because of ineffective clearing of secretions, intensive physiotherapy may be helpful. The use of mechanical cough assistance may prevent extubation failure consequent to sputum retention, especially in patients with weak cough [1].

PART 4.8

Extracorporeal support

CHAPTER 104

Extracorporeal respiratory and cardiac support techniques in the ICU

Claire Westrope and Giles Peek

Key points

- Extra-corporeal life support (ECLS) is an essential tool for the modern intensivist and surgeon.
- The addition of extracorporeal therapy should be considered when pathology is reversible and conventional therapy is failing.
- There are different types of extracorporeal therapies, each with their own nuances, which need to be understood in order to be used effectively and appropriately.
- Techniques required for providing successful ECLS in adult respiratory and cardiac failure are described in this chapter.
- Increasing use of mobile extracorporeal membrane oxygenation (ECMO) and extracorporeal cardiopulmonary resuscitation (ECPR) demonstrate how extracorporeal support has progressed and advanced in recent years.

Background

Extracorporeal life support (ECLS) is a general term to describe prolonged, but temporary support of heart and lung function using mechanical devices. Device applications require a combination of vascular access catheters, connecting tubing, a blood pump, a gas exchange device (oxygenator), a heat exchanger, measuring and monitoring devices, and systemic anticoagulation.

There are various sub-types of ECLS (with varying degrees of overlap) including:

- Extracorporeal lung assist ECLA (low flow extracorporeal membrane oxygenation (ECMO) to prevent intubation or minimize ventilation).
- ECMO (high flow ECLS to replace lung and/or heart function, used synonomously with ECLS).
- Extracorporeal carbon dioxide removal ($ECCO_2R$, same as lung assist).
- Extracorporeal cardiopulmonary resuscitation (ECPR, emergency cardiac support in cardiac arrest).

When blood pumps alone are used for cardiac support then ECLS is termed as left ventricular assist device (LVAD), right ventricular assist device (RVAD), or biventricular assist device (BiVAD).

The Extracorporeal Life Support Organization's (ELSO) recent international summary (July 2012) [1] shows that to date over 50,000 patients have been treated with ECLS (Fig. 104.1). Adult respiratory activity has increased year-on-year (Fig. 104.2) following the publication of the CESAR trial [2] and successful use of ECMO in the H1N1 outbreaks of 2009 and 2010, which have raised awareness of ECMO use in adults globally [3].

With improved knowledge and experience in adult respiratory extracorporeal techniques, use in adult cardiac support has also increased (Fig. 104.3).

ECLS techniques

Team

No ECMO programme can be run without a dedicated team with extensive knowledge of and ability to manage all of the following—patient selection, patient transport (including mobile ECMO), ECMO circuit, ECMO circuit–patient interaction, ECMO complications, specific patient and disease management pre, during and post-ECMO, and advanced ventilator techniques for pre- and post-ECMO patients. This requires engagement and teamwork across several disciplines.

ECMO circuit

The ECMO/ECLS circuit has undergone significant changes in the last few years, which has resulted in a shorter more biocompatible circuit.

The essential components (venous drainage line, blood pump, or oxygenator with gas supply, heat exchanger, arterial return) of an ECMO circuit are shown in Fig. 104.4.

Newer tubing materials and heparin coating have resulted in ELCS circuits causing less patient systemic inflammatory response, having decreased heparin requirement for systemic anticoagulation and reduced thrombotic complications.

The traditional silicone oxygenator has been replaced by the hollow fibre polymethlypentene (PMP) oxygenators, which have lower resistance, better gas exchange, lower priming volumes, increased efficiency, cause less consumption of platelets and clotting factors, and survive longer.

Mendler type centrifugal blood pumps are superseding the occlusive roller pump and the first generation centrifugal pump. These are smaller and non-occlusive, and so are inherently safer. The central hole in the rotor of the Mendler type pump prevents clot

build-up and has improved heat dissipation, making it mechanically more reliable. ECLS circuits overall are shorter as centrifugal pumps generate active suction and do not depend on gravity for venous drainage. They generate a new problem of negative pressure on the drainage side of the circuit. The main disadvantage of this negative pressure is that it increases the risk of air entrainment if access ports are placed in the drainage side of the circuit. As air in the circuit is the nemesis of the ECMO specialist removing circuit access ports from the drainage side of the circuit and placing them post-centrifugal pump/pre-oxygenator (i.e. in the positive pressure side of the circuit) almost completely eliminates the risk of air entrainment.

Fig. 104.5 illustrates how the ECMO circuit has changed over the years with the first photo showing the simplified modern circuit.

Definite proof that new systems (centrifugal pump, PMP oxygenator) are better than traditional systems (silicone oxygenator and roller head occlusive pump) is lacking, but various single centre reports are encouraging. Sivarjan et al. [4] compared two groups of paediatric ECMO patients in different time periods, 1998 (Biomedicus centrifugal pump and silicone oxygenator) and 2001 (Jostra centrifugal pump and quadrox oxygenator). Patient survival improved from 24 to 49% in the latter group and mechanical complications per 10,000 hours fell from 70 to 50; pump heads used from 160 to 110 and oxygenators from 130 to 110.

Mobile ECMO

Despite advances in technology, a significant number of adult patients fail maximal medical therapy and ultimately require ECMO. A proportion of these patients can be moved to an ECMO centre in a timely manner by conventional means, but increasingly they rapidly become too unstable, requiring emergency cannulation/ECPR in their own centre, and transport on ECMO to an ECMO centre.

Advances in technology and experience mean that ECMO centres should now consider mobile ECMO retrieval as a standard part of their service provision.

This requires medical, nursing, and perfusion professionals to be available round the clock, and trained in ECMO and transport medicine. It also requires a dedicated transport system (trolley and vehicle), which can be adapted to the transport mode (air/rotary/fixed wing).

Veno-venous ECLS support

In veno-venous (VV) ECLS support blood is drained from the venous circulation and re-infused back into the venous circulation after passing through the extracorporeal circuit. It requires the patient to have adequate cardiac output to pump the oxygenated blood around the body. Oxygenation is proportional to ECMO flow. High flow VV ECLS is for oxygenation (ECMO) and low flow for CO_2 removal ($ECCO_2R$).

Cannulation for VV support is traditionally through the right internal jugular vein into the right atrium and via the femoral vessels, and the degree of ECMO support provided depends on cannula size and site. Percutaneous access over a wire via the Seldinger technique has been a major advantage in ECMO cannulation. Traditionally, a two cannula approach is used in adults. A 23–28F (external diameter) single lumen catheter inserted into the inferior vena cava (IVC) via either femoral vein and a second 23–28F cannula inserted into the right atrium (RA) via the right internal jugular vein will give adequate support for most adult patients (up to 5 L/min flow). Direction of flow is optional, drainage from the neck (with a shorter cannula) allows higher flow, but has more recirculation while drainage from the groin gives less drainage and recirculation, but may

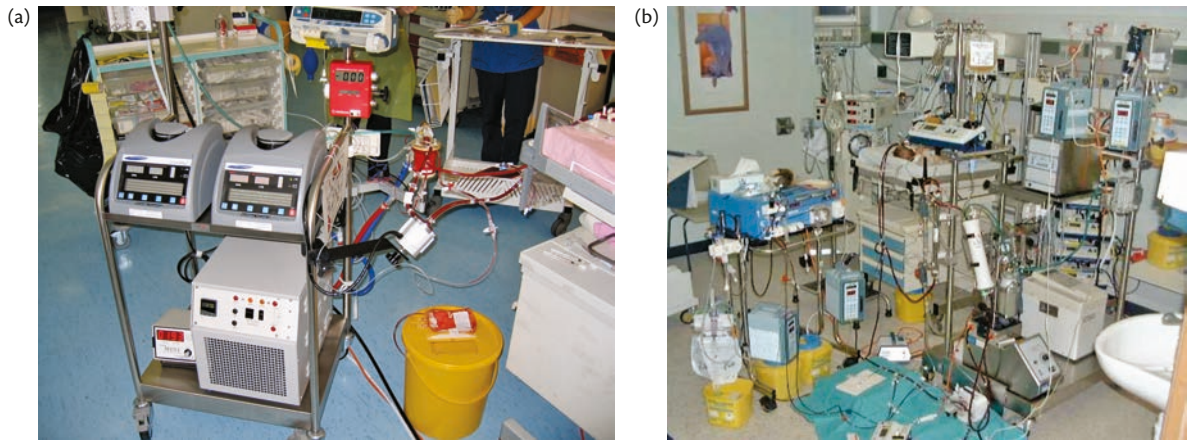

Fig. 104.5 Changes to ECMO circuit over time with panel (a) showing the simplified modern circuit and panel (b) showing the older more complex circuit.

provide better oxygen delivery. Additional drainage cannulae can be placed in the other femoral vein with drainage from IVC and RA, and reinfusion into IVC, if flow is inadequate.

Recently, the bicaval double lumen venous cannula has allowed a single point of venous access with inherently low levels of recirculation making ECMO much more efficient. The Bicaval double lumen cannula, Avalon Elite® (Maquet) is designed to be inserted percutaneously via the right internal jugular vein with its tip placed in the IVC. Drainage holes placed proximally and distally to sit in SVC and IVC minimize recirculation as oxygenated blood is returned via a separate return hole placed in the middle of these two drainage ports and directed toward the tricuspid valve (Fig. 104.6).

Cannulae are available in sizes 16–31F and provide adequate flows in most patients up to 100 kg. Insertion requires X-ray screening to confirm wire then cannula position in IVC and to minimize complications, particularly misplacement/pneumothorax and cardiac perforation. If additional flow is required, a second femoral drainage cannula (23f biomedicus) can be inserted percutaneously into the lower IVC via either femoral vein.

Advantages of the bicaval double lumen cannula include single site access (reducing the risk of vascular injury, cannula site bleeding, and infection) and reduced circuit length (less contact activation, mobile ECMO, improved patient mobility). A perceived disadvantage of the bicaval cannula is a reduced ECMO flow compared with two single cannulae. However, as there is reduced recirculation this does not impact on oxygen delivery. It is recommended that flows should be maintained above 2.5 L/min in adults in order to avoid clot formation.

VV ECMO can provide total CO_2 removal, but provides less O_2 delivery than veno-arterial (VA) support. It relies on adequate pumping of the native heart to distribute the extracorporeal oxygenated blood to the body. Many centres default to VA ECMO support in patients who have high inotropic requirements secondary to severe respiratory failure. However, one potential benefit of VV support is that the highly oxygenated blood returned back to the right atrium flows through the heart and into the coronary arteries, resulting in improved oxygen delivery to the myocardium and cardiac function.

The goal of ECMO for respiratory failure is to support gas exchange so that the iatrogenic side effects of intensive care treatment (such as ventilator-associated lung injury and sedation complications) can be minimized. Patients are therefore transitioned immediately to 'rest settings' on the ventilator, this is either a low frequency, high PEEP, low positive inspiratory pressure (PIP) strategy (i.e. 25/15 rate 10, FiO_2 0.3) or a low pressure high-frequency oscillatory ventilation approach, i.e. MAP 10–15 cmH_2O for patients with severe barotrauma and air leak. Once the acute phase of the illness has passed patients are either extubated or (more commonly) tracheostomized, while still on ECMO, woken up, and allowed to breathe for themselves. Many teams are now able to mobilize patients on ECMO.

VA support

VA support in adult patients is reserved for those cases with profound cardiac failure or in the situation of cardiac arrest when it is termed as ECPR.

Blood is drained from the venous system (from RA via RIJ or IVC via the femoral vein and returned into the arterial system via the aorta (via common carotid, axilliary, or the femoral artery).

The right internal jugular is preferred for venous drainage as it is the shortest route, but femoral venous access is sometimes more easily achievable. Direct right atrial access after cardiac surgery is also possible if the sternum is left open, although the risk of infection is high and the decision whether to change the cannula insertion site to percutaneous in the neck or groin should be made early.

Historically, the common carotid artery was the preferred route for the arterial return cannula, largely as a result of early ECMO experience with VA support in neonates. Because the carotid artery could be ligated distally, distal perfusion was not required, and it delivered fully oxygenated blood direct to the aortic root. Unfortunately, 15% of adults develop an intracranial ischaemic injury following carotid ligation. The right femoral artery is now the preferred site for arterial return (it is usually slightly bigger than the left). In centres who perform purely VA ECMO for all adult cardiac and respiratory indications, the femoral artery is directly accessed using a cut-down technique, a distal perfusion cannula is placed electively into the superior femoral artery and then the arterial cannula (17, 19, or 21F) is inserted into the femoral artery under direct vision. This minimizes compromise to the distal collateral circulation of the leg. Other centres electively insert a distal perfusion catheter into the posterior tibial artery once the patient has stabilized on ECMO. Whichever technique is used for femoral artery cannulation, the associated leg should be monitored hourly for signs of compromised distal perfusion. Compartment syndrome of the leg requiring fasciotomies is not an infrequent complication of VA ECMO.

Total bypass of the cardiopulmonary system during VA ECMO is not recommended. Some blood is required to flow through the patient's heart to supply the coronary arteries. As the blood going through the heart in VA ECMO is deoxygenated, oxygenation of coronary artery blood is dependent on oxygenation via ventilatory support of the lungs. It is routine, therefore, for the amount of ventilatory support to be higher in VA ECMO (FiO_2 routinely 40% or above), although care should still be taken to minimize ventilator-induced lung injury.

An adverse effect of VA ECMO is that it increases left ventricular afterload, which may result in complete left ventricular failure. Chemical afterload reduction may not be adequate to manage the

situation. Patients can require a left atrial vent (line into left atrium connected to the venous drainage line of ECMO circuit) if the chest is open or an atrial septosomy. If a patient has these interventions it should be noted that mixed venous saturations taken from the venous line below the vent will be falsely elevated, as oxygenated blood from the left heart will be vented into the right atrium or the venous side of the ECMO circuit, and so a true mixed venous gas should be taken proximal to the site of mixing. Near-infrared spectroscopy (NIRS) can be a useful adjunct in tailoring oxygen delivery in this situation.

The goal of VA ECMO is to provide adequate haemodynamics, oxygenation, and perfusion, while optimizing the conditions for cardiac and respiratory rest and recovery.

Other extracorporeal respiratory therapies

Mini ECMO/novalung™/ILA active™

In recent years miniature extracorporeal lung assist (ECLA) devices have become available, e.g. Novalung™ (Germany). These devices require percutaneous cannulation of the femoral artery and vein, utilizing the patient's own blood pressure to drive blood across the low resistance oxygenator. More recently, Novalung has released the ILA active™ device, which allows venous cannulation only using a double lumen cannula (24F NOVAPORT twin™) and relying on a centrifugal pump to drive blood through the oxygenator. Novalung is limited to lower flows 1–2 L/min and are only able to provide CO_2 removal to support patients with moderate respiratory failure. The technique can avoid the need for intubation and mechanical ventilation in high-risk patients, shorten the duration of mechanical ventilation and allow suitable patients to be awake and mobile prior to lung transplantation. The ILA active™ device will allow flow up to 8l/min, but would require a larger cannula than 24F to achieve this flow, so it is usually used in low flow $ECCO_2R$ mode. Other $ECCO_2R$ devices include A-Lung and DECAP.

Adult ECPR

Use of ECPR is relatively new. It can be viewed as an extreme form of cardiac support using VA ECMO cannulation for cardiac arrest. Cannulation is usually of the femoral vessels (artery and vein) using percutaneous techniques.

Adult in-hospital cardiac arrest results in an 80% mortality (survival range 10–40% depending on underlying rhythm at onset of the arrest) [5]. ELSO registry data shows survival to hospital discharge of 29% in 591 adults who required ECPR [1]. Shin et al. [6] demonstrated that when ECMO was used early as part of an overall plan for the resuscitation of adults with cardiac arrest, there was improved survival and quality of life when compared with conventional CPR. This was only demonstrated when ECMO was considered (within 10 minutes of onset of arrest) and implemented (within 60 minutes of arrest) early. In the event of an unexpected arrest, even with an unsuccessful outcome ECPR and VA ECMO support may give relatives and clinical teams time to reflect and come to terms with the loss of the patient.

Conclusion

ECLS is an essential tool for the modern intensivist, cardiologist and surgeon. The addition of extracorporeal therapy should be considered in all cases when pathology is potentially reversible and conventional therapy is clearly failing.

CHAPTER 105

Treating respiratory failure with extracorporeal support in the ICU

Giacomo Bellani and Antonio Pesenti

Key points

- Veno-venous extracorporeal life support is a solid tool in rescuing patients with severe hypoxaemia.
- While a low-flow bypass can remove comparatively high amounts of CO_2 from blood, oxygenation is limited by venous haemoglobin saturation and therefore requires high extracorporeal blood flows.
- As shown by several data registries, a shorter duration of mechanical ventilation before initiation of extracorporeal support is associated with a decreased mortality rate.
- The recent improvements in efficacy and safety of extracorporeal support technology might lead to an earlier application of this technique to remove CO_2, decreasing the need for ventilation and, hence, decreasing ventilator-induced lung injury.
- Extracorporeal support still bears severe risks of complications. Centralizing patients to selected specialized centres with a high case volume is likely to improve the outcome of the treatment.

Historical background

Extracorporeal respiratory support technology was developed in the 1940s as an essential tool in cardiac surgery. Its successful use in an adult patient with acute respiratory distress syndrome (ARDS) was first described in 1971 by J. D. Hill. Following this first report, one multicentre randomized trial was conducted, but no effect on mortality was observed in patients treated with extracorporeal membrane oxygenation (ECMO) [1]. The trial was doomed by a very high incidence of severe bleeding and by the use of immature technology. The result of this and other studies led to an almost complete stop of ECMO in adults, confining its application to newborns [2]. The reasons leading to the failure of the adult early trial might probably be identified in the continuous lung damage caused by an injurious setting of mechanical ventilation (MV) in spite of extracorporeal support. Subsequently, Kolobow and Gattinoni suggested the concept that by removing CO_2 through an artificial lung, ventilation could be reduced virtually down to zero [3], allowing to put the lung at rest minimizing the negative effect of ventilation.

Present status of ECMO

The concept of ECMO is apparently very simple [4,5]—blood is diverted from the patient to an artificial lung for gas exchange (oxygenation and CO_2 removal) and then returned into the patient's circulation once arterialized. The bypass may be veno-arterial, veno-venous, or arteriovenous (Table 105.1). While a low-flow bypass can remove comparatively high amounts of CO_2 from the blood, oxygenation is limited by venous haemoglobin saturation and, therefore, requires high extracorporeal blood flows, in the range of 3–5 L/min. Several technical improvements led to a profound change in the safety and applicability of ECMO in recent years, and even allowed to transfer patients undergoing ECMO [6]. Surgical was largely replaced by percutaneous cannulation [7], with a greater bedside applicability and less bleeding complications. Moreover, double lumen cannulas [8], specifically designed to minimize recirculation, allow for single vessel access for both drainage and reinfusion. The introduction of heparin-coated surface for tubings and artificial lungs drastically reduced the need for systemic anticoagulation. Roller pumps were largely abandoned in favour of centrifugal pumps. Until the late 1990s, the flat sheet silicon rubber membrane artificial lungs were the standard of care. These oxygenators required a large priming volume, and had a very high flow resistance. A revolution in oxygenators came from the introduction of hollow-fibre membrane oxygenators whose initial problems with plasma leakage are now largely solved since polymethylpentene membranes came into use. These oxygenators have a much lower priming volume and resistance to blood flow (tens, rather than hundreds of mmHg/L/min). The very low resistance of these circuits permitted the design a pumpless system, which takes advantage of the arteriovenous pressure gradient to pump blood through the oxygenator; this circuit type is not very efficient in oxygenating blood, due to the relatively low blood flow and the high haemoglobin saturation of the blood entering the oxygenator [9]. However, the efficient CO_2 removal allows a decrease in traditional ventilation needs.

Table 105.1 Extracorporeal respiratory support

Technique	Blood flow	Bypass type	Main suggested indications
Extracorporeal membrane oxygenation (ECMO)*	3–5 L/min	Veno-venous Veno-arterial	Rescue of hypoxia in ARDS
Extracorporeal CO_2 removal	0.5–2.5 L/min	Veno-venous Arteriovenous	Prevention of VILI in ARDS COPD Bronchopleural fistulas with air leaks Bridge to transplant

*Brings CO_2 removal as a fringe benefit.

ECMO as a rescue procedure for the severely hypoxic patient

ECMO has been mainly proposed as salvage-therapy for the most severe ARDS patients. The substitution for the lung's gas exchange function reduces the ventilatory requirement and warrants viable levels of oxygenation.

An important contribution in this field came from the Extracorporeal Life Support Organization (ELSO) [10], which collected in 1986 from data of patients treated with ECMO in 130 centres, mainly located in the United States. In 2009 the results from 1473 patients were published, constituting the largest published dataset on this topic. Notwithstanding the severe hypoxaemia (median PaO_2/FiO_2 was 57 mmHg) and high peak inspiratory pressure (median 40 mmHg) before ECMO institution, the survival rate was 50%. Interestingly, one of the factors associated with a lower mortality was a short duration of mechanical ventilation prior to ECMO. This underlines the importance of an early initiation of ECMO in the most severe patients, rather than a last desperate rescue after failure of 'traditional' therapies. Another important case series was published by the group of the Karolinska hospital [11]. The authors reported data from 16 patients with a very high lung injury score (average 3.5): the survival rate was 76%. Patients were managed with minimal sedation, with the use of pressure support ventilation, and accepting arterial saturation as low as 70%.

Until recently, however, no randomized trial had proven a clear survival in patients with ARDS treated with ECMO. In 2009, the publication of the results of the CESAR trial provided the first formal evidence in favour of ECMO application in adults [12]. This study was conducted in the UK and followed a particular design, modelled on the template of a previous ECMO study in neonates. Adult patients (18–65 years) with severe, but potentially reversible respiratory failure were enrolled. Severe respiratory failure was defined as a Murray score ≥3 or uncompensated hypercapnia with a pH <7.20. Patients randomized to ECMO were transferred to the ECMO centre in Leicester; control patients continued the conventional treatment according to the best available clinical practice. In most of the patients assigned to the treatment group, veno-venous ECMO via percutaneous cannulation was used. The system was designed to provide full substitution of pulmonary gas exchange with high blood flows (> 5 L/min), and high gas exchange surfaces. The average duration of bypass was 9 days. During ECMO the ventilator settings were gradually reduced to allow lung rest, limiting the peak inspiratory pressure to 30 cmH_2O and respiratory rate to 10 breaths/min. In 5 years, 180 patients were enrolled onto the study. Survival at 6 months or the absence of severe disability was achieved in 63% of the ECMO patients, comparing very favourably with 47% of the control group. This accounted for one life without severe disability saved every six patients treated. In spite of the peculiarity of the study design, this is the first, long-expected, positive randomized clinical trial on adult ECMO application. These results are achieved through lung protection by the total or almost total substitution of the lung gas exchange function.

An important impulse to the early use of ECMO in ARDS came from the experience with the recent outbreak of H1N1 influenza. The pandemic was characterized by a high incidence of severe respiratory complications. Different series of patients with H1N1 infection requiring ICU admission have been described in Mexico, Canada, Australia, and United States. All patients required MV with high PEEP and frequent use of rescue therapies. Davies et al. have recently described a series of 68 patients with H1N1-associated ARDS treated with ECMO in 15 Australian ICUs—the median duration of extracorporeal support was 10 days and the overall mortality was 21% [13].

To cope with the H1N1 influenza epidemic outbreak in Italy, the Italian Ministry of Health organized a multicentre network for the transferring of more severe patients to specialized centres equipped to apply ECMO treatment. Eight of the 14 ECMO centres were also able to start ECMO in outside centres and transport the patient to the referral hospital, while on ECMO. Thus, if patient transportation was considered risky, patient was connected to ECMO at bedside and then transferred while on ECMO to the tertiary centre. Between August 2009 and March 2010, 60 patients with suspected H1N1 affected by severe ARDS were treated with ECMO, H1N1 diagnosis being confirmed later in 49. Twenty-eight patients were transported while on ECMO. Overall ICU discharge survival was 68%. No major complications were reported during the transportation of patients in ECMO. In keeping with the data of the ELSO registry, non-survivors had a longer duration of mechanical ventilation when compared with survivors, in addition to higher SAPS II and SOFA scores [14].

A smaller case series from Marseille, France had been previously published [15], where nine patients with H1N1 were treated with ECMO; six of these had been connected to ECMO in a referral hospital by a mobile team.

A similar system was set up in the UK, with similar results. The British ECMO group recently published a cohort study in which ECMO-referred patients, defined as all patients with H1N1-related ARDS, who were transferred to one of the four adult ECMO centres in the UK, were matched with similar non-ECMO-treated H1N1 ARDS patients using data from a concurrent, longitudinal cohort study. Detailed demographic, physiological, and comorbidity data were used in three different matching techniques. The hospital mortality rate for ECMO-referred patients was almost one half of that for non–ECMO-referred patients in all the three matching used [16].

Future perspectives in extracorporeal respiratory support: extracorporeal gas exchange to avoid injury from mechanical ventilation

Ventilator-induced lung injury (VILI) has been known as a potential mechanism of lung injury, which can further aggravate ARDS.

The benefits of reduction of tidal volume and plateau airway pressure reduction are well known, but the need for CO_2 removal, even if hypercapnia is tolerated to a certain extent, represent a limiting factor to a further ultra-preventive lung strategy. In this respect, CO_2 removal by ECMO could dramatically decrease the ventilatory needs. As stated, in order to effectively remove a large fraction of total CO_2 production (without the need for an effective oxygenation), a lower blood flow is required, further reducing the size of the cannulas, the need for anticoagulation and the invasiveness of the technique. Terragni et al. showed that extracorporeal CO_2 removal by a low flow device allows the reduction of tidal volume from 6 to 4 mL/kg, with a reduction of circulating inflammatory cytokines and lung hyperinflation. However, more data are necessary in order to understand whether extracorporeal CO_2 removal is able to improve the outcome of ARDS patients [17].

Pushing this concept to its furthest end, ECMO could be conceived as an alternative to MV and endotracheal intubation, although some preliminary reports indicate that COPD patients failing non-invasive ventilation might successfully be managed with [low flow] ECMO and avoid intubation [18].

Conclusion

The fire of ECMO has been smouldering under the ashes for many years, but improved technologies, deeper knowledge of the risk of VILI and flu pandemics gave a new burst to its flame. Clinicians should use ECMO with caution, in order to avoid unnecessary risks for their patients. The role of ECMO in severe hypoxia is hardly debatable, but, in such cases, an early application of the technique and a centralization of cases to a few specialized experienced centres (taking advantage of ECMO provided by mobile teams also for a safe patient transport) are mandatory to success. We will hopefully learn, in the next years, if low flow CO_2 removal will become a lighthouse for safer, less invasive ventilation, eventually finding its place, in some patients.

PART 4.9

Aspiration and inhalation

CHAPTER 106

Aspiration of gastric contents in the critically ill

Sara Froio and Franco Valenza

Key points

- Several pulmonary syndromes may occur after aspiration, depending on the amount and nature of the aspirated material, the frequency of aspiration, and the host's response to the aspirated material.
- Aspiration of gastric contents results in a chemical burn of the tracheobronchial tree and pulmonary parenchyma, causing pneumonitis.
- Aspiration pneumonia may involve fluid or particulate matter, which are not inherently toxic to the lung, but can cause airway obstruction or reflux airway closure.
- The causative micro-organism in aspiration pneumonia, similar to community-acquired pneumonia, are thought to be bacteria residing in the oral cavity. In the treatment of aspiration pneumonia, use of antimicrobials for pneumonia itself is important.
- The aspiration of gastric contents is generally preventable by good anaesthetic practice and attention to details in the intensive care unit.

Introduction

Aspiration is defined as the inhalation of oropharyngeal or gastric contents into the larynx and lower respiratory tract. Several pulmonary syndromes may occur after aspiration, depending on the amount and nature of the aspirated material, the frequency of aspiration, and the host's response to the aspirated material. Aspiration pneumonitis is a chemical injury caused by the inhalation of sterile gastric contents, whereas aspiration pneumonia is an infectious process caused by the inhalation of oropharyngeal secretions that are colonized by pathogenic bacteria. Other aspiration syndromes include airway obstruction, lung abscess, exogenous lipoid pneumonia, and chronic interstitial fibrosis [1,2].

The three syndromes that are most frequently seen clinically and are best studied are chemical pneumonitis, bacterial infection, and airway obstruction. Although there is some overlap among these syndromes, they are distinct clinical entities. This chapter focuses on the pathophysiology, clinical features, and management of these three syndromes (Table 106.1).

The lack of specific and sensitive markers of aspiration complicates the epidemiological study of aspiration syndromes. Furthermore, most studies do not distinguish between aspiration pneumonitis and aspiration pneumonia.

The risk of aspiration pneumonitis is approximately 10% after a drug overdose. This condition is very common in patients with reduced consciousness level due to general anaesthesia, particularly during pregnancy, where there is increased intra-abdominal pressure and delayed gastric emptying. The most recent report suggests an incidence of 1 in 3000 patients receiving general anaesthesia. However, mortality remains very high and accounts for 10–30% of all deaths related to anaesthesia. The elderly, particularly the nursing home population, is at increased risk of aspiration secondary to both an increased incidence of pharyngeal dysmotility and gastro-oesophageal reflux. Aspiration pneumonia and pneumonitis are the most common causes of death in patients with dysphagia caused by neurological disorders [1].

Conditions that predispose to aspiration of gastric content include:

- Reduced consciousness resulting in a compromise of the cough reflex and glottic closure.
- Neurological dysphagia.
- Disorders of the upper gastrointestinal (GI) tract, including oesophageal disease, surgery involving the upper airways or oesophagus, and gastric reflux.
- Disruption of the gastro-oesophageal junction due to tracheostomy, endotracheal intubation, bronchoscopy, upper endoscopy, and nasogastric feeding.
- General anaesthesia.
- Extremes of age.

Clinical syndromes

Aspiration pneumonitis

Pathophysiology

The term aspiration pneumonitis refers to the aspiration of substances that are toxic to the lower airways, independent of bacterial infection. Gastric acid is the most frequently encountered and the most completely studied substance that can initiate an inflammatory reaction. Historically, the syndrome most commonly described as aspiration pneumonitis is Mendelson's syndrome, reported in 1946 in patients who aspirated while receiving

Table 106.1 Classification of aspiration syndromes

Syndromes	Pulmonary sequelae	Clinical features	Management features
Aspiration pneumonitis	Chemical injury	Dyspnoea, tachycardia Hypoxaemia	Tracheal suction Antibiotics for superimposed infection
Aspiration pneumonia	Bacterial infection	Usually insidious onset Cough, fever, purulent sputum **Radiograph**: infiltrate involving dependent pulmonary segment or lobe	Antibiotics
Airways obstruction	Mechanical obstruction	**Dependent upon level of obstruction**: ◆ Acute dyspnoea ◆ Cyanosis ◆ Apnoea **Pulmonary oedema**	Tracheal suction Extraction of particulate matter

general anaesthesia during obstetrical procedures. Mendelson revealed the importance of acid in the pathogenesis of this syndrome when he showed that acid gastric contents introduced into the lungs of rabbits caused severe pneumonitis that was indistinguishable from that caused by an equal amount of 0.1 N hydrochloric acid. Later, it was shown that if the pH of gastric contents was neutralized before aspiration, the pulmonary injury was minimal. In experimental studies, the severity of lung injury increased significantly as the volume of the aspirate increases and as its pH decreases [3,4].

The pathophysiology of acid pneumonitis has been studied in experimental animals by intratracheal inoculation of sterile hydrochloric acid. These animal models require an inoculum that has a pH of ≤2.5 and that is relatively large (usually 1–4 mL/kg). This would translate to an inoculum of at least 25 mL of gastric acid in adult humans. It is probable that smaller volumes produce a more subtle process that either escapes clinical detection or causes a less fulminant form of pneumonitis. The clinical observation that patients with oesophageal or gastric reflux experience frequent bouts of recurrent pneumonitis, often accompanied by pulmonary fibrosis, supports this concept [5–7].

Aspiration of gastric contents results in a chemical burn of the tracheobronchial tree and pulmonary parenchyma, causing an intense parenchymal inflammatory reaction. Experimental animal studies have shown that the toxic effects of acid are immediate and extensive. Within 3 minutes there is atelectasis, due to acid denaturation of surfactant, peribronchial haemorrhage, pulmonary oedema, and degeneration of bronchial epithelial cells [8].

By 4 hours, the alveolar spaces are filled with polymorphonuclear leucocytes and fibrin. Hyaline membranes are seen within 48 hours. The lung at this time is also grossly oedematous, haemorrhagic, and with alveolar consolidation.

At first, the caustic effects of the low pH of the aspirate are directed to the cells lining the alveolar–capillary interface—a second phase is associated with the infiltration of neutrophils into the alveoli and lung interstitium, with histological findings characteristics of acute inflammation. The mechanisms of the lung injury after gastric aspiration involve the release of pro-inflammatory cytokines, especially tumour necrosis factor-alpha (TNFα) and interleukin IL-8. In animal studies, neutropenia, inhibition of neutrophil function, inactivation of IL-8, and complement inactivation attenuate the acute lung injury induced by acid aspiration.

Under normal condition the gastric contents are sterile because of acidity. Bacterial infection does not have an important role in the early stages after the aspiration of gastric contents, but it may occur at later stages. Colonization of gastric contents may occur when the pH in the stomach is increased by the use of antacids. In addition, there may be gastric colonization by Gram-negative bacteria in patients who receive enteral feeds, as well as in patients with gastroparesis or small bowel syndrome [9,10].

Clinical features and diagnosis

The diagnosis of acid pneumonitis is usually presumptive.

The following clinical features should raise the possibility of chemical pneumonitis:

- Abrupt onset of symptoms with prominent dyspnoea.
- Fever that is usually low grade.
- Cyanosis and diffuse crackles on lung auscultation.
- Severe hypoxaemia and infiltrates on chest radiograph involving dependent pulmonary segments.

The dependent lobes in the upright position are the lower lobes. However, aspiration that occurs while patients are in the recumbent positions may result in pneumonia in the superior segments of the lower lobes and the posterior segments of the upper lobes. After a suspected aspiration, chest X-ray abnormalities typically appear within 2 hours. If performed, bronchoscopy demonstrates erythema of the bronchi, indicating acid injury.

The course of the disease varies. In one retrospective review of 50 cases, three outcomes were observed:

- 12% of patients had a fulminant course and died shortly after aspiration presumably from acute respiratory distress syndrome (ARDS).
- 62% had a rapid clinical improvement with clearing of the chest radiograph.
- 26% had initial rapid improvement, but then developed new expanding infiltrates on chest X-ray, which probably represented secondary bacterial infection or the development of ARDS superimposed on the acid injury [11].

Management

Patients with an observed aspiration should be placed in the head-down position on the right side and should have also immediate tracheal suction to maintain a clear airway. However, this manoeuvre will not protect the lungs from chemical injury, which occurs instantly in a manner that has been compared with a 'flash burn'. The acid inoculum is rapidly neutralized by the physiological response. Pulmonary lavage is futile, since the full extent of injury has usually occurred by the time the diagnosis is recognized.

The major therapeutic approach is to correct hypoxia and support pulmonary function by assisted ventilation or positive-pressure oxygen. Endotracheal intubation should be considered for patients who are unable to protect their airways.

The use of corticosteroids in the treatment of chemical pneumonitis is controversial. Studies in animals have failed to demonstrate beneficial effects of corticosteroids on pulmonary function, lung injury, alveolar–capillary permeability, or outcome after acid aspiration. Furthermore, given the failure of two multicentre, randomized controlled trials to demonstrate a benefit of high-dose corticosteroids in patients with ARDS, the administration of corticosteroids cannot be recommended [12–14].

Although it is common practice, the prophylactic use of antibiotics in patients in whom aspiration is suspected or witnessed is not recommended. Similarly, the use of antibiotics shortly after aspiration in patients in whom a fever, leukocytosis, or a pulmonary infiltrate develops is discouraged, since the antibiotic may select for more resistant organisms in patients with an uncomplicated chemical pneumonitis. However, empirical antibiotic therapy is appropriate for patients who aspirate gastric contents, and who have small-bowel obstruction or other conditions associated with colonization of the gastric contents. Antibiotic therapy should be considered for patients with aspiration pneumonitis that fails to resolve within 48 hours following aspiration. Empirical therapy with broad-spectrum agents is recommended; antibiotics with anaerobic activity are not routinely required. Sampling of the lower respiratory tract (with a protected specimen brush or by broncho-alveolar lavage) and quantitative culture in intubated patients may allow targeted antibiotic therapy, or in patients with negative cultures, the discontinuation of antibiotics.

Aspiration pneumonia

Pathophysiology

Aspiration pneumonia develops after the inhalation of colonized oropharyngeal material. Aspiration of colonized secretions from the oropharynx is the primary mechanism by which bacteria gain entrance to the lungs. The causative micro-organism in aspiration pneumonia, similar to community-acquired pneumonia, are thought to be bacteria residing in the oral cavity. In fact, the risk of aspiration pneumonia is lower in patients without teeth and in patients who receive aggressive oral care.

Any condition that increases the volume or the bacterial burden of oropharyngeal secretions in a person with impaired defence mechanisms may lead to aspiration pneumonia.

This condition is generally less fulminant than acid pneumonitis and the actual episode of aspiration is seldom observed.

Clinical features and diagnosis

In patients with aspiration pneumonia, unlike those with aspiration pneumonitis, the episode of aspiration is frequently not witnessed and the diagnosis is often inferred when a patient at risk of aspiration has radiographic evidence of an infiltrate in characteristic bronchopulmonary segment. The presenting findings in aspiration pneumonia due to bacterial infection are variable depending on the time when the patient is seen during the course of the infection, the bacterial agents involved, and the status of the host.

Compared with most cases of community-acquired pneumonia, the course of the disease in this type of aspiration pneumonia often evolves slowly. The majority of patients presents with the common manifestations of pneumonia, including cough, fever, purulent sputum and dyspnoea, but the process evolves over a period of days or weeks instead of hours. If not treated, these patients have a high incidence of cavitation and abscess formation in the lungs in later stages [15].

Organisms that assume the greatest importance in terms of pathogenetic potential are anaerobic bacteria. Expectorated sputum is unsuitable for anaerobic culture because of inevitable contamination by the normal flora of the mouth. There is a limited experience with quantitative cultures of specimens obtained at bronchoscopy by a protected brush or broncho-alveolar lavage. In current practice, anaerobic bacteria are virtually never detected in pulmonary infections due to the lack of access to specimens that are uncontaminated with the normal flora of the upper airways, such as needle aspirated, trans-tracheal aspirates and pleural fluid.

Most patients with aspiration pneumonia acquired in the community have infection of mixed agents (anaerobic and aerobic bacteria such as *S. pneumoniae, S. aureus, H. influentiae*, and Enterobacteriaceae). By contrast, patients with nosocomial aspiration pneumonia commonly involve a mixture of anaerobes and Gram-negative bacilli such as *E. coli, Klebsiella*, and *Pseudomonas*. One recent prospective study of 95 patients from a long-term care facility admitted to an intensive care unit with pneumonia and risk factors for aspiration found that Gram-negative bacilli were the most common isolates (49%) followed by anaerobes (16%) and *S. aureus* (12%) [16].

One explanation for the difference in organisms accompanying anaerobic bacteria in hospitalized patients is the high frequency of upper airway colonization by enteric Gram-negative bacilli.

Management

In contrast to chemical pneumonitis, antibiotics are the most important component of treatment of aspiration pneumonia due to bacterial infection. The choice of antibiotics should depend on the setting in which the aspiration occurs, as well as the patient's general health. Historically, the antibiotic of choice for the treatment of aspiration pneumonia and lung abscess involving anaerobic bacteria was penicillin, usually given intravenously or orally in high doses. However, a recent trial evaluated the efficacy of agent with specific anaerobic activity, such as clindamycin and metronidazole. Antibiotic agents with activity against Gram-negative organism, such as third-generation cephalosporins, fluoroquinolones, and piperacillin, are usually required.

When anaerobic bacteria are suspected, clindamycin (600 mg iv every 8 hours) is suggested as first line therapy. Alternative agents, as suggested by clinical trials, are amoxicillin-clavulanic acid (875 mg po bd) or the combination of metronidazole (500 mg po or endovenous tds) plus amoxicillin (500 mg po tds). For nosocomial aspiration pneumonia aerobic bacteria, especially Gram-negative

bacilli and *S. aureus*, are usually more important than the anaerobes and therapy should be directed at these organisms [17].

The usual duration of therapy for cases that are not complicated by cavitation or empyema is 7–10 days. Patients with lung abscesses need a longer course of antibiotics, usually until there is radiographic clearance or significant improvement.

Airway obstruction

Pathophysiology

Aspiration pneumonia may involve fluid or particulate matter, which are not inherently toxic to the lung, but can cause airway obstruction or airway closure.

Typical fluids that are aspirated and are not toxic to the lungs per se, include saline, barium, ingested fluid (including water), and gastric contents with a pH exceeding 2.5. Aspiration of large volumes of non-toxic fluid produces abrupt suffocation by mechanical obstruction. Failure to clear the airways may be impaired in patients who lack an effective cough reflex due to a neurological deficit or coma [18].

Clinical features and diagnosis

Patients who have aspirated gastric material may present with dramatic signs and symptoms. In solid particle aspiration, the severity of respiratory obstruction depends on the relative size of the particle that is aspirated and the calibre of the lower airways. When smaller particulate reaches peripheral airways causing complete or partial obstruction, the initial symptom is cough due to bronchial irritation. Chest radiograph shows atelectasis or obstructive emphysema. When major bronchi are involved there may be severe dyspnoea, cyanosis, wheezing, chest pain, pulmonary oedema, hypotension, and hypoxaemia with rapid progression to severe ARDS and death.

Bacterial superinfection is a frequent complication when the obstruction persists for more than 1 week.

Management

The obvious therapeutic modality for the aspiration of large volume of non-toxic fluids is immediate tracheal suction. In the absence of a residual pulmonary infiltrate, no further treatment is indicated.

The immediate suggested treatment when major bronchi are involved is the Heimlick manoeuvre to dislodge the particle. When the obstruction is only partial, the primary therapeutic modality is removal of the particles with fibre optic or rigid bronchoscopy.

Prevention

The main aim of aspiration treatment is prevention. Patient at risk must be identified, including emergency cases, pregnant women, and diabetics. A good anaesthetic practice and attention to detail for patients in the intensive care unit (ICU) are required. Safe intubation needs to be fasted after a rapid sequence induction with correct use of cricoid pressure.

The accepted minimum time for solid food to be emptied from the stomach in adults is 6 hours. Other approaches to prevention include the use of awake intubation and the use of balloon-tipped nasogastric tubes to attempt to occlude the cardia. Another element in prevention is the prophylactic use of anti-acids. A number of agents given pre-operatively have been shown to both increase effectively the pH and to reduce the volume of gastric contents.

In the ICU, similar preventive measures should be applied for intubation of patients, many of whom will also have nasogastric tubes inserted. Even a tracheostomy does not completely eliminate the risk of aspiration.

Bacterial colonization of gastric contents and oropharyngeal secretions, with subsequent aspiration to the lower airways are the most commonly recognized pathogenic factors for the development of nosocomial pneumonia.

Safe extubation is also an important factor in ICU, where patients can have an endotracheal tube in position several days. Patients must be able to cough and have an adequate gag reflex, the stomach contents must be aspirated, and the patient should be placed in the sitting position.

It has been recently observed that both body position and the time the patient is kept in that position are factors that increase the risk of aspiration of gastric contents to lower airways, increasing the risk of nosocomial pneumonia development. This suggests that the semi-recumbent position could be a non-cost prophylactic measure for nosocomial pneumonia.

A number of research groups are studying factors that affect aspiration from the oropharynx into the lower airways in mechanically-ventilated patients as the type of endotracheal cuff, with low-volume high-pressure cuffs.

In ICU patients, once nasogastric feeding has commenced, preventing gastric dilatation by regular aspiration of gastric contents to determine effectiveness of gastric emptying is essential. In patients with gastroparesis leading to gastric distention and regurgitation, the use of post-pyloric tube for feeding may have advantages [19,20].

Measures that should be implemented to prevent silent aspiration include elevating the head (of the bed), oral care, and adequate nutrition to prevent muscle deterioration.

CHAPTER 107

Inhalation injury in the ICU

Silvia Coppola and Franco Valenza

Key points

- Smoke inhalation causes three types of injuries—thermal injury to the upper airways, chemical injury to the tracheobronchial tree, and systemic poisoning.
- When a patient presents with known or suspected smoke inhalation, the patient's airway, breathing, and circulation should be immediately and repeatedly assessed.
- Carbon monoxide and hydrogen cyanide interfere with the delivery and utilization of oxygen.
- Prevention or early diagnosis, and treatment of associated life-threatening complication are necessary to decrease morbidity and mortality after inhalation injury.
- Bronchoscopy is currently a standard diagnostic regimen for inhalation injury.

Introduction

Inhalation injury is an acute respiratory tract insult caused by steam or toxic inhalant, such as fumes, gases, and mists. Inhalation injury may occur without cutaneous burn injury, although the two injuries usually occur together [1]. Inhalation injury continues to be one of the most serious associated injuries, complicating the care of thermally-injured patient. Prevention or early diagnosis, and treatment of this associated life-threatening complication are necessary to decrease its associated morbidity and mortality. Airway injury is present in up to one-third of patients with major burns, and the risk of concurrent pulmonary damage is directly related to the extent of the body surface area burned [2]. Inhalation injury greatly increases the incidence of respiratory failure and acute respiratory distress syndrome (ARDS). It is also the cause of most early deaths in burn victims. [1] The mortality rate following smoke inhalation ranges from 45 to 78% [3–5].

Pathophysiology

Three mechanisms are responsible alone or in combination with inhalation injury—thermal injury to the respiratory tract, chemical injury of airways and lung parenchyma due to exposure to irritating gases and particulate matter, and systemic oxygen supply impairment.

Thermal injury

The inhalation of extremely hot smoke may produce thermal injury to the upper airway. Direct thermal injury below the vocal cords is very unusual because of the efficient heat-exchanging system of the mucous membranes of the upper airway and the limited capacity of dry air to conduct heat. Thermal injury due to smoke inhalation may very rapidly cause erythema, ulceration, and life-threatening intra-oral, pharyngeal, or laryngeal oedema. The oedema may also be progressive during the first 18–24 hours [1]. Therefore, early recognition of thermal injury is very important to perform tracheal intubation before oedema progresses to airway obstruction. Lower airway mucosal oedema is usually not clinically evident until 24 hours after exposure. This oedema can cause damage to the tracheal and bronchial mucosa resulting in bronchorrhoea (that may not appear until 36 hours after exposure), ulceration, and damage to the ciliary system. Tracheal and bronchial epithelial sloughing may also occur [5–7].

Chemical injury

Chemical injury of the airway can be caused by irritants or cytotoxic compounds. The type and volume of the irritants generated by combustion can vary depending on the material burned, the temperature of the fire, and the amount of oxygen present in the fire environment.

Gases with high water solubility such as ammonia, hydrogen chloride, and sulphur dioxide, react with water in the mucous membranes of the upper airway, and produce strong acids and alkalis leading to irritation, ulceration, and oedema of the mucosal surface. This irritation is well perceived by the victims provoking escape responses. Less water-soluble gases (nitrogen oxides, phosgene, chlorine) are transported to the lower airway. Since these lipid-soluble constituents are not as irritating, protracted exposures are more likely before irritation and inflammatory reaction of the upper and lower airways occur [8]. Moreover, smoke contains particulate matter, usually less than 0.5 mm in size, which is formed by the incomplete combustion of organic material. These small particles easily reach all parts of the respiratory tract including the alveoli.

A short duration of exposure to highly reactive irritants may result in loss of cilia and epithelial erosions of the tracheobronchial tree.

When irritant gasses and particulate matter reach the terminal bronchioles, they can initiate an inflammatory reaction [5,7].

Oxygen delivery impairment

The tissue hypoxia is multifactorial, including the inspiration of air with a FiO_2 of less than 0.15 during the fire and the impaired delivery and utilization of oxygen (O_2) by the tissues. Fires occurring in enclosed spaces rapidly remove the available O_2 from the environment. Asphyxiant gases lower the ambient oxygen tension. Both mechanisms lead to hypoxaemia in the victims.

Carbon monoxide (CO) and hydrogen cyanide are the two major tissue asphyxiants, which interfere with the delivery and utilization of O_2.

The decrease of the O_2 delivery to the brain and other organs interferes with mental and physical capabilities. Gases that produce significant hypoxaemia are indirectly toxic to the heart. If hypoxaemia progresses, the aerobic metabolism shifts to the anaerobic pathway leading to metabolic acidosis.

Injury activates the inflammatory cascade resulting in histologically evident inflammatory changes of the respiratory mucosa within 2 hours of injury. In addition, inflammatory mediators such as thromboxane have been shown to decrease mucociliary activity. Both direct toxic injury, as well as the release of inflammatory mediators, allow particles and toxins to exert their effects on other local defence mechanisms and initiate a cascade of parenchymal damage and bacterial infection [6].

It is thought that inhalation of burn products, as well as respiratory tract thermal injury can impair surfactant function and production. Lung injury models have shown that increased capillary permeability leads to reduced surfactant production causing a loss of force that maintain alveolar patency thus resulting in alveolar collapse [7].

Of particular importance is the fact that inhalation injuries have been proven to increase the risk of pneumonia in burned ICU patients. The risk for pneumonia depends on the impaired function of alveolar macrophages, polymorphonuclear leukocytes, and mucociliary clearance mechanisms. Age >60 years and total burn surface area >20% have been shown to be associated with the development of pneumonia [9]. Both factors might prolong the length of stay and, thus, the risk of pneumonia. The mortality for the combination of inhalation injury and nosocomial pneumonia can reach 50–86% [4]. The root cause of this synergistic effect has to do with both direct lung injury from inhalation, as well as systemic inflammation and immune dysfunctions. Endogenous organisms that often cause infections are those present in the oral and respiratory tract or in the gut at the time of admission. These include *Staphylococcus aureus, Streptococcus pneumoniae, Haemophilus influenzae, Proteus mirabilis*, and *Escherichia coli*. Exogenous organisms include methicillin-resistant *S. aureus, Acynetobacter, Pseudomonas aeruginosa*, and other opportunistic organisms. Early infections tend to originate from endogenous organisms, whereas infections at a later time tend to be from exogenous organisms. Recognition and understanding of the pathogens involved in inhalation injury and the time for the onset of infections are important to tailor effective antimicrobial therapy and avert serious complications. ARDS is a complication that may develop several days after the exposure. During thermal injury, inflammatory mediators increase vascular permeability, recruit immune cells, and reduce surfactant function [10]. Thus, burn and inhalation injury carry a significant risk in the development of ARDS that results in a fairly high mortality rate (50–60%) [9].

Diagnosis

An accurate diagnosis of the inhalation burn injury in the early stage is essential for achieving a good prognosis. However, this is not entirely true because the inhalation burn injury has a latent period for 3–4 days prior to the occurrence of respiratory complications. For this reason, inhalation injury is difficult to diagnose and need to be suspected on the basis of a history of smoke exposure in an enclosed space [11].

Patients can be symptomatic within minutes or be asymptomatic for several hours. Symptomatic patients may show some of the following symptoms—mental confusion, unconsciousness, burns to face, lips, mouth and neck, burned nasal or facial hair, soot in the mouth, around the nares or in sputum, hoarseness, and laryngeal stridor. Symptoms of inhalation injury below the glottis include—dyspnoea, bronchorrhoea, wheezing sounds, productive cough, and increased labour in breathing. Bronchospasm and upper airway oedema can occur rapidly. Lower airway oedema can be asymptomatic for up to 24 hours [1].

Inhalation injury should be suspected in the presence of a high carboxyhaemoglobin level after exposure to smoke in an enclosed space. Nevertheless, carboxyhaemoglobin levels may not be reliable if O_2 has been administered or significant time has passed from initial exposure to carbon monoxide (CO). Arterial blood gases may be initially normal. The presence of hypoxaemia and hypercarbia is suggestive of pulmonary injury. All victims of smoke inhalation should be evaluated for cyanide and CO poisoning. Carbon monoxide and hydrogen cyanide poisoning may produce metabolic acidosis and a decreased difference in arteriovenous O_2 content due to tissue hypoxia.

Until 1–2 days after the onset of inhalation burn injury, abnormal findings cannot be identified on a chest radiography or on arterial blood gas analysis. Chest X-ray may show some abnormalities 24–48 hours after the injury, such as atelectasis, and interstitial and alveolar infiltrates that could suggest the presence of pulmonary infection or oedema. Computed tomography may be useful for the diagnosis of delayed respiratory sequelae, such as bronchiectasis, pulmonary fibrosis [12]. Laryngoscopy and bronchoscopy can be performed and have a very high accuracy in the diagnosis of the full extent of the airway injury. The initial exploration may not reveal injured areas for the first 24 hours. This technique may show mucosa erythema, oedema, blisters, ulcerations, presence of particulate matter. Inhalation injury should be assessed by examination of both the upper and lower airway, since any of those may be affected independently. It has been reported that the findings seen on bronchoscopy are useful in predicting the progression of acute lung injury. Fibre optic bronchoscopy is considered the most direct diagnostic method for the definitive diagnosis of inhalation injury and is considered to be more accurate than the diagnosis based on clinical manifestations and signs [13,14].

The literature suggests that the shock phase of burning can lead to colour changes in the airway epithelium that are caused by poor perfusion affecting the correct estimation of the depth of the injury. Fibrescopic bronchoscopy should be performed 3 days after injury, after the shock phase, in order to obtain more accurate results. In conclusion, fibre optic bronchoscopy can evaluate airway epithelial congestion, oedema, erosion haemorrhage, epithelial necrosis, and slough-off. For patients with malignant arrhythmias, refractory hypoxaemia, or severe, uncorrectable bleeding diathesis, bronchoscopy is not recommended [14].

Ventilation–perfusion radionuclide scanning with Xenon-133 is a reliable method for identification of small airway obstruction. This technique is indicated in case of normal findings on chest X-ray and bronchoscopy to determine the extent of the inhalation injury [4].

Pulmonary function tests may give information about respiratory rate, lung compliance, and decreased vital capacity [10]. However,

they are usually difficult to perform due to the critical condition of the patients.

Management

When a patient presents with smoke inhalation, immediate assessment of the patient's airway, breathing, and circulation is indicated. This should take only a few seconds to perform.

The cornerstone of management includes management of airways patency, adequate fluid resuscitation and mechanical ventilation when required, and vigilant surveillance for infectious complications [6].

Intubation is justified if any of the following signs are present—stridor, use of accessory respiratory muscles, respiratory distress, hypoventilation, deep burns to the face or neck, or blistering or oedema of the oropharynx. If these findings are absent, the oropharynx should be examined, followed by laryngoscopy if there is erythema. Some centres routinely perform bronchoscopy, rather than laryngoscopy. Other centres consider that laryngoscopy is preferable to bronchoscopy, because thermal injuries tend to be limited to the supraglottic airways and the appearance of the subglottic airways does not definitively affect management or predict the need for ventilator support [15].

Upper airway oedema or blistering seen during laryngoscopic examination should prompt intubation. Intubation with a large lumen endotracheal tube is preferable to facilitate optimal management of secretions and bronchoscopy. Humidified oxygen may help avoid inspissation [11].

In contrast, in the absence of upper airway oedema or blistering, close observation for 24 hours is reasonable, particularly if serial laryngoscopies are performed. If upper airway oedema is going to occur, it will usually manifest within 24 hours of the exposure.

For patients who are intubated, the endotracheal tube should be left in place until resolution of the upper airway oedema has been documented. Changing the endotracheal tube and failed extubation requiring re-intubation are dangerous in the presence of upper airway oedema and should be avoided [3].

When intubation is necessary, the use of succinylcholine or other depolarizing agents may be appropriate for patient intubation if neuromuscular blockade is required. These drugs are contraindicated for intubation in burn patients 48 hours after injury, since they may worsen post-burn hyperkalaemia.

Patients who do not require intubation should receive supplemental oxygen at a fraction of inspired oxygen of 100%. The purpose of a high concentration of supplemental oxygen is to quickly reverse tissue hypoxia, and to displace CO and cyanide from protein binding sites [6].

Subsequent management of the patient with smoke inhalation consists of monitoring the patient for the development of upper airway compromise due to thermal injury, as well as the development of lower airway sequelae due to direct toxin damage. The former tends to occur within 24 hours of exposure and is managed by intubation until the upper airway oedema subsides, which generally occurs in 3–5 days [3]. The latter tends to occur within 12–36 hours, has a variable duration and is managed by aerosolized bronchodilatators [8].

The hallmark of ventilator management during the treatment of inhalation injury is to minimize further damage and inflammation to lung tissue, and provide adequate ventilation and oxygenation. The increased capillary permeability, coupled with changes in surfactant, results in increased opening alveolar pressures and extensive atelectasis. Studies have shown that increasing positive end expiratory pressure (PEEP) above hydrostatic pressures can prevent collapse of these regions. However, because hydrostatic pressures are not equally distributed and atelectasis tends to occur in dependent lung regions, increasing PEEP to overcome the collapse in these regions could lead to overdistention of other regions, resulting in barotrauma [11]. One way of counteracting the mechanical ventilation-induced damage to lung parenchyma could be the high frequency ventilation (HFV) that uses rapid respiratory rates and small tidal volumes. Several trials of HFV in patients with acute lung injury have shown improvements in oxygenation and ventilation. However, sample sizes for these studies have not been large enough to show a significant survival benefit [6]. Extracorporeal membrane oxygenation is used in situations in which mechanical ventilation fails to provide adequate oxygenation or elimination of carbon dioxide.

Because of the increased pulmonary vascular permeability, the fluid management strategy incorporates providing minimal amounts of fluid to maintain adequate haemodynamic parameters and urine output [6].

Inhalation injury predisposes the patient to nosocomial infections by opportunistic organisms. Prophylactic antibiotic coverage did not show any benefits; on the contrary, it may lead to increased antimicrobial resistance by these organisms. Currently, broad spectrum antibiotics are used when infections or sepsis is suspected. Once an infection agent is identified by culture or Gram stain, the antibiotic therapy is directed at that source.

The presence of CO poisoning, a non-inflammatory form of inhalation injury, should always be considered in those patients suspected of having inhalation injury. CO interferes with oxidative metabolisms by decreasing the oxygen-carrying capacity of the blood, shifting the oxygen–haemoglobin dissociation curve to the left and binding to cytochrome oxidase. For these reasons, any patients suspected of inhalation injury should receive 100% oxygen via a tight-fitting non-rebreathing mask until CO poisoning is excluded and the carboxyhaemoglobin level is less than 10%. The half-life of carboxyhaemoglobin is reduced from approximately 240 minutes at an FIO_2 of 0.21 to around 75–80 minutes at an FIO_2 of 1.0. Hyperbaric oxygen decreases the half-life of carboxyhaemoglobin to approximately 20 minutes [16]. Hyperbaric oxygen treatment has been shown to have an advantage over normobaric oxygen treatment for CO poisoning [6].

A release of hydrogen cyanide also occurs in the smoke of residential fires during combustion of polyurethane, acrylonitrile, and nylon. Hydrogen cyanide can be present in 50% of all fires and its toxicity is synergic with that of carbon monoxide. Cyanide poisoning is nearly impossible to confirm during the initial hours following smoke inhalation because cyanide levels cannot be measured soon enough to be clinically useful. The symptoms and signs are non-specific, and may be due to CO poisoning or an alternative inhaled toxin (including coma, central apnoea, cardiac dysfunction, severe acidosis, high mixed venous oxygen, and low arteriovenous O_2 content difference) [17].

Cyanide inhalation is a potentially life-threating occurrence that requires immediate intervention.

Cyanide, by virtue of its uncoupling of oxidative phosphorylation, is a known cellular toxin. In the patient with an unexplained severe acidosis, tachycardia, and tachypnoea, yet a normal arterial

oxygen content, cyanide poisoning may be present and treatment should be initiated. The first treatment consists of creating a cyanide link in the form of a ferric ion on haemoglobin by the delivery of inhaled amyl nitrite (Amyl Nitrite®) or intravenous sodium nitrite (Nithiodote®). Further treatment includes supplying substrate, such as thiosulphate, which transfers a sulphur group to cyanide and converts it to thiocyanate, which is excreted by the kidneys. A third therapeutic agent, is hydroxycobalamin (Cyanokit®) that combines with cyanide to form the inactive compound cyanocobalamin and is usually given intravenously as a 5-g dose, which should be doubled for patients with blood cyanide levels greater than 40 μmol/L [17].

PART 4.10

Acute respiratory distress syndrome

CHAPTER 108

Pathophysiology of acute respiratory distress syndrome

Lorraine B. Ware

Key points

- ARDS can occur in disparate clinical settings including both children and adults, both medical and surgical patients, and in both the immunocompetent and the immunocompromised.
- Common aetiologies of ARDS include sepsis, pneumonia, severe traumatic injury and aspiration of gastric contents.
- Clinical identification of cases of ARDS is based on the acute onset of both radiographic infiltrates and significant hypoxaemia.
- Alveolar flooding causes decreased lung compliance, ventilation perfusion mismatch, and shunt leading to increased work of breathing and hypoxaemia.
- The pathophysiology of ARDS is complex and involves acute lung inflammation, increased permeability of the lung endothelial and epithelial barriers, inhibition of surfactant function, impairment of alveolar fluid clearance mechanisms and systemic inflammation.

Clinical presentation

The acute respiratory distress syndrome (ARDS) is a common clinical syndrome with an estimated incidence in the United States of 180,000 cases per year [1]. ARDS can occur in disparate clinical settings, and is seen in both children and adults, in medical and surgical patients, and in both the immunocompetent and the immunocompromised. Common aetiologies of ARDS include sepsis, pneumonia, severe traumatic injury, and aspiration of gastric contents [2]. Less common aetiologies include acute pancreatitis, transfusion-associated acute lung injury (TRALI), ischaemia reperfusion injury, drug overdose, fat embolism, and near drowning. Environmental factors, such as alcohol abuse and cigarette smoke exposure may increase the risk of developing ARDS in at risk patients.

Regardless of the underlying cause, ARDS is characterized by the acute onset of non-cardiogenic pulmonary oedema leading to increased work of breathing and acute hypoxaemic respiratory failure. The majority of patients require invasive mechanical ventilation. Although ARDS is defined by its pulmonary manifestations, multi-organ system failure is common and contributes to morbidity and mortality. Current mortality rates in unselected patients are in the 30–50% range. Mortality rates in clinical trials tend to be lower due to exclusion of patients with severe comorbidities. Morbidity is likewise high; survivors have both short- and long-term sequelae, including pulmonary function abnormalities, cognitive impairment, and other neurologic problems [3].

Diagnosis and clinical definitions

The diagnosis of ARDS should be considered in any patient presenting with acute respiratory failure, and an appropriate risk factor for ARDS, such as sepsis, pneumonia, or severe trauma. Although recent efforts have been aimed at identifying patients at risk for ARDS [4] or with early ARDS [5], the clinical definitions of ARDS, established by expert consensus, are intended for diagnosis of established ARDS. The Berlin definitions [6], the most recent, are a minor modification of the 1994 American European Consensus Conference definitions [7]. Diagnosis is based on the acute onset (within 1 week) of radiographic infiltrates consistent with acute pulmonary oedema (Fig. 108.1) accompanied by hypoxaemia as assessed by the arterial to inspired oxygen fraction. In addition, there should be no clinical evidence of a cardiogenic cause of pulmonary oedema. Echocardiography to exclude a cardiac cause should be considered in patients without a risk factor for ARDS [6]. Despite the simplicity of the definitions, they are under-utilized and the diagnosis of ARDS is often missed leading to under-treatment. The need for arterial blood gas measurement may be one factor that limits uniform application of ARDS definitions, particularly in children. Several investigators have studied the use of the oxygenation saturation (as measured by pulse oximetry) to inspired oxygen ratio [SpO_2/FiO_2] as a substitute for the PaO_2/FiO_2 ratio in determining the severity of hypoxemia across various patient populations [8].

Pathologically, ARDS is characterized by diffuse alveolar damage (Fig. 108.2) [2]. This injury pattern is consistent regardless of the underlying cause of ARDS. Invasive diagnosis of ARDS by lung biopsy is not commonly undertaken due to the morbidity and mortality associated with lung biopsy in the critically ill. Of note, in autopsy studies, neither the American European Consensus Conference [9] nor the Berlin ARDS definitions [10] have high specificity for diffuse alveolar damage. Other pathological diagnoses that were made at autopsy in patients who met the Berlin definition of ARDS include pneumonia, abscess, tuberculosis, cancer, pulmonary embolism, acute pulmonary oedema, pulmonary haemorrhage, interstitial pneumonia/fibrosis, and severe emphysema, underscoring the fact that a variety of clinical conditions can present with clinical features consistent with ARDS [10].

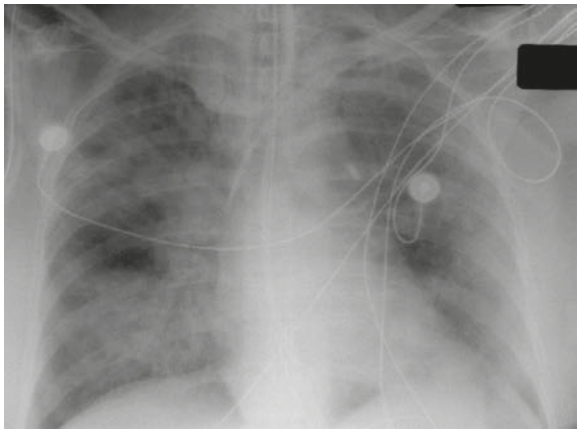

Fig. 108.1 Frontal chest radiograph of a patient with ARDS.

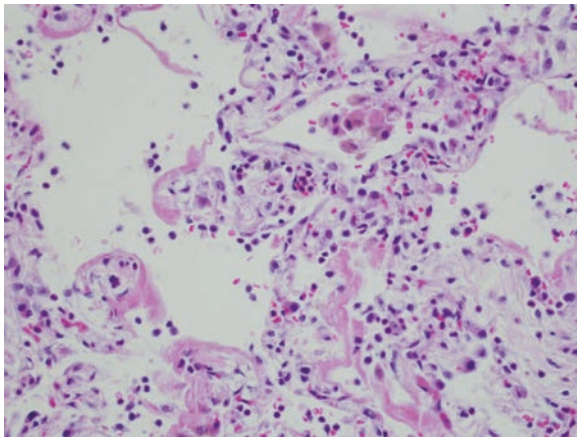

Fig. 108.2 Photomicrograph (×400) of lung tissue from a patient with ARDS showing diffuse alveolar damage with hyaline membrane formation, and intra-alveolar and interstitial neutrophilic inflammation.

Physiological mechanisms of impaired gas exchange and alterations in pulmonary mechanics in ARDS

Acute non-cardiogenic pulmonary oedema is a prominent clinical feature of ARDS. Pulmonary oedema formation in ARDS is caused by increased lung endothelial and alveolar epithelial permeability. Increased endothelial permeability leads to increased rates of filtration of fluid and solute from the lung microvasculature into the lung interstitium. In the absence of increased epithelial permeability, oedema fluid accumulates in the peribronchial interstitial space, and is drained from the peribronchial interstitium by the lung lymphatics that arise in this space. The early interstitial phase of non-cardiogenic pulmonary oedema may not be recognized clinically since interstitial oedema alone does not typically cause significant hypoxaemia and pulmonary oedema may not be visible on chest radiograph until lung water content increases by over 30%.

Although some patients with very mild lung injury may have only interstitial oedema, increased alveolar epithelial permeability due to injury to the epithelial barrier combined with fluid filtration rates that exceed the capacity of the lung lymphatics for fluid removal leads to frank alveolar flooding. Alveolar flooding is a major cause of hypoxaemia in ARDS. Lung units that are flooded contribute to ventilation–perfusion mismatch and intrapulmonary shunt. Inactivation of surfactant by alveolar fluid accumulation may also cause atelectasis of alveolar units, contributing to ventilation–perfusion mismatch and shunt.

Both interstitial and alveolar oedema decrease lung compliance contributing to the increased work of breathing, as well as to the need for ventilation with relatively high distending pressures to deliver sufficient tidal volumes to maintain alveolar ventilation. Accumulation of pulmonary oedema fluid in the peribronchial interstitial space can increase airway resistance, further contributing to increased work of breathing.

Although increased permeability is the primary cause of pulmonary oedema in ARDS, any increases in pulmonary microvascular hydrostatic pressure will raise the driving force for oedema fluid formation across the permeable alveolar–capillary barrier. Increased pulmonary microvascular hydrostatic pressure is common in patients with ARDS [11]. As is discussed in more detail in the chapter on treatment of ARDS, treatment to lower pulmonary microvascular hydrostatic pressure can reduce duration of mechanical ventilation in ARDS likely due to diminished pulmonary oedema formation [11].

Although plain chest radiographs may suggest that pulmonary oedema is diffusely distributed throughout the lung in ARDS, computed tomography demonstrates substantial heterogeneity in oedema distribution [12]. In some patients, particularly those with an extra-pulmonary cause of ARDS [13], pulmonary oedema is indeed diffuse, while others have more focal oedema which tends to be concentrated in dependent regions with less dependent regions appearing more normal.

Molecular mechanisms of acute lung injury and ARDS

A variety of cellular and molecular mechanisms contribute to the pathophysiology of ARDS [14]. Although our understanding of the pathophysiological pathways has improved substantially in the past two decades, therapies targeted at specific mechanisms of injury have largely been ineffective, perhaps due to the complexity and redundancy of injury pathways. In addition, many of these pathways are critically important in host defence.

Inflammation

Dysregulated inflammation is a pathophysiological hallmark of ARDS. Innate immune response pathways are activated in ARDS by pattern recognition receptor binding by either pathogen-derived or cell injury-derived molecules that serve as danger signals. Pattern recognition receptors, such as the Toll-like receptors are highly expressed on the lung epithelium and alveolar macrophages. Activation of these receptors leads to pro-inflammatory signalling, and robust cytokine and chemokine production, activating alveolar macrophages and recruiting neutrophils from the vasculature into the alveolar space. Intracellular pattern recognition receptors such as the Nod-like receptors can also be activated leading to inflammasome activation, caspase-1 cleavage, and release of the pro-inflammatory cytokines interleukin-1 and interleukin-18. Activated neutrophils can release a variety of potentially injurious products, including proteases, oxidants, lipid mediators, histones, and neutrophil extracellular traps, networks of extracellular

antimicrobial factors, and chromatin that can cause endothelial injury. Although these neutrophil-derived mediators are important for host defence against pathogens, excessive, rather than controlled production can contribute to lung injury.

Molecular mechanisms of increased endothelial permeability

The integrity of the lung endothelial barrier is maintained by adherens junctions that are formed by structural proteins, including endothelial-specific VE-cadherin. Factors that stabilize and destabilize the adherens junctions regulate endothelial permeability [15]. Destabilizing factors that may increase permeability in ARDS include pro-inflammatory agonists, such as thrombin, vascular endothelial growth factor, TNF, interleukin-1, microbial products such as lipopolysccharide and leukocyte signals. These factors can disrupt the adherens junction by disrupting homophilic bonds between VE-cadherin molecules. Stabilizing factors include sphingosine-1 phosphate, a glycosphingolipid, and the Robo/Slit signalling pathway. Other endothelial stabilizing agonists include angiopoietin-1, atrial natriuretic peptide, activated protein C, and ATP. Although targeting endothelial stabilization pathways is an attractive avenue for development of potential therapies for ARDS and sepsis, increased endothelial permeability also facilitates leukocyte margination, a process that is critically important for host defence.

Molecular mechanisms of epithelial injury and permeability

The alveolar epithelium is an important site of injury in ARDS that contributes to increased alveolar–capillary barrier permeability and pulmonary oedema formation. In ultrastructural studies of patients dying with ARDS, epithelial lesions range from mild injury with cytoplasmic swelling, vacuolization, and bleb formation to frank necrosis and complete loss of the epithelial layer [16].

In addition to impairing barrier function, injury to the lung epithelium facilitates leukocyte migration, reduces surfactant production and inhibits the clearance of pulmonary oedema fluid from the airspace. Alveolar fluid clearance is normally driven by transcellular active transport of sodium and chloride across the lung epithelial layer from the airspace into the interstitium, which creates a mini-osmotic gradient for resorption of water. In patients with ARDS, intact lung epithelial fluid transport function is associated with better clinical outcomes suggesting that the degree of alveolar epithelial injury is an important determinant of clinical severity of lung injury. In addition to simple loss of barrier function, a variety of other mechanisms have been identified that impair alveolar fluid clearance in ARDS including deleterious effects of pro-inflammatory cytokines, oxidants, and hypoxia.

Regulation of lung epithelial permeability has not been as well studied as endothelial permeability. In general, the lung epithelial barrier is much tighter than the endothelial barrier. Like the endothelium, the epithelial barrier is maintained by cadherin-mediated adherens junction bonds and tight junctions, but contains epithelial specific E-cadherin, rather than VE-cadherin. Recent evidence suggests that the tight junction proteins claudins may be critical regulators of lung epithelial permeability in ARDS.

Ventilator-induced lung injury

Although mechanical ventilation is an important supportive therapy for patients with ARDS, ventilation with high volumes, and high pressures can injure the normal lung and exacerbate injury and oedema formation in the injured lung. There are several mechanisms by which mechanical ventilation is injurious. Because of heterogeneity in the distribution of alveolar consolidation, tidal volumes are delivered predominantly to alveoli that are relatively uninjured, leading to over distension. Alveolar over distension can cause capillary stress failure with endothelial and epithelial injury and initiation of a pro-inflammatory cascade, as well as release or metalloproteinases and oxidative stress. Clinical trials aimed at reducing alveolar over distension by reducing tidal volume have improved clinical outcomes in ARDS [17]. In addition to alveolar over distension, the repeated collapse and re-opening of atelectatic alveoli in areas where surfactant function is impaired can be pro-inflammatory. However, therapies targeted at maintaining alveolar recruitment have not yet had a major impact on clinical outcomes, perhaps because it is difficult in an individual patient to improve alveolar recruitment without causing alveolar over distension.

Dysregulated coagulation and fibrinolysis

In patients with ARDS, both intra- and extravascular coagulation and fibrinolytic pathways are dysregulated [18]. Intra-alveolar fibrin deposition, as evidenced by hyaline membrane formation, is promoted by increased procoagulant, and decreased anticoagulant and fibrinolytic mediators in the airspace. Tissue factor, a potent activator of the extrinsic coagulation cascade, is elevated in the airspace in ARDS, and is associated with increased procoagulant activity. Active tissue factor is also shed into the airspace on membrane-bound microvesicles. Levels of the endogenous anticoagulant protein C are decreased and high levels of plasminogen activator inhibitor-1 impair fibrinolysis.

The systemic procoagulant antifibrinolytic state in ARDS is characterized by increased circulating levels of tissue factor, and PAI-1 and decreased levels of protein C. Microvascular thrombosis occurs both systemically and in the lung in ARDS. Systemic microvascular thrombosis probably contributes to the frequent occurrence of multi-organ system failure in patients with ALI/ARDS. Microvascular thrombosis in the lung capillary bed contributes to ventilation–perfusion mismatch and elevated pulmonary dead space fraction.

Initiation of coagulation is a potent pro-inflammatory stimulus that has been postulated to amplify lung inflammation in ARDS. Thrombin generation induces neutrophil adhesion to the endothelium, expression of selectin, and activation of platelet receptors. Fibrin generation also increases vascular permeability, activates endothelial cells, and induces neutrophil adhesion and margination. However, anticoagulant therapies have not been effective at reducing mortality in clinical ARDS or sepsis. Several recent experimental studies suggest that procoagulant pathways are critically important in regulating barrier permeability and host defence in ARDS, findings that could explain the lack of clinical benefit of anticoagulant strategies.

Resolution of ARDS

Although patients with ARDS continue to die from refractory respiratory failure and multi-organ system failure, with improvements in supportive care and ventilator management, the majority of patients (>50%) with ARDS now survive to hospital discharge.

Although ARDS survivors may have chronic neurological and cognitive impairments related to critical illness, lung function in survivors of ARDS gradually returns to normal or near normal. By 1 year, only modest decrements in diffusing capacity for carbon monoxide may persist. In order for normal lung function to be restored, a variety of resolution pathways need to be activated.

In order for lung epithelial integrity to be restored, the alveolar epithelium must be repopulated to replace injured and necrotic cells. Alveolar epithelial type I cells, which cover the majority of the alveolar surface are regenerated through proliferation and differentiation of the more injury-resistant alveolar epithelial type II cells. Recent evidence also suggests a role for broncho-alveolar stem cells that reside in the broncho-alveolar junction. Therapies that accelerate alveolar epithelial regeneration, such as keratinocyte growth factor can improve experimental lung injury suggesting that epithelial regeneration is a key determinant of outcome of ARDS. Endothelial integrity must also be restored, but this process is less well understood.

Resolution of pulmonary oedema is mediated by alveolar epithelial fluid transport, which requires an intact alveolar epithelium. Although various mediators such as beta-adrenergic agonists have been identified that accelerate the rate of alveolar fluid clearance in animal and human lungs, clinical trials have been disappointing [19,20].

Resolution of inflammation is a coordinated process that involves termination of pro-inflammatory signalling, elaboration of anti-inflammatory signals such as lipoxin A4, resolvin E1, and clearance of apoptotic neutrophils by alveolar macrophages. Recent experimental evidence suggests that T-regulatory lymphocytes are important regulators of resolution of lung inflammation, enhancing neutrophil apoptosis, and suppressing cytokine secretion, in part by release of TGF-beta.

CHAPTER 109

Therapeutic strategy in acute respiratory distress syndrome

Charlotte Summers and Geoffrey Bellingan

Key points

- Acute respiratory distress syndrome (ARDS) is not a single condition, hence a variety of supportive and therapeutic approaches may be required for optimal management.
- The mainstay of ARDS management is the identification and treatment of the pre-disposing condition, together with supportive care, which includes lung-protective ventilation, and even prone ventilation in more severe cases.
- Fluid restriction, after patients are appropriately resuscitated, is probably of benefit.
- The early, and short-term, use of cisatracurium in more severe ARDS cases may improve outcome over and above lung-protective ventilation.
- There are currently no licensed pharmacological therapies for ARDS, although there are a number of novel agents under development.

Introduction

Acute respiratory distress syndrome (ARDS) is a pathological syndrome characterized by arterial hypoxaemia and bilateral pulmonary infiltrates, in the absence of evidence of left atrial hypertension (see Fig. 109.1a). Histologically, the syndrome features epithelial and endothelial injury, with diffuse alveolar damage, hyaline membrane formation, and infiltration of neutrophils and macrophages into the pulmonary interstitium observed (see Fig. 109.1b), and fibrosis can be prominent. Until recently, the diagnosis of ARDS was made in accordance with the America-European Consensus Conference (AECC) criteria established in 1994, however, an updated 'Berlin' definition was produced in 2012 [1]. It is important to remember that almost all clinical studies to date have utilized the AECC criteria, and also that ARDS is not a single disease, but rather a constellation of conditions with similar pathophysiology, and thus there may not be one unifying clinical treatment.

Supportive care

Treatment of predisposing factor and intercurrent infection

The development of ARDS is associated with several risk factors including pneumonia, non-pulmonary sepsis (e.g. peritonitis), aspiration of gastric contents, major trauma, transfusion, and acute pancreatitis. Diagnosis and appropriate treatment of predisposing factors is key to clinical management. It may be necessary, particularly in the immune-compromised host, to undertake invasive diagnostic procedures, such as bronchoscopy, to establish a diagnosis. Furthermore, it has been shown that intercurrent pulmonary infection occurs in 34–70% of patients with ARDS [2], necessitating vigilance for the subsequent development of infection in ARDS patients.

Lung protective mechanical ventilation

It is well established that mechanical ventilation using tidal volumes of 6 mL/kg predicted body weight (PBW), and a plateau pressure less than 30 cmH_2O, confers a mortality benefit, and should be undertaken whenever possible [3]. A trial of high versus low positive end expiratory pressure (PEEP) in patients receiving 6 mL/kg PBW ventilation, with a plateau pressure below 30 cmH_2O, did not find any significant difference between groups, suggesting that the level of PEEP may not be as critical as the need for low tidal volume ventilation in all patients with ARDS [4]. However, retrospective subgroup analysis has suggested that higher PEEP levels may be of benefit in severe ARDS.

Non-conventional gas exchange technologies

There has been significant interest in the use of non-conventional gas exchange technologies, including extracorporeal membrane oxygenation (ECMO), extracorporeal carbon dioxide removal ($ECCO_2R$) and oscillatory devices. To date, none of these devices have been proved to be of universal benefit in ARDS, although it is possible that there may be sub-populations of ARDS patients (e.g. H1N1 influenza patients and ECMO [5]) that derive benefit from these interventions.

Fluid management

Close attention to fluid balance has long been thought to be important in the management of ARDS, and a theoretical case can be made for minimizing the use of fluid therapy, once the patient is adequately resuscitated, to reduce the formation of pulmonary oedema, but the evidence to support this strategy is not conclusive. In 2006, the FACCT study [6] found that a conservative fluid management strategy (in those patients who had been fully resuscitated) was not associated with decreased 60-day mortality when compared with a more liberal regimen. However, improvements in pulmonary physiological values, and a reduction in the duration

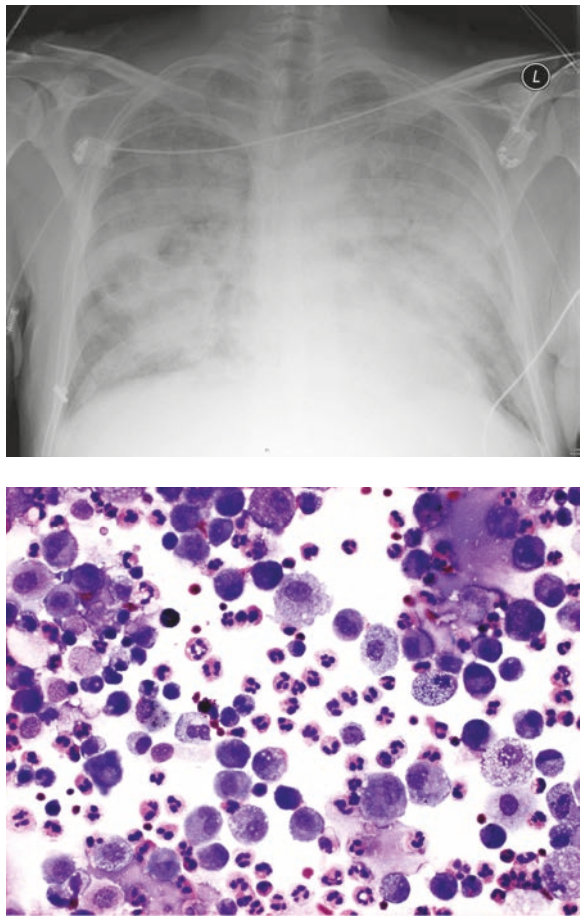

Fig. 109.1 (a) Chest radiograph illustrating the bilateral pulmonary infiltrates of ARDS. (b) Inflammatory cells present within the broncho-alveolar lavage fluid of patient with chest radiograph shown in Fig. 109.1a.

of mechanical ventilation and intensive care stay were observed in the conservative fluid group, with no associated increase in renal failure, need for renal replacement therapy, or non-pulmonary organ failures. Subsequently, a retrospective study examined data from patients enrolled in the lung-protective ventilation ARDSnet clinical trial, finding that a cumulative negative fluid balance on day 4 after the diagnosis of ARDS was independently associated with lower hospital mortality, and increased ventilator- and ICU-free days.

Blood transfusion

Transfusion-related ARDS, or transfusion-related acute lung injury (TRALI), is defined as the development of ARDS during or within 6 hours following transfusion of one or more units of blood or blood components. A recent study identified both recipient (shock, chronic alcohol abuse, liver surgery, current smoking, positive fluid balance before transfusion, and peak airway pressure >30 cmH_2O if mechanically ventilated) and transfusion (plasma or whole blood from female donor, volume of HLA class II antibody, and volume of antihuman neutrophil antigen positivity) related risk factors for TRALI. Interestingly, in contrast to previous studies, an increase in the incidence of TRALI associated with older red blood cell units was not observed [7].

Nutrition

The provision of supportive care involves the administration of nutrition to the ARDS patient. A multicentre study examining the role of trophic (25% of caloric requirement) feeding found no benefit over full standard feeding in terms of ventilator-free days, organ-failure free days, ICU-free days, or incidence of infection [8]. The benefit of dietary supplementation with n-3 fatty acids, gamma-linoleic acid (GLA), and antioxidants on both clinical and physiological outcomes in ARDS has been proposed by several small randomized studies, although a large multicentre double-blinded, placebo-controlled randomized trial to examine the effects of dietary supplementation on ventilator-free days was stopped early on futility grounds, and the intervention group had significantly more reported side effects attributed to the therapy [9]. Currently, there is no evidence to support a specific feeding regimen in ARDS patients, over and above the evidence to suggest that adding parenteral nutrition to enteral nutrition, to facilitate the early meeting of caloric goals, may be detrimental in critically-ill patients.

Neuromuscular blockade

Neuromuscular blockade is often used in ARDS to permit lung-protective ventilation, although concerns have been raised about the potential of these agents to induce ICU-acquired weakness. A multicentre double-blinded placebo-controlled randomized trial of short-term cisatracurium therapy showed a decrease in the adjusted 90-day mortality of more severe ARDS patients, i.e. those with a PaO_2/FIO_2 ratio below 150 mmHg, who received lung-protective ventilation [10]. Paralysis was commenced within 48 hours of patients fulfilling study entry criteria, and was continued for 48 hours according to a standardized protocol. No increase in the incidence of ICU-acquired weakness was observed between the study groups. It remains to be seen in further planned trials, whether the improved mortality seen was due to the effect of neuromuscular blockade, or a specific effect of cisatracurium.

Pharmacological therapies for acute lung injury

Hydroxymethyglutaryl-coenzyme A reductase inhibition (statin therapy)

Hydroxymethyglutaryl-coenzyme A reductase inhibitors, or statins, have been shown to have pleotropic immunomodulatory effects, in addition to their cholesterol-reducing action. Hence, interest has developed in their use as potential anti-inflammatory agents in ARDS. Observational studies examining the impact of prehospital statin use have produced conflicting results, with some suggesting prehospital statin use was associated with a reduced risk of developing ARDS and/or severe sepsis, and others reporting no effect. A single centre, double-blinded placebo-controlled randomized trial of simvastatin showed no significant reduction in pulmonary oedema (extravascular lung water, EVLW), or improvement in pulmonary physiological variables over 14 days, and no improvement in clinical outcomes, although the study was under-powered to detect clinical outcome differences [11]. Furthermore, a multicentre randomized controlled trial (RCT) of rosuvastatin in sepsis-induced ARDS (SAILS; ClinicalTrials.gov: NCT00979121) has recently been stopped, on grounds of futility, after the recruitment of 745

patients. Currently, there is no evidence to support the clinical use of statins in ARDS, particularly as the latest multicentre, HARP2, has shown no benefit (ISTCTN 88244364).

Corticosteroids

Due to the inflammatory nature of ARDS there has been much interest in the use of corticosteroid therapy. Several studies have shown no benefit from the use of high-dose short-course corticosteroids early in the clinical course of ARDS, and a double-blinded placebo RCT in patients diagnosed with ARDS for at least 7 days prior enrolment found no benefit of methylprednisolone, and in fact a significantly increased mortality amongst patients diagnosed with ARDS at least 14 days prior to commencing corticosteroid therapy [12]. However, interest remains in the use of low-dose corticosteroids for established ARDS, with several clinical trials planned.

Beta-adrenergic receptor agonists

Alveolar fluid clearance has been shown to be defective in ARDS. Previous studies demonstrating the ability of beta-adrenergic receptor agonists to improve the resolution of pulmonary oedema led to multicentre randomized controlled trials of both intravenous [13] and aerosolized [14] salbutamol in ARDS. Both studies were stopped early, the aerosolized study on grounds of futility, and the intravenous study due to a significantly increased 28-day mortality in the intervention arm. The lack of benefit of beta-adrenergic agonist therapy on mortality and ventilator-free days was consistent between the two studies, with both concluding that the routine use of this therapy in ARDS patients cannot be recommended. Furthermore, there is evidence that intravenous salbutamol usage in ARDS may be associated with worsened outcomes.

Surfactant

Decreased surfactant levels and altered surfactant composition have been identified in the lungs of patients with ARDS. Clinical trials of replacement therapy with synthetic surfactants have not proved successful, despite significant improvements in oxygenation and a multicentre RCT of large volume natural porcine surfactant replacement, within 36 hours of the onset of ARDS, showed no benefit and a trend towards increased mortality and adverse events in the treatment group [15].

Inhaled nitric oxide

The ventilation–perfusion mismatch, and pulmonary hypertension, often observed in ARDS has led to clinical trials of inhaled nitric oxide therapy. Nitric oxide is a potent pulmonary vasodilator, and also has anti-inflammatory properties. Unfortunately, meta-analysis has shown that inhaled nitric oxide, whilst associated with improved oxygenation in ARDS patients, does not lead to shortened duration of mechanical ventilation, or improved survival [16].

Emerging therapies

Interferon beta

Adenosine is a key regulator of endothelial cell permeability. Preclinical studies have suggested that using interferon beta to induce CD73, a cell surface enzyme that de-phosphorylates AMP to adenosine, may be of benefit in ARDS by improving endothelial barrier function [17]. Interferon beta therapy is currently undergoing phase III clinical trials in ARDS.

Aspirin

The accumulation of activated platelets and neutrophils within the pulmonary vasculature has been demonstrated to be a key step in the pathogenesis of ARDS. Preclinical studies show that platelet inhibition with aspirin leads to improved outcomes in animal models of ARDS [18]. Clinical trials of aspirin therapy are underway in both Europe and the United States (Clinicaltrials.gov: NCT01504867 and NCT02326350).

Biologics

Recently, much interest has developed within the pharmaceutical industry for new therapies for ARDS, leading to the development of novel agents, such as a domain antibody to inhibit the p55 TNF receptor [19].

Cell-based therapies

A multicentre phase one clinical trial to investigate the role of allogeneic bone marrow-derived mesenchymal stem cells (MSCs) for the treatment of ARDS is currently underway in the United States (ClinicalTrials.gov: NCT01775774). However, engraftment in the lung does not seem to be the major therapeutic effect of MSCs, rather the effect derives from their capacity to secrete paracrine factors that modulate immune responses and alter the host responses to injury. Preclinical work has shown that clinical-grade, cryopreserved allogeneic human MSC are therapeutic in a human, ex vivo, *E. coli* pneumonia model, but the antimicrobial effects of the MSCs could be largely duplicated by KGF, a major paracrine product of MSCs [20]. A phase II trial investigating the efficacy and safety of intravenous KGF in ARDS is currently also under way (ISRCTN95690673).

PART 4.11

Airflow limitation

CHAPTER 110

Pathophysiology and causes of airflow limitation

David V. Tuxen

Key points

- Control dynamic hyperinflation during mechanical ventilation by using low minute ventilation, low tidal volume, and high inspiratory flow to achieve a plateau pressure ≤25 cmH_2O.
- Accept high peak inspiratory pressure that results from high inspiratory flow so long as plateau pressure is safe.
- Recognize lactic acidosis from salbutamol.
- Avoid myopathy by avoiding or minimizing neuromuscular blockade.
- Reduce the ventilator rate if a pneumothorax is suspected to protect the second lung.

Introduction

Airflow limitation occurs in asthma, chronic obstructive pulmonary disease (COPD), cystic fibrosis, bronchiectasis, bronchiolitis obliterans, and a component of airflow limitation can accompany a number of other less common conditions.

Both acute severe asthma and exacerbations of chronic airflow limitation can be life-threatening emergencies, requiring urgent medical treatment and ventilatory support. If these are not available or instigated in a timely way, cardiorespiratory arrest can occur, resulting in death or hypoxic cerebral injury. Even after instigation of invasive ventilatory support the risk is not over, as both medical therapy and the ventilator technique also have significant risk of morbidity and mortality. Understanding the mechanism of these problems is key to avoiding them.

Pathophysiology and causes of airflow limitation

The pathogenesis of asthma has both genetic and environmental factors. There is an increase in worldwide prevalence [1]. Reduced exposure to childhood infections as a result of antibiotics and a more hygienic lifestyle are believed to lead to increased IgE-dependent airway inflammation and bronchial hyperreactivity (the 'hygiene hypothesis') with local allergen exposure determining the specific antibody responses [2]. Triggers of acute asthma can be non-specific (cold air, exercise, pollutants), specific allergens (house mite, pollen, animal danders), modifiers of airway control (aspirin, β-blockers), or stress or emotion. No precipitant can be identified in over 30% of exacerbations.

Two patterns of acute severe asthma have been identified [3]. Usual acute severe asthma is the more common group (80–90%), with progression of symptoms over many hours or days, often with a background of poor control and recurrent presentations. This group is predominantly female, triggered by upper respiratory infections and responds slowly to treatment. Pathology is dominated by mucous inspissation and chronic bronchial wall inflammation with eosinophilia [3]. 'Hyperacute', 'fulminating', 'asphyxic', or 'sudden onset' severe asthma is where the interval between onset of symptoms and intubation is less than 3 hours [3–5]. This presentation is less common (approximately 10–20% of life-threatening presentations) and tends to occur in younger male patients with relatively normal lung function, but high bronchial reactivity. Massive respiratory allergen exposure, cold air or exercise and psychosocial stress are the most frequent triggers [3]. This group characteristically has neutrophilic inflammation, typically responds quickly to bronchodilators and is thought to be mainly due to bronchial smooth muscle contraction.

COPD also has both host and environmental factors. Environmental factors include tobacco smoke, air pollution, indoor fumes (e.g. from solid biomass fuel) and poor socio-economic status. The biggest single factor in over 95% of patients with COPD is tobacco smoking. Marijuana smoking may cause premature and quite advanced bullous emphysema due to extremely hot and toxic inhaled smoke held at peak inspiration for prolonged periods of time [6]. Host factors are the balance between circulating proteases and antiproteases (e.g. alpha-1 antitrypsin deficiency) and the intake of antioxidant vitamins (A,C,E) [7]. Only approximately 15% of smokers develop COPD.

In both asthma and COPD, reduced expiratory airflow is primarily due to increased small airway resistance usually due to varying combinations of mucosal oedema and hypertrophy, secretions, bronchospasm, airway tortuosity, and airflow turbulence. In COPD, the loss of lung parenchyma and its elastic tissues (the emphysema component) further reduces expiratory airflow by a decrease in elastic support of the small airways and reduced lung elastic recoil. Reduction of lung elastic recoil pressure is due both to loss of lung elastin and loss of alveolar surface tension from alveolar wall destruction.

Common problems associated with treatment

Dynamic hyperinflation

The majority of critically-ill patients who require mechanical ventilation do not have airflow limitation; their lungs return to

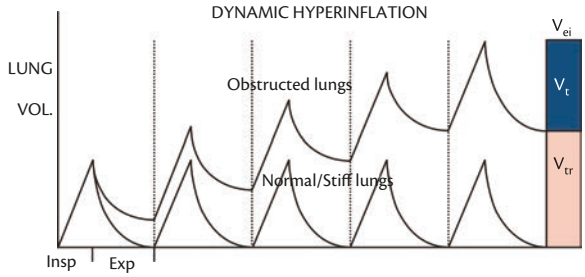

Fig. 110.1 Comparison of the initial effects of mechanical ventilation on lungs with and without airflow limitation. Dynamic hyperinflation is the result of incompletely exhaled gas being 'trapped' by the arrival of the next breath.
V_t, tidal volume; V_{tr}, trapped gas volume above FRC; V_{ei}, end-inspiratory lung volume above FRC; FRC, functional residual capacity.
Data from Tuxen D and Lane S, 'The effects of ventilatory pattern on hyperinflation, airway pressures, and circulation in mechanical ventilation of patients with severe airflow obstruction', *American Review of Respiratory Disease*, 1987, **136**, pp. 872–9.

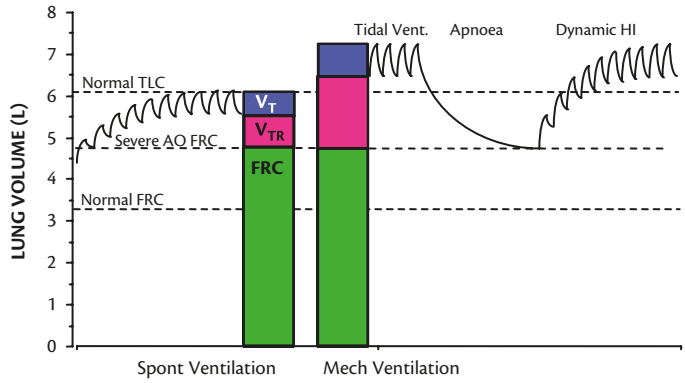

Fig. 110.2 Comparison of dynamic hyperinflation (HI) between spontaneous ventilation and mechanical ventilation in severe airflow limitation [8,10]. Dotted lines show normal total lung capacity (TLC), normal FRC and the elevated FRC in severe airflow obstruction (AO). The effects of periods of apnoea during mechanical ventilation are shown.
Data from Tuxen D and Lane S, 'The effects of ventilatory pattern on hyperinflation, airway pressures, and circulation in mechanical ventilation of patients with severe airflow obstruction', *American Review of Respiratory Disease*, 1987, **136**, pp. 872–9; and Williams T, et al., 'Risk factors for morbidity in mechanically ventilated patients with acute severe asthma', *American Review of Respiratory Disease*, 1992, **146**(3), pp. 607–15.

functional residual capacity or passive relaxation volume at the end of tidal expiration (Fig. 110.1) where the recoil pressures of the lungs (to collapse) and chest wall (to expand) are balanced.

This is not the case in a patient with any significant airflow limitation. Slower expiratory flow results in incomplete exhalation of the inspired tidal volume (V_T) in the expiratory time available and part of the inspired volume is trapped by the arrival of each new breath after commencement of mechanical ventilation ('gas trapping', Fig. 110.1). The lungs undergo dynamic hyperinflation [8]. The expiratory time to complete exhalation in severe airflow limitation may be 30–90 sec [8]. Gas trapping does not continue indefinitely, but increases lung volume over 6–12 breaths until an equilibrium point is reached where the inspired V_T (which could not be completely expired at lower lung volumes) is able to be expired in the same expiratory time [8]. This equilibrium point is enabled by two factors—the increase in lung elastic recoil pressure and in small airway calibre, both of which normally occur as lung volume increases. The three primary determinants of this equilibrium point are the volume going in (V_T), the time for it to come out (determined both by respiratory rate and inspiratory flow or the I:E ratio) and, of course, the severity of airflow limitation.

In moderate airflow limitation with spontaneous breathing this process is adaptive; it allows the desired minute ventilation to be achieved at a higher lung volume, albeit with increased work of breathing and loss of inspiratory reserve. When airflow limitation becomes severe during spontaneous breathing, dynamic hyperinflation will continue to total lung capacity (Fig. 110.2). Hypercapnia occurs in the absence of fatigue as a result of the physical limits on inspiration and expiration, where the maximum achievable minute ventilation is less than that required for normocapnia. Of course, at this lung volume, the inspiratory muscles length is very short and has little mechanical advantage over the already maximally-inflated chest wall and so muscle fatigue can rapidly occur with worsening hypercapnia.

Once mechanical ventilation is commenced, ventilation is easily increased, resulting in more dynamic hyperinflation to above total lung capacity (Fig. 110.2) where hypotension and risk of pneumothorax will readily occur [9].

The passive relaxation volume of the lung, i.e. the functional residual capacity (FRC) after prolonged expiration (30–90 sec in a paralysed patient), is elevated in moderate to severe airflow obstruction by airway closure that occurs throughout expiration. In severe asthma requiring mechanical ventilation FRC is 50% above normal [10] and only 1.4 L below total lung capacity (Fig. 110.2). A period of 30–90 sec apnoea during mechanical ventilation will allow the lungs to exhale all dynamically-trapped gas and return to this FRC (Fig. 110.2) with release of circulatory compromise [11]. Restoration of ventilation will return the lungs to their previous hyperinflation within 6–10 breaths (Fig. 110.2). It has been shown that ventilation to end-inspiratory lung volumes above total lung capacity (TLC) greatly increases the risk of hypotension and pneumothorax, while ventilation that keeps the plateau pressure (P_{plat}) ≤25 cmH_2O reduces that risk [9].

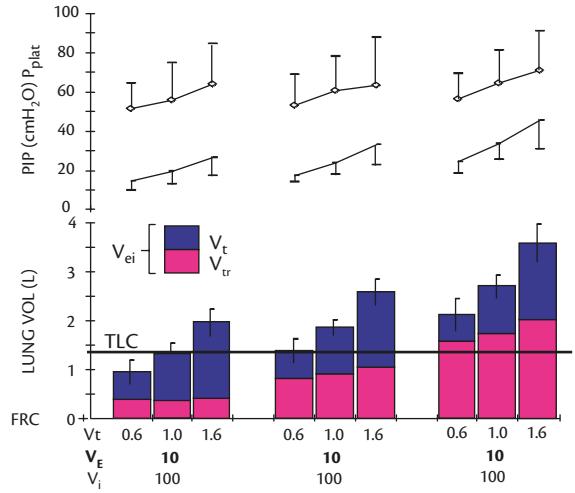

Fig. 110.3 The effects of minute ventilation (V_E) on trapped gas (V_{tr}) above FRC, end-inspiratory lung volume (V_{ei}), peak inspiratory pressure (PIP) and plateau airway pressure (P_{plat}) at a constant inspiratory flow setting (V_I). The effect of different V_t and ventilator rate combinations to achieve each V_E [8].

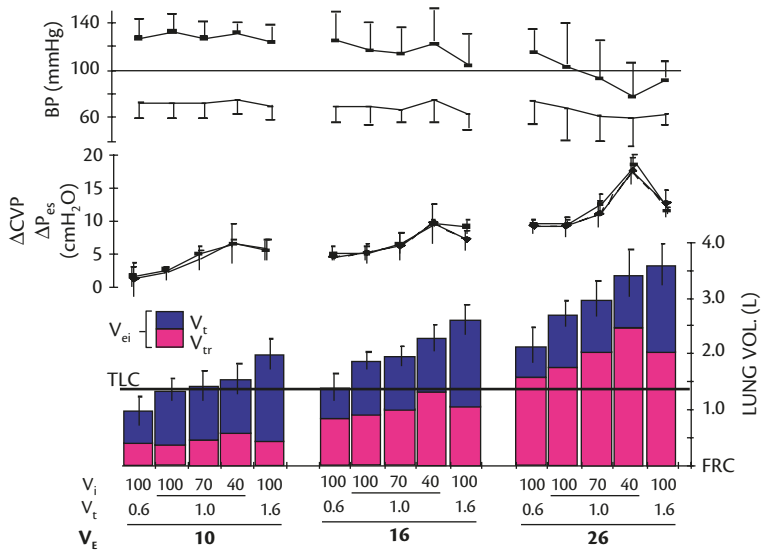

Tuxen & Lane. Am Rev Respir Dis 1987; 136: 872-879

Fig. 110.4 The effects of different mechanical ventilation patterns on blood pressure, central, and oesophageal pressures on patients with severe airflow limitation [8].
V_t, tidal volume; V_{TR}, trapped gas volume above FRC; V_{ei}, end-inspiratory lung volume above FRC; FRC, functional residual capacity; BP, blood pressure; CVP, central venous pressure; P_{es}, oesophageal pressure.

The biggest single ventilator variable affecting the trapped gas volume (Fig. 110.3) is the minute ventilation (V_E, Fig. 110.3) [8]. A large V_T slightly increases trapped gas levels at each level of V_E, but greatly increases the end-inspiratory lung volume with risk of pneumothorax. The changes in central venous and oesophageal pressures, and the reductions in mean arterial pressure most directly relate to the end-expiratory lung volume [8] (Fig. 110.4). The only ventilator pattern that places all patients below the safety line equivalent to TLC is a low V_T and a low V_E (Fig. 110.3).

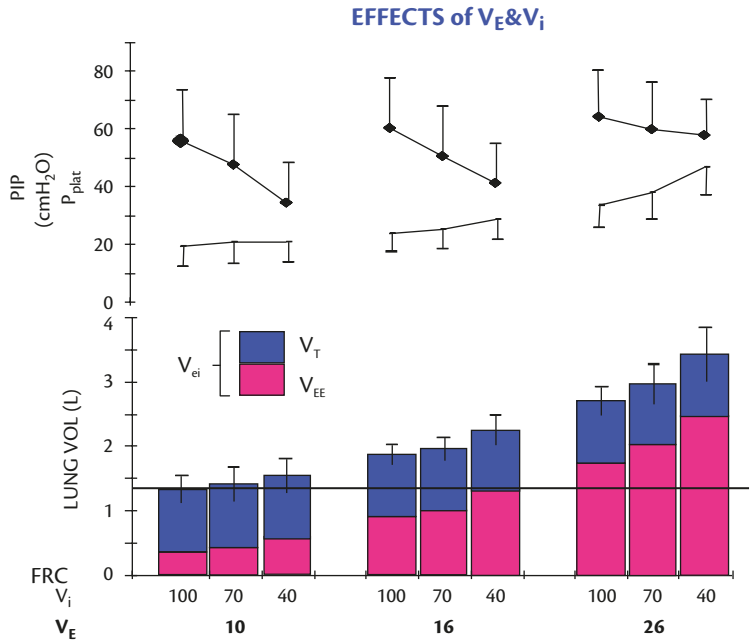

Fig. 110.5 The effects of reducing V_i from 100 to 40 L/min, at each level of V_E, on V_{ei}, PIP and P_{plat} [8].
V_{ei}, end-inspiratory lung volume above FRC; FRC, functional residual capacity; V_E, minute ventilation, V_{TR}, trapped gas; P_{plat}, plateau airway pressure; V_i, constant inspiratory flow setting; V_{EE}, end-expiratory.

In patients requiring mechanical ventilation for severe asthma, the minute ventilation required to normalize $PaCO_2$ and pH can require a high level of V_E. If these levels of V_E are used, the result is excessive dynamic hyperinflation in most patients, significant risk of hypotension and pneumothorax, and increase in asthma ventilation mortality [9,12]. Safe ventilation should result in an end-inspiratory lung volume (V_{ei}) ≤20 mL/kg (1.4 L) and a P_{plat} of less than 25 mLH_2O. This usually requires a V_E of ≤115 mL/kg/min (≤8 L/min), which will result in most patients being initially hypercapnic.

At any given V_T and respiratory rate, putting the V_T in quickly (high inspiratory flow, short inspiratory time) will result in a longer expiratory time and less gas trapping (Fig. 110.5) [8].

During volume controlled ventilation, the use of a high inspiratory flow (V_i) in the presence of airflow limitation will result in a high peak inspiratory pressure (PIP), but a lower P_{plat}. When the V_i is turned down there is a very gratifying reduction in PIP at every level of minute ventilation, but hidden beneath this falling airway pressure is an increasing P_{plat} (Fig. 110.5) that may convert a patient from a safe to an unsafe level of dynamic hyperinflation [8,12].

A safe level of dynamic hyperinflation (P_{plat} 25 cmH_2O) with a high PIP may not need change, accepting that high PIP is necessary in severe asthma to allow inspiration of a safe tidal volume over a short time inspiratory time. A high PIP in the presence of otherwise safe ventilation has never been shown to cause harm in severe airway obstruction.

Treatment-induced lactic acidosis

Both intravenous salbutamol and continuously nebulized salbutamol can, and often do, cause lactic acidosis [13,14]. Over the course of 1–2 hours, particularly after a bolus dose of intravenous salbutamol, the lactate level may rise as high as 12 mmol/L [15]. The benefits of nebulized salbutamol in acute severe airway obstruction are beyond question [16]. Intravenous salbutamol has never been shown to have additional benefit above maximal doses of nebulized salbutamol [13,17], but has the theoretical advantage of reaching airways that are completely occluded and, hence, inaccessible to nebulized salbutamol.

It is commonly used in acute severe asthma refractory to initial treatment in some countries. Thus, intravenous salbutamol may improve airflow limitation, but may concurrently increase dyspnoea, distress, and fatigue by the production of lactic acid. This resolves rapidly with infusion reduction or cessation. With continued infusions, the lactic acidosis is usually resolved within 24 hours. This phenomenon is shared with other intravenous beta-agonists. The mechanism is not clear, but is probably a direct effect on intracellular metabolism.

Necrotizing myopathy after prolonged ventilation

It has now been widely reported [15,18,19] that patients with severe asthma who receive prolonged neuromuscular blockade or even effective paralysis by heavy sedation [20] can suffer from an acute necrotizing myopathy. This characterized by generalized weakness and hyporeflexia, which can range from mild weakness (not delaying ICU discharge) to profound weakness requiring prolonged mechanical ventilation, rehabilitation, and significant disability at 12 months. Sensation is intact. Electromyography shows a myopathic pattern, sometimes with false features of neuropathy. Serum creatine kinase (CK) levels are always abnormal and levels may range from mild elevation to greater than 10,000 IU. Levels do not correlate well with weakness as a muscular person may have a large, but transient CK rise with minimal weakness and an elderly person with poor muscle mass might have small elevations for an extended time period with severe weakness. Muscle biopsy shows three characteristic features:

- Non-uniform muscle wasting with pale staining.
- Nuclear crowding, but lack of inflammatory infiltrate.
- Vacuolation (Fig. 110.6).

Myopathy severity has been shown to correlate with dose of neuromuscular blocking agents received [15].

Ventilation-induced circulatory collapse

A small subset of patients have such severe asthma that the usual safe ventilation results in extreme dynamic hyperinflation with acute circulatory collapse and apparent electromechanical dissociation within a short time of commencing mechanical ventilation. If this phenomenon is not recognized early it can lead to prolonged, futile standard resuscitation, eventually leading

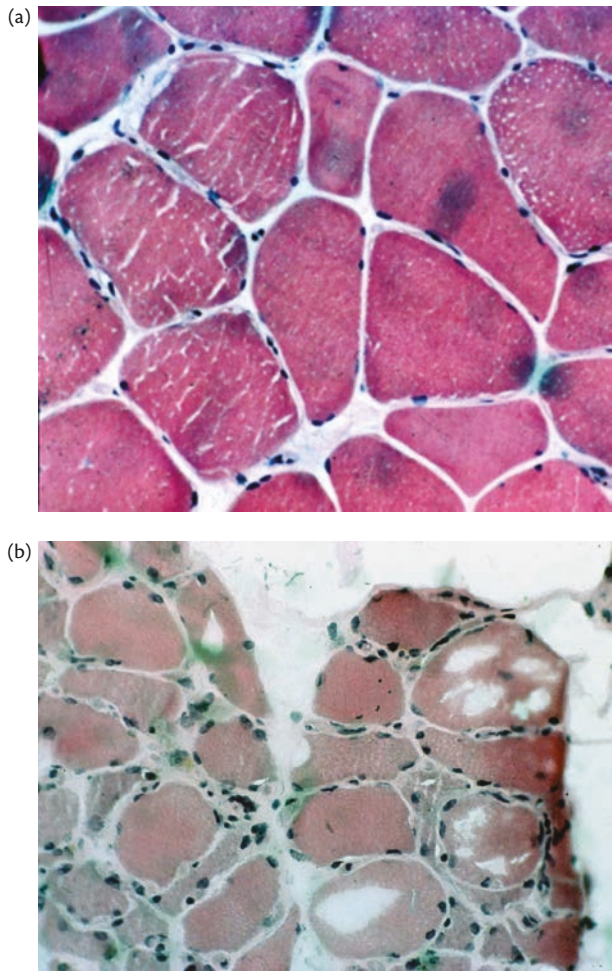

Fig. 110.6 Comparison of a normal muscle biopsy (a) with one from a patient with severe necrotizing myopathy following prolonged neuromuscular blockade for refractory asthma (haematoxylin and eosin staining). Note the non-uniform muscle wasting, nuclear crowding, absence of inflammatory infiltrate, and vacuolation (b).

Reproduced with kind permission from David Tuxen.

to asystole, and brain damage or death. A period of apnoea or much reduced minute ventilation will usually result in circulatory improvement. Additional fluid resuscitation and inotropes may also be required.

Pneumothorax

Pneumothoraces in severe airflow limitation are most commonly caused by excessive dynamic hyperinflation, central venous cannulation, or intercostal insertion of an intravenous cannula for a suspected pneumothorax. They are almost always under tension during mechanical ventilation because the airways themselves expand during inspiration, and collapse during expiration resulting in a valve-like effect and airway closure prevents the lung from collapsing and sealing the air leak. Such a pneumothorax will significantly reduce ventilation to that lung and increase ventilation to the second lung greatly increasing the risk of bilateral tension pneumothoraces. While either an urgent chest X-ray (if mild hypotension) or an intercostal catheter insertion (if severe hypotension) is required promptly, the first action should be a reduction in ventilation to prevent a pneumothorax in the second lung.

CHAPTER 111

Therapeutic approach to bronchospasm and asthma

Brett G. Sampson and Andrew D. Bersten

Key points

- Risk factors for life-threatening asthma include chronic severe asthma, taking ≥3 asthma medications, previous intensive care unit admissions, previous invasive ventilation, and psychosocial factors.
- β_2 agonists, anticholinergics, and corticosteroids are the mainstay of treatment.
- A ventilation strategy of hypoventilation and permissive hypercapnoea minimizes barotrauma and dynamic hyperinflation.
- Hypotension, cardiovascular collapse, and cardiac arrest may result from dynamic hyperinflation, tension pneumothorax, acute right heart failure, or arrhythmia.
- Non-established therapies include leukotriene antagonists, non-invasive ventilation, and extracorporeal support.

Clinical assessment

A focused asthma history and examination enables grading of severity (Box 111.1). Risk factors for life-threatening asthma include chronic severe asthma, taking ≥3 asthma medications, previous intensive care unit (ICU) admissions, previous invasive ventilation, and psychosocial factors [1,2]. Chest examination should assess for pneumothorax, lung collapse, and hyperinflation. A 'silent chest' from maximally hyperinflated lungs may portend respiratory arrest. Alternative diagnoses, including left ventricular failure, inhaled foreign body, upper airway obstruction, and vocal cord dysfunction should be considered, especially if unresponsive to bronchodilator therapy.

Vocal cord dysfunction

Early recognition of vocal cord dysfunction (VCD), the inappropriate adduction of the vocal folds during respiration, may prevent β_2 agonist toxicity and unnecessary intubation. VCD may mimic refractory asthma, affects 4–10% of asthma clinic patients, is more common in females, and a physical cause is identified in only 25% [3]. Diagnosis is by fibre optic observation of paradoxical vocal cord movement and possibly by computed tomography (CT) of the larynx [3].

β_2 agonist toxicity

Adverse effects of β_2 agonists range from tolerable side effects to serious toxicity. Side effects include tachycardia, arrhythmia, hypertension, hypotension, tremor, hypokalaemia, worsening of V/Q mismatch, and hyperglycaemia. β_2 agonist toxicity may cause lactic acidosis with respiratory compensation, which can be mistakenly attributed to worsening or unresponsive asthma; often leading to further inappropriate β_2 agonist administration [4]. β_2 agonist toxicity is most often seen with intravenous (iv) infusions and continuous nebulization. ICU admission for closely supervised cessation, or reduction, of β_2 agonist therapy allows safe resolution of the hyperlactataemia.

Chest radiograph

A chest radiograph is indicated in unresponsive severe asthma, when lower respiratory tract infection or barotrauma is suspected, after initiation of ventilation, and if the diagnosis is in doubt.

Pulse oximetry and arterial blood gas analysis

Pulse oximetry enables accurate titration of oxygen therapy. Hypoxaemia from V/Q mismatch and mucous plugging is common in severe asthma. Hypocapnoea and respiratory alkalosis from hyperventilation is seen initially in severe asthma. Normal $PaCO_2$ or hypercapnoea usually represents more severe asthma, especially if the $PaCO_2$ is rising on serial measurements. Arterial blood gas sampling is indicated to confirm hypoxaemia, and to measure $PaCO_2$, pH, and lactate. Lactic acidosis and hypokalaemia from β_2 agonist toxicity can be detected by arterial blood gas analysis.

Therapeutic management

Oxygen

Humidified oxygen should be applied to maintain SpO_2 between 94 and 98% [2]. Hyperoxia from uncontrolled oxygen administration can worsen V/Q mismatch by releasing hypoxic vasoconstriction, leading to increasing hypercapnoea.

β_2 agonists

Inhaled short-acting β_2 agonists are the first line treatment. β_2 agonist via metered dose inhalers (MDI) and spacer is more effective in cooperative patients than nebulization. Typically, four to eight puffs of salbutamol are administered 1–4-hourly [2,5]. Oxygen-driven nebulization is recommended in life-threatening asthma as delivery by MDI and spacer method is usually not possible. Nebulized salbutamol (5 mg every 15–30 minutes) is a common initial regimen, increasing the dosing interval to 1–4 hours according to

Box 111.1 Clinical features of severe and life-threatening acute asthma

Acute severe asthma

Any one of:

- Respiratory rate ≥25/min.
- Heart rate ≥110.
- Inability to complete sentences in one breath.
- PEFR 33–50% best or predicted.*
- Pulsus paradoxus > 15 mmHg.**

Life-threatening asthma

Any of the following in a patient with severe asthma:

- Altered conscious state.
- Exhaustion.
- Arrhythmia.
- Hypotension.
- Cyanosis.
- Silent chest.
- Poor respiratory effort.
- PEFR <33% best or predicted.*
- SpO_2 < 92%.
- PaO_2 < 8 kPa (60 mmHg).
- Normal or rising $PaCO_2$.

*PEFR may not be possible in severe and life-threatening asthma, and may worsen bronchospasm.
**Absence of pulsus paradoxus does not exclude severe and life-threatening asthma.

response [2]. Continuous nebulization, e.g. salbutamol 5–10 mg/hour, may be more effective than intermittent administration [6]. Despite a lack of evidence, and a higher risk of toxicity, iv infusions of β_2 agonist may be considered in life-threatening asthma unresponsive to continuous nebulization, e.g. salbutamol 5-20 micrograms/min. An iv bolus of 100–300 micrograms of salbutamol may be life-saving in the unintubated patient *in extremis*. While unresponsiveness to maximal β_2 agonist therapy may suggest refractory asthma or a complication of asthma (Box 111.2), alternative diagnoses, and β_2 agonist toxicity should always be considered.

Box 111.2 Complications of severe and life-threatening acute asthma

- Pneumothorax, pneumomediastinum, pneumopericardium.
- Atelectasis.
- Mucous plugging.
- Respiratory arrest.
- **β_2 agonist toxicity**: arrhythmias, tremor, lactic acidosis, hypokalaemia.

Anticholinergics

Combining nebulized ipratropium bromide (500 micrograms 4–6-hourly) with nebulized β_2 agonist produces significantly greater bronchodilation than β_2 agonist alone [1,2,7]. An initial three doses 20 minutes apart might have additional benefit.

Corticosteroids

Prednisolone 50 mg daily (or 100 mg hydrocortisone 6-hourly if the oral route is not possible) should be commenced as early as possible and continued for at least 5 days [1,2]. Following recovery of the acute exacerbation, systemic steroids should be stopped or returned to maintenance dose, without tapering and inhaled steroids recommenced.

Magnesium sulfate

A single iv dose (1.2–2 g iv over 20 minutes) may be beneficial in severe and life-threatening asthma in patients who are unresponsive to maximal bronchodilator therapy [1,2,8]. However, evidence for the nebulized route is lacking [8]. While serious side effects from a single dose are uncommon, iv magnesium may cause respiratory muscle weakness, hypotension, flushing, sedation, areflexia, and arrhythmias, and therefore, repeat doses should be avoided.

Adrenaline

A slow iv bolus dose of 0.2–1 mg, over 3–5 minutes, followed by an infusion of 1–20 micrograms/min may be effective in selected patients. Subcutaneous and intramuscular adrenaline (0.3–0.5 mg) appears to be efficacious and safe in the prehospital environment for near fatal asthma that is unresponsive to β_2 agonists.

While there is insufficient evidence for iv adrenaline in acute severe asthma, it may avert invasive ventilation when a patient is in extremis [9].

Heliox

Helium/oxygen mixtures (e.g. Heliox 70:30) may decrease resistance to airflow, enhance delivery of nebulized bronchodilators, and improve pulmonary function in severe acute asthma [10]. However, the existing evidence does not support its use in asthma [1,10].

Anaesthetic agents

Ketamine infusion (0.5-2 mg/hr) has been reported to induce bronchodilation and avoid intubation in severe asthma [11], but there is insufficient evidence to recommend its use. The use of volatile anaesthetic agents (e.g. halothane) in ventilated patients has been described; hypotension, myocardial depression, and rebound bronchospasm, as well as the requirement for an anaesthetic machine with scavenging have limited their use.

Aminophylline

Aminophylline does not provide additional bronchodilation beyond that achieved by β_2 agonist therapy in adults [1,12]. However, aminophylline is beneficial in children with unresponsive severe acute asthma [13]. Aminophylline has a narrow therapeutic index and unfavourable side effect profile (headache, nausea, vomiting, cardiac arrhythmias, and seizures).

Leukotriene antagonists

Leukotriene antagonists have shown early promise in the treatment of acute asthma [14,15], but their use is currently limited to clinical trials.

Ventilatory support

Dynamic hyperinflation and intrinsic PEEP

Dynamic hyperinflation is the progressive increase in lung volume occurring when severe airflow limitation prevents complete exhalation before onset of the next breath (commonly known as 'gas trapping') [16]. Functional residual capacity (FRC) progressively increases, shifting tidal ventilation into higher lung volumes, resulting in flattening of the diaphragm, mechanical disadvantage, and increased elastic load. Together with the underlying increase in resistive work, the minute ventilation required to maintain normocapnoea eventually becomes unachievable, resulting in hypercapnic respiratory failure.

Intrinsic positive end expiratory pressure ($PEEP_i$) results from incomplete exhalation with progressively higher end-expiratory lung volumes and failure of alveolar pressure to return to zero at end expiration [16]. $PEEP_i$ measured as the airway pressure after an end-expiratory occlusion is the most common method used; however, this requires a relaxed patient and sufficient time for equilibration. Due to the heterogeneous distribution of inflammation and bronchospasm (and consequently dynamic hyperinflation and $PEEP_i$), $PEEP_i$ should be considered an average value. Also, airway closure may prevent regional $PEEP_i$ from being measured underestimating gas trapping (Fig. 111.1) [16].

During spontaneous and supported ventilation, inspiratory effort must overcome $PEEP_i$ and reduce airway pressure below extrinsic PEEP ($PEEP_e$), or below atmospheric pressure if no $PEEP_e$ is applied, before inspiratory flow can occur. This additional elastic load contributes to increased work of breathing and respiratory insufficiency. During supported or triggered ventilation a low level of $PEEP_e$ (typically 5 cmH_2O), which is less than the $PEEP_i$, can reduce inspiratory (threshold) work and allow easier triggering of the ventilator. During controlled ventilation, when there is no spontaneous respiratory effort, the traditional approach is to set $PEEP_e$

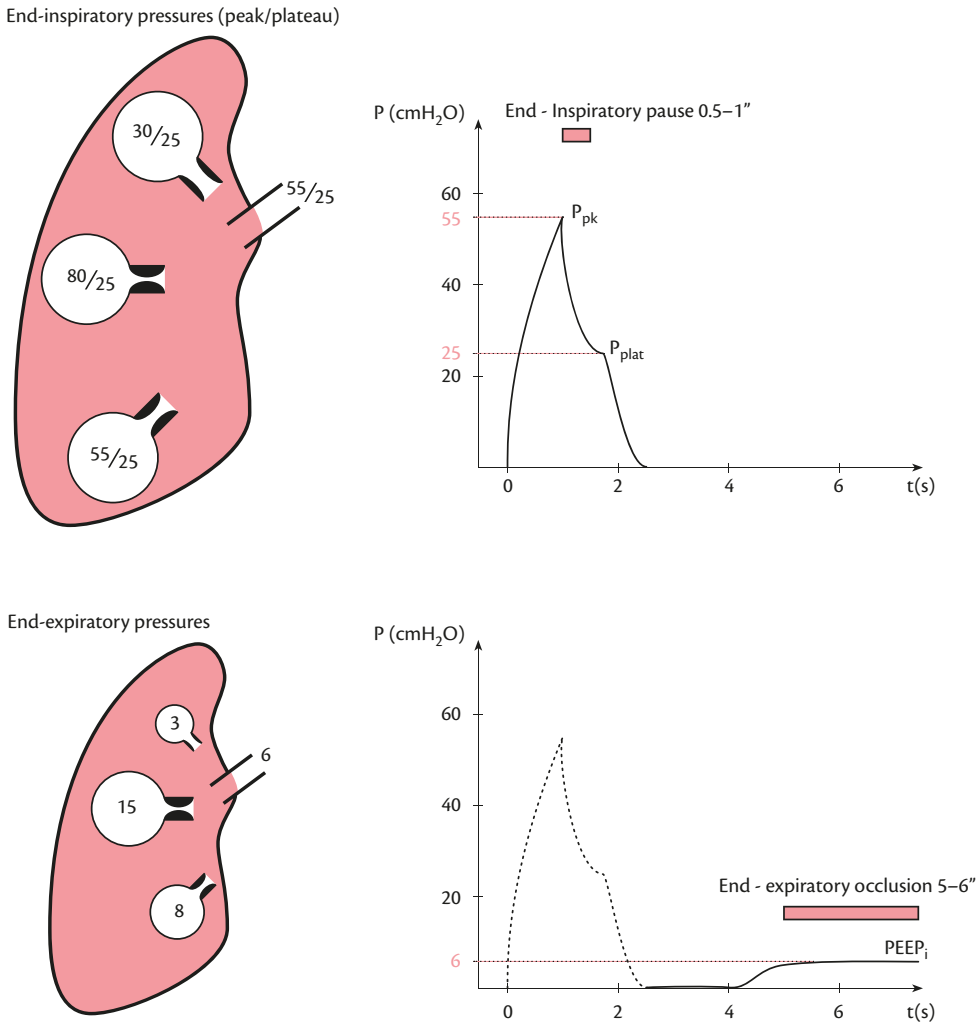

Fig. 111.1 Schematic representation of the heterogeneous distribution of airflow limitation and lung mechanics at end-inspiration and end-expiration in acute asthma. The figure represents the lung at both end-inspiration and end-expiration with associated airway time curves and relevant pressures during controlled mechanical ventilation in a relaxed patient. At end-inspiration a 0.5-second pause results in a fall from a peak airway pressure (P_{pk}) to the plateau airway pressure (P_{plat}) followed by a fall to the set $PEEP_e$ of 0 cmH_2O. The difference between P_{pk} and P_{plat} is determined by the average inspiratory resistance and the inspiratory flow rate. As there is heterogeneous distribution of resistance, different lung units have different P_{pk}, but a constant P_{plat}. The average P_{pk} and P_{plat} is also shown in the major conducting airway. At end-expiration differences in resistance between lung units results in heterogeneous degrees of gas trapping and $PEEP_i$. The result of an end-expiratory occlusion is shown in the airway pressure time relation with a rise in pressure to the average $PEEP_i$ (6 cmH_2O) occurring over some seconds.

to zero to prevent further increases in lung volume. However, one study suggests that an empirical trial of $PEEP_e$ during controlled ventilation may paradoxically relieve over inflation [17].

Non-invasive ventilation

Although non-invasive ventilation (NIV) has potential benefits, there is insufficient evidence to support its use in asthma [18]. NIV applied $PEEP_e$ (5 cmH_20) may reduce the inspiratory effort required to overcome $PEEP_i$, shorten inspiratory time and improve minute ventilation; without worsening dynamic hyperinflation. Other possible benefits include reduced V/Q mismatch, improved response to bronchodilators, avoidance of mechanical ventilation, improved PEFR and FEV1, and shorter ICU and hospital stay. However, NIV has potential serious complications including gastric insufflation, aspiration, hypotension, and pneumothorax. A trial of NIV may be warranted in cooperative patients with severe asthma, but must not delay intubation and invasive ventilation. Non-invasive positive pressure ventilation (NPPV) is the most studied mode of NIV in asthma, with inspiratory positive airway pressures (IPAP) of 12–15 cmH_2O and an expiratory positive airway pressure (EPAP) of 5 cmH_2O [18].

Invasive ventilation

The decision to intubate should be made by an experienced clinician after a period of observation, taking into consideration the rapidity of asthma onset, response to treatment and projected clinical course. It may be safe to withhold intubation in hypercapnic hyperacute asthma responding to treatment, but may be necessary in normocapnic chronic severe asthma with exhaustion. Absolute indications for intubation include respiratory and cardiac arrest, severe hypoxaemia, severe exhaustion, and rapidly deteriorating conscious state [19].

Induction with ketamine may provide additional bronchodilation [19]. Intubation-induced bronchospasm may be attenuated by maximal pre-induction β_2 agonist therapy; intravenous lidocaine has not been shown to be effective [19]. Once endotracheal tube placement is confirmed, slow hand ventilation (4–10 breaths/min) will maximize expiratory time until connection to the ventilator. A ventilation strategy that provides adequate oxygenation, while avoiding dynamic hyperinflation is required. This mandates a prolonged expiratory time with accompanying relative hypoventilation and permissive hypercapnoea. Prolonged expiratory time may be safely achieved with volume control ventilation at an initial tidal volume of 5–7 mL/kg and respiratory rate of 6–12/min. CO_2 clearance may be improved by incrementally increasing tidal volume and reducing respiratory rate (preserving constant minute ventilation) to reduce the anatomical dead space ventilation fraction. $PEEP_e$ is usually set at zero to prevent further increases in lung volume and dynamic hyperinflation. Inspiratory flow rates should be initially set at 30–60 L/min. Although higher inspiratory flow rates (70–100 L/min) may reduce inspiratory time, resultant high peak airway pressures may expose over distended, well-ventilated lung units to barotrauma (Fig. 111.1). A constant inspiratory flow pattern offers the advantage of a simple estimate of inspiratory resistance when an inspiratory pause is used and prevents dissipation of visco-elastic forces aiding expiratory flow. However, the peak airway pressure will be higher than if a descending ramp inspiratory flow pattern is used. Adjustments of tidal volume, respiratory rate and inspiratory flow should be made to maintain a $P_{plat} < 25$ cmH_2O. Acidaemia from permissive hypercapnoea is usually well tolerated. Sodium bicarbonate administration may be of benefit if the pH is below 7.15, although it can worsen intracellular acidosis. Deep sedation and intermittent neuromuscular blockade are usually required in the early ventilation period to avoid asynchrony.

Box 111.3 Complications of invasive ventilation in acute asthma

- **Dynamic hyperinflation**:
  - Barotrauma; pneumothorax (tension), pneumomediastinum, pneumopericardium.
  - Hypotension (↓ right ventricular preload).
  - Cardiac arrest (pulseless electrical activity).
  - Acute right heart failure.
- Patient-ventilator asynchrony.
- Ventilator-associated lung injury.
- Ventilator-associated pneumonia.
- Myopathy (corticosteroids and neuromuscular blockade).
- Gastric mucosal ulceration.

Withdrawal of ventilation

Withdrawal of ventilation may be attempted once airflow limitation has improved, suggested by a decreasing Pplat and PEEPi. Sedation is reduced, respiratory rate increased and pressure support ventilation commenced once spontaneous respiratory effort returns. PEEPe (3-7 cmH_20) may be cautiously introduced to assist triggering and reduce work of breathing.

Complications of ventilation

Hypotension, cardiovascular collapse, and cardiac arrest may result from dynamic hyperinflation, tension pneumothorax, acute right heart failure, or arrhythmia (Box 111.3). Cardiac arrest with pulseless electrical activity can occur from severe dynamic hyperinflation alone or from tension pneumothorax. Return of circulation after disconnection from the ventilator (for up to 60 seconds), the apnoea test, is both diagnostic and therapeutic for dynamic hyperinflation. Tension pneumothorax is difficult to diagnose and confirmation by chest radiograph should occur unless the patient is in cardiac arrest. Management is with chest drain insertion by blunt dissection; needle thoracentesis should be avoided to prevent iatrogenic pneumothorax. Complications such as myopathy and ventilator-associated pneumonia may prolong ventilator dependence.

Acute necrotizing myopathy associated with deep sedation, corticosteroids, and prolonged neuromuscular blockade may prolong ventilation weaning and slow overall recovery. Neuromuscular blockade should be used sparingly and systemic corticosteroid ceased as soon as possible to reduce the risk of myopathy. Mucous plugging and lung collapse may require bronchoscopic airway toilet.

Extracorporeal support

Extracorporeal support has been described in life-threatening asthma; registry data demonstrated an 83.3% survival to hospital discharge, compared with 50.8% in non-asthmatics [20].

CHAPTER 112

Therapeutic strategy in acute or chronic airflow limitation

Francesco Macagno and Massimo Antonelli

Key points

- Oxygen therapy is used for the hypoxia in acute exacerbation of chronic obstructive pulmonary disease (AECOPD). The objective is to reach PaO_2 60 mmHg (8 kPa; SpO_2 90%.). The Venturi mask is the best method for administering oxygen.
- Inhalation therapy with beta 2 agonists, and anticholinergics reduce bronchial tone and dynamic hyperinflation. This type of administration is superior to intravenous administration and has significantly reduced side effects. Prednisolone at the daily dosage of 0.5 mg/kg for a duration of 8–15 days causes a reduction of hospital stay and therapeutic failures.
- In AECOPD patients, bacterial infections account for 50% of the cases of exacerbation. The first-line antibiotics are co-amoxiclav, third-generation cephalosporin, or fluoroquinolones.
- The early use of non-invasive ventilation (NIV) with conventional medical therapies decreases the need for intubation, and reduces the risk of complications and mortality in patients with acute or chronic respiratory failure. The treatment can be started for pH values between 7.25 and 7.35. Pressure support is the most used mode of ventilation and different interfaces can be used to improve tolerance and increase the success rate. In case of In AECOPD patients with previous negative trials of weaning, NIV can be used for reducing the weaning time, and prevent re-intubation.
- The failure of non-invasive treatment requires endotracheal intubation and mechanical ventilation. To reduce the risk of volutrauma and the worsening of the hyperinflation, tidal volumes between 6 and 8 mL/kg can be used with low respiratory rates and longer expiratory times.

Introduction

The medical history of a chronic obstructive pulmonary disorder (COPD) patient is characterized by the recurrence of worsening symptoms whose severity is closely related to compromised respiratory function, modifications in the intrapulmonary gas exchanges and comorbidities.

The objective of the initial evaluation of these patients is to increase the success of diagnostic tools, in order to provide the assistance proportional to the severity of the clinical condition. The fragility of patients with acute exacerbation of chronic obstructive pulmonary disease (AECOPD) accounts for their frequent hospitalization and their high intensive care unit (ICU) risk.

The decision-making process for hospital admission of a patient with AECOPD must take into account various aspects, including the severity of the clinical picture, the socio-economic situations, and family context. Advanced age, male gender, previous or current tobacco use, concomitant illnesses, nutritional state, important respiratory function deterioration, frequency of hospitalizations, altered intrapulmonary gas exchange, and long-term oxygen therapy constitute all negative predictors for the development of AECOPD.

In addition to clinical evaluation, arterial blood gas sampling (ABG), chest X-ray evaluation, serum electrolytes, albumin depletion, and biomarkers, such as NTproBNP, C reactive protein (CRP) and pro-calcitonin (PCT) also play an important role for prognosis. In a differential diagnosis of AECOPD patients, pneumothorax or a pulmonary embolism must be ruled out, especially when inflammation markers are negative [1].

Therapy for AECOPD is varied and the need for hospitalization must be always carefully evaluated, considering the risk factors related to the presence of multi-resistant pathogens or the need of invasive procedures.

Oxygen therapy

Oxygen therapy is the most effective and commonly used therapy for the treatment of hypoxia. The prolonged use of oxygen requires an accurate monitoring of blood gases and continuous oximetry. Arterial blood gas analysis allows the simultaneous evaluation of PaO_2, $PaCO_2$, and pH. A reasonable target for hospitalized patients might be PaO_2 60 mmHg (8 kPa), which correspond to a peripheral oxygen saturation (SpO_2) close to 90%. The attempt to improve PaO_2 values through the progressive increase of FiO_2 is not justified, due to the haemoglobin dissociation curve–small increases of SpO_2 require high inhaled fractions (FiO_2). The consequent risk is the respiratory centres depression, due to the altered physiologic response, resulting in CO_2 retention and subsequent pH worsening. The Venturi mask is the most used method for administering oxygen. This equipment ensures a quite precise administration of FiO_2. As an alternative, nasal cannula or transtracheal catheters can be used. A useful decisional algorithm is that proposed by the Infectious Disease Society of America and American Thoracic Society (IDSA_ATS) illustrated in Fig. 112.1 [2].

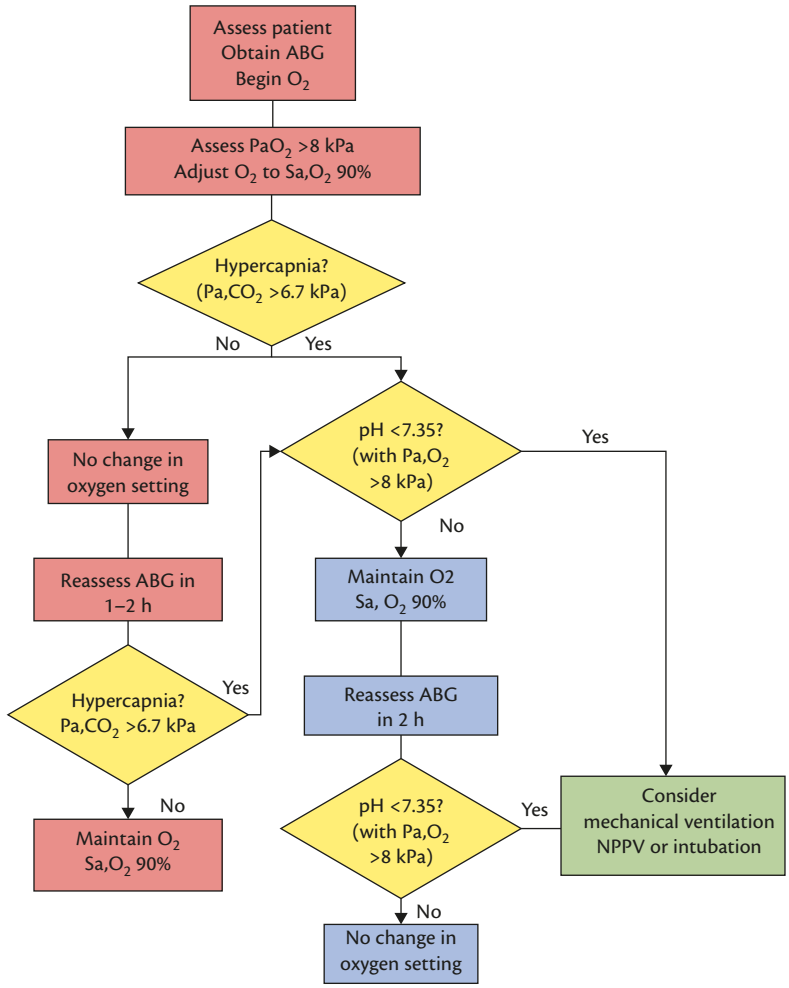

Fig. 112.1 ATS/ERS TASK FORCE: Standards for the diagnosis and treatment of patients with COPD.
Reproduced with permission of the European Respiratory Society: *Eur Respir J* June 2004 **23**, 932–46; doi:10.1183/09031936.04.00014304.

Bronchodilators

At present, three kinds of bronchodilators are normally used—beta 2 agonists, anticholinergics, and methylxantine. Their main effect is to reduce bronchial tone, dynamic hyperinflation, respiratory fatigue, and dyspnoea.

In AECOPD, beta 2 agonists and anticholinergics are commonly administered via inhalation. This route is superior to intravenous administration and significantly reduces side effects. Usually the nebulized dose of salbutamol (the most used beta 2 agonist) varies from 2.5 to 5 mg qds. Nebulized ipratropium (the most used anticholinergic) dose is 0.5 mg bd. Due to its many side effects, theophylline has a narrow therapeutic index. Theophylline serum levels correlate with both therapeutic and toxic effects. Concentrations of 10–20 mg/L are needed to produce bronchodilation with a minimum of side effects. Serum levels exceeding 20 mg/L are associated with an unacceptable incidence of adverse reactions. Theophylline levels above 35 mg/L increase the incidence of seizures and cardiac arrhythmias. Studies have suggested that low dose theophylline (at plasma concentrations below 10 mg/L) has some anti-inflammatory effect on the COPD airway. Low doses seem to increase the anti-inflammatory effects of steroids by increasing the activity of the histone deacetylase [3].

Inhalation therapy can be performed using nebulizers, pre-dosed aerosols, or powders for inhalation. The choice depends on the method, circumstances, and clinical conditions of the patient.

Corticosteroids

Corticosteroids for oral and systemic use now play an established role in AECOPD. Random control clinical studies have confirmed the effectiveness of prednisolone at the dosage of 0.5 mg/kg daily for a duration of 8–15 days. In particular, a reduction in hospital stay and therapeutic failures has been observed with an improvement in lung function and the reduction of dyspnoea. Longer treatments have not confirmed their effectiveness, with high risk of side effects as hyperglycaemia, osteoporosis, and muscular weakness.

Antibiotics

The use of antibiotics in AECOPD plays an important role because bacterial infections account for 50% of exacerbations. The presence of symptoms including leukocytosis, fever, variation of secretion volume, and characteristics, and the presence of markers such as the PCT or reactive protein C RPC) can help the diagnosis, limiting the prescription of empirical antibiotics to cases with high suspicion

Table 112.1 Antimicrobial therapy in acute exacerbations of chronic obstructive pulmonary disease (AECOPD)

Category	Likely pathogens	Antimicrobial treatment
Uncomplicated AECOPD Age <65 years; FEV1 > 50% predicted; <4 exacerbations/year; no comorbid conditions	*H. influenza* (more prevalent); *S. pneumoniae; M. catarrhalis; H. parainfluenzale*; viral; *M- pneumonie; C. pneumonie.*	Macrolide (azithromycin and clarithromycin); Doxycycline; 2nd or 3rd generation cephalosporin; Respiratory quinolone (moxifloxacin, gatifloxacin, gemifloxacin: against penicillin-resistant *S. pneumonie*)
Complicated AECOPD Age ≥65 years; FEV1 < 50% predicted; ≥4 exacerbations/year; Comorbid conditions	*H. influenza* (more prevalent); *S. pneumoniae; M. catarrhalis; H. parainfluenzale*; viral; *M. pneumonie; C. pneumonie*; Gram-negative enteric bacilli	Respiratory quinolone (moxifloxacin, gatifloxacin, gemifloxacin: against penicillin-resistant *S. pneumonie*); amoxicillin/clavulanate
Complicated AECOPD at risk for *Pseudomonas aeruginosa* infection FEV1 < 35% predicted; recurrent courses of antibiotics or steroids; bronchiectasis	*H. influenza* (more prevalent); *S. pneumoniae; M. catarrhalis; H. parainfluenzale*; viral; *M. pneumonie; C. pneumonie*; Gram-negative enteric bacilli; *Pseudomonas aeruginosa.*	Fluoroquinolone with antipseudomonal activity (ciprofloxacin and levofloxacin)

of infection. The overall objective is to decrease the development of multiresistant strains and mortality risk. Although there is no definite consensus regarding the most appropriate therapy and given the heterogeneousness of various pathogens in question, the proposed first-line antibiotics are co-amoxiclav, third-generation cephalosporin or fluoroquinolones. In case of community-acquired pneumonia the presence of comorbidities, such as COPD requires a respiratory fluoroquinolone (moxifloxacin, gemifloxacin, or levofloxacin [750 mg]; strong recommendation; level I evidence) or a β-lactam plus a macrolide (strong recommendation; level I evidence; Table 112.1) [4].

Mechanical ventilator support

In AECOPD, the increase of the airway resistances and the need for greater minute ventilation exacerbate the limitation of expiratory flow, increasing dynamic hyperinflation and intrinsic PEEP (positive end-expiratory pressure). This leads to an increase in respiratory effort with deterioration of respiratory muscle function. When respiratory muscles have exhausted their capacity to maintain adequate alveolar ventilation, CO_2 retention leads to worsening respiratory acidosis. Ventilatory support represents a milestone of the treatment of exacerbated AECOPD patients.

The rationale to start a form of ventilator assistance is well summarized in Fig. 112.2.

Non-invasive ventilation

NIV must be considered the first option in AECOPD patients and acute respiratory failure if there are no contraindications, such as severe impairment of consciousness, facial trauma, or incapability to control the airways or intolerance. The effectiveness of NIV lies in the reduction of the workload of the respiratory muscles with reduction of dyspnoea and respiratory rate and a subsequent improvement of the respiratory gases and pH [5].

The main advantages of an early trial of NIV are the easy and prompt application, and its possible use outside the ICU. Many prospective randomized and controlled studies have verified the effectiveness of NIV in the treatment of acute or chronic respiratory failure. Compared with traditional treatments, early application of NIV improves survival, reduces the need for endotracheal intubation and related complications, and reduces the length of stay in ICU and hospital. Treatment of patients with light to moderate respiratory failure characterized by pH values between 7.25 and 7.35 has shown a failure rate not higher than 20%. The treatment of more severe and later conditions had failure rates close to 50% and inversely correlated to the severity of respiratory acidosis. In these cases, the use of NIV as an alternative to invasive ventilation does not increase mortality, while reducing the risk of complications as ventilator-associated pneumonia (VAP) or difficult weaning [6]. The use of NIV in critically-ill patients should be avoided when contraindications or the impairment of consciousness (Glasgow coma scale <10) are present and, in case of shock, serious arrhythmias or acute coronary syndrome, serious agitation, and vomiting with the risk of inhalation. NIV failures are more frequent during the first hours of use and are mainly related to the severity of the acidosis, mental deterioration, and comordities. The lack of improvement of gas exchanges during the first hours of ventilation is a predictor of failure. Patients with COPD and severe respiratory failure, who have already been evaluated with precrisis functional respiratory damage, are more prone to fail NIV, requiring endotracheal intubation, notwithstanding an initial improvement [7,8].

When the case of exacerbation is a community acquired pneumonia the failure rate is higher.

In hypercarbic AECOPD with respiratory failure with a cardiac component, NIV has shown a high success rate with rapid resolution of the lung oedema [9].

One crucial element for the success of NIV is due to the choice of ventilators and interfaces. Air leaks from the mask have significant effects on the triggering of the ventilator and patient–ventilator interaction. The majority of the ventilators conceived for home-use have an efficient internal algorithm for leak compensation. Old ICU ventilators are without these features and, if used for delivering NIV, require a fine-tuned set-up of the trigger sensitivity to avoid auto-triggering phenomena and asynchrony. Recently, the introduction of specific modules, based on sophisticated algorithms for leaks compensation, have resolved this inconvenience

The preferred interfaces for delivering NIV are oro-nasal or face masks. However, lack of tolerance, skin lesions, and leaks can cause a failure requiring endotracheal intubation. Recently, helmets introduced for NIV therapy have reduced discomfort, cutaneous pressure lesions, eye irritation, and gastric distension. The main limitations of this interface are, however, determined by a quote of

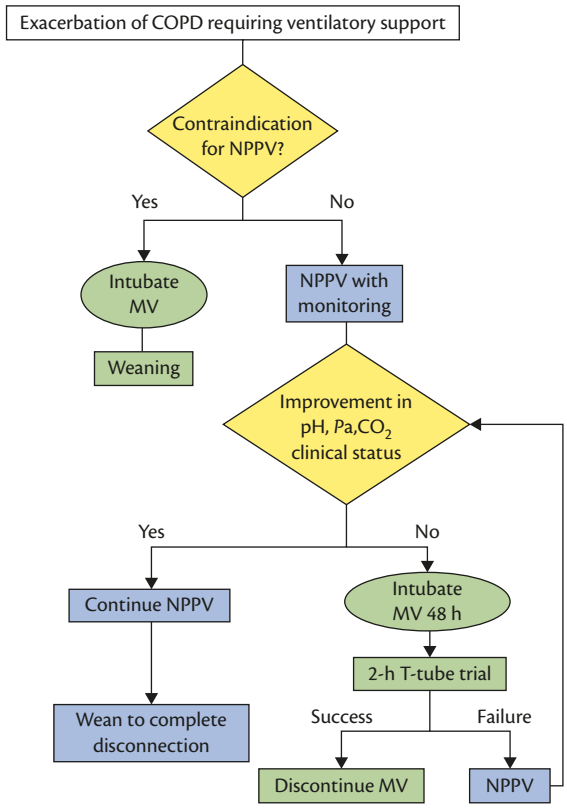

Fig. 112.2 ATS/ ERS TASK FORCE: Standards for the diagnosis and treatment of patients with COPD.
Reproduced with permission of the European Respiratory Society: *Eur Respir J* June 2004 **23**, 932–46; doi:10.1183/09031936.04.00014304.

potential rebreathing and the possibility of dyssynchrony that need specific settings [10].

Several ventilation modes can be used. The ones most frequently used are pressometric techniques.

PSV is the most common mode applied for NIV. It allows the patient to determine the respiratory frequency and tidal volume (V_T). The main limitation of this modality is the possible decrease in volume occurring as a result of an increase of resistance of the respiratory apparatus and the need for proper synchronization between patient and machine, more difficult in case of leaks. Pressure support is given to reduce the work of breathing and prevent barotrauma. In general, the level of pressure support are tuned between 10 and 20 cmH_2O according to clinical response, the relief of the accessory muscles of respiration and the reduction of respiratory frequency. PEEP is set between 4 and 6 cmH_2O to compensate the intrinsic PEEP and ineffective respiratory efforts.

Pressure assisted and controlled modes can be also used. They allow a better control of the effective volume, but are preferred substitute at least in part for spontaneous respiratory activity.

Controlled volume modes are rarely used, in the absence of leakage ensure respiratory frequency and a determined current volume, but invariably cause discomfort with possible asynchrony, and increase ineffective respiratory efforts and work. This ventilator mode is more commonly adopted in the early phases of invasive mechanical ventilation of the most severe patients, after intubation, to assure adequate ventilation and control hyperinflation.

The careful monitoring of the patient and the response to NIV are indispensable elements for therapeutic success. Peripheral oxygen saturation monitoring, blood gas analyses, evaluation of arterial pressure, respiratory and cardiac frequency are aimed to constantly adapting ventilation parameters to the changing needs of the patient. The therapeutic response will therefore establish the assistance needs and the duration of ventilation support.

NIV weaning can be achieved by reducing the duration of ventilation periods during the day and keeping patient on nocturnal sessions to lighten the work of respiratory muscles and improve sleep quality [11].

The resolution of the causes of exacerbation, the adequate oxygen saturation with a PaO_2/FIO_2 above 120, a PEEP level below 5 cmH_2O, a pH above 7.35 with a stable haemodynamic condition without sign of cardiac ischaemia, dyspnoea, or tachypnoea suggest the suspension of ventilation support.

Invasive mechanical ventilation

The failure of non-invasive treatments, the need to protect airways, shock, and changes in the state of consciousness, serious arrhythmias or severe cardiac failure require endotracheal intubation and mechanical ventilation.

The initial regulation of the ventilator is usually adjusted in Volume controlled mode with great attention to minimize the effects of auto-PEEP. In order to reduce the risk of volutrauma, low current volumes are used in the order of 6-8 ml/kg with low respiratory frequencies and with an I/E ratio adequate to allow a longer expiration time to avoid hyperinflation. In general, high respiratory flows should be used, usually greater than 60 litres/minute in order to reduce the length of insufflations.

The improvement of clinical conditions with low level or absent sedation are crucial to start weaning from invasive mechanical ventilation. The preferred techniques of weaning are the progressive decrease to Pressure Support and PEEP up to value respectively of 8 cmH2O Pressure support and 3–5 cmH_2O PEEP, or T piece trials [12].

The weaning failure in chronic patients is high. The stability of vital parameters, a respiratory rate lower than 35 breath/min and the capacity to maintain adequate peripheral O_2 saturation for at least 2 hours are predictors of success.

In AECOPD patients with previous negative weaning trials, NIV can be applied immediately after extubation to improve the chances of success and prevent re-intubation.

PART 4.12

Respiratory acidosis and alkalosis

CHAPTER 113

Pathophysiology and therapeutic strategy of respiratory acidosis

Luciano Gattinoni and Alfredo Lissoni

Key points

- Respiratory acidosis is a process in which the low pH is primarily due to a rise in PCO_2. In critically-ill patients the CO_2 load may be greatly increased due to hypermetabolism, excessive parenteral nutrition, or titration of HCO_3^- by fixed acids.
- CO_2 buffering in vivo leads to an increase in HCO_3^- of 1 mmol/L for every increase of 10 mmHg (1.33 kPa) in PCO_2 above 40 mmHg (5.33 kPa). In chronic conditions the kidney-related increase of strong ion difference (reduction in plasma chloride) leads to a plasma HCO_3^- increase of approximately 3.5 mmol/L for every increase of 10 mmHg (1.33 kPa) in PCO_2 above 40 mmHg (5.33 kPa).
- If respiratory acidosis is present, identifying the precipitating factors and assessing whether the associated signs (hypoxaemia, hypercapnia, and acidosis) are themselves life-threatening is fundamental. Assessment of the precipitating factors and the time required for their correction is of paramount importance in planning therapeutic strategy.
- Since hyperinflation of the lung, with its cardiovascular consequences, is the most harmful complication of mechanical ventilation in chronic respiratory acidosis, it is essential to set a small tidal volume associated with an adequate expiratory time. Non-invasive ventilation appears to be a promising treatment of chronic respiratory acidosis.
- The artificial lungs to remove CO_2 extracorporeally and are increasingly employed during bridge to lung transplantation, acute respiratory distress syndrome, and the hyperinflation states of COPD re-exacerbation or status asthmaticus.

Pathophysiology

Introduction

Although carbon dioxide (CO_2) is not an acid *per se*, it becomes a proton (H^+) donor when it is combined with water:

$$CO_2 + H_2O \Leftrightarrow H_2CO_3 \Leftrightarrow H^+ + HCO_3^- \quad \text{[eqn 1]}$$

When PCO_2 increases above its physiological levels (i.e. above 40–45 mmHg (5.33–6 kPa), corresponding to 1.2–1.35 mmol/L), acidaemia usually develops. Thus, respiratory acidosis can be defined as a process in which the tendency for the arterial pH to decrease is primarily due to an increase in PCO_2.

The CO_2 load

In normal man, the amount of CO_2 produced metabolically is approximately 200–250 mL/min, corresponding to an acid load of 13,000–16,000 mmol/day. This amount may be increased by 30–100% because of increased metabolism, burns, infection, and an excessive calorific intake, particularly during parenteral nutrition [1]. An additional source of CO_2, not metabolically produced, is the titration of HCO_3^- by fixed acid, as lactic acid (LAH), particularly relevant in critically-ill patients.

Excretion of CO_2

The acid load expired by the lungs can be expressed as:

$$VCO_2 = K \times PaCO_2 \times V_A \quad \text{[eqn 2]}$$

where VCO_2 is the expired CO_2, V_A is alveolar ventilation, $PaCO_2$ is the partial pressure of CO_2 in arterial blood, and K is a factor converting pressure to volume fraction. Of note, we will refer always to the alveolar ventilation, which is the fraction of the minute ventilation, which actually reaches the perfused alveoli. The difference between the total ventilation and the alveolar ventilation is modelled as physiological dead space, in part anatomical (ventilation of regions not designed for gas exchange) and in part alveolar, i.e. the fraction of alveolar ventilation ventilating unperfused alveoli.

VCO_2 can also be expressed according to Fick's law as:

$$VCO_2 = Q(CvCO_2 - CaCO_2) \quad \text{[eqn 3]}$$

where Q is the cardiac output, and $CvCO_2$ and $CaCO_2$ are, respectively, the CO_2 contents of mixed venous and arterial blood. Assuming, for simplicity, that the relationship between CO_2 content and partial pressure is linear in the range of physiological interest, and combining and rearranging equations 2 and 3, it follows that:

$$PaCO_2 \propto (Q / (V_A + Q))PvCO_2 \quad \text{[eqn 4]}$$

This equation shows that $PaCO_2$, for a given acid load (which increases the $PvCO_2$) is directly proportional to cardiac output and inversely proportional to alveolar ventilation.

Body response to respiratory acidosis

Buffer system (minutes)

Of the 15,000 to 30,000 mmol of protons delivered daily to the extracellular fluid, only 40–60 nmol/L (i.e. only 1 mmol of H^+ out of 1 million) are found free in the blood. The remainder are bound

by the buffer system. Buffers that are present in extracellular and intracellular fluids, are substances characterized by pK values (i.e. $-\log_{10} K$, where K is the acid dissociation constant) close to the pH value and which are able to bind or release H^+, thus preventing large changes in free H^+ concentration. In general, buffers are weak acids, which may be present electrically neutral (AH) or electrically charged (A^-). At a given pH their electrical status is defined by the Henderson–Hasselbalch equation:

$$pH = pK + (A^- / AH) \quad \text{[eqn 5]}$$

where $[A^-]$ and [AH] are the concentrations of dissociated base and undissociated acid, respectively. The pK values and the concentrations of the various extracellular buffers are listed in Table 113.1.

Of note, only proteins and phosphates are available to buffer the CO_2 load. It is important to note that the buffer mechanism described remains entirely in the 'buffer base dominion,' this means that the total amount of dissociated buffers does not change as the free H^+ deriving from CO_2 load hydration are buffered by A^-, forming AH, while CO_2 becomes HCO_3^-. In vivo, this immediate buffering mechanism produces ≈ 1 mmol/L HCO_3^- increase every ≈10 mmHg of increased PCO_2.

Kidneys response (days)

The normal kidneys compensate the low pH by increasing plasma strong ion difference (SID). To perform this variation the kidneys must excrete the appropriate amount of strong ions. In the urine the electrolyte equilibrium can be written as:

$$Na^+ + K^+ + UI^+ = Cl^- \quad \text{[eqn 6]}$$

where UI^+ and UI^- are the unmeasured positive or negative strong urinary ions. The most important unmeasured positive strong ion is NH_4^+, the most important unmeasured negative ions is SO_4^{2-}, which derives from sulphur acid metabolism. To manipulate the difference of strong ions that are relevant in generating the plasma SID (and pH) it follows that:

$$Na^+ + K^+ + CI^- = UI^- - UI^+ \quad \text{[eqn 7]}$$

To increase plasma SID (traditionally called compensatory metabolic alkalosis), urinary SID must decrease, and this occurs by increasing Cl^- excretion. To maintain electroneutrality, the difference $UI^- - UI^+$ must decrease and this occurs by rising NH_4^+ excretion, which is the best way to excrete an increased amount of Cl^- while retaining Na^+ [2,3]. Therefore, immediately after the PCO_2 rise and the pH decrease, the kidneys start to increase the ammonium production, thus increasing the chloride excretion. Indeed, during respiratory acidosis, plasma chloride decreases (increasing plasma SID), while urine chloride and the ammonium increase (with associated reduction in urinary pH). It takes approximately 2–3 days to excrete a sufficient amount of chloride in order to significantly affect the plasma SID. When plasma SID is increased the buffer base ($HCO_3^- + A^-$) increases equally. In vivo this process leads to an increase of ≈3.5 mmol/L of HCO_3^- every ≈10 mmHg of PCO_2 chronically increased.

Acid–base regulation in critically-ill patients

Every step of acid–base regulation may be affected in critically-ill patients:

- The acid load may be altered by both the underlying disease (hypoperfusion, shock, increased metabolism, etc.) and therapeutic intervention (excessive parenteral feeding).
- The buffer system is frequently abnormal in critically-ill patients; decreased levels of albumin, the most important component of the A^-–AH buffer pair, are not unusual. A decreased concentration of both A^-–AH and HCO_3^-–CO_2 buffer pairs implies a greater change in pH for a given acid load.
- Transport of blood from the venous to the arterial side may also be affected (low-flow states). In these conditions, the CO_2 clearance may be altered, resulting in a large difference between the acid–base status of the venous and arterial blood, with increases in the PCO_2 and pH gradients.
- The physiological response to increased PCO_2 and decreased pH, i.e. increased ventilation, is usually impaired in critically-ill patients for two main reasons. The underlying disease may affect the lung, thus preventing increased ventilation (due to reduced minute ventilation or increased dead space), and these patients are usually on mechanical ventilation. If volume-controlled ventilation is used, PCO_2 will rise as the patient (usually sedated and sometimes paralyzed) cannot change either the tidal volume or the respiratory rate. If pressure-support ventilation is used, the patient may respond to the increase in PCO_2 by triggering mechanical breathing more frequently. However, the depth of breath (i.e. the tidal volume) is often out of the patient's control. Thus it is obvious that mechanical ventilation has a deleterious effect on the physiological response to changes in acid–base status.

Table 113.1 The blood buffers

Buffer pairs	Normal concentration (dissociated + undissociated)	pK	Base-to-acid ratio at pH 7.4 (dissociated/undissociated)
Bicarbonate–carbonic acid (mmol/L)	25	6.1	$[HCO_3^-]/[CO_2]$ = 20/1
Dibasic–monobasic phosphate (mmol/L)	2	6.8	$[HPO_4^{2-}]/H_2PO_4^-$ = 4/1
Proteins (mmol/L)	14 (7 g/dL)	6.8	Pr–/HP = 4/1
Haemoglobin (mmol/L)	90 (15 g/dL)	6.8	Hb–/HHb = 4/1

- The physiological response to decreased pH in the renal tubular cells, in which HCO_3^- losses are replaced, may also be impaired in the critically ill, whose renal function is often affected. It is also important to realize that some forms of renal support, as haemofiltration, may lead to HCO_3^- losses, with consequent additional derangement of the acid–base balance.

To summarize, it is important to remember that the physiological control of the acid–base equilibrium is often impaired in critically-ill patients, and physicians must understand which mechanisms are altered so that an adequate substitute can be provided for the physiological control which has been lost.

Therapeutic strategies

Approach to respiratory acidosis

In patients presenting with hypercapnia, acidosis, and hypoxaemia, two lines of action are required:

- Identification of the causes of respiratory acidosis, with particular focus on the correction of precipitating factors which may be reversible.
- Treatment of the symptoms and signs if they are themselves a possible cause of unfavourable outcome.

These two actions should be pursued together, as correction of the precipitating factors may lead to almost immediate resolution of the respiratory acidosis. However, the first goal in intensive care is the maintenance of homeostasis, and correction of life-threatening conditions is the priority. Thus, the indications for symptomatic treatment will be discussed first.

Hypoxaemia, hypercapnia, and acidosis

Hypoxaemia

Hypoxemia unavoidably occurs during CO_2 retention when the patient breathes room air ($F_IO_2 = 21\%$) since:

$$F_AO_2 = F_IO_2 - F_ACO_2 \qquad \text{[eqn 8]}$$

where F_AO_2 is the alveolar fraction of oxygen, F_IO_2 is the inspired fraction of oxygen, and F_ACO_2 is the alveolar fraction of CO_2. This type of hypoxaemia can easily be corrected by increasing F_IO_2. For example, when $P_ACO_2 = 80$ mmHg (10.66 kPa) ($F_ACO_2 = 11.2\%$), F_AO_2 can be restored to its normal values by increasing F_IO_2 from 21 to 26.6%. Therefore, the hypoxaemia due to hypercapnia is easily corrected by increasing the inspired oxygen fraction, differently from the hypoxaemia due to the right to left shunt. The pathophysiological meaning of different PO_2/PCO_2 combinations are listed in Table 113.2 (conditions of high altitude or inhalation of hypoxic gas mixtures are excluded).

Hypercapnia and acidosis

Similarly to PO_2, there is no threshold value of PCO_2 or pH which is 'harmful' per se. Many factors may influence the response to increased CO_2, such as the rate of increase in PCO_2 (acute or chronic), age, and cardiovascular conditions. If associated with normoxia, near-normal pH, consciousness, and haemodynamic stability, a high PCO_2 does not need any therapeutic intervention. The indications for mechanical assistance should be based on a global clinical assessment, considering the three main consequences of increased PCO_2, i.e. tissue acidosis, impairment of the central nervous system, and the cardiovascular response [4].

Tissue acidosis

As molecular CO_2 enters the cell membrane faster than HCO_3^-, it is generally believed that intracellular pH decreases more than extracellular pH. However, there is increasing evidence that the intracellular buffers limit tissue acidosis and hypercapnia is well tolerated. If cellular acidosis develops, cell function and viability are impaired.

Effects on the central nervous system

Increasing PCO_2 may have a severe effect on central nervous system activity. Experimentally, the brain excitability first decreases, then increases, with associated seizures, and finally decreases to anaesthesia and coma. CO_2 is one of the major determinants of the cerebral vascular reactivity, both directly and indirectly (through pH changes), and acute hypercapnia may result in an increased cerebral blood flow and intracranial pressure.

Circulatory response to hypercapnia

The effect of hypercapnia on the cardiovascular system depends on the balance between the direct depressant effects of PCO_2 on heart and peripheral vascular smooth muscles, and the increased plasma levels of epinephrine and norepinephrine due to activation of the sympathetic nervous system. In normal conditions, the net result is an increase in cardiac output and a slight decrease in peripheral resistance. The arterial pressure tends to rise and the pulmonary artery pressure may increase substantially. It is important to remember that these reactions are observed in intact subjects. In patients given β-blockers, for example, hypotension and decreased cardiac output may be observed.

Table 113.2 Relationship between PO_2 and PCO_2

	Normal PCO_2	**Low PCO_2**	**High PCO_2**
Normal PO_2	Normal	Pure hyperventilation if $F_IO_2 = 21\%$ (stress + anxiety, metabolic acidosis); if $F_IO_2 > 21\%$, the above conditions plus shunt	Ventilatory impairment while inhaling $F_IO_2 > 21\%$
Low PO_2	Oxygenation impairment due to shunt plus relative ventilatory impairment	Oxygenation impairment due to shunt with physiological ventilatory response	Ventilatory impairment if $F_IO_2 = 21\%$; oxygenation impairment due to shunt if $F_IO_2 > 21\%$ associated with ventilatory impairment
High PO_2	$F_IO_2 > 21\%$ without ventilatory impairment	Hyperventilation during inhalation of $F_IO_2 > 21\%$	Ventilatory impairment while inhaling $F_IO_2 > 21\%$

Causes of respiratory acidosis and precipitating factors

The most common causes of respiratory acidosis and the time required for their correction are summarized in Table 113.3. They can be classified into three groups:

- In this group the cause of hypercapnia can be removed easily. If hypoxaemia can be corrected by supplemental oxygen administration, it is better, after removal of the precipitating factors, to wait for a spontaneous increase in alveolar ventilation. Hypercapnia does not require any treatment if associated with a stable pH, high HCO_3^-, and haemodynamic stability in a conscious patient.
- In this group, the correction of the precipitating factors will probably require hours or days. The need for mechanical ventilation should be determined on the basis of a global clinical assessment. In patients in whom hypercapnia is associated with clinical signs of severely increased work of the respiratory muscles, mechanical support should be introduced before the development of respiratory fatigue, which may lead to a sudden deterioration of PCO_2 and pH.
- In the final group the cause cannot be corrected (e.g. late-stage neuromuscular disease). In most cases, the issue is more ethical than medical, and the therapeutic plan should be discussed with the patients and relatives (e.g. planning for home ventilation).

Assessment and correction of hypercapnia

Knowledge of the previous respiratory status is of paramount importance in determining the goal of respiratory support. A reasonable goal in a previous healthy subject could be normal blood gases ($PaCO_2$ = 40 mmHg (5.33 kPa), PaO_2 > 80 mmHg (10.66 kPa)). In a subject with previous chronic respiratory impairment, the goal should be the blood gas values present before the superimposed acute derangement (e.g. PaO_2 = 60 mmHg (8 kPa), $PaCO_2$ = 50 mmHg (6.66 kPa)). An accurate history is essential for differentiating chronic and acute respiratory impairment (i.e. to define the target blood gases). Measurement of the blood gases alone may be misleading. In fact, the normal increase in HCO_3^- of ≈1 mmol/L (acute conditions) or ≈3.5 mmol/L (chronic condition) for every increase of 10 mmHg (1.33 kPa) in $PaCO_2$ may be offset by the concurrent presence of metabolic acidosis, which 'consumes' the HCO_3^-. Under these conditions the HCO_3^- level does not discriminate between acute and chronic respiratory acidosis.

In typical chronic respiratory acidosis, hypoxaemia is usually corrected by increasing FIO_2. The risk of high PaO_2 in chronic patients breathing spontaneously (coma) has probably been overestimated [5], and reasonable oxygenation is a mandatory target.

Since $PaCO_2 \propto VCO_2/VA$, it is evident that it can be decreased by either decreasing VCO_2 or increasing the alveolar ventilation VA. Methods of decreasing VCO_2 include withdrawal of the excessive load of glucides delivered by parenteral nutrition, control of temperature in a hyperthermic patient, and artificial removal of part of VCO_2 by extracorporeal methods such as dialysis or artificial lungs. However, the usual way of correcting hypercapnia is to increase alveolar ventilation, and this is usually achieved by mechanical ventilation. When the causes of hypercapnia are extrapulmonary, such as central nervous system or neuromuscular diseases, and the lung parenchyma is normal, mechanical ventilation causes no more problems than during general anaesthesia in a normal patient.

Major problems may occur in patients in whom hypercapnia is due to dysfunction of the small airways (e.g. bronchospasm or asthma), parenchymal lesions (e.g. emphysema), or diseases involving both airways and parenchyma (e.g. severe chronic obstructive pulmonary disease (COPD)). If mechanical support of these patients is unavoidable, it is essential to avoid worsening hyperinflation, which may lead to devastating haemodynamic consequences including cardiac tamponade. Small tidal volumes and prolonged expiratory time must be maintained when ventilating these patients, even at the cost of a relatively high PCO_2. The

Table 113.3 Causes of respiratory acidosis

	Immediate reversibility	Reversibility within hours/days	Irreversible
Respiratory drive	Drugs (antidotes available) Nutritional insufficiency	Chronic loading Metabolic alkalosis Endocrine disturbances	Congenital
Airways	Secretions Foreign bodies Bronchospasm Airways apparatus	Asthma Bronchial stenosis	Terminal COPD
Muscles	Drugs (antidotes available)	Neuromyopathies Endocrine/electrolyte disorders Abdominal distension Hyperinflation	Quadriplegia Terminal neuromuscular Disease
Chest wall		Flail chest	Kyphoscoliosis Thoracoplasty
Lung parenchyma	Pneumothorax Pleural effusion	Pulmonary oedema Pulmonary embolism	Terminal obstructive and restrictive lung disease

advantages of this setting have been shown in asthmatic patients [6] and suggested in other patient populations [7]. As a general rule, non-invasive ventilation is preferable to mechanical ventilation with intubation in the hypercapnic patient [8]. If the patient is hypercapnic, hyperinflated, and performing excessive respiratory work, the use of continuous positive airway pressure may decrease respiratory work and enable the patient to maintain spontaneous breathing. It must be noted, however, that when mechanical ventilation is per se harmful to correct hypercapnia, the artificial lungs are the appropriate solution. This form of support is increasingly used worldwide as it allows to remove varying amounts of VCO_2, up to removal of all the metabolically-produced CO_2, therefore abolishing the need for mechanical ventilation [9,10]. The main indications are, to date, bridge to lung transplant, acute respiratory distress syndrome and COPD re-exacerbation.

CHAPTER 114

Pathophysiology and therapeutic strategy of respiratory alkalosis

Thomas Langer and Pietro Caironi

Key points

- Respiratory alkalosis is an increase in arterial pH due to an imbalance between metabolic CO_2 production and CO_2 removal, in favour of the latter.
- Respiratory alkalosis is usually a sign of an underlying pulmonary or central nervous system disease.
- An excessive CO_2 removal during controlled mechanical ventilation or extracorporeal CO_2 removal can also cause hypocapnia and, therefore, result in respiratory alkalosis.
- The metabolic compensation (mainly renal) restores pH values close to normality in 24–48 hours, through the reduction in plasma strong ion difference (increase in plasma chloride concentration).
- Respiratory alkalosis per se is rarely dangerous, and the clinical approach is directed towards diagnosis and treatment of the underlying disorder.

Definition

Respiratory alkalosis is a condition characterized by low partial pressure of carbon dioxide (PCO_2) and an associated elevation in arterial pH caused by an imbalance between CO_2 production and removal, in favour of the latter. The increase in CO_2 removal usually occurs because of increased alveolar ventilation. Respiratory alkalosis is a primary acid–base derangement, i.e. the increased CO_2 elimination is the manifestation of a clinical condition and not a compensatory response to metabolic acidosis.

Pathophysiology of the control of breathing

In physiological conditions, alveolar ventilation is finely tuned by the activity of two groups of sensors—central chemoreceptors (located at the ventral surface of the medulla, within the central nervous system) and peripheral chemoreceptors (type 1 glomus cells of carotid and aortic arch bodies) [1]. These receptors are mainly stimulated by changes in PCO_2 and pH, i.e. an increase in PCO_2 and/or a reduction in pH will activate the receptors and thus increase the signal strength (input) to the central controller, causing an increased output signal to the effectors (respiratory muscles), and a consequent increase in alveolar ventilation. This mechanism will eventually reduce PCO_2, normalize arterial pH and thereby reduce the input to the central controller. In addition to increases in PCO_2/reductions in pH, also very low values of PO_2 (less than 50 mmHg) can activate peripheral chemoreceptors and have a similar effect on alveolar ventilation [2]. In the case of hypocapnia and slight alkalosis, however, this hypoxic respiratory response is abolished [3]. Finally, besides central and peripheral chemoreceptors, lung receptors (Table 114.1) might also play a role in the pattern of respiration. These receptors are usually not active in physiological conditions.

Pathophysiology of hypocapnia

Conditions that cause increased alveolar ventilation, without having as input stimulus a reduction in pH, will cause hypocapnia associated with a variable degree of alkalosis. These conditions can be schematically divided into three categories (Table 114.2).

Table 114.1 Schematic representation of lung receptors' types and evoked reflexes

Receptor type	Type	Stimuli	Respiratory reflex/effect
Slowly adapting receptor	Mechanosensitive	Lung inflation	Termination of inspiration (Breuer–Hering reflex), expiratory facilitation, bronchodilation
Rapidly adapting receptor	Mechanosensitive and chemosensitive	Lung inflation and deflation, and chemical irritants	Augmented breath/gasp, irregular inspiration, and shortened expiration
C-fibre receptor, former J-receptors	Chemosensitive	Irritants, inflammation, congestion, pulmonary oedema, micro-embolism	Rapid, shallow breathing, apnoea (simultaneous chemical stimulation)

Table 114.2 Causes of respiratory alkalosis

Central	Condition
Voluntary hyperventilation	
Psychogenic	Pain, panic attack, hysteria
Central neurogenic hyperventilation	Brainstem injuries, invasive brain tumours, brain infarcts
Hormonal	Increased progesterone levels in pregnancy and liver cirrhosis
Infectious	Meningitis, encephalitis
Thermal hyperpnoea	Fever, hyperthermia
Intoxication	Salicylate, topiramate
Peripheral	
Chemoreceptors	Hypoxic pulmonary disease, high altitude
Lung receptors	Pulmonary oedema, pneumonia, acute respiratory distress syndrome, asthma, pulmonary embolism, interstitial fibrosis
Iatrogenic	
Mechanical ventilation	Excessive mechanical ventilation (accidental or therapeutic for traumatic brain injury)
Extracorporeal CO_2 removal	Excessive extracorporeal CO_2 removal

Increased activity of the 'central controller'

Conditions characterized by an increased activity of the 'central controller', dissociated from input arising from peripheral sensors, result in an increased activity of the respiratory muscles, which in turn cause an augmented alveolar ventilation [4,5]. In theory, this might be due to an increased activity of the central controller per se (such as voluntary hyperventilation and central neurogenic hyperventilation) or by an increased activity of central chemoreceptors, as hypothesized in salicylate and topiramate intoxications [6,7].

Increased input from the peripheral chemoreceptors and lung receptors

In case of severe hypoxaemia, the peripheral chemoreceptors (mainly carotid bodies) will increase their signalling activity and cause increased alveolar ventilation [2,3]. Of note, peripheral chemoreceptors respond to PO_2, and not to oxygen content or oxygen delivery. Moreover, respiratory alkalosis due to an increased signalling from lung receptors (Table 114.1) is a common finding in several pulmonary diseases, including pneumonia, pulmonary oedema, pulmonary embolism, and fibrosis [8,9]. In fact, in pathological conditions, also vagal afferents, i.e. signals arising from lung receptors, can trigger pulmonary reflexes and might have a role in the control of breathing [10].

Excessive CO_2 removal through controlled mechanical ventilation and/or extracorporeal CO_2 removal

In case of mechanical ventilation in sedated and paralysed patients, the 'effectors', i.e. the respiratory muscles, are no longer regulated by the 'central controller'. Indeed, it is the attending physician deciding the rate of alveolar ventilation through the settings of the ventilator. The lack of feedback mechanisms can therefore ensue in an excessive CO_2 removal, leading to respiratory alkalosis, as often occurring during general anaesthesia in operating rooms. A similar scenario is the result of excessive ventilation of the membrane lung in mechanically-ventilated patients treated with extracorporeal respiratory supports.

Effects of respiratory alkalosis

The major effect of hyperventilation is the increase in pH and the consequent shift of electrolytes that occurs in relation to it. As a general law, anions (chloride) will increase (mainly exiting from erythrocytes), while cations (sodium and potassium) will decrease, as they enter in erythrocytes and other cells. Moreover, the acute reduction in ionized calcium due to the change in extracellular pH may cause neuromuscular symptoms ranging from paraesthesias, up to tetany and seizures. Finally, acute respiratory alkalosis causes a constriction of cerebral arteries that can lead to a reduction of cerebral blood flow [11]. This phenomenon is of particular importance for patients with traumatic brain injury.

Metabolic compensation

The kidneys respond to respiratory alkalosis by uncoupling sodium from chloride excretion. Indeed, sodium is excreted with a weak anion (mainly bicarbonate), while chloride is retained. The effect on urine is an increase in urinary strong ion difference (SID)/urinary anion gap and a consequent increase in urinary pH [12,13]. This, in turn, causes an increase in plasma chloride concentration, and a reduction in plasma SID, which tend to bring back plasma pH towards normal values. The renal compensation restores pH values close to normality within 24–48 hours. Another, quantitatively less important mechanism of compensation, is the electrolyte shift, mainly chloride, from red blood cells to plasma.

Therapeutic strategies

The clinical approach to respiratory alkalosis is usually directed toward the diagnosis and treatment of the underlying clinical disorder. To reduce hypocapnia, especially in pathological activation of the central controller, both physical (increase in dead space) and pharmacological means (opiates and benzodiazepines) have been described [14].

PART 4.13

Pneumonia

CHAPTER 115

Pathophysiology of pneumonia

Jordi Rello and Bárbara Borgatta

Key points

- Hypoxaemia is a key element in pathogenesis, diagnosis, and prognosis of ventilator-associated pneumonia (VAP).
- Aspiration of secretions from the airway is the main source of infection for VAP in mechanically-ventilated (MV) patients, and infection develops when bacteria overwhelms the host's defences.
- Prevention care bundles reduce the incidence of VAP, as well as MV duration and intensive care unit (ICU) length of stay.
- Early antibiotic therapy is responsible for decrease in VAP incidence, but facilitates selection of multidrug-resistant organism.
- Mortality is low, but VAP is an important cause of morbidity, with prolonged MV, ICU length of stay, and excessively high estimated costs.

Introduction

Hospital-acquired pneumonia (HAP) is defined as pneumonia developing 48 hours or more after hospital admission. Ventilator-associated pneumonia (VAP) is a type of HAP that occurs after 48–72 hours of endotracheal intubation and is responsible for approximately 80% of HAP, and so, is the most frequent form of infection in the intensive care unit (ICU). New definitions include worsening of oxygenation as a major criteria for differentiating VAP from other respiratory tract infections.

Epidemiology

VAP occurs with an incidence of 5–20 cases per 1000 ventilator days. Improving preventive measures have dramatically decreased its incidence over the last decade. Cumulative risk for developing VAP is 1–3% per day of MV, condensed within the first week following intubation. Rates are usually higher in surgical than medical ICUs. More than half of prescribed antibiotics in the ICU are for VAP treatment. It is an important cause of morbidity, with prolonged MV, ICU/hospital length of stay, and estimated costs as high as $40,000 per patient. ICU mortality ranges from 24 to 76%, with overall attributable mortality lower than 10%, focusing on surgical patients (in contrast with medical or trauma) [3]. Furthermore, infections caused by multiresistant pathogens, such as methillicin-resistant *Staphyloccocus aureus* (MRSA), *Pseudomonas aeruginosa, Acinetobacter baumannii*, and *Stenotrophomonas maltophilia,* have substantially higher mortality. VAP is a prognostic marker in chronic obstructive pulmonary disease (COPD) patients who undergo cardiac surgery and are MV.

Pathogens

Bacteria are the almost exclusively responsible for HAP and VAP in immunocompetent patients, fungal and viral micro-organism are exceptionally isolated in this group of patients. Aetiological agents differ widely between populations since they are determined by the type of ICU, hospital or ICU length of stay, prior antimicrobial therapy, and diagnostic method used. Considering this, the most frequently isolated micro-organisms in VAP are *Pseudomonas aeruginosa, Staphylococcus aureus*, and Enterobacteriaceae. On the other hand, *Candida* and *Enterococcus* species should be considered as colonizers since there is not histological prove of them causing pneumonia.

Classification

Early-onset HAP or VAP is the one occurring during the first 4 days of hospitalization (ward or ICU respectively), whereas when it develops at the 5th day or afterwards is referred as late-onset HAP/VAP. Each one presents with a specific profile.

Early VAP

Usually due to aspiration of normal oropharynx flora in comatose patients or during intubation [1–6]. Caused by community-acquired pathogens (*Streptococcus pneumoniae, Haemophilus influenza*, or meticillin-susceptible *S. aureus*), where antimicrobial resistances are rare.

Late VAP

This is caused by micro-organisms that colonize the upper airway, biofilm, and respiratory tract [1–6], often by pathogens with strong intrinsic or acquired antimicrobial resistance. Risk factors for late-onset VAP include tracheobronchial colonization with enteric Gram negative bacilli (GNB) or *P. aeruginosa*, duration of MV, prolonged antibiotic treatment, and prior use of antibiotics within the preceding 30 days. Late VAP is independently associated with higher mortality. Caused mainly by GNB, 30–70% of cases are due to *P. aeruginosa, Acinetobacter*, or MRSA. Very late VAP in tracheostomized patients is associated with non-fermentative GNB.

Colonization of the lower respiratory tract

Patterns of colonization differ within ICU depending on infectious diseases protocols, hand hygiene, and airway management. Classically, four routes have been described; nevertheless, micro-aspiration of secretions from upper airways remains as the most important source, representing almost 90% of all cases.

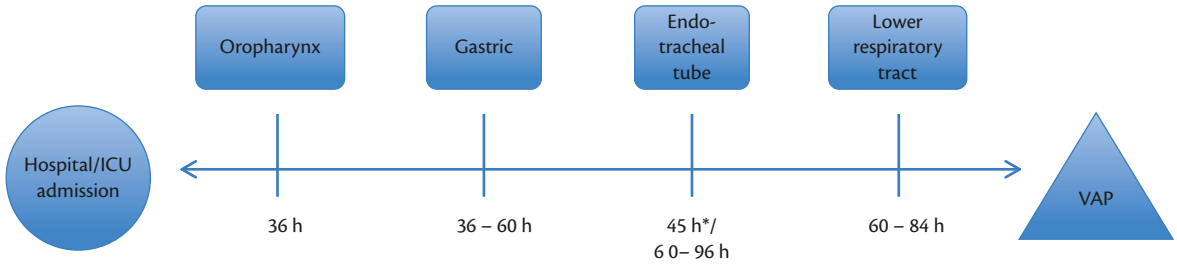

Fig. 115.1 Organ colonization time-evolution during ICU stay.
*At 48 hours 80% of ETT are colonized, but heavy colonization occurs at 60–96 hours.

During hospitalization there's a shift of flora colonizing the airway; initially, there's a reduction of the normal flora, which facilitates the adhesion, and growth of enteric GNB and *S. aureus*. See Fig. 115.1 for the colonization's evolution in MV patients.

Endogenous

Oropharyngeal colonization

More than half of healthy patients can be chronically colonized by normal flora, with COPD patients being especially prone. In MV patient's teeth, a composite of bacteria, mucus and detritus is formed—an adherent matrix called biofilm, which is a source for further bacterial colonization in addition to inflammation of periodontal tissue that can shed bacteria and inflammatory products into the lower respiratory tract.

Aspiration from the upper respiratory tract

- **The main route by which the bacteria invade lower respiratory tract:** favoured by impaired or abolished cough reflex by sedatives and muscle paralysers.
- **Facilitated by the endotracheal tube (ETT) as a result of various mechanisms:**
  - First, it keeps the vocal chords open.
  - Secondly, above ETT a pool of secretion is formed that by capillary leak goes down longitudinal channels formed by the folds of the cuff, even when correctly positioned and inflated at standard pressure. Subglottic secretion drainage reduces the risk for developing VAP.
  - Gross leakage occurs with tracheal suctioning, absence of positive end-expiratory pressure (PEEP), low pressure of the cuff, and disconnection from MV.
  - Furthermore, at the ETT's inner surface biofilm forms, serving as a reservoir for infection and protection from antibiotic effects. This biofilm is reduced with a silver-coated ETT; on the other hand, it can be embolized into lung parenchyma with manipulation of the inner surface of the ETT.

Gastric: macro-aspiration

A nasogastric tube causes oesophageal sphincter incompetence resulting in oesophageal reflux [2,4,6,7] and the possibility of aspiration, especially in patients receiving enteral nutrition. Nonetheless, it is a secondary source of aspiration.

Contiguous and haematogenous spread

Both routes have been described, but are unusual sources of colonization.

Exogenous

Exogenous ways of colonization represent approximately <5% of all routs [2,4,6,7]. It refers to direct inoculation of the microorganism through the ETT by health care workers that manipulates the patient's airway. Inadequate hand washing may contribute to cross-infection with resistant species. The ventilator circuit is often highly colonized (80% of condensate after 24 hours by enteric gram-negative bacteria (EGNB)); however, when it is routinely changed, there's no impact on VAP incidence. Potential bacterial aerosolization can occur from precipitate of the condensate from warm humidifiers, which justifies the use of cascade humidifiers, which do not generate micro-aerosols.

Box 115.1 Risk factors for HAP

- Artificial airway.
- Sedation.
- Massive aspiration.
- ICU/ hospital length of stay.
- Primary disease:
  - Trauma.
  - Burns.
  - Central nervous system disease.
  - Cardiac disease.
- Age > 70 years.
- Chronic lung disease.
- Severity of underlying illness.
- Depressed consciousness.
- Acute respiratory distress syndrome.
- Prior antibiotic treatment:
  - Protective against early-VAP.
  - Increases risk for late-VAP.
- Reintubation.
- H2 blockers/antacids.
- Nasogastric tube.
- Intracranial pressure monitor.

Risk factors and prevention

Artificial airway is the most important risk factor for developing HAP, increasing the risk from 6 to 21-fold. Indeed, many authors use HAP and VAP interchangeably. Antibiotic exposure has a protective effect in early VAP, but increases risk for late VAP, since it selects multiresistant species. Risk factors for HAP are summarized in Box 115.1. Prevention [8,9] of VAP can be achieved with implementing care bundles, which include hand hygiene before airway manipulation, oral care with chlorhexidine, maintenance of intracuff pressure above 20 cmH_2O to reduce leakage of oropharyngeal secretions to the lower airways tract, and sedation control protocols. Minimizing sedation is a strategy to be enhanced to prevent VAP. Furthermore, full bundles compliance reduces duration of MV and ICU length of stay.

Host response

VAP develops when micro-organisms present in distal lung tissue (alveoli) overwhelm host defences with its virulence and burden. Pneumonia in ventilated patients is a multifocal process disseminated within each pulmonary lobe. These foci of pneumonia are predominantly distributed in lower lobes and dependent zones of the lungs. Histological lesions are always located within large zones of altered lung parenchyma, which correspond to an inflammatory exudate with fibrin and some capillary congestion, ensuing at the 3rd to 7th day of pneumonia. Because of this multifocal and patchy distribution, quantitative biopsy cultures cannot reliably discriminate between patients with or without evidence of histological pneumonia [7].

In patients who develop VAP, altered innate and adaptive immune responses have been reported. Decreased T-helper lymphocytes (CD^{3+} and CD^{4+}) due to accelerated apoptosis, increased monocyte apoptosis, and both peripheral and lung neutrophil dysfunction, all resulting in decreased clearing of pathogens.

Additionally, there is also a genetic component influencing the host's response to the infection, polymorphism of the complement pathway (specifically C2 E318D) is associated with increased risk for VAP and higher mortality. Micro-arrays have demonstrated specific different immunological signatures for VAP and VAT.

CHAPTER 116

Diagnosis and management of community-acquired pneumonia

Antoni Torres and Adamantia Liapikou

Key points

- The microbial pattern of the severe community-acquired pneumonia (SCAP) has changed, with *Streptococcus. pneumoniae* still the leading pathogen, but a decrease in atypical pathogens, especially *Legionella*, and an increase in viral and polymicrobial pneumonias.
- At least two blood samples should be drawn for culture and urinary antigen tests for *Legionella pneumophila* and *S. pneumoniae* performed. For intubated patients, an endotracheal aspirate and bronchoscopic samples should be obtained. Polymerase chain reaction (PCR) techniques in respiratory samples and in blood is a promising new method for the detection of viruses and atypical pathogens.
- New variables, such as hypoglycaemia and thrombocytosis, and a biomarker-procalcitonin will be useful for predicting ICU admission in patients with CAP.
- Combination treatment offers an advantage over monotherapy by expanding the antimicrobial coverage and improving survival among critically-ill patients with bacteraemic pneumococcal illness. The recommended antibiotic regimen in depends of the presence of *Pseudomonas aeruginosa* infection.
- In unresponsive patients, careful re-evaluation of treatment, particularly the initial choice of antibacterials, and further extensive and invasive diagnostic efforts are warranted.

Introduction

Community-acquired pneumonia (CAP) is a significant cause of morbidity and mortality, and the most common infectious cause of death in the developed world [1]. In general, the mortality of patients with CAP who require admission to the intensive care unit (ICU) increases to 20–50%. Nearly all patients who die as a consequence of severe CAP develop severe sepsis or septic shock. Approximately 50% of CAP admissions to Spanish ICUs are associated with septic shock.

Aetiology

The spectrum of causal pathogens in severe pneumonia is broader than that in non-severe cases. *S. pneumoniae* is still the leading pathogen, followed by *H. influenzae, S. aureus, L. pneumophila, Enterobacteriaceae*, especially *Escherichia coli, Klebsiella species*, and *P. aeruginosa* [2]. Bacteraemia is more common than CAP and up to 20% of severe CAP episodes are caused by polymicrobial infection.

Viruses are the most common aetiological agents after *S. pneumoniae.* Easily transmissible viruses such as influenza, metapneumovirus (hMPV), respiratory syncytial virus (RSV) and adenovirus are most common.

In 2009, a new H1N1 strain of influenza A virus emerged, causing a pandemic. Rapidly progressive viral pneumonia, affecting mainly young, obese patients represented the primary cause of ICU admission with mortality ranging from 17.3% to 46% among different sites [3].

In patients admitted in the ICU the most common aetiologies were *S. pneumoniae* (62%), atypical pathogens (14%) and polymicrobial aetiologies (11%). The most frequent polymicrobial pattern was *S. pneumoniae* and viral infection, particularly influenza virus [4].

There is a classical correlation of influenza virus infection and pneumonia due to *S. aureus* and *S. pneumoniae*.

The microbial pattern of the severe CAP has changed over the years, with the decrease of atypical pathogens, especially *Legionella* and the increase of viral pneumonia [5]. This may be due to improvement in diagnostic tools, such as PCR techniques. A large number of micro-organisms other than *S. pneumoniae* must be considered, especially *Pseudomonas aeruginosa,* and CA—MRSA.

- The risk factors for *Pseudomonas* pneumonia [6] include:
- Recent hospitalization.
- Frequent (>4 courses per year) or recent administration of antibiotics (last 3 months).
- Severe disease (FEV1 < 30%) and oral steroid use (>10 mg of prednisolone daily in the last 2 weeks).

Accordingly, the risk factors for community-acquired methicillin-resistant *Staphylococcus aureus* (CA-MRSA), an emerging problem, are participating in contact sport, living in crowded or unsanitary conditions, intravenous drug abuse, and male homosexuality.

Diagnosis

Clinical presentation

Severe CAP is characterized as an acute febrile illness with severe respiratory failure (PO_2/FIO_2 < 250) requiring invasive or non-invasive ventilation. The patient with sepsis or septic shock

from CAP presents with mental confusion, hypotension with the need for vasopressors, tachypnoea, tachycardia, or organ dysfunction as renal failure.

Often the severity reflects a progressive pneumonia with complicated pleural effusion or empyema, or metastatic infection as pericarditis, endocarditis.

Often severe CAP presents with decomposition of an underlying comorbidity such as chronic obstructive pulmonary disorders (COPD), diabetes, congestive heart failure, chronic liver, or renal insufficiency.

Radiographic evaluation

A chest radiograph is required to establish the diagnosis, suggest the aetiological agent, extent, or complications of CAP, prognosis, and to aid in differentiating CAP from other common causes of cough and fever, such as acute bronchitis.

The radiograph of severe CAP consists more often of multilobar infiltrates or a rapid increase in the size of infiltrates>50% during the first day of treatment. Moreover, the chest X-ray may show complications of pneumonia as pleural effusion or abscess formation.

Microbiological diagnosis

Diagnostic efforts to isolate a defined pathogen are necessary, as the results may influence both initial treatment and secondary therapy after initial treatment failure. However, the responsible pathogen is not isolated in up to 50% to 60% of patients with severe CAP [1].

The recommendations of IDSA/ATS for microbiological diagnosis are summarized in Table 116.1.

Sputum samples

A culture from a purulent sputum specimen of a bacterial species compatible with the morphotype observed in the Gram stain should be considered for confirmation of the species identification and antibiotic susceptibility testing. The sensitivity of sputum Gram stain was 82% for pneumococcal pneumonia, 76% for staphylococcal pneumonia and 79% for *Haemophilus influenzae* pneumonia, with specificities ranging from 93 to 96% [7].

In addition to routine cultures, a specific request for culture of respiratory secretions on buffered charcoal yeast extract agar to isolate *Legionella* species may be useful in areas where *Legionella* is endemic, as well as in patients with a recent travel history [1]. Sputum cultures for *Legionella* spp. should always be attempted for patients who are *Legionella* urine antigen positive in order to provide isolates for epidemiological typing and comparison with isolates from putative environmental sources.

During bronchoscopy in severe CAP, bronchoalveolar lavage (BAL) quantitative culture (cut-off 10^4 cfu) is a sensitive method for aetiological diagnosis (resistant microorganism, polymicrobial, unusual pathogen). In mechanical ventilation a BAL or protected sheath brush (PSB)/BAL have to be taken from the very beginning and may be useful in guiding therapy even performed during antibiotic treatment.

PCR techniques increased the total viral yield five-fold compared with direct fluorescence antibody assay in the respiratory samples of critically-ill patients [8]. This rapid tool minimizes the proportion of undiagnosed severe CAP, especially in immunocompromised patients, and guides treatment towards a more specific antibiotic regimen.

Blood cultures

Although the overall yield of blood cultures is probably less than 20% in patients hospitalized for SCAP, the positivity of the results and the likelihood of changes in treatment based on the results, increases with severity.

Immunological methods

The *S. pneumoniae* urinary antigen test in adults has a sensitivity of 65–100% and a specificity of 94%. This test should also be considered whenever a pleural fluid sample is obtained in the setting of a parapneumonic effusion [6]. In the diagnosis of CAP caused by *L. pneumophila* urinary antigen detection for serotype 1 has a sensitivity of almost 80% and a specificity approaching 100% [1].

Paired serology for infections caused by *M. pneumoniae*, *C. pneumonia*, and *Legionella* sp. is more useful in epidemiological studies than clinical practice.

Real-time PCR (rt-PCR) assay detected *S. pneumoniae* DNA in 85.3% of patients with positive blood culture findings, whereas blood culture findings were positive in only 50% of the patients with detectable *S. pneumoniae* DNA [9]. This study confirms the superior sensitivity of PCR in blood and the association between a high quantitative bacterial genomic load of *S. pneumoniae* in blood samples and increased risk of death.

A Finish study [10] proved that sputum is clearly superior to both nasopharyngeal aspirates and throat swabs for reliable detection of *M. pneumoniae* by PCR.

Table 116.1 Recommendations IDSA/ATS and ERS for microbiological diagnosis of SCAP

1. Pre-treatment Gram stain and culture of expectorated sputum should be performed only if a good-quality specimen can be obtained and quality performance measures for collection, transport, and processing of samples can be met.	Moderate recommendation; level II evidence.
2. Patients with severe CAP, should have at least two blood samples drawn for culture, urinary antigen tests for *Legionella pneumophila* and *S. pneumoniae* performed, and expectorated sputum samples collected for culture. For intubated patients, an endotracheal aspirate sample should be obtained.	Moderate recommendation; level II evidence.
3. Diagnostic thoracentesis should be performed in hospitalized patients with CAP when a significant (as judged by the admitting physician) pleural effusion is present.	A3; consistent evidence, level 3.
4. Bronchoscopic sampling of the lower respiratory tract can be considered in intubated patients and selected non-intubated patients, where gas exchange status allows.	A3; consistent evidence, level 3.

Reproduced from Mandell LA et al., 'Infectious Diseases Society of America/American Thoracic Society consensus guidelines on the management of community-acquired pneumonia in adults', *Clinical Infectious Diseases*, 2007, **44**(Suppl. 2), pp. S27–72, by permission of Oxford University Press. Data from Woodhead M et al., 'Guidelines for the management of adult lower respiratory tract infections', *Clinical Microbiological Infections*, 2011, **17**(Suppl. 6), pp. E1–59.

Definition of severity

Many studies of the epidemiology of patients with CAP have demonstrated the importance of assessing severity of illness and stratifying patients on the basis of their risk of mortality.

The pneumonia severity index (PSI) and CURB-65 have low sensitivity and specificity for predicting ICU admission compared with the predictive power of mortality in patients with CAP [11].

Furthermore, in comparison with PSI, the CURB-65 has been shown to outperform generic sepsis and early warning scores [12].

IDSA/ATS issued guidelines on the management of CAP include specific criteria (Box 116.1) to identify patients for ICU admission [1]. Other models specific to severe CAP have been developed.

There is considerable clinical and research interest in the use of novel biomarkers to diagnose and classify CAP. Of the novel biomarkers, most attention has been focused on procalcitonin. Ramirez et al. [13], in a recent study of 685 patients with CAP, assessed biomarkers for the prediction of ICU admission and the IDSA/ATS guidelines minor criteria for severe CAP. Inflammatory biomarkers (C-reactive protein (CRP), tumour necrosis factor-a, procalcitonin and interleukin-6) identified patients needing ICU admission. Patients with severe CAP by minor criteria and low levels of procalcitonin may be safely admitted to wards.

Available simple biomarkers also have prognostic significance. Hypoglycaemia on admission is associated with nearly three-fold greater inpatient mortality, unaffected by the presence of diabetes [14]. Thrombocytosis may also be a risk factor for 30-day mortality. Hypoglycaemia and thrombocytosis are not presently in the list of IDSA/ATS minor criteria for severe CAP, but may need to be considered.

Box 116.1 Criteria for ICU admission. One of the major or three or more of the minor criteria would indicate ICU admission

Major criteria

- Invasive mechanical ventilation.
- Septic Shock with the need for vasopressors.

Minor criteria

- Respiratory rate ≥30 breaths/min.
- PaO_2/FIO_2 ≤250.
- Multilobar infiltrates.
- Confusion disorientation.
- Uraemia (blood urea nitrogen (BUN) level ≥20 mg/dL).
- Leucopenia (white blood cell count $<4 \times 10^9$/L).
- Thrombocytopenia (platelet count $<100 \times 10^9$/L).
- Hypothermia (core temperature <36°C).
- Hypotension (SBP <90 mmHg) requiring aggressive fluid resuscitation.

Reproduced from Mandell LA et al., 'Infectious Diseases Society of America/American Thoracic Society consensus guidelines on the management of community-acquired pneumonia in adults', *Clinical Infectious Diseases*, 2007, 44(Suppl. 2), pp. S27–72, by permission of Oxford University Press.

Empirical treatment: algorithms

Recommendations for antibiotic treatment for severe CAP are based on illness severity, frequency of specific pathogens, local microbial resistance patterns, and drug safety profiles.

In patients with CAP and septic shock, delay must not be more than 1 hour after diagnosis [6].

Empirical recommended therapy for severe CAP is listed in Box 116.2.

Combination treatment offers an advantage over monotherapy by expanding the antimicrobial coverage and by improving survival among critically-ill patients with bacteraemic pneumococcal illness [15]. The recommended antibiotic regimen consists of a β-lactam (preferably intravenously) with a macrolide or with a respiratory fluoroquinilones, especially ciprofloxacin or levofloxacin.

If the patient has risk factors for *Pseudomonas* infection the combination of an antipseudomonal β-lactam with macrolide+ aminoglycoside or an antipseudomonal β-lactam with ciprofloxacin is the favourable treatment [6].

The role of glucocorticoids in severe CAP is still controversial with positive [16] and negative [17] studies. Melvis et al. [18] reported dexamethasone added to antibiotic treatment can reduce length of hospital stay, but not mortality in a population of CAP hospitalized patients.

Low molecular heparin should be given in patients with acute respiratory failure [A3, recommendation].

Several studies indicate that non-invasive ventilation (NIV) may also work in patients with pneumonia, particularly in patients with COPD. NIV has been shown to reduce intubation in patients with ARDS in 54% of treated cases [6].

Box 116.2 Therapy of CAP admitted to ICU

No risk factors for *P. aeruginosa*

- Non antipseudomonal cefalosporin III + macrolide.

  or

- Non-antipseudomonal cefalosporin III +/– moxifloxacin or levofloxacin.

Risk factors for *P. aeruginosa*

- Antipseudomonal cefalosporin[a] or acylureidopenicillin/β-lactamase inhibitor or carbepenem (meropenem preferred, up to 6 g possible, (2 g every 8 hours, three doses) in 3-hour infusion

  plus

- Ciprofloxacin[b]

  or

- Macrolide + aminoglycoside (gentamicin, tobramycin, amikacin).

[a]Ceftazidime + penicillin G coverage for *S. pneumonia*.
[b]Levofloxacin 750 mg/24 hours or 500 mg bd is an alternative.
Reproduced with permission from Woodhead M et al., 'Guidelines for the management of adult lower respiratory tract infections', *Clinical Microbiology and Infection*, 2011, **17**(Suppl. 6), pp. E1–59 © 2011 Woodhead et al. *Clinical Microbiology and Infection* © 2011 European Society of Clinical Microbiology and Infectious Diseases.

Definitive adjusted treatment

Table 116.2 lists the recommended antibiotic therapies for the most important pathogens in severe CAP, according to ERS/ESCMID guidelines [6]. Panton–Valentine leukocidin-producing *Staphylococcus aureus* (PVL-SA) or CA-MRSA cause severe pneumonia with rapid lung cavitation and multi-organ failure. The recommended antibiotic treatment for this necrotizing pneumonia includes the combination of intravenous linezolid, clindamycin, and rifampicin [1,6]. Antibiotic resistance among *S. pneumoniae* is the main concern owing to the dominance of this organism as a cause of severe CAP, and because penicillin and macrolide resistance are frequently linked. The prevalence of *S. pneumoniae* strains resistant to penicillin dropped to 10% or lower in most reports. In patients with pneumococcal pneumonia resistant (low-level) to penicillin a new formulation of co-amoxiclav acid (2000/125 instead of 875–1000/125), offers the advantage of higher penicillin dosing [19].

In pneumococci, erythromycin MICs >0.5 mg/L predict clinical failure. The prevalence of resistance in many countries compromises the efficacy of macrolides in the treatment of pneumococcal infection [1,6]. In patients with risk factors for *P. aeruginosa*, meropenem offers advantages over imipenem because of the option to increase the dose significantly up to 3.2 g. Patients at risk of CAP through *P. aeruginosa* should always be treated by two antipseudomonal drugs in order to reduce the chance of inadequate treatment.

The emergence of new influenza virus subtypes has rekindled the interest in the clinical course and outcome of patients with influenza-associated pneumonia. The implementation of early (<2 days) antiviral therapy was associated with lower mortality in ventilated patients with 2009 H1N1. Apart from neuraminidase inhibitors such as oseltamivir and zanamivir for pneumonia caused by influenza viruses, antibacterial agents targeting *S. pneumoniae* and *S. aureus* are necessary.

Table 116.2 Therapy of specific microorganisms in CAP

Pathogen	Recommended treatment
Highly resistant *S. pneumoniae* (MIC > 8 mg/dL)	Levofloxacin, moxifloxacin, vancomycin, teicoplanin, linezolid
MSSA	Flucloxacillin, cephalosporin ii, clindamycin, levofloxacin, moxifloxacin
MRSA	Vancomycin, teicoplanin +/– rifampicin linezolid, clindamycin(if sensitive)
Ampicillin-resistant *Haemophilus influenzae*	Aminopenicillin plus B-lactamase inhibitor levofloxacin, moxifloxacin
Mycoplasma, *Chlamidophila pneumoniae*	Doxycycline, macrolide, levofloxacin, moxifloxacin
Legionella pn.	Macrolide (azithromycin preferred), levofloxacin, moxifloxacin +/– rifampicin
Coxiella burnetti	Doxycycline, levofloxacin, moxifloxacin
Acinetobacter baumanii	Cefalosporin III + aminoglycoside, ampicilin-sulbactam

Response to treatment

For patients initially admitted to the ICU, the risk of failure to respond to therapy is already high. As many as 40% will experience deterioration even after initial stabilization in the ICU. The inadequate response depends on factors related to initial severity, with the causative organism and host characteristics [1].

Non-responding pneumonia occurring in the first 72 hours of admission is usually due to antimicrobial resistance or an unusually virulent organism or a host defence defect. Non-responsiveness after 72 hours is usually due to a complication (empyema, endocarditis, acute respiratory distress syndrome). The evaluation of non-responding pneumonia depends on the clinical condition.

The percentage of treatment failure in severe CAP is 6–15%. The causes of non-responding pneumonia are classified according to the aetiology as infectious, non-infectious, and of unknown origin.

In hospitalized CAP, infections are responsible for 40% of non-responding CAP. The most frequent micro-organisms found are *S. pneumoniae, Legionella, P. aeruginosa* and *S. aureus*. Micro-organisms may show resistance against antibiotics prescribed or may develop resistance during therapy. Unusual micro-organisms requiring specific antibiotic treatment other than that recommended in the guidelines include *Mycobacteria, Nocardia* spp., anaerobes, fungi, *Pneumocystis jirovecii*, and others [20]. Non-infectious diseases include neoplasms (especially alveolar cell cancer), pulmonary haemorrhages, bronchiolitis obliterans, and organizing pneumonia, eosinophilic pneumonia, hypersensitivity pneumonitis, and drug-induced lung disease.

Careful re-evaluation of treatment, particularly the initial choice of antibacterials, and further diagnostic efforts are warranted. New microbiological and imaging studies (CT of the chest) must be performed to rule out other alternative diagnoses. If simpler procedures do not provide a rapid diagnosis, invasive techniques (i.e. bronchoscopy) are recommended in most cases of non-responding pneumonia. Both PSB and BAL sampling should be done during the same procedure.

Changing of the initial empiric antibiotic regimen with a broader spectrum antibacterial coverage is the optimal management.

CHAPTER 117

Diagnosis and management of nosocomial pneumonia

Jean Chastre

Key points

- Although appropriate antibiotics may improve survival in patients with pneumonia, the use of empirical broad-spectrum antibiotics in patients without infection is potentially harmful, facilitating colonization and superinfection with multiresistant micro-organisms. Any strategy designed to evaluate patients suspected of having developed nosocomial pneumonia (NP) should be able to withhold antimicrobial treatment in patients without pneumonia.
- Because even a few doses of a new antimicrobial agent can negate results of microbiological cultures, pulmonary secretions in patients suspected of having developed NP always should be obtained before new antibiotics are administered.
- Empirical treatment of patients with NP should be selected based on available epidemiological characteristics, information provided by direct examination of pulmonary secretions, intrinsic antibacterial activities of antimicrobial agents, and their pharmacokinetic characteristics.
- Altered pharmacokinetics secondary to increase in volume of distribution in critically-ill patients can result in insufficient serum β-lactam concentrations when standard dosages are administered, emphasizing the need to carefully monitor peak and trough levels of antibiotics when treating resistant pathogens.
- Once the microbiological data become available, antimicrobial therapy should be re-evaluated in order to avoid prolonged use of a broader spectrum of antibiotic therapy than is justified by the available information. For many patients, including those with late-onset infection, the culture data will not show the presence of highly resistant pathogens, and in these individuals, therapy can be narrowed or even reduced to a single agent in light of the susceptibility pattern of the causative pathogens without risking inappropriate treatment.

Introduction

Nosocomial pneumonia (NP) is the most frequent ICU-acquired infection among patients who are treated with mechanical ventilation (MV) [1,2]. Because several studies have shown that appropriate antimicrobial treatment of patients with NP significantly improves outcome, rapid identification of infected patients and accurate selection of antimicrobial agents are important clinical goals [1].

Diagnosis

NP is typically suspected when a patient has new or progressive radiographic infiltrates and clinical findings suggesting infection, such as the new onset of fever, purulent sputum, leukocytosis, increased minute ventilation, and/or a decline in arterial oxygenation. Because interpretation of chest radiographs is difficult, particularly in patients with prior abnormalities, it is also mandatory to consider the diagnosis of NP in ventilated patients who deteriorate clinically, and/or in whom vasopressors need to be increased in order to maintain blood pressure, even in the absence of a clear-cut progression of the radiographic abnormalities.

Two diagnostic algorithms can be used when NP is suspected. The first option is to treat every patient with new antibiotics, even when the likelihood of infection is low, arguing that several studies showed that the immediate initiation of appropriate antibiotics was associated with reduced mortality. The second option is to use an invasive diagnostic strategy based on quantitative cultures of distal respiratory specimens obtained using bronchoscopic or non-bronchoscopic techniques, such as bronchoalveolar lavage (BAL), in order to improve the identification of patients with true NP and facilitate decisions about whether or not to treat with antibiotics [3]. Although using different diagnostic techniques, these two algorithms share the same goals, i.e. early, appropriate treatment of patients with true pneumonia, while avoiding antibiotics in patients without NP [1,2].

The clinical strategy

Using this strategy, antimicrobial therapy is started just after having obtained a specimen of the proximal airway secretions for qualitative microbiological testing. Initial therapy is then adjusted according to culture results and/or clinical response. Antibiotics are discontinued if and only if the following three criteria are fulfilled on day 3:

- Clinical diagnosis of NP is unlikely (there are no definite infiltrates found on chest radiography at follow-up and no more than one of the three following findings are present: temperature > 38.3°C, leukocytosis (>12,000/mm^3) or leukopenia (<4000/mm^3), and purulent tracheobronchial secretions) or an alternative non-infectious diagnosis is confirmed.
- Tracheobronchial aspirate culture results are non-significant.
- Severe sepsis or shock are not present [4].

While the simple qualitative culture of endotracheal aspirates (EA) is a technique with a high percentage of false-positive results due

to bacterial colonization of the proximal airways in many ICU patients, recent studies using quantitative or semi-quantitative culture techniques suggest that the diagnostic accuracy of EA cultures is similar to the accuracy of more invasive techniques [1]. The inherent advantages of these techniques are that they are also available to non-bronchoscopists, they are less expensive than bronchoscopy, and they can be performed safely in patients not receiving MV. Disadvantages include misclassification of some patients, either because the diagnosis of pneumonia is missed when EA quantitative culture results grows below the threshold defining a positive result (10^5–10^6 CFU/mL), or because a false diagnosis of pneumonia is established in patients with only airway colonization.

The invasive strategy

This strategy uses quantitative cultures of lower respiratory secretions collected by BAL, with or without a bronchoscope to define both the presence of pneumonia and the aetiological pathogen(s). Using this strategy, therapeutic decisions are tightly protocolized, using the results of direct examination of distal pulmonary samples and of quantitative cultures in deciding whether to start antibiotic therapy, which pathogens are responsible for infection, which antimicrobial agents to use, and whether to continue therapy (using a cut-off of 10^4 CFU/mL) [2].

Quantitative cultures of BAL specimens consistently yield fewer micro-organisms growing above the diagnostic threshold than are present in qualitative cultures of tracheal aspirates [2]. Thus, when therapeutic decisions have been based on these data, fewer patients have been treated with antibiotics, and a potentially narrower spectrum of therapy was used, compared with the clinical approach, thereby limiting the emergence and dissemination of drug-resistant strains and minimizing antibiotic-related toxicity [3]. Another compelling argument in favour of the invasive strategy is that this approach directs attention away from the lungs as the source of fever when BAL quantitative culture results are negative. Many ICU patients with negative bronchoscopic cultures have other potential sites of infection that need to be identified in order to avoid delays in initiating appropriate treatment.

The accuracy of bronchoscopic techniques is questionable in patients who have received prior antibiotics, particularly when new antibiotics have been introduced after the onset of the symptoms suggestive of NP and before pulmonary secretions were collected. However, several investigators have found that cultures of respiratory secretions are not modified in a major way when pneumonia develops in patients who have been receiving systemic antibiotics for several days before the appearance of the new pulmonary infiltrates. The reason for this appears to be that the bacteria responsible for the new infection are likely to be resistant to the antibiotics that have been used [5].

One major technical problem with all bronchoscopic techniques is correct selection of the sampling area in the tracheobronchial tree. The sampling area is usually selected based on the location of the radiographic infiltrate, or the bronchoscopic identification of a pulmonary segment that has purulent secretions. In patients with diffuse pulmonary infiltrates or minimal new changes in a previously abnormal chest radiograph, determining the correct segment to sample can be difficult. In such cases, sampling should be directed to the area where endobronchial abnormalities are maximal. Because autopsy studies indicate that NP frequently involves the posterior portion of the right lower lobe, this area should probably be given priority for sampling [2].

Summary of the evidence

Besides decision-analysis studies and a single retrospective study, five trials have used a randomized scheme to assess the effect of a diagnostic strategy on antibiotic use and outcome in patients suspected of having ventilator-associated pneumonia (VAP) [6]. In a French study in which 413 patients were randomized, those receiving bacteriological management using BAL had a lower mortality rate on day 14, lower sepsis-related organ failure assessment scores on days 3 and 7, and less antibiotic use [3]. Pertinently, 22 non-pulmonary infections were diagnosed in the bacteriological strategy group and only five in the clinical strategy group, suggesting that over-diagnosis of VAP can lead to errors in identifying non-pulmonary infections. More recently, a randomized trial conducted in Canada investigated the effect of different diagnostic approaches on outcomes of 740 patients suspected of having VAP [7]. There was no difference in the 28-day mortality rate in patients in whom BAL was used, versus those in whom EA was used as the diagnostic strategy. The BAL and the EA groups also had similar rates of targeted antibiotic therapy on day 6, days alive without antibiotics, and maximum organ dysfunction scores. Unfortunately, information about how the decision algorithms were followed in the two diagnostic arms once cultures were available was not provided, raising uncertainties about how de-escalation of antibiotic therapy was pursued in patients with negative BAL cultures. Obviously, the potential benefit of using a diagnostic tool such as BAL for safely restricting unnecessary antimicrobial therapy in such a setting can only be obtained when decisions regarding antibiotics are closely linked to bacteriological results, including both direct examination and cultures of respiratory specimens.

Treatment

Initial therapy

Failure to initiate prompt appropriate and adequate therapy (the aetiological organism is sensitive to the therapeutic agent, the dose is optimal, and the correct route of administration is used) has been a consistent factor associated with increased mortality [1]. Because pathogens associated with inappropriate initial empirical antimicrobial therapy mostly include antibiotic-resistant micro-organisms, such as *Pseudomonas aeruginosa, Acinetobacter* spp., *Klebsiella pneumoniae, Enterobacter* spp., and methicillin-resistant *Staphylococcus aureus* (MRSA), patients at risk for infection with these organisms should initially receive a combination of agents that can provide a very broad spectrum of coverage (see Table 117.1) [1]. Several observational studies have now confirmed that the use of a regimen that initially combines a broad-spectrum β-lactam with an aminoglycoside increases the proportion of patients appropriately treated compared with monotherapy or to a regimen combining a β-lactam with a fluoroquinolone [8,9]. Only patients with early-onset infection, mild or moderate disease severity, and no specific risk factors for multiresistant strains, such as prolonged duration of hospitalization (>5 days), admission from a health care-related facility, recent prolonged antibiotic therapy, and specific local epidemiological data, can be treated with a narrow-spectrum drug, such as a non-pseudomonal third-generation cephalosporin [1,2].

Table 117.1 Initial antimicrobial therapy in patients with VAP

	Micro-organisms usually responsible	Initial antimicrobial therapy
Early-onset VAP: (<5–7 days of MV) and no risk factors for drug-resistant pathogens (admission from a health care-related facility, recent prolonged antibiotic therapy, and specific local epidemiological data)	Streptococci, methicillin-sensitive *S. aureus*, *H. influenzae*, *Moraxella catarrhalis*, enteric Gram-negative (non-pseudomonal)	Non-pseudomonal 3rd-generation cephalosporin or β-lactam–β-lactamase inhibitor combination, plus one dose of an aminoglycoside in case of severe sepsis or septic shock
Late-onset and/or risk factors for drug-resistant pathogens	Difficult-to-treat Gram-negative bacilli, such as Enterobacter, *Citrobacter freundii*, *Serratia*, indole + *Proteus*, *Morganella*, *Providencia*, extended spectrum beta lactamase (ESBL)-producing Enterobacteriaceae, *P. aeruginosa*, and *Acinetobacter baumannii*, MRSA	Aminoglycoside (amikacin), plus one of the following: ◆ Antipseudomonal penicillin: ◆ Piperacillin+tazobactam ◆ Ceftazidime ◆ Carbapenem (imipenem, meropenem, doripenem) ◆ Cefepime Consider adding vancomycin or linezolid when the patient is colonized by MRSA and/or local prevalence of infection caused by MRSA is high, particularly when Gram staining of respiratory secretions shows Gram-positive cocci

Optimizing antimicrobial therapy

Several published reports have demonstrated the need to adjust the target dose of antimicrobial agents used in treating severe NP to individual patient's pharmacokinetics and putative bacterial pathogens' susceptibilities. Most investigators distinguish between antimicrobial agents that kill by a concentration-dependent mechanism (e.g. aminoglycosides and fluoroquinolones) from those that kill by a time-dependent mechanism (e.g. β-lactams and vancomycin). Altered pharmacokinetics secondary to an increase in volume of distribution in critically-ill patients can result in insufficient serum β-lactam concentrations when standard dosages are administered, emphasizing the need to carefully monitor peak and trough levels of antibiotics when treating resistant pathogens [10]. Higher dosing regimens than those usually recommended and/or prolonged duration of infusion are frequently needed in such circumstances [11]. Development of *a priori* dosing algorithms based on minimal inhibitory concentrations (MIC), patient creatinine clearance and weight, and the clinician-specified area under the inhibitory curve (AUIC) target might be a valid way to improve treatment of these patients, leading to a more precise approach than current guidelines for use of antimicrobial agents [11].

Focusing therapy once the agent of infection is identified

Once the results of respiratory tract and blood cultures become available, therapy can often be focused or narrowed, based on the identity of pathogens and their susceptibility to specific antibiotics, in order to avoid prolonged use of a broader spectrum of antibiotic therapy than is justified by the available information [1]. For example, vancomycin and linezolid should be stopped if no MRSA is identified, unless the patient is allergic to β-lactams and has developed an infection caused by a Gram-positive micro-organism. Very broad-spectrum agents, such as carbapenems, piperacillin–tazobactam, and/or cefepime should also be restricted to patients with infection caused by pathogens only susceptible to these agents. Unfortunately, several studies have shown that, although de-escalation was not associated with any adverse outcomes, it was not consistently performed in many ICUs [12,13].

Switching to monotherapy at days 3–5

The two most commonly cited reasons to use combination therapy for all the antibiotic-treatment duration are to achieve synergy and prevent the emergence of resistant strains. Synergy, however, has only been clearly documented to be valuable in the therapy of *P. aeruginosa* or other difficult-to-treat Gram-negative bacilli (GNB) and in patients with neutropenia or bacteraemic infection, which is uncommon in NP. When combination therapy was evaluated in randomized controlled studies, its benefit was inconsistent or null, even when the results were pooled in meta-analyses or the analysis was restricted to patients infected by *P. aeruginosa* [14,15]. Based on these data, therapy could be safely switched to monotherapy in most patients after 3–5 days, provided that initial therapy was appropriate, clinical course appears favourable, and that microbiological data do not suggest a very difficult-to-treat micro-organism, with a very high in vitro MIC, as it can be observed with some non-fermenting-GNB.

Shortening duration of therapy

Based on data obtained from several randomized trials, an 8-day regimen can probably be standard for most patients with NP [16]. Possible exceptions to this recommendation include immunosuppressed patients, those whose initial antimicrobial treatment was not appropriate for the causative micro-organism(s), and patients whose infection was caused by non-fermenting GNB and had no improvement in clinical signs of infection.

Many clinicians, however, remain hesitant about prescribing fewer fixed days of antibiotics for patients with NP, and would prefer to customize antibiotic duration based on the clinical course of the disease and/or using serial determinations of a biological marker of infection, such as procalcitonin (PCT). The rationale for using a biomarker to tailor antibiotic-treatment duration relies on the fact that the inflammatory response is most often proportional to infection severity. When that response is absent or low, it might be logical to discontinue antibiotics earlier. Thus, adapting antimicrobial-treatment duration to PCT kinetics seems reasonable, and has been demonstrated to be useful in several randomized trials targeting patients with acute

respiratory infection, including five trials conducted in the ICU [17,18].

Conclusion

Nosocomial pneumonia is associated with mortality in excess of that caused by the underlying disease alone, particularly in case of infection caused by high-risk pathogens, such as *P. aeruginosa* and MRSA. The high level of bacterial resistance observed in patients who develop NP limits the treatment options available to clinicians and encourages the use of antibiotic regimens combining several broad-spectrum drugs, even if the pretest probability of the disease is low, because initial inappropriate antimicrobial therapy has been linked to poor prognosis. Besides its economic impact, this practice of 'spiralling empiricism' increasingly leads to the unnecessary administration of antibiotics in many ICU patients without true infection, paradoxically resulting in the emergence of infections caused by more antibiotic-resistant micro-organisms that are, in turn, associated with increased rates of patient mortality and morbidity. Every possible effort should therefore be made to obtain reliable pulmonary specimens for direct microscopic examination and cultures from each patient clinically suspected of having developed NP in order to be able to de-escalate treatment every time it is possible.

CHAPTER 118

Diagnosis and management of atypical pneumonia

Martin Langer and Edoardo Carretto

Key points

- 'Atypical pneumonia' is not rare in the critically-ill patient and 'atypical micro-organisms' are intrinsically resistant to β-lactams. Specific empiric antimicrobial treatment (macrolides, newer fluorquinolones) is mandatory.
- 'Atypical' pneumonia belongs mainly to the community-acquired pneumonia (CAP) and consequently CAP-guidelines include diagnosis and treatment of the 'atypical' pneumoniae.
- Hospital-acquired 'atypical' pneumonia are almost exclusively caused by *L. pneumophila* and may occur in immunocompromised patients with cancer, organ transplant, or undergoing immunosuppressive treatment, who are exposed to contaminated water in the hospital.
- For *L. pneumophila* infections, the **urinary antigen test** is a rapid assay, easy to perform, and widely available. Its major limitation is the specificity only for serogroup 1 (>70%, but <100%). Since the isolation of *L. pneumophila* from respiratory tract is still considered the diagnostic gold standard in microbiology, an attempt to culture the micro-organism should be made whenever is possible.
- Evaluation of serological response (IgM and IgG) in both, acute, and convalescent (3–4 weeks) sera, permit the diagnosis of *M. pneumoniae* and *C. pneumoniae*. In the near future, it is expected that Nucleic Acid Amplification tests (NAAT) techniques will represent the future key points for the diagnosis.

Introduction

The term 'atypical pneumonia' is probably obsolete and also questionable [1], but still widely used, and this chapter refers to pneumonia caused by *Legionella pneumophila, Mycoplasma pneumoniae,* and *Chlamydophila pneumoniae* [2]. 'Atypical' pneumonia belongs mainly to the type community-acquired pneumonia (CAP) occurring both in immunocompromised and in immunocompetent patients, and consequently all CAP-guidelines extensively discuss clinical features, diagnosis, and treatment of the so-called atypical pneumoniae. Hospital-acquired (mainly not intensive care unit (ICU)-acquired) 'atypical' pneumonia are almost exclusively caused by *L. pneumophila* and may occur in immunocompromised patients with cancer, organ transplant, or undergoing immunosuppressive treatment, who are exposed to contaminated water in the hospital [3].

As shown in Table 118.1 and Fig. 118.1 the definition of 'atypical pneumonia' is not inclusive of viral pneumonia, and attempts to identify viruses that are of particular importance for epidemiological purposes [4–6].

The British Thoracic Society reports prevalence data for patients admitted to the ICUs with CAP: 17.8% of infections are due to *Legionella pneumophila*, and 2.7% and 2.2% to *Mycoplasma* and *Chlamydophila*, respectively [7]. In the Italian GiViTI—ICU surveillance project from 2009, *Legionella pneumophila* was identified in 4.6% of patients admitted for severe CAP. Legionellosis must therefore be considered in all patients admitted to the ICU with severe CAP. *Mycoplasma pneumoniae* and *Chlamydophila pneumoniae* causes infrequently severe illness in immunocompetent adults, but are more often diagnosed in children, the elderly, or immunocompromised hosts.

Clinical diagnosis

The clinical diagnosis of 'atypical pneumonia' in patients admitted to the ICU because of severe sepsis or respiratory failure is difficult and there are no specific clinical or radiological findings. 'Atypical pneumonia,' more than just a pneumonia, is a syndrome with pulmonary and extrapulmonary manifestations. Pneumonia with concomitant non-specific central nervous system (CNS) abnormalities, such as headache, mental confusion, lethargy, renal, and hepatic involvement (microscopic haematuria, increased creatinine, transaminases, and increased lactate dehydrogenase), cardiac abnormalities (relative bradycardia), diarrhoea, electrolyte abnormalities (hyponatraemia, hypophosphataemia), but also absence of sputum production and 'no growth' from standard cultures may suggest 'atypical' micro-organisms, and request adequate and urgent empirical treatment and diagnostic work-up. In an observational study, legionellosis, probably because not suspected/treated in a timely manner, was independently associated with early treatment failure and this increases the risk of death [8].

Radiology, albeit not specific, is a cornerstone of the diagnosis of 'atypical pneumonia' in patients admitted to the ICU. Severe CAP due to *Legionella* spp. usually cause patchy, localized infiltrates in the lower lobes, being frequently multilobar and even bilateral. In rare instances, legionellosis is associated with cavitations, more frequently in patients treated with steroids. Clinical history and evidence of contact with animals are important elements that support the suspicion of 'atypical' pneumonia due to infrequent diseases

Table 118.1 The most frequently isolated 'typical' and 'atypical' micro-organisms in CAP patients with increasing severity

	Micro-organisms		
	'Typical' pathogens	**'Atypical' pathogens**	**Other pathogens**
Outpatient	*Streptococcus pneumoniae, Haemophilus influenzae, Moraxella* spp.	*Mycoplasma pneumoniae, Chlamydophila pneumoniae, Legionella pneumophila*	**Respiratory viruses:** influenza A-B, adenovirus, respiratory syncytial, para-influenza, H1N1
Inpatient: non-ICU	*Streptococcus pneumoniae, Haemophilus influenzae, Moraxella* spp., Gram-negative bacilli	*Legionella pneumophila, Mycoplasma pneumoniae, Chlamydophila pneumoniae*	**Respiratory viruses:** influenza A-B, adenovirus, respiratory syncytial, para-influenza, H1N1 Aspiration
Inpatient: ICU	*Streptococcus pneumoniae, Staphylococcus aureus, Haemophilus influenzae,* Gram-negative bacilli	*Legionella pneumophila* (*Mycoplasma pneumoniae*)	**Respiratory viruses (H1N1):** *Aspergillus* spp., *Pneumocistis jiroveci* Aspiration

Data from File TM, 'Community-acquired pneumonia', *Lancet*, 2003, **362**, pp. 1991–2001.

such as Q fever, psittacosis, and tularaemia, which are hardly ever aetiologies seen outside a specific context.

Knowledge of the diseases and clinical suspicion are important, but not sufficient for diagnosis. Only specific microbiological investigations allow a reliable diagnosis, which is useful for the obligatory reporting and of great value for epidemiological purposes. A reliable microbiological diagnosis permit the tailoring of the type and duration of the treatment, even in cases where an adequate empiric, guideline-orientated treatment had been prescribed.

Microbiological diagnosis

Legionella infections

From the microbiological point of view, to date more than 50 *Legionella* species have been classified. *Legionella pneumophila* was the first species described and it causes 80–90% of reported cases of legionellosis. *L. pneumophila* is divided into 16 different serogroups, but serogroup 1 accounts for more than 70% of all of the legionellosis [9,10].

The diagnostic tools of *Legionella* infections have been focused on culture and serological investigation. A significant improvement was achieved using methods able to detect the urinary antigens of the micro-organism. Recently, nucleic acid amplification tests (NAATs) revealing the DNA of *Legionella* strains from environmental and clinical samples have been made available.

The urinary antigen test is based on the qualitative detection of a soluble antigen specific for *Legionella pneumophila* serogroup 1 [11], revealed through a rapid immunochromatographic assay. This antigen has been detected in urine as early as 3 days after the onset of symptoms and it may persist for months [12]. These tests

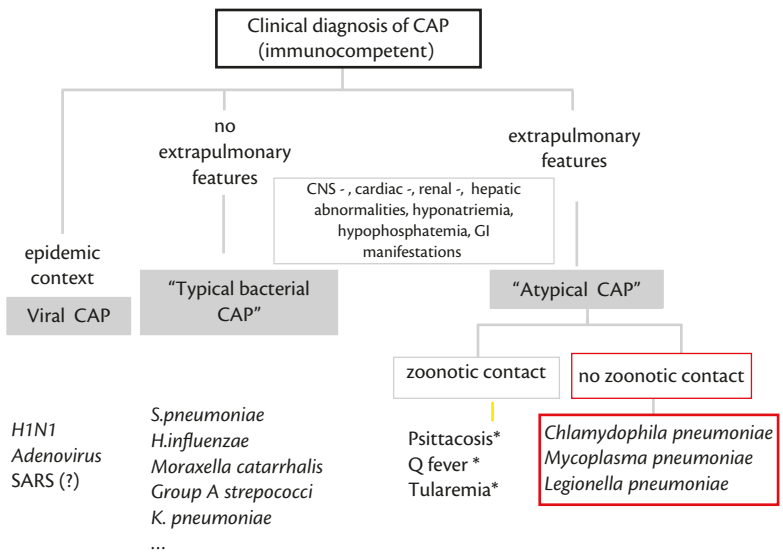

Fig. 118.1 Flow chart—'atypical pneumonia'—data from [5] and [6]. B. A. Cunha extensively investigated 'atypical pneumonia', and his work is helpful to understand similarities and differences with respect to 'typical' CAP.

*For psittacosis, Q fever, and tularaemia see specific literature.

Data from Cunha BA, 'Clinical features of legionnaires' disease', *Seminars in Respiratory Infections*, 1998, **13**, pp. 116–27; and Cunha BA, 'The atypical pneumonias: clinical diagnosis and importance', *Clinical Microbiology and Infection*, 2006, **12**(Suppl. 3), pp. 12–24.

provide quick results (15 minutes) using a common urine sample, and detect the antigen in early, as well as later, stages of disease, and antimicrobial treatment does not influence the result of the test. In infections due to *L. pneumophila* serogroup 1 the sensitivity of the method varies from 60 to 100%, with a specificity of more than 99% [13]. The major disadvantage of this test is its inability to diagnose infections caused by serogroups 2–16. Furthermore, the prolonged persistence of the antigen in the urinary samples may mislead the diagnosis if the patient had an asymptomatic *Legionella* infection, or a Pontiac fever, in the months before the episode of pneumonia that is to be investigated.

Isolation of *L. pneumophila* from respiratory specimens (e.g. sputum, tracheal aspirate, broncho-alveolar lavage, etc.) using selective media is considered to be the diagnostic gold standard. However, this kind of culture has to be specifically requested by the laboratory, since specific media are necessary, which are not routinely used. The culture is also time-consuming, because *Legionella* spp. take 3–7 days to grow. However, although the sensitivity of this method varies from laboratory to laboratory, an attempt to culture the micro-organism should be made whenever is possible. Through cultural methods it is possible to diagnose infections caused by *Legionella pneumophila* (serogroups different from 1) or by *Legionella* spp. different from *Legionella pneumophila* (most frequently involving *Legionella micdadei*, now reclassified as *Tatlockia micdadei*). Moreover, the isolation of the strain will allow epidemiological studies or could be required for comparison, with molecular techniques, of the isolate to environmental strains if necessary. If a patient is positive to the urinary antigen, allowing epidemiological studies, the clinician should immediately collect a respiratory sample, trying to isolate and identify the micro-organism. Even if there are no data about the decreased sensitivity of the culture in patients treated with effective antibiotics, it can be postulated that every day of effective therapy decreases the likelihood of isolating the micro-organism.

As far as serological analysis is concerned, different techniques are available and should be performed on paired sera (acute and convalescent). The most commonly used techniques are enzyme immunoassays (EIAs), even if detection of antibodies with indirect fluorescence has better performances, but they are time-consuming and require skilled personnel. The main disadvantage of serology is that the host response is typically slow, and sometimes specific antibodies can be detected only months after the onset of symptoms. Thus, serological testing is useful for epidemiological purposes, but has little or no impact for the diagnosis and treatment of the early stage of the disease [14].

Recently, nucleic acid-based methods have been applied to the detection of *Legionella* species, both in clinical and in environmental samples. The polymerase chain reaction (PCR) techniques, if used in combination with the urinary-antigen test, increase the diagnostic chances in the early stage of the disease compared with the use of each test alone [15]. These tests have been successfully used in reference and research laboratories, although most of these experiences were with 'home-made' techniques. At the time of writing, only one out of the three commercial available assays is FDA-cleared. Although these methods have high capability for the future, they should be used only in reference settings and in selected cases, such as suspected infections in patients exposed to *L. pneumophila* strains different from serogroup 1 (e.g. for environmental exposure).

Mycoplasma pneumoniae and *Chlamydophila pneumoniae*

The aetiological diagnosis of these two entities implies common problems. The diagnosis of both pathogens is based on serological tests and on NAATs. Culture is very difficult and time-consuming, and can be performed only in reference laboratories.

For *Mycoplasma* infections, serological tests should be performed on paired sera (acute and convalescent), using complement fixation test and EIAs. However, this approach is useful only for epidemiological purposes. The diagnosis of acute infections can be achieved by evaluating the IgM antibodies even if they are lacking in children under 6 months of age, in some cases of primary infections and during re-infections. For *M. pneumoniae,* IgMs are produced 3–4 days or later after the onset of symptoms, and sometimes persist for several weeks to months.

Regarding serological tests for *C. pneumoniae,* determined in paired sera, the micro-immunofluorescence (MIF) test is able to document infections and is useful for epidemiological purposes and is currently considered the gold standard.

Both for *Mycoplasma pneumoniae* and *Chlamydophila pneumoniae*, PCR systems have been developed and used for diagnosis. For these micro-organisms, comparison of NAATs with culture and/or serology is difficult, since there are problems in defining a reliable gold standard. To date, there are no commercial FDA-cleared assays, although a wide variety of PCR-based protocols, using different target genes, have been developed in research laboratories. These techniques, and in particular real-time PCR, will represent the future key points for the diagnosis [16].

What should clinicians do for the diagnosis?

If an 'atypical pneumonia' is suspected, clinicians should:

- Collect a urinary sample for detection of *Legionella pneumophila* serogroup 1 antigen.
- If legionellosis is strongly suspected, or if the urinary antigen is positive, appropriate respiratory samples should be collected as soon as possible and sent to the laboratory, with a previous communication to the microbiologist.
- Collect acute and convalescent (3–4 weeks) sera for IgM and IgG serology for *L. pneumophila, M. pneumoniae*, and *C. pneumoniae.*
- Contact the laboratory to discover whether NAATs are available for the diagnosis and also to find the correct way to collect samples to be used with these techniques.

Transmission within the ICU and isolation practice

While hospital acquisition of legionellosis from contaminated water in hospital is of great concern, and may present in clusters or outbreaks, a person-to-person transmission has never been reported [17]. Isolation of *Legionella*-infected patients is therefore unnecessary.

Treatment

Starting from the well-known unresponsiveness of 'atypical' bacteria to β-lactam antibiotics and the impossibility to perform 'standard'

sensitivity testing, the cornerstone of treatment is empirical therapy with macrolides or newer fluorquinolones. In the absence of adequate clinical studies, all available guidelines are based on in vitro investigations, observational studies and expert opinions.

Every CAP-guideline includes 'anti-atypical' drugs as their first line CAP treatment, mainly a combination of a respiratory fluorquinolone or a macrolide (with a β-lactam). In many severe and poorly responsive cases diagnosed as legionellosis, combination therapy, adding rifampicin to the fluorquinolone has been tried, but the efficacy is still controversial [3,18]. From 2 to 3 weeks of treatment are usually considered adequate, but this information too is not 'evidence based.'

Once the microbiological diagnosis becomes available, the treatment of 'atypical' pneumonia may also be targeted according to the pathogen [19]:

- ***Mycoplasma pneumoniae*:** doxycycline, macrolide, newer fluoroquinolones (most data available for levofloxacin).
- ***Chlamydophila pneumoniae*:** doxycycline, macrolide, fluoroquinolones.
- ***Legionella* spp.:** newer fluoroquinolones (most data available for levofloxacin), macrolide (azitromycine preferred) +/– rifampicin.

PART 4.14

Atelectasis and sputum retention

CHAPTER 119

Pathophysiology and prevention of sputum retention

John J. Marini and Paolo Formenti

Key points

- Common predispositions to secretion retention are airway intubation, prolonged sedation, muscular weakness, aspiration of oral secretions, coughing discomfort, restricted breathing after surgery, bronchitis due to smoking, and advanced age.
- Effective removal of secretions from the respiratory tract depends on two key factors—integrity of the mucociliary transport system and the ability to cough productively.
- Mucus retained within the airway lumen impairs effective delivery of aerosol therapies, while predisposing to lung collapse, inflammation, and infection.
- Intubation for mechanical ventilation impairs cough, interrupts mucociliary clearance, and encourages formation of a tube-lining biofilm that is isolated from blood flow and body defences.
- Respiratory and coughing muscle strength, body position, lung volume, airway secretion viscosity and location, depth of sedation, and suctioning effectiveness are some of the important variables that determine the impact of secretion retention on ventilation, gas exchange, and patient outcome.

Introduction

A thin lining of tracheobronchial secretions contributes importantly to normal respiratory system defence, whereas retained airway mucus complicates the care of the critically-ill ventilated patient. Excessive secretions that must be cleared from the airways by coughing, huffing, or catheter aspiration, are defined as **sputum**. They may arise acutely or be present chronically, but they are always abnormal. Retained secretions in the acute care setting may impair gas exchange, increase the breathing workload, predispose to infection, or contribute to atelectasis. Prevention and reversal of the latter phenomenon is a fundamental goal of effective intensive care.

Pathogenic mechanisms of secretion retention and atelectasis

Sputum retention may either cause or result from atelectasis. Once established, parenchymal collapse impairs clearance of mucus from the central airways. Among the most common predispositions to secretion retention are airway intubation, prolonged sedation, muscular weakness, aspiration of oral secretions, coughing discomfort, restricted breathing after surgery, bronchitis due to smoking, and advanced age [1]. Obstructive atelectasis involves narrowing or occlusion of the bronchial tree by foreign bodies or mucus, tumours, or lymph nodes. In some cases, a lack of surfactant increases the surface tension of alveoli, encouraging their collapse [2]. Whatever the setting, strong measures must be taken to reduce the prevalence of these ubiquitous disorders.

The following mechanisms may contribute to the development of atelectasis:

- Compression atelectasis occurs when the transmural pressure distending the alveolus is reduced sufficiently to allow alveolar collapse. Common causes include loss of muscular tone, as during the induction of anaesthesia, pleural effusion, abdominal distention, supine positioning, and lung oedema.
- Obstructive atelectasis, a common cause for the generation of atelectasis or a contributor to its persistence, results from reabsorption of gas from the alveoli when communication between the gas exchange interface and the trachea is interrupted by foreign bodies, tumours, or mucus plugs. Gas uptake by the blood then continues while replenishing gas inflow is prevented (Fig. 119.1).
- Adhesive atelectasis results from surfactant deficiency. Increased alveolar surface tension cannot be counterbalanced by tidal transalveolar pressures, leading to alveolar instability and collapse. This mechanism probably makes an important contribution to the maintenance of established collapse, but is less central to its generation, given normal surfactant reserve and high rate of surfactant turnover.

Bronchial secretions

Effective removal of secretions from the respiratory tract depends on two key factors—integrity of the mucociliary transport system and the ability to cough productively. Airway mucus traps inhaled particulate toxins and transports them out of the lungs by means of ciliary beating and cough. A deficient mucous barrier leaves the lungs vulnerable to injury, and excessive mucus or impaired clearance contributes to all common airway diseases.

Mucus is continuously swept from distal to proximal airways, propelled in a proximal direction by ciliary beating. This action clears inhaled particles, pathogens, and dissolved chemicals that might otherwise threaten the lungs [3]. While the small airways produce a thin mucus gel layer, a thicker layer (up to 50 μm) accumulates

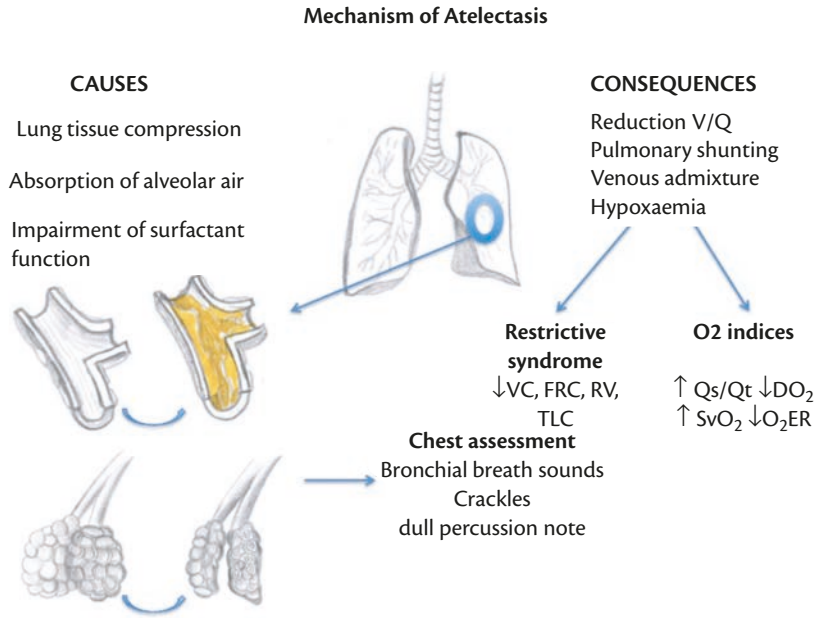

Fig. 119.1 Schematic figure to explain mechanism of atelectasis and physiological/clinical implication.
VC, vital capacity; FRC, functional residual capacity; RV, residual volume; TLC, total lung capacity; DO_2, oxygen delivery.

in the larger airways from accumulated mucus transported from distal airways and any drying that may result from suboptimally conditioned inspired gas. After mucus ascends the trachea, it is normally transported mouthward past the vocal cords by ciliary epithelium in the posterior commissure of the larynx. It then enters the pharynx and is swallowed, with approximately 30 mL of airway mucus eliminated via the gastrointestinal tract daily [4]. The rate of mucociliary clearance increases with greater hydration [5], and the rate of ciliary beating can be increased by purinergic, adrenergic, cholinergic, and adenosine-receptor agonists, as well as by irritant chemicals. Sputum retention occurs when patients are unable to clear secretions by themselves or with assistance. Retention of airway secretions may lead to obstruction of major bronchopulmonary units and lobar atelectasis.

A second mechanism of fundamental importance for the expulsion of pathological mucus from the airways is cough clearance. Coughing is a complex phenomenon that is usually triggered by local 'irritation' caused by the stimulation of vagal afferents in the intrapulmonary airways or in the larynx and pharynx. Reflex activation of the expulsive abdominal and intrathoracic muscles makes it possible to quickly evacuate accumulated secretions from the central bronchi. Assuming that the airway is not intubated, the glottis can temporarily close during forceful contraction of the abdominal and internal intercostal muscles [6]. After airway pressure rapidly elevates, sudden opening of the glottis allows compression of the central airway and sufficiently high flow to shear the debris from its mucosal attachments.

During invasive mechanical ventilation, cough efficiency is impaired because the glottis cannot close, even though increased resistance of the upper airways (intubation tube, ventilatory circuit) may predispose to an increase in tracheal pressure during forceful exhalation. Coughing is suppressed during general anaesthesia and can be significantly reduced by the administration of opioids. In patients who are *not* intubated, neuromuscular weakness(phrenic paralysis, myasthenia, Guillain–Barré syndrome, etc.), pain, or impaired consciousness are often responsible for 'ineffective' cough. In others, peripheral obstruction of the airways chokes off maximal expiratory flow, detrimentally affecting cough.

Dyspnoea often results when mucus obstructs airflow by narrowing the 'effective' airway lumens within the collective airway system. Physical signs of impaired mucus clearance include persistent cough, bronchial breath sounds, rhonchi, and wheezes. Retained mucus and inflammatory exudates may appear as localized haze, atelectasis, or linear or branched opacities on plain radiographs of the chest. Not only is it important to recognize the role of mucus in clinical presentations of increased effort and impaired oxygenation, but also to understand that mucus must be cleared from the airway lumen to facilitate effective delivery of aerosol therapies and, in many cases, to address patient–ventilator asynchrony. In addition, the presence of retained mucus may predispose to or be a sign of inflammation or infection that warrants additional treatment.

Factors modulating the formation of atelectasis

Several important clinical circumstances influence the formation of atelectasis. Atelectasis develops both during intravenous and inhalational anaesthesia. Ventilatory effects of regional anaesthesia depend on the type and extent of motor blockade. The maximum decreases of functional residual capacity (FRC) seem to occur within the first few minutes of general anaesthesia and as a consequence of changing positions. Transition from the upright to the supine position causes FRC to decrease 0.5 L to 1.2 L, even in the awake state, with a further reduction of 0.5–0.7 L in FRC occurring during general anaesthesia. High inspired oxygen concentrations are associated with 'absorption' atelectasis. Absorptive collapse is prevalent, as the use of high FIO_2 (i.e. approaching 1.0) is standard practice among many anaesthesiologists. Obesity worsens arterial oxygenation through multiple mechanisms, of which development of atelectasis is an important contributor [7]. Markedly reduced

FRC limits expiratory reserve and promotes airway closure to a greater extent in obese patients than in patients of normal weight. Two practical points are important regarding ventilator settings during deep sedation. In contrast to volume-controlled ventilation, pressure-controlled ventilation delivers smaller tidal volumes when respiratory system compliance declines (e.g. during surgical retraction or after placement of abdominal packs). Smaller tidal volumes may then lead to atelectasis (unless volume alarms are appropriately set) and may go undiagnosed because there is no tell-tale change in the peak airway pressure [8].

Risk factors

There are several risk factors associated with the development of atelectasis caused by obstruction of the major airways and bronchioles, or by pressure originating outside the lung, e.g. from fluid or air in the pleural space (Box 119.1). Some predispositions are directly linked with the sputum retention that tends to occur commonly as a complication in the post-operative period.

It is clear that low V/Q areas in dependent lung regions (i.e. areas of relative underventilation) are inclined to develop progressive atelectasis. Any influence that enhances such underventilation will increase this tendency. Apart from inhibition of diaphragmatic action, the most important of these risk factors is airways disease, particularly chronic bronchitis and/or emphysema. In chronic airways disease, inspired gas is unevenly distributed, both temporally and spatially. Reduced peak expiratory flow impedes expulsion of accumulated secretions.

Another common factor augmenting the tendency toward collapse is a rapid shallow pattern of ventilation, commonly seen in patients with obesity and in those with post-operative pain, when the discomfort of an abdominal or thoracic incision inhibits normal depth of inspiration. The latter problem may be partially alleviated or, conversely, compounded by the use of sedative and narcotic analgesics, which relieve pain, but depress ventilation, suppress coughing and retard sputum clearance. Depressed central respiratory drive due to chronic obstructive lung disease, neurological disease, or hypoventilation syndromes also aggravates the atelectatic tendency. Reduced inspiratory reserve due to peripheral nerves (Guillain–Barré syndrome or spinal cord injury), neuromuscular (myasthenia gravis, post-anaesthetic persistent curarization syndrome), muscular (muscular dystrophies), and musculoskeletal disorders (ankylosing spondylitis, thoracoplasty, kyphoscoliosis) may also be associated with a shallow breathing pattern, increased hypoventilation of dependent lung regions, and an enhanced tendency to atelectasis.

Box 119.1 Atelectasis risks factor associated with airways obstruction

- Impaired swallowing function, particularly in older adults—aspirating secretions into the lungs is a major source of infections.
- Any condition that interferes with spontaneous coughing, yawning, and sighing.
- Lung disease, such as asthma, bronchiectasis, or cystic fibrosis.
- Confinement to bed, with infrequent change of position.
- Abdominal or chest surgery.
- Recent general anaesthesia.
- *Shallow breathing:* a result of abdominal pain or rib fracture.
- Respiratory muscle weakness, due to muscular dystrophy, spinal cord injury, or another neuromuscular condition.
- *Obesity:* fat in the abdomen can elevate the diaphragm and hamper the ability to inhale fully.
- Age.

Ventilation patterns and airway secretion clearance

Intubation for mechanical ventilation impairs cough, interrupts mucociliary clearance, and encourages formation of a tube-lining biofilm that is isolated from blood flow and body defences. These factors lead to sputum retention, airway occlusion, atelectasis, and ventilator-associated pneumonia. Respiratory muscle strength, position, lung volume, viscosity, and location of airway secretions, depth of sedation, and 'coughing strength' (expiratory flow generated spontaneously or in response to suction) are some of the variables that may determine the impact of secretion retention on ventilation, gas exchange, and patient outcome [8]. The minimum standard of airway management requires adequate gas humidification and airway suctioning [9]. Open suctioning, higher suction pressures, wide-bore suction catheters, and the release of positive end-expiratory pressure (PEEP)—a manoeuvre that encourages mouthward migration of secretions retained in the periphery of the PEEP-distended lung can improve secretion clearance, but may compromise gas exchange in the short term. Closed suctioning can minimize potential adverse physiological effects of airway suctioning, but may not be as effective for secretion clearance [10].

It has been demonstrated that airway clearance can be augmented by imposing an expiratory flow bias or by manual lung hyperinflation, which transiently improves airway resistance, recoil force, and dynamic lung/thorax compliance. Chest wall vibration, with or without manual lung hyperinflation and suctioning, can improve expiratory flow, airway resistance, and dynamic lung/thorax compliance, but has not been demonstrated to improve secretion clearance [11].

Consequences of atelectasis

Atelectasis decreases pulmonary compliance and is associated with a worsening in systemic oxygenation associated with a reduction in FRC [12]. In the presence of increased airway resistance or decreased lung compliance, increased transpulmonary pressure is required to achieve a given tidal volume, with consequent increase in the work of breathing. Most often, this volume reduction impairs the efficiency of systemic oxygenation, and prompts hyperoxic gas inhalation with subsequent reabsorption. In the hyperoxic range, such effects are better detected by arterial blood gas analysis, rather than simply observing oxygen saturation.

High tidal ventilating pressures when the lung is not fully recruited may inflict lung damage. Yet, use of 'lung protective' low tidal volumes may not be sufficient to avert lung inflammation. It has been demonstrated that in the absence of PEEP, impaired lung compliance is accompanied by increased cytokine production. Pulling together all recent findings it seems reasonable to suggest

that using low tidal volume without preventing atelectasis by adequate PEEP may be a misguided ventilation strategy [13].

Prevention of sputum retention and atelectasis

Invasive mechanical ventilation via endotracheal intubation or tracheostomy bypasses the upper airways, and its normal heat and moisture exchanging process. Humidification is necessary to prevent hypothermia, disruption of the airway epithelium, bronchospasm, atelectasis, and airway obstruction [14]. Moreover, a continuous loss of moisture and heat occurs during prolonged mechanical ventilation with poorly-conditioned inspired gas and predisposes to airway damage. Inadequate humidification and heating of the inspired gas mixture promotes mucosal damage (destruction of cilia and mucous glands). During normal respiration, humidity in the trachea can range from 36 to 40 mg/L, and the optimal moisture concentration beyond the carina approximates 44 mg/L (100% relative humidity (RH) at 37°C). When providing active humidification to patients who are invasively ventilated, it is suggested that the device provides a humidity level between 33 mgH_2O/L and 44 mgH_2O/L, and a gas temperature between 34°C and 41°C with a RH of 100% in order to prevent the drying of secretions in the artificial airway.

Active humidification through a heated humidifier (HH) and passive humidification through a heat and moisture exchanger (HME, 'artificial nose'), are available for warming and humidifying gases delivered to mechanically-ventilated patients. HMEs operate passively by storing heat and moisture from the patient's exhaled gas and releasing it to the inhalation gas stream.

Very recently, recommendations regarding gas humidification have been published that follow the grading of recommendations assessment, development, and evaluation (GRADE) system for scoring evidence quality [15].

- Humidification is recommended for every patient receiving invasive mechanical ventilation.
- Active humidification is suggested for non-invasive mechanical ventilation, as it may improve secretion mobility and comfort.
- When providing active humidification to patients who are invasively ventilated, it is suggested that the device provides a humidity level between 33 mgH_2O/L and 44 mgH_2O/L, and gas temperature between 34°C and 41°C at the circuit Y-piece, with a relative humidity of 100%.
- When providing passive humidification to patients undergoing invasive mechanical ventilation, it is suggested that the HME provide a minimum of 30 mgH_2O/L.
- Passive humidification is not recommended for non-invasive mechanical ventilation.
- When providing humidification to patients with low tidal volumes, such as when lung-protective ventilation strategies are used, HMEs are not recommended because they provide additional dead space, which can increase the ventilation requirement and $PaCO_2$.
- It is suggested that HMEs are not useful as a prevention strategy for ventilator-associated pneumonia.

Box 119.2 Prevention of sputum retention and atelectasis

- *Active humidification:* humidity level between 33 mgH_2O/L and 44 mgH_2O/L, and gas temperature between 34°C and 41°C.
- Adequate hydration to thin the secretions.
- Oxygen has a drying effect.
- Adequate analgesia.
- *Physiotherapy:* active cycle of breathing, body positioning and manual techniques (i.e. percussion, shaking and vibrations).

Supplemental strategies to prevent sputum retention include hydration, dry mouth prevention, oxygen modulation, adequate pain relief, and timely airway suctioning [16]. Adequate **hydration** helps to thin and lubricate secretions, making them easier for the patient to expectorate. Damage to the cilia can be prevented by **humidification** of the respiratory tract via humidifiers and nebulizers.

Because **oxygen** has a drying effect, sufficient humidification of high inspired concentrations of oxygen is important, especially if there is an existing lung disease. Nebulized β-2-adrenoceptor agonists, such as salbutamol, and mucolytics, such as recombinant human deoxyribonuclease (Dornase alfa) have been shown to increase mucociliary clearance. It is well known that **smokers** with a history of ischaemic heart disease and inadequate pain control are at high risk of developing sputum retention. There is also a strong risk of sputum retention in an individual with a history of chronic obstructive pulmonary disease and/or cerebrovascular accident. Adequate **analgesia** is usually needed to facilitate effective coughing during the post-operative period. Other post-operative pain factors that may limit a patient's ability to cough effectively include decreased levels of consciousness, narcotic analgesics, abnormal chest wall compliance, vocal cord dysfunction, expiratory muscle weakness, and obstructed airflow,

Physiotherapy can help patients to remove excess secretions by using active exercise to enhance mucociliary clearance. Apart from cough encouragement, active breathing, body positioning, and vibration techniques (i.e. manual percussion, chest wall shaking, and high frequency airway vibration with asymmetrical flow patterns) can be used to loosen secretions and, thus, facilitate expectoration. Other devices that manipulate the airway with positive pressure, including the positive expiratory pressure masks, intermittent positive pressure breathing, and insufflation-exsufflation (assisted coughing) can also be used [17] (Box 119.2). Manual hyperinflation techniques may be required with some intubated patients.

Airway suctioning is usually necessary to clear secretions from patients with an endotracheal tube or tracheostomy. However, a suctioning manoeuvre should only be used when other efforts to clear secretions have failed. It is an unpleasant procedure for the patient and can cause damage to the tracheal epithelium. Deleterious effects can be minimized by using an appropriate suction catheter and suction technique. Unless unavoidable, suctioning should not be performed on patients with stridor, severe bronchospasm, clotting disorders, pulmonary oedema, and recent pneumonectomy or oesophagectomy [18]. In theory, coughing stimulated by suctioning may promote propagation of mobile inflammatory biofluids from diseased zones into previously unaffected sectors of the lung [19].

CHAPTER 120

Lung recruitment techniques in the ICU

Thomas Kiss and Paolo Pelosi

Key points

- 'Recruitment manoeuvre' stands for a process of intentional transient increase of transpulmonary pressure above values used during regular mechanical ventilation, whose main objective is to open unstable distal airways and/or airless alveoli.
- The effectiveness of recruitment manoeuvres is probably related to the nature, phase, and/or extent of the lung injury, as well as the recruitment technique itself.
- Recruitment manoeuvres can be performed in several different ways. Today, the most relevant recruitment manoeuvres in terms of clinical applicability in the intensive care unit (ICU) are sustained inflation manoeuvres, high pressure-controlled ventilation, incremental PEEP, and intermittent sighs.
- Anaesthesiologists commonly perform bag squeezing as a recruitment manoeuvre, as it is simple to perform during surgery. This procedure closely resembles the sustained inflation technique.
- Ventilation with variable tidal volumes, may be a simple and interesting alternative for lung recruitment in the ICU, but clinical evidence has to be demonstrated yet.

Introduction

Protective mechanical ventilation (MV) represents one of the most important interventions in patients suffering from the acute respiratory distress syndrome (ARDS). Albeit MV is not curative, it is useful for reducing the work of breathing and maintaining an adequate gas exchange.

Lung recruitment manoeuvres (RMs) have been suggested as a means of homogenizing the lung structure and distribution of the mechanical stress across the lungs. Such effects of RMs can be achieved provided enough pressure is applied for sufficient time at the airways, and maintained if adequate levels of positive end expiratory pressure (PEEP) are used. When RMs effectively open atelectatic tissue, shear stress and cyclic collapse/reopening are reduced. Also, if an increased end-expiratory lung volume is achieved after RMs, the applied tidal volume (V_T) will be distributed across a larger lung surface, resulting in reduced regional dynamic stress and strain.

Results from clinical trials have suggested that RMs are useful to revert life-threatening hypoxaemia and derecruitment resulting from suctioning procedures of the airways, as well as disconnection from the mechanical ventilator. Nevertheless, no study has shown that RMs reduce mortality or the duration of mechanical ventilation in patients with ARDS. In contrast, there is increasing clinical evidence that low V_T in combination with RMs and adequate levels of PEEP are useful for reducing the incidence of post-operative pulmonary complications in patients undergoing open abdominal surgery. However, those beneficial effects cannot be ascribed solely to RMs themselves.

This chapter aims at:

- Defining RMs and describing host-dependent factors that may influence their performance.
- Describing established RMs and their functional and biological impact.
- Presenting experimental data on new promising forms of RMs that may become relevant in clinical practice.

Definition of recruitment manoeuvre

RM stands for a process of intentional transient increase of transpulmonary pressure (P_L) above values used during regular mechanical ventilation, whose main objective is to open unstable distal airways and/or airless alveoli. RM is also often termed *alveolar recruitment manoeuvre*, since opening of collapsed alveolar units is believed to represent the major effect of a RM. It must be kept in mind, however, that the existence of alveoli closure, and obviously also its potential reversal by RMs, in ARDS has been questioned. It has been shown in dogs with experimental ARDS induced by intravenous administration of oleic acid, that the alveoli of dependent zones were not collapsed, but rather filled with exudate. Whereas the end expiratory lung volume did not change after RMs and higher PEEP, the lung function improved importantly. Thus, it is possible that RMs exert part of their effects through redistribution of intra-alveolar fluid across lung units.

While non-supported spontaneous breathing, patient position, and higher levels of PEEP alone can increase the regional P_L and result in opening of lung units, they cannot be termed RMs in a strict sense.

Factors influencing the efficacy of recruitment manoeuvres

The lung response to RMs is determined mainly by host-dependent factors—cause and severity of lung injury and position of the lungs with respect to the gravity gradient.

Origin and severity of lung injury

ARDS is the result of different insults to the lungs. There are two major types of ARDS, namely primary (also known as

direct or pulmonary) and secondary (also known as indirect or extra-pulmonary) ARDS. The structure that is primarily damaged in pulmonary ARDS is the alveolar epithelium, and its typical hallmark is filling of the intra-alveolar space by oedema, fibrin, and neutrophilic aggregates. In extrapulmonary ARDS, distal organs release pro-inflammatory mediators into the bloodstream. Those mediators initiate the damage of the pulmonary capillary endothelium, leading to microvessel congestion and interstitial oedema with comparatively less flooding of intra-alveolar space.

There is a considerable body of evidence showing that the type of lung injury in ARDS importantly influences the performance of RMs. In an investigation on three models of ARDS in dogs, namely saline lung lavage (surfactant depletion), intravenous oleic acid administration and pneumonia, RMs were particularly effective in improving oxygenation and increasing the end-expiratory lung volume after surfactant depletion. In contrast, animals with pneumonia showed almost no improvement in lung function following RMs and high PEEP. Riva et al. compared the effects of a RM in models of pulmonary and extrapulmonary ARDS induced by intratracheal and intraperitoneal instillation of *Escherichia coli* lipopolysaccharide with similar transpulmonary pressures. They found that the RM was more effective for opening collapsed alveoli in extrapulmonary compared with pulmonary ARDS, improving lung mechanics and oxygenation with limited damage to alveolar epithelium. In contrast, Grasso et al. reported that RMs combined with high PEEP levels can lead to hyperinflation due to inhomogeneities in the lung parenchyma, independent from the origin of the injury insult (pulmonary or extrapulmonary).

In patients suffering from ARDS, Gattinoni and colleagues found that RMs are more efficient in severe, compared with non-severe ARDS. Using whole lung computed tomography, those authors showed that the reduction in non-aerated and poorly aerated lung tissue was more pronounced in those patients showing the most severe gas exchange and lung tissue abnormalities.

Positioning

Prone positioning may not only contribute to the success of RMs, but can be considered itself to be a RM. During prone position, the transpulmonary pressure in dorsal lung areas increases, opening alveoli and improving gas exchange. Some authors reported that in healthy, as well as lung-injured animals, mechanical ventilation leading to lung over distension and cyclic collapse/reopening is associated with less extensive histological change in dorsal regions when animals are in prone, as compared with supine position. It is still unclear if body position affects the distribution of lung injury, but the development of ventilator-induced lung injury (VILI) due to excessively high V_T seems to be delayed during prone compared with supine position.

In 2013, Guerin et al. demonstrated in a multicentre trial that the early application of prone-positioning sessions of at least 16 hours significantly decreased 90-day mortality in patients with severe ARDS.

Types of recruitment manoeuvre

Intensive care unit setting

RMs can be performed in several different ways. Today, the most relevant RMs in terms of clinical applicability are sustained inflation (SI) manoeuvres, high pressure-controlled ventilation, incremental PEEP, and intermittent sighs. However, the best way to perform RMs has not been established and, in fact, it may vary according to specific circumstances.

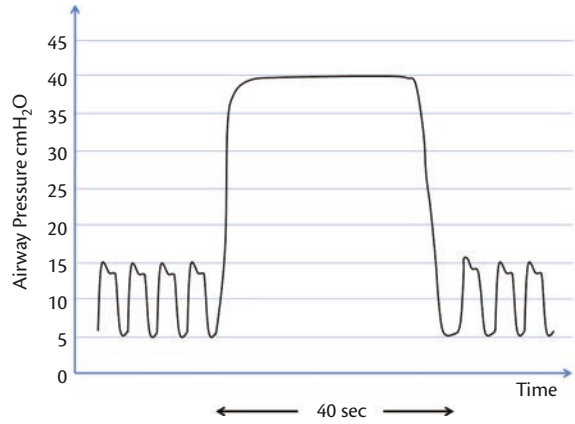

Fig. 120.1 Sustained inflation manoeuvre, with respiratory system plateau pressure of 40 cmH_2O for 40 seconds.

The SI is by far the most frequently used RM. Commonly, it is performed by application of a continuous pressure of ≈40 cmH_2O for up to 60 seconds at the airways [1], as illustrated in Fig. 120.1. The SI is effective in decreasing lung atelectasis, improving lung functional variables of oxygenation and respiratory mechanics, and also counteracting endotracheal suctioning-induced alveolar derecruitment [2]. However, the efficacy of SI has been questioned and other studies showed that SI may be ineffective [3], short-lived, associated with circulatory impairment [4], increased risk of baro-/volutrauma, reduced net alveolar fluid clearance, and even worsened oxygenation [5].

Due to those side effects, researchers developed other types of RMs, among which the most important are:

- Incrementally increased driving pressure at a fixed level of PEEP (Fig. 120.2) [6].

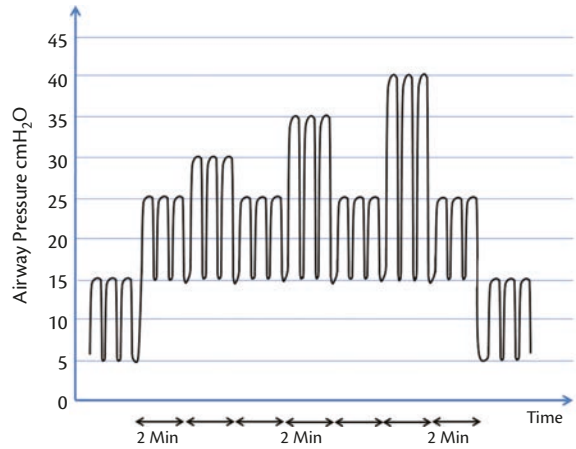

Fig. 120.2 Prolonged recruitment manoeuvre (PRM) consisting of progressively increase of driving pressure levels in 2-minute steps of 5 cmH_2O, with a fixed PEEP of 15 cmH_2O in pressure-controlled mode (frequency 10/min).
Adapted from *Respiratory Physiology and Neurobiology*, **169**(3), Rzezinski AF et al., 'Prolonged recruitment manoeuvre improves lung function with less ultrastructural damage in experimental mild acute lung injury', pp. 271–81, Copyright 2009, with permission from Elsevier.

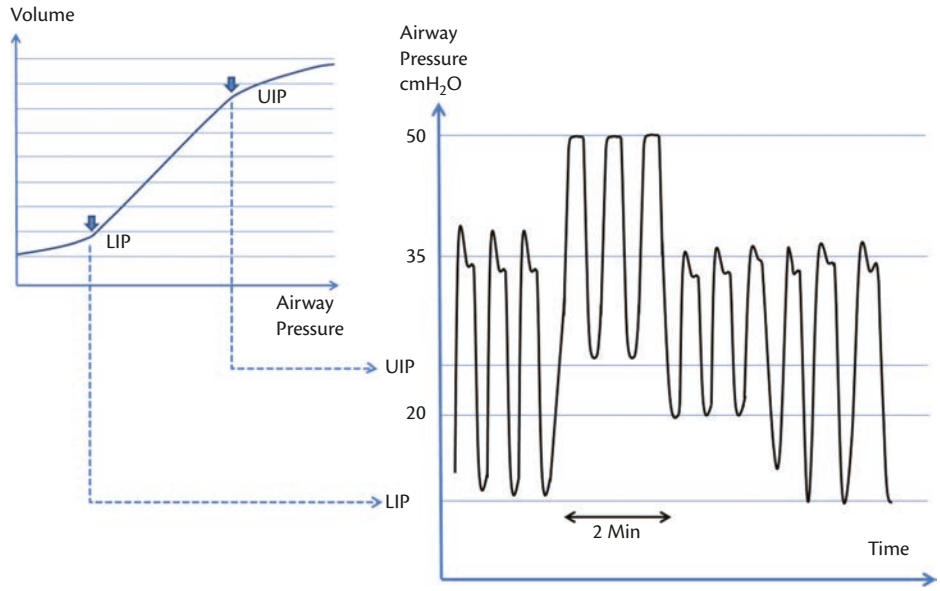

Fig. 120.3 Recruitment manoeuvre (RM) according to pressure-volume (P–V) curve of the respiratory system [3]. P–V curve, lower and upper inflection point (lower inflection point (LIP) and upper inflection point (UIP), respectively) are obtained at zero end-expiratory pressure. Patients are ventilated in volume control mode with tidal volume 8 mL/kg (predicted body weight) and positive end-expiratory pressure (PEEP) 3–4 cmH_2O higher than the LIP. This RM is performed in pressure control ventilation with a peak pressure of 50 cmH_2O and a PEEP level 3 cmH_2O higher than the UIP for 2 minutes. Peak pressure and PEEP are then gradually decreased to 35 and 20 cmH_2O, respectively. Following that, the ventilation mode is switched from pressure–volume controlled ventilation mode, and the PEEP is decreased in 2-cmH_2O steps until the PEEP level before RM is reached. After the RM, tidal volume and PEEP are equal to the values set before RM.

- PCV applied with PEEP above the upper inflection point of the pressure–volume curve of the respiratory system, followed by change to VCV with stepwise decrease of PEEP and inspiratory plateau pressure below the upper inflection point (Fig. 120.3) [3].
- Prolonged lower pressure recruitment manoeuvre with PEEP elevation up to 15 cmH_2O and end-inspiratory pauses for 7 seconds twice per minute over a 15-minute session (Fig. 120.4) [7].
- Intermittent sighs to reach a specific plateau pressure in volume or pressure control mode (Fig. 120.5) [8].
- Long slow increase in inspiratory pressure up to 40 cmH_2O (so-called 'RAMP' manoeuvre) (Fig. 120.6) [9].
- 'Maximum recruitment strategy' (MRS) according to Borges et al. [10], and adapted by Matos et al. (Fig. 120.7) [11].

Among those manoeuvres, the MRS is probably the one with the highest clinical impact. This manoeuvre was described in detail by Borges et al. [10], who treated 26 patients with sequential increments in PEEP at constant driving pressure until PaO_2 + $PaCO_2$ ≥ 400 mmHg. During the MRS, PEEP values of 45 cmH_2O and inspiratory peak pressures as high as 60 cmH_2O can be achieved. The major side effects of the MRS are transient haemodynamic depression and hypercapnia, major clinical consequences, e.g.

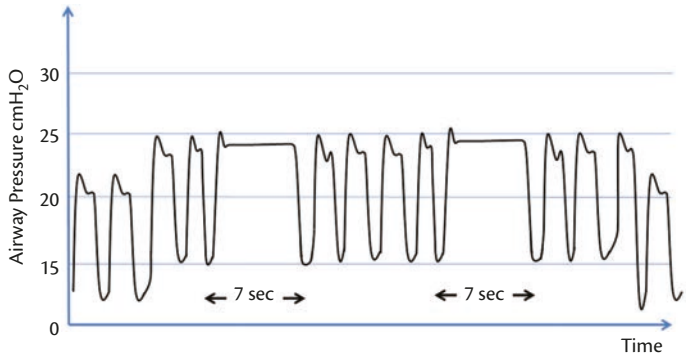

Fig. 120.4 Recruitment manoeuvre (RM) according to Odenstedt [7]. Basal ventilation (BV) during the recruitment protocol is delivered with volume controlled ventilation (tidal volume of 10 mL/kg, respiratory rate of 20/min, inspiratory to expiratory ratio (I:E) of 1:2 and inspiratory oxygen fraction of 0.5). The RM consists of PEEP increase to 15 cmH_2O, while maintaining the other ventilator settings, and end-inspiratory pauses of 7 seconds at a rate of 2/min, over a period of 15 minutes.

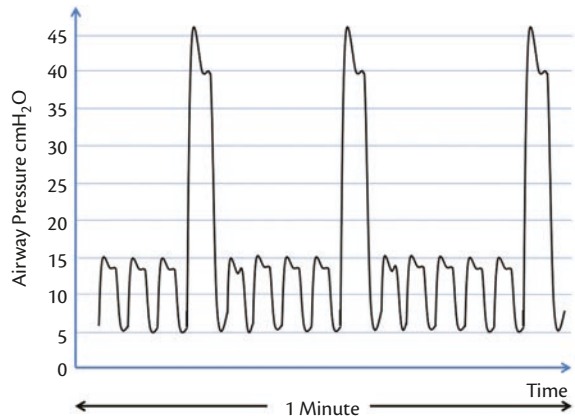

Fig. 120.5 Recruitment manoeuvres according to Steimback [8]. Baseline ventilation is delivered with volume controlled ventilation (tidal volume of 4 mL/kg, positive end-expiratory pressure of 5 cmH_2O). Sighs with inspiratory plateau pressure of 40 cmH_2O are delivered in the volume control mode, 3 times per minute.

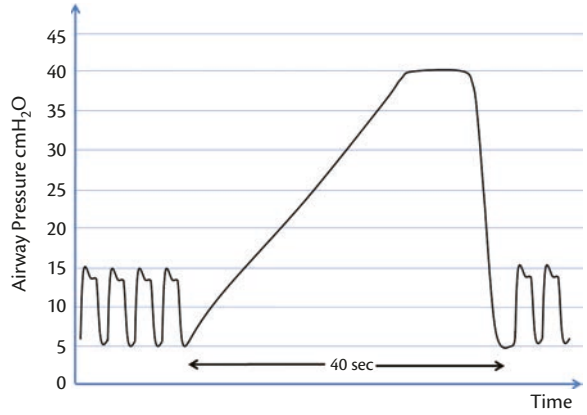

Fig. 120.6 Recruitment manoeuvre 'RAMP' consisting of slow and continuous increase of the airway pressure up to 40 cmH_2O, over a period of 40 seconds, according to Riva [9].
Data from Riva DR et al., 'Recruitment maneuver: RAMP versus CPAP pressure profile in a model of acute lung injury', *Respiratory Physiology and Neurobiology*, 2009, **169**(1), pp. 62–8.

pneumothorax, have not been observed. Recently, de Matos et al. [11] enhanced MRS by combining Borges' recruitment phase with a PEEP titration phase consisting of decremental PEEP steps from 25 to 10 cmH_2O. They concluded that MRS successfully recruited non-aerated lung areas for extended periods of time. These authors also did not observe barotrauma, nor significant clinical complications despite peak airway pressures of up to 60 cmH_2O during the MRS, mean titrated PEEP of 25 cmH_2O, and resulting inspiratory plateau pressures as high as 40 cmH_2O in the first day following the MRS.

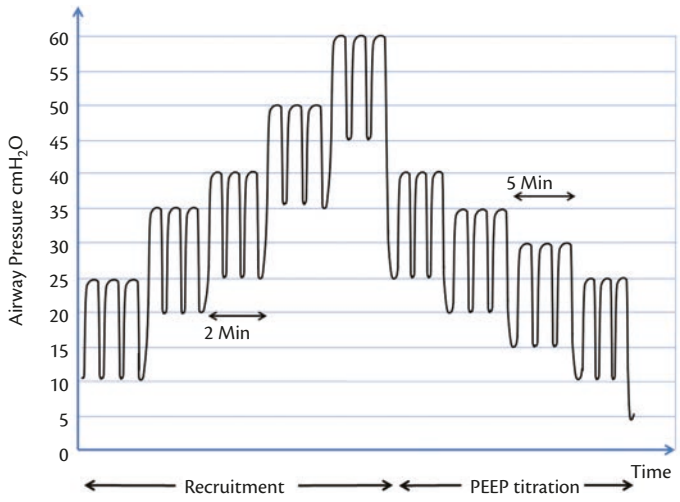

Fig. 120.7 Two-phase maximum recruitment strategy (MRS) according to Borges et al. [10] and modified from Matos et al. [11]). The first phase (recruitment phase) consists of 2-minute steps of tidal ventilation with pressure-controlled ventilation, fixed driving pressure of 15 cmH_2O, respiratory rate of 10–15/min, inspiratory: expiratory ratio of 1:1 and increments in PEEP levels of 5 cmH_2O up to 45 cmH_2O. During the second phase (PEEP titration phase), the PEEP is decreased to 25 cmH_2O and then in steps of 5 cmH_2O, whereby each step lasts 5 minutes.

Medicine*, 2006, 174, 3, pp. 268–278.

Operation room setting

There is a robust physiological rationale supporting the use of RMs for reversing lung collapse during general anaesthesia. Loss of lung aeration in dorsal lung zones is well documented in general anaesthesia, and invariably related to the development of atelectasis [12].

Anaesthesiologists more commonly perform RMs by squeezing the anaesthesia bag, in a procedure that closely resembles SI. Bag squeezing is relatively easy and simple to perform, but keeping the airway pressure, while fresh gas flows from the anaesthesia machine is tricky, even using pressure-release valves. Furthermore, when switching from manual to controlled ventilation the pressure in the anaesthesia circuit may drop to zero, leading to derecruitment. Certainly, SI can be applied by using continuous airway pressure (CPAP), but this mode is not present in most anaesthesia ventilators. Thus, during general anaesthesia, RMs are more easily conducted under tidal ventilation, mainly during volume controlled ventilation (VCV).

Fig. 120.8 illustrates two strategies for recruiting the lungs in the VCV mode. In the first variant, the PEEP is increased stepwise until the desired PEEP and inspiratory plateau pressure levels are achieved. Following that, the PEEP is reduced in steps of 2–5 cmH_2O to determine which PEEP value is associated with the lowest static elastance of the respiratory system (decremental PEEP trial). In the second variant, the PEEP is increased to 10–15 cmH_2O and maintained constant thereafter. The respiratory rate is reduced to 6–10/min, while V_T is increased stepwise by 2–4 mL/kg until an inspiratory plateau pressure of 30–40 cmH_2O is achieved. Finally, an adequate and protective V_T is set at the ventilator. This manoeuvre has been used successfully in a multicentre randomized clinical trial on the intra-operative use of PEEP [13]. Furthermore, using a similar RM and higher PEEP levels in patients undergoing open abdominal surgery, Severgnini et al. reported an improved lung function as long as 5 days after surgery, compared with a ventilation strategy without RMs and low PEEP.

Shall the anaesthesia ventilator not be able to provide higher PEEP values, the V_T or the driving pressure can be titrated to achieve the desired opening pressure target during a few breaths. The appropriate target must take into account the elastance of the chest wall, which will reduce the effective transpulmonary pressure. In patients with non-injured lungs and normal chest wall elastance, airway pressures of 40 cmH_2O are enough to recruit the lungs (14), but morbidly obese patients may require up to 60 cmH_2O (15).

Impact of recruitment manoeuvres on ventilator-induced lung injury

While much is known about the impact of RMs on lung mechanics and gas exchange, only a few studies addressed their effects on VILI. Steimback et al. [8] evaluated the effects of frequency and inspiratory plateau pressure (P_{plat}) during RMs on lung and distal organs in rats with acute lung injury (ALI) induced by paraquat. They observed that, although a RM with standard sigh (180 sighs/hour and P_{plat} = 40 cmH_2O) improved oxygenation, and decreased $PaCO_2$, lung elastance, as well as alveolar collapse, it resulted in hyperinflation, ultrastructural changes in alveolar capillary membrane, and increased lung and kidney epithelial cell apoptosis.

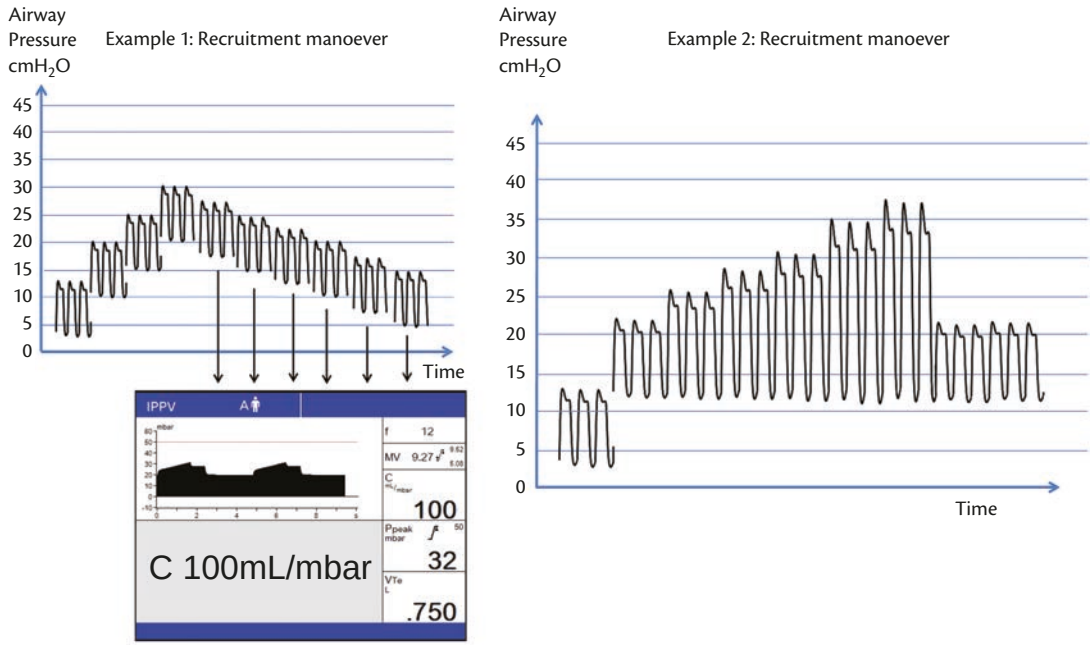

Fig. 120.8 Recruitment manoeuvres that can be performed with the anaesthesia ventilator. The manoeuvres are performed under volume controlled ventilation and FiO_2 of 1.0. The tidal volume is set at 10 mL/kg and the inspiratory to expiratory ratio (I:E) ratio at 1:1. In the first variant (left panel) the positive end-expiratory pressure (PEEP) is increased by 5 cmH_2O every 3–5 breaths, up to 20 cmH_2O. Following that, the PEEP is decreased in steps of 2–3 cmH_2O and the respiratory system compliance is measured at each step (decremental PEEP trial). The lungs are re-expanded in the same way and the PEEP of highest respiratory system compliance set at the ventilator. In the second variant (right panel), the PEEP is increased to 10–15 cmH_2O and maintained constant. The tidal volume is increased in steps of 2–4 mL/kg until an inspiratory plateau pressure of 30–40 cmH_2O is achieved. Finally, the tidal volume is set again at the initial value.
Data from Hemmes SN et al., 'Rationale and study design of PROVHILO - a worldwide multicenter randomized controlled trial on protective ventilation during general anesthesia for open abdominal surgery', *Trials*, 2011, 12, p. 111.

On the other hand, the reduction of the sigh frequency from 180 to 10 sighs/hour at the same P_{plat} (40 cmH_2O) diminished lung elastance and improved oxygenation, with a marked decrease in alveolar hyperinflation, and apoptosis in lung and kidney epithelial cells. The association of this sigh frequency with a lower P_{plat} of 20 cmH_2O worsened lung elastance, histology and oxygenation and increased $PaCO_2$. We speculate that there is a sigh frequency threshold beyond which the intrinsic reparative properties of the lung epithelium are overwhelmed. Although the optimal sigh frequency may be different in healthy and ALI animals/patients, our results suggest that RMs with high frequency or low plateau pressure should be avoided. Theoretically, a RM using gradual inflation of the lungs might yield a more homogeneous distribution of pressure throughout the lung parenchyma, avoiding repeated manoeuvres and reducing lung stretch while allowing effective gas exchange.

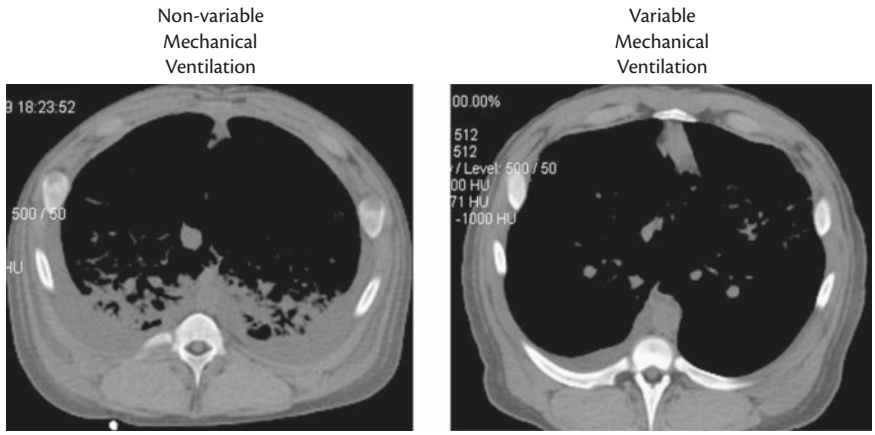

Fig. 120.9 Computed tomography scans of two pigs with lung injury induced by saline lung lavage and higher tidal volumes. Left: after approximately 7 hours of protective non-variable mechanical ventilation according to the ARDS Network protocol. Right: after approximately 7 hours of protective variable mechanical ventilation with higher levels of PEEP. Note that the animal treated with non-variable mechanical ventilation presented large areas of non-aeration in dependent dorsal zones, whereas the animal treated with variable mechanical ventilation did not, suggesting full and stable lung recruitment through variable tidal volumes combined with higher PEEP.

Riva et al. [9] compared the effects of SI using rapid high recruitment pressure at 40 cmH_2O for 40 s with the so-called RAMP manoeuvre, a slow increase in airway pressure up to 40 cmH_2O during 40 seconds in paraquat-induced ALI. They reported that the RAMP manoeuvre improved lung mechanics with less alveolar stress. Among other RMs proposed as alternatives to SI, RAMP may differ according to the time of application and mean airway pressure.

Variable mechanical ventilation as recruitment manoeuvre

Variable mechanical ventilation is characterized by breath-by-breath changes in airway pressures and V_T. Variable mechanical ventilation has been shown to improve oxygenation, respiratory mechanics, and reduce diffuse alveolar damage in experimental models of ARDS [16]. Among the possible mechanisms of variable mechanical ventilation, lung recruitment is likely the most important one.

The use of variable V_T during volume controlled ventilation significantly improved lung function in experimental models of atelectasis [17]. In patients during surgery for repair of abdominal aorta aneurysms, variable mechanical ventilation improved arterial oxygenation and compliance of the respiratory system, as compared with non-variable mechanical ventilation [18].

Experimental evidence suggests that variable mechanical ventilation is superior to conventional RMs regarding the efficiency of opening and keeping lung units open. Variable ventilation improved recruitment in both normal and injured lungs in mice [19]. Fig. 120.9 illustrates the effects of variable mechanical ventilation on lung aeration in a model of experimental ARDS.

Despite the large evidence regarding the potential of variable ventilation to promote lung recruitment, this mechanism is less probable during assisted ventilation. In experimental ALI, it has been shown that variable pressure support ventilation improved oxygenation [20], but this effect was mainly related to lower mean airway pressures and redistribution of pulmonary blood flow towards better ventilated lung zones.

Conclusion

The use of RMs in patients suffering from ARDS, as well as in patients undergoing surgery under general anaesthesia, remains controversial. The effectiveness of such manoeuvres is likely related to the nature, phase, and/or extent of the lung injury, as well as the recruitment technique itself. The SI represents the most commonly used RM, but it may lead to a paradoxical impairment of oxygenation due to redistribution of pulmonary blood flow and also to circulatory depression. With the purpose of reducing such side-effects, several RMs have been suggested. In order to be effective, RMs must take different aspects into account, namely the level of the recruiting pressure, the time, as well as the pattern/frequency with which this pressure is applied to achieve recruitment. Besides the SI, a couple of RMs that seem particularly interesting for use in clinical practice on the ICU are:

- Incrementally increased driving pressure at a fixed level of PEEP.
- PCV applied with PEEP above the upper inflection point of the pressure-volume curve of the respiratory system, followed by change to VCV with stepwise decrease of PEEP and inspiratory plateau pressure below the upper inflection point.
- Prolonged lower pressure recruitment manoeuvre with PEEP elevation up to 15 cmH_2O and end-inspiratory pauses for 7 seconds twice per minute during a 15-minute period.
- Intermittent sighs to reach a specific plateau pressure in volume or pressure control mode.
- Long slow increase in inspiratory pressure up to 40 cmH_2O.
- 'Maximum recruitment strategy'.

In the operation room, the RM that can be performed with all anaesthesia ventilators consists of a PEEP increase to 10–15 cmH_2O, a reduction of the respiratory rate to 6–10/min, and a stepwise increase of V_T by 2–4 mL/kg until an inspiratory plateau pressure of 30–40 cmH_2O is achieved. The use of variable ventilation, i.e. application of random variable tidal volumes, may also prove a simple and interesting alternative for lung recruitment in the clinical scenario, mainly on the ICU. Clinical evidence suggests that the use of RMs is useful as a rescue strategy for hypoxaemia, but studies on the impact of RMs on morbidity and mortality in intensive care, as well as surgical patients are warranted.

CHAPTER 121

Chest physiotherapy and tracheobronchial suction in the ICU

Gianluigi Li Bassi and J. D. Marti

Key points

- Ventilated patients often retain respiratory secretions because of hypersecretion, impaired clearance, and immobilization.
- Several clinical studies that evaluated the role of chest physiotherapy in the intensive care unit have been limited by inappropriate outcomes, accurate definitions of complications, and diversity in the applied methods. Thus, well-designed clinical studies are warranted to substantiate benefits associated with routine use of chest physiotherapy techniques.
- Posture change, chest percussion, incentive spirometry, and manual hyperinflation are the most common techniques applied in the intensive care unit to improve mucus clearance and prevent pulmonary complications.
- In intubated or tracheostomized patients, endotracheal suctioning is essential to remove accumulated mucus within the large airways.
- Endotracheal suctioning should be performed by qualified personnel with extensive training in recognizing indications, properly perform the procedure, and promptly respond to any potential complication.

Introduction

In mechanically-ventilated patients, chest physiotherapy and tracheobronchial suction are essential procedures to maintain airway patency and prevent pulmonary complications. Patients on invasive mechanical ventilation commonly present retention of airway secretions, which constitutes a daily challenge for respiratory therapists, nurses, and physicians.

Mucus clearance

The airway lining fluid is a biphasic layer, with antimicrobial and immunomodulatory properties, formed by a gel-phase (mucus), and a low-viscosity inner layer (sol-phase), which mainly provides lubrication for ciliary beating. Mucus production in healthy subjects is approximately 10–100 mL/day.

Mucociliary clearance

Mucociliary clearance is a primary defence mechanisms of the respiratory system [1]. Each ciliated cell has approximately 200 cilia on its surface, which move within the periciliary liquid layer at 8–15 Hz. Mucus overlying the periciliary fluid is transported by the outermost parts of the cilia [2]. Mucociliary clearance rates range between 4 and 20 mm/min.

Mucus clearance via two-phase gas–liquid mechanism

During mechanical ventilation, inspiratory and expiratory airflows interact with mucus. As a result, mucus is propelled in the direction of the highest airflow via the two-phase gas–liquid flow mechanism [3,4]. The majority of chest physiotherapy techniques rely on this mechanism to clear mucus. The critical factors necessary to move mucus through airflows are:

- The shear stress exerted by the airflow on the liquid layer.
- The ratio between thickness of the mucus layer and the airway diameter.
- The rheological properties of secretions.
- Gravity [3,4].

Inspiratory and expiratory airflows exert opposite shear forces on the mucus layer [5]. The difference between inspiratory and expiratory flow rate can be modulated by adjusting ventilator parameters that affect the inspiratory flow, i.e. duty cycle [6,7]. Additionally, in patients, positioned in the semirecumbent position, mucus transport mainly depends on a balance between the airflow shear forces on the liquid layer and gravitational force.

Mucus clearance in critically-ill patients

Mucus retention is highly prevalent in mechanically ventilated patients because mucociliary velocity is drastically reduced [8], and the inflated endotracheal tube cuff averts mucus clearance. Therefore, mucus accrues [7], unless it is aspirated through suctioning. Contributing factors to mucus retention are hypersecretion of mucus, immobilization, weak cough, and muscle weakness.

Chest physiotherapy

Several chest physiotherapy techniques are routinely applied in critically-ill patients [9] (Table 121.1). The role of chest physiotherapy in the intensive care unit (ICU) to mobilize secretions and improve patient's outcomes lacks of compelling evidence [10,11]. Additionally, bedside techniques to routinely monitor mucus

Table 121.1 Indications for different physiotherapy regimes

	Specific indications	Absolute contraindications	Relative contraindications	Scientific evidence to support the routine use in ICU*	Frequency of treatment	Duration of treatment
Posture change	Deep sedation Neuromuscular disease Pharmacological paralysis	Unstabilized spine Fractures	Rib fractures Spine fractures	Sufficient	Every 1–2 hours	NA
Postural drainage	Lung atelectasis Unilateral lung injury	Increased intracranial pressure Unstabilized spine Fractures	Spine fractures Haemodynamic instability Respiratory instability Obesity	Insufficient	Every 4–6 hours	30 minutes to 12 hours
Percussion	Lung atelectasis Presence of thick mucus Deep sedation Neuromuscular disease Pharmacological paralysis	Bone diseases associated with extremely fragile bones	Bronchospasm (consider bronchodilators before and following the intervention) Rib fractures Subcutaneous emphysema Recent thoracic surgery Coagulopathy or thrombocytopenia	Insufficient	Every 4–6 hours	15–30 minutes
Assisted high-frequency airway clearance techniques	Cystic fibrosis Chronic obstructive pulmonary disease Bronchiectasis	NA	Bronchospasm Rib fractures Subcutaneous emphysema Recent thoracic surgery	Insufficient	Every 6 hours	20–30 minutes
Forced expiratory technique	Neuromuscular disease Slight sedation	Untreated pneumothorax	Recent abdominal surgery Recent thoracic surgery Deep sedation Increased intracranial pressure Active tuberculosis Pneumothorax Bullous emphysema Coagulopathy or thrombocytopenia	Insufficient	Every 2–4 h	5–10 minutes
Cough-assist device	Neuromuscular disease	Untreated pneumothorax	Pneumothorax Bullous emphysema. Recent thoracic surgery Increased intracranial pressure Coagulopathy or thrombocytopenia	Insufficient	Every 6 h	10 minutes
Incentive spirometry	Abdominal surgery Thoracic surgery Conscious patient	NA	Uncooperative patient Vital capacity less than 10 ml/kg	Insufficient	10 times every h	1 breath
Manual hyperinflation	Lung atelectasis Deep sedation Excessive mucus production Inefficient cough	Untreated pneumothorax	Haemodynamic instability Pneumothorax Bullous emphysema. Increased intracranial pressure	Insufficient	Every 6 hours	2–4 minutes
Manual ribcage compression	Lung atelectasis Inefficient cough	NA	Haemodynamic instability Pneumothorax Bullous emphysema. Increased intracranial pressure	Insufficient	Every 6 hours	15 minutes

*Although there is insufficient evidence to support routine clinical use of chest physiotherapy techniques in the intensive care unit, it is pivotal to identify patients at greater risk of pulmonary complications and to prescribe treatments on an individual basis.

ICU, intensive care unit; NA, not available.

clearance are not available. Thus, surrogate end points have been used in research, all of which increase the odds for negative studies and produce controversy in the field. Only qualified personnel with appropriate training should perform chest physiotherapy. Appropriate analgesia is essential throughout the interventions in order to ensure patient's comfort and efficacy of the intervention.

Posture change and postural mucus drainage

The deleterious effects of prolonged immobility have been extensively studied [12]. As a general rule, in ICU patients, changes in posture should be performed every 1 or 2 hours.

Postural mucus drainage therapy consists of placing atelectatic pulmonary segments in a position that allows drainage of mucus through gravity and redistribution of pulmonary ventilation. Postural drainage can be associated with other physiotherapy techniques to enhance benefits. The therapeutic indications must be carefully reviewed, due to the associated potential complications [13].

Percussion and high-frequency airway clearance techniques

Chest percussion and high-frequency airway clearance techniques cause a change in airways diameter and airflow, ultimately resulting in mobilization of secretions adherent to the bronchial walls. Preventive or curative percussion can be applied in intubated or tracheostomized patients [14]. Assisted high-frequency airway clearance techniques, through external devices such as the Percussionaire®, the Vest Airway Clearance System®, and the Hayek Oscillator System®, develop small airflow pulses that alter the rheological properties of mucus and enhance the expiratory-inspiratory flow bias [15]. Following extubation, their use can be indicated on a case-by-case basis in patients who regularly use these devices in out-of-hospital settings.

Directed cough and cough-assist devices

In patients with neuromuscular weakness, who present paradoxical abdominal outward motion during coughing, it is beneficial to compress the lower thorax and upper abdomen to improve peak cough expiratory airflow. Forced expiratory technique (FET), also called 'huffing', is indicated for patients, who present with compliant central airways that collapse during cough. FET consists of coughing efforts with an open glottis at mid- to low lung volume followed by ample ventilation. Huffing can also be applied in tracheally-intubated patients, exerting manual pressure to the thorax and epigastric zone during exhalation.

The mechanical insufflation–exsufflation is a technique applied through the CoughAssist In-Exsufflator (Respironics, Murrysville, Pennsylvania) to simulate cough. The device delivers a pressure-targeted lung insufflation. This is immediately followed by a forced exsufflation, applying negative pressure.

Incentive spirometry

Incentive spirometry (IS) is the most widely applied physiotherapy technique in surgical patients at risk of developing lung atelectasis. The evidence supporting its use is limited by heterogeneous techniques, inconsistent definitions of outcomes, and poor-quality trials. Thus, IS should be used within a well-organized post-surgical physiotherapy programme to accelerate lung recovery and avoid post-operative complications. The technique is best taught prior to surgery. Several volume- or flow-orientated IS are available, aimed at achieving a 1.5 L maximal inspiratory volume and 600–900 mL/sec inspiratory flow. Studies have shown that volume-orientated devices require less inspiratory efforts, generate greater diaphragmatic motion and higher tidal volumes [16]. Cough is essential to mobilize secretions following IS.

Manual hyperinflation

The goals of MH are mobilization of retained secretions, recruitment of atelectatic lung regions and improvement of gas exchange. MH is performed by disconnecting the patient from the ventilator and slowly insufflating a large tidal volume (up to 50% above baseline or up to 40 cmH_2O of inspiratory pressure), via a resuscitator bag. After an inspiratory hold, the circuitry pressure is quickly released in order to assure a high expiratory flow rate. The Mapleson-C circuit generates faster expiratory flow and improved mucus retrieval than do circuits with self-inflating bags [17]. During the procedure, in-line manometers should be used to avoid injurious airway pressures.

Manual rib-cage compression

Manual rib-cage compression (MRCC) technique consists of gentle compression of the rib cage during the expiratory phase and release from the compression at the end of the expiration.

Tracheobronchial suctioning

Box 121.1 details tracheobronchial suctioning indications and methods.

Box 121.1 Tracheobronchial suction

Potential indicators for endotracheal suctioning

- Visible secretions within the artificial airway.
- Dyspnoea or apparent increased work of breathing.
- Pathological sounds (i.e. rhonchi, coarse and gurgling) heard *via* a stethoscope over the trachea.
- Progressive pulse oxymetry desaturation not otherwise explained.
- Increased peak inspiratory pressure in volume controlled MV or decreased V_T in pressure-controlled MV.
- Saw-tooth pattern identified at the real-time flow-volume loop.

Preparation prior endotracheal suctioning

Patient preparation

- In patient on MV, heart rate, pulse oximetry, arterial pressure, and in specific cases, intracranial pressure, should be monitored throughout the procedure.
- If patient is conscious explain the procedure.
- The use of saline to hydrate inspissated secretions and centralize secretions through cough lacks of clear evidence. If secretions appear dehydrated check if humidification of inspired gases is appropriate
- Hyperoxygenate for 120 seconds using in adults FiO_2 of 100 and a 10% increase from baseline in infants. Of note, several ventilators now provide a single working control for suction support.

Operator preparation

- Wash hands.
- Wear disposable apron and protector visor, particularly during open suctioning.
- Wear a sterile glove on the hand manipulating the catheter and a non-sterile glove on the other hand.
- During open suctioning, retrieve the catheter from the sleeve and hold it. In particular, avoid manipulation of the distal catheter tip.
- Connect the catheter to suction tubing.
- During closed or quasi-closed suctioning, the ventilator should be allowed to trigger to provide gas in response to negative pressure.

Equipment

- Consider closed suctioning system (or swivel connector) in patients with severe respiratory disease requiring high level of PEEP and FIO_2.
- Ratio of catheter outer diameter/artificial airway internal diameter should be ≤0.7 in adults and ≤0.5 in children.
- Suction catheter diameter (Fr) = (Artificial airway internal diameter x 3)/2.
- Choose catheters with non-parallel lateral suction holes. In selected cases, a curved tipped catheter may be helpful to suction mucus within bronchi difficult to access.
- Prepare suction tubing.
- The level of vacuum should always be adjusted to the lowest level of vacuum that efficiently removes secretions. In general, vacuum ≤150 mmHg in adults and 80–100 mmHg in infants.

Procedure

- Insert the catheter into the artificial airway and advance its distal tip up to the proximal trachea.
- Intermittent suction should be applied through occlusion of the catheter suction control port.
- Withdraw suction catheter continuously rotating it.
- The procedure should last 15 seconds or less from catheter insertion.
- Check and appropriately treat any potential cardiovascular, pulmonary, and neurological complication throughout the procedure.

Follow-up

- Assess respiratory cardiovascular and neurologic parameters.
- Consider hyperoxygenation.
- Consider recruitment manoeuvre in selected patients with acute respiratory distress syndrome and acute lung injury.
- Rinse suction tubing and, in case of closed suctioning system, suction catheter.
- Dispose of the suction catheter apron and gloves into the proper containers.

Patient preparation

Adequate patient preparation is necessary to avoid complications. Patients commonly remember endotracheal suctioning as one of the most uncomfortable procedures throughout their stay in the ICU; thus, if the patient is conscious, the procedure should be overly explained. Additionally, suctioning should not be performed routinely to minimize the risk of unnecessary complications [18].

Material

Catheter

A larger catheter increases endotracheal tube resistance and facilitates loss of lung volume, because aspirated gas is not rapidly replaced by gas flowing through the endotracheal tube. In patients with thick secretions, catheters with larger and non-parallel side holes should be applied [19].

Closed versus open suctioning

Endotracheal suctioning can be performed either by disconnecting the patient from the ventilator (open suctioning) or through the use of a catheter in-line with the ventilatory circuit (closed suctioning). During closed suctioning, triggered ventilator autocycling should compensate for the loss of pressure. Studies suggest that closed suctioning is beneficial in patients with most severe lung failure [20]. A quasi–closed suctioning system, via a swivel adapter is a potential alternative.

Sterile water

The use of saline, instilled into the endotracheal tube before suctioning remains controversial. The main concern is that saline instillation, may drip into the lungs and cause adverse effects.

CHAPTER 122

Toilet bronchoscopy in the ICU

Gianluigi Li Bassi and Carles Agusti

Key points

- Toilet bronchoscopy should only be applied when other less invasive methods of secretion removal have failed to dislodge retained mucus and revert to pulmonary atelectasis.
- Toilet bronchoscopy is highly efficient when retained secretions are visible during the procedure, air-bronchograms are not present on the chest radiograph, and when indicated to reverse lobar atelectasis.
- Potential complications associated with toilet bronchoscopy comprise hypoxaemia, cardiac dysrhythmia, haemodynamic instability and pulmonary haemorrhage.
- Overall safety of the intervention is drastically enhanced through proper setting of the mechanical ventilator, adequate sedation and analgesia, and exhaustive monitoring of physiological parameters.
- Specific patient populations on non-invasive mechanical ventilation can also benefit from a bronchoscopic approach to clear retained secretions.

Introduction

Retention of respiratory secretions is common in critically-ill patients [1], and it may interfere with ventilation, impair gas exchange, predispose to respiratory infections, and lead to the development of lung atelectasis. Toilet bronchoscopy is a potentially therapeutic intervention to aspirate retained secretions within the endotracheal tube and airways and revert atelectasis. Aspiration of airway secretions is the most common indication to perform a therapeutic bronchoscopy in the intensive care unit (ICU) [2].

Toilet bronchoscopy efficacy

The reported efficacy of toilet bronchoscopy in removing retained secretions and reversing atelectasis ranges between 19 and 89%, according to the studied ICU population [3]. Toilet bronchoscopy is particularly beneficial when retained secretions are visible during the procedure and when air-bronchograms are not present at the chest radiograph [4]. It is also beneficial when there is an indication to reverse lobar atelectasis [5], rather than simply to remove accumulated mucus. In specific populations, the applied technique may be modified to enhance its efficacy. For instance, in patients with asthma, mucus is highly viscous because of an abnormal concentration of plasma proteins, DNA, cells, and proteoglycans, which results in an inability to remove secretions. In those patients, toilet bronchoscopy with concomitant broncho-alveolar lavage, with or without the use of mucolytics, achieves removal of distal mucus plugs [6]. Finally, some researchers advocate that the sole removal of mucus may not be sufficient to re-expand an atelectatic lobe. Tsao et al. [7] originally reported resolution of lobar atelectasis through selective intrabronchial toilet and air insufflation. A three-way port was connected to the bronchoscope working channel. One port was attached to an ambu bag and the other port was used to monitor insufflation pressure. The bronchoscope was wedged into each subsegment of the collapsed lobe to keep the airway pressure at 30 cmH_2O for 1–2 minutes. These methods were slightly modified later on, through the connection of a standard 15-mm endotracheal tube connector to the bronchoscope working channel port (Fig. 122.1). To date, only one study [4] has compared the effects of chest physiotherapy with toilet bronchoscopy for the treatment of atelectasis in a small ICU population. Chest physiotherapy comprised of deep breathing or manual hyperinflation for 3 minutes, then coughing or tracheal suctioning and finally nebulization of saline, chest percussion, and postural drainage. In both groups, after 24 hours, atelectasis was reversed in 80% of the cases with no indication of advantages in the use of toilet bronchoscopy over less invasive approaches.

Indications

Toilet bronchoscopy is specifically indicated for patients who present with significant retention of airway secretions and pulmonary atelectasis (Fig. 122.2). In critically-ill patients, mucus retention is frequent, because of immobilization, post-operative pain, weak cough, and muscle weakness. Additionally, in intubated ICU patients, mucociliary transport is drastically reduced [8], and outward mucus clearance is not possible because of the endotracheal tube cuff inflated within the trachea. Patients with underlying diseases associated with overproduction of mucus and impairment of its clearance, such as asthma, chronic obstructive pulmonary disease (COPD), bronchiectasis, and cystic fibrosis, may benefit from toilet bronchoscopy. In particular, mucus retention and potential benefits of toilet bronchoscopy in asthma should not be underestimated. In these patients, mucus is typically stationary within distal airways, as consistently corroborated in patients who die of status asthmaticus [9], and it is difficult to remove through suctioning. Finally, patients with neuromuscular diseases and ineffective cough seem to benefit from a bronchoscopic approach to clear secretions [10].

Contraindications and adverse effects

Toilet bronchoscopy is generally well tolerated by ICU patients and only a few absolute contraindications exist to its use (Box 122.1). Only personnel experienced in the procedure, who are trained to

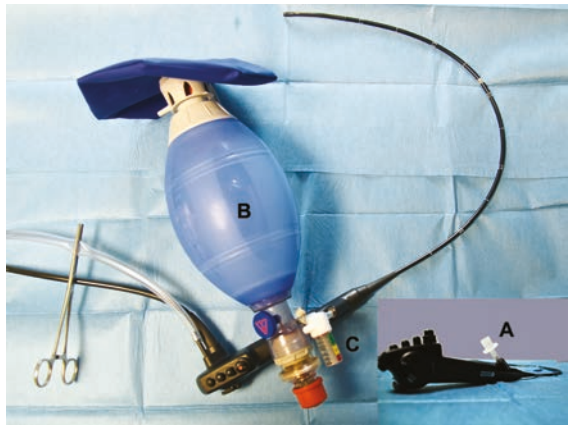

Fig. 122.1 Fibre optic bronchoscopy—ambu bag apparatus for selective segmental bronchial insufflation. Following intrabronchial mucus suctioning, the bronchoscope is wedged into each segment or subsegment of the atelectatic lobe and gas is slowly insufflated through the ambu bag into the bronchoscope working channel to achieve 30 cmH_2O airway pressure for a few minutes. Courtesy Hugo Loreiro, MD Hospital Clinic, Barcelona, Spain.

recognize and treat all potential complications, should perform the intervention. The risks associated with the procedure should always be weighed against the potential benefits. In general, toilet bronchoscopy should only be applied when other less invasive methods of secretion removal have failed to remove mucus plugging and revert atelectasis. Nevertheless, toilet bronchoscopy is recommended as a first-line treatment when significant mucus accumulation causes life-threating ventilatory obstruction and standard suctioning fails to promptly clear secretions. In the ICU, bronchoscopic procedures are associated with a 4% incidence of complications [11], most of them minor and transient [2]. However, no studies have specifically evaluated the complication rate of toilet bronchoscopy in ICU patients. The most common complications comprise severe refractory hypoxaemia [12], cardiac arrhythmias and ischaemia [13], haemodynamic instability and pulmonary haemorrhage (Box 122.2) [14].

Monitoring

A chest X-ray should be routinely performed prior to the procedure to identify areas of atelectasis. Strict monitoring is strongly advised during toilet bronchoscopy. Throughout the procedure, heart rate, oxygen saturation, ventilatory parameters, arterial pressure, and, in specific cases, intracranial pressure, and end-tidal carbon dioxide should be assessed.

Equipment

Bronchoscope

In intubated and mechanically-ventilated patients the insertion of the bronchoscope into the artificial airway drastically increases airflow resistance [12] and hinders ventilation. In order to prevent barotrauma and to allow adequate ventilation, it is suggested to use a bronchoscope with a diameter at least 2-mm smaller than the endotracheal tube's internal diameter [15]. Toilet bronchoscopy is an invasive procedure and the use of a sterile bronchoscope is mandatory to avoid iatrogenic respiratory infections.

Additional equipment

Strict hand hygiene is essential prior to and after the procedure. The bronchoscopist should wear protective clothing (gloves, disposable

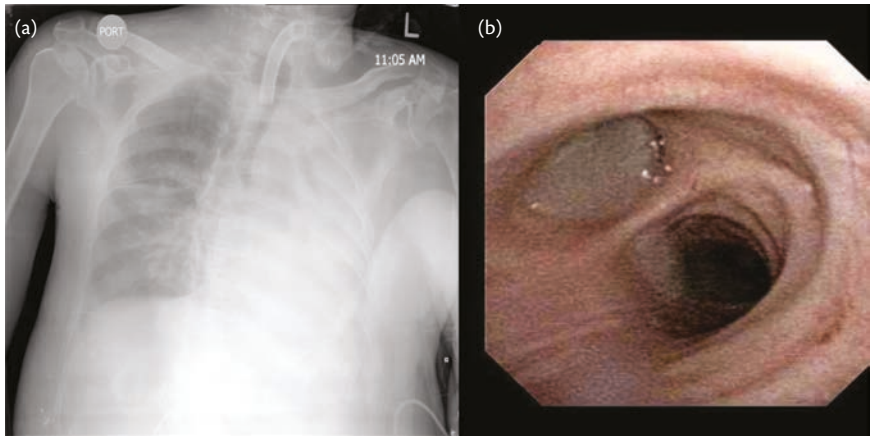

Fig. 122.2 Toilet bronchoscopy indication. (a) Chest radiograph of a tracheostomized critically-ill patient who was admitted for acute exacerbation of chronic obstructive pulmonary disease. The radiograph depicts extensive left lung atelectasis with no evidence of air-bronchograms. (b) Following unsuccessful chest physiotherapy, toilet bronchoscopy showed full obstruction of the left main bronchus by copious airways secretions.

Box 122.1 Toilet bronchoscopy contraindication

Absolute contraindications

- Absence of consent from the patient or his/her representative, unless a medical emergency exists and patient is not competent to give permission.
- Inexperienced bronchoscopist.
- Inadequate facility and/or equipment.
- Inability to adequately oxygenate the patient during the procedure.
- Current myocardial ischaemia.
- Significant haemodynamic instability.
- Life-threatening cardiac arrhythmias.
- Current significant bronchospasm.
- Undrained pneumothorax.

Relative contraindications

- Thrombocytopenia (platelet count ≤50,000 platelets/mm^3).
- INR of 2 or greater, or an elevated PTT.
- BUN >30.
- High-grade tracheal obstruction.
- Recent myocardial ischaemia and/or unstable angina.
- Severe hypoxaemia.
- Intracranial hypertension.
- Poorly-controlled heart failure.
- Recent oral intake.*

INR, International normalized ratio; PTT, partial thromboplastin time, BUN, blood urea nitrogen. *Enteral feeding or oral intake should be discontinued for 4 hours before the procedure.

apron, and protector visor) to minimize potential contamination with colonized respiratory secretions. A swivel adapter should be positioned at the proximal tip of the endotracheal tube to allow insertion of the bronchoscope and mechanical ventilation during toilet bronchoscopy. The outer surface of the bronchoscope should be lightly lubricated with water-soluble lubricant to allow easy passage through the artificial airway. Intrabronchial instillation of sterile saline solution, or mucolytics (10 or 20% acetylcysteine, dornase alfa, 2-mercaptoethane sulphonate), is commonly performed to aspirate inspissated secretions. Sterile saline and mucolitycs are also occasionally used to perform a broncho-alveolar lavage aimed at removing distal mucus plugs [6]. Nevertheless, to date, no studies are available to confirm the additional benefits associated with broncho-alveolar lavage. Finally, a sterile mucus trap may be connected to the working channel to collect and culture aspirated mucus.

Vacuum

It is recommended the level of vacuum be adjusted before performing toilet bronchoscopy to improve the efficacy of suctioning and minimize complications. No studies have comprehensively evaluated the efficacy and safety of toilet bronchoscopy at increasing vacuum levels. When using a 5.2-mm outer diameter bronchoscope the vacuum level is commonly set at −400 mmHg. Nevertheless, in patients with loose secretions, acute lung injury (ALI)/acute respiratory distress syndrome (ARDS), or those intubated with a 7-mm internal diameter endotracheal tube, the vacuum should be decreased to the lowest level that efficiently removes secretions to reduce risks of lungs collapse. Importantly, the primary aim of toilet bronchoscopy is aspiration of secretions; hence, suctioning when the bronchoscope is not close to secretions, or when all the mucus has already been aspirated should be avoided.

Setting the mechanical ventilator

Several ventilatory parameters should be adjusted to safely perform toilet bronchoscopy. However, no international consensus exists on how to set the mechanical ventilator during the procedure. First and foremost, given the significant risk for developing hypoxaemia, the inspiratory fraction of oxygen should be increased to 100%. Secondly, bronchoscopy is usually performed during either flow- or pressure-controlled modes of ventilation. The flow-controlled mode ensures the delivery of the set tidal volume, and the resulting pressure applied to the airway opening can rise to any value according to the impedance to inflation and the pressure limit

Box 122.2 Toilet bronchoscopy potential complications

Respiratory complications

- Hypoxaemia.
- Hypercapnia.
- Atelectasis.
- Bleeding.
- Bronchospasm.
- Pneumothorax.
- Respiratory arrest.

Cardiovascular complications

- Bradycardia.
- Tachycardia.
- Cardiac arrest.
- Hypotension.
- Hypertension.
- Myocardial infarction.

Neurological complications

- Intracranial hypertension.
- Seizures.

Infectious complications

- Fever.
- Pneumonia.
- Bacteraemia.

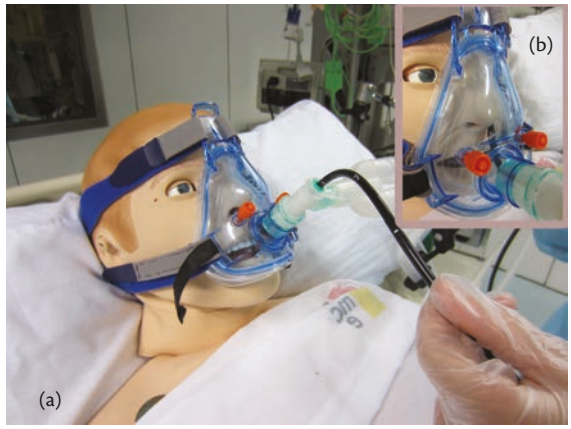

Fig. 122.3 Toilet bronchoscopy during non-invasive ventilation. (a) Transnasally insertion of the flexible bronchoscope during non-invasive ventilation. (b) The T-adapter was attached to the face-mask for the insertion of flexible bronchoscope and its passage through the nose.

alarm. Thus, prior to insertion of the bronchoscope the pressure limit alarm needs to be increased to allow for ventilation. During pressure-controlled ventilation minute ventilation can drastically decrease, unless the set inspiratory pressure is adjusted to overcome the bronchoscope-related airflow resistance. Finally, there is evidence from laboratory [15] and clinical studies [16] that the insertion of a bronchoscope into the artificial airway significantly increases the positive end-expiratory pressure (PEEP), because of the added resistance to passive exhalation and gas trapping. Nevertheless, during toilet bronchoscopy frequent aspirations could ultimately result in lung derecruitment, rather than significant gas trapping [17]. For these reasons the ventilatory mode should be set based on the patient's underlying conditions and associated risks. In patients with significant intrinsic PEEP or at risk for barotrauma, pressure-controlled mode of ventilation should be preferred, whereas in patients with acute lung injury, ARDS, hypercapnic, or who require high levels of PEEP, volume-controlled mode could be a safer choice. Thirdly, the external PEEP should be markedly decreased during the procedure to at least 50% of the baseline values, or even less in patients with underlying bronchoconstriction, emphysema, and auto-PEEP. Finally, the ventilator should be allowed to trigger during suctioning to prevent lung derecruitment, thus flow- or pressure- trigger should be set accordingly.

Sedation, analgesia, and topical anaesthesia

Toilet bronchoscopy is an invasive procedure, which is highly uncomfortable for patients. The use of sedatives, analgesics and topical anaesthetics is mandatory to achieve favourable procedural condition, improve patient tolerance and reduce potential complications [18]. Commonly, in deeply sedated and intubated patients on mechanical ventilation toilet bronchoscopy can be performed by applying topical anaesthetics, administered as needed through the bronchoscope working channel. 1 or 2% lidocaine solution is the most commonly used anaesthetic. Care should be taken with the total administered dose in patients of advanced age, and with impaired liver function and cardiac conditions. In lightly sedated, mechanically-ventilated patients and those on spontaneous ventilation, systemic sedation, analgesia, and topical anaesthetics are recommended. Short-acting sedatives, i.e. midazolam and propofol achieve optimal sedation, anxiolysis, and amnesia, and are highly recommended for toilet bronchoscopy. Fentanyl is the preferred analgesic during toilet bronchoscopy due to its rapid onset of action, short half-life, and efficient suppression of cough. In specific cases, short-acting neuromuscular blocking agents can be used to optimize ventilation during the procedure and to prevent potential complications.

Toilet bronchoscopy during invasive ventilation

The bronchoscope is initially inserted into the artificial airway and secretions accumulated within its lumen are fully aspirated. When lobar atelectasis is detectable at the chest radiograph, the bronchoscope should first be advanced toward the secondary bronchus tributary of the lung consolidation, and mucus plugs fully removed. Next, all lobar bronchi should be comprehensively assessed and built up secretions removed. In patients with disseminated retention of airways secretions, a systematic approach should be undertaken in order to ensure full removal of airway secretions from all secondary bronchi. Follow-up chest radiograph is recommended to demonstrate resolution of the atelectasis.

Toilet bronchoscopy during non-invasive ventilation

Several patients who require non-invasive ventilation are often unable to efficiently clear respiratory secretions. In those patients toilet bronchoscopy may prevent respiratory deterioration and the need of endotracheal intubation. Studies have reported feasibility and safety of fibre optic bronchoscopy in critically-ill patients with acute lung injury [19] and COPD exacerbation [20]. Nevertheless, to date, no randomized controlled studies have been conducted to assess the clinical usefulness of toilet bronchoscopy in patients who require non-invasive ventilation. Topical anaesthesia of the nasopharynx and larynx with lidocaine should be performed prior the procedure. Systemic light sedation and/or analgesia should be considered on a case-by-case basis. It is highly recommended that the inspiratory fraction of oxygen be increased to 100%. Inspiratory and end-expiratory pressures should be adjusted to

achieve optimal ventilation and oxygenation. During the procedure, the bronchoscope can be inserted through a T-adapter attached to a face mask (Fig. 122.3) or a specific connector placed in the plastic ring of a helmet and advanced into the airways via either a nasal or oral route.

PART 4.15

Pleural cavity problems

CHAPTER 123

Pathophysiology of pleural cavity disorders

Davide Chiumello and Cristina Mietto

Key points

- The pleural cavity is a virtual space. Negative (subatmospheric) pressure is essential to guarantee the mechanical coupling between the lung and the chest wall.
- The three major determinants of this balance are the Starling forces, the lymphatic drainage, and the active transmembrane transport.
- When fluid or air accumulates inside the pleural cavity, pleural pressure rises to atmospheric level. The consequence is that the lung and chest wall tend to their resting position—the lung collapses, while the chest wall tends to expand. The displacement is not equally distributed between lung and chest wall, because it depends upon the individual compliance.
- Pneumothorax can be defined as primary if it is not associated with any lung disease. Otherwise, pneumothorax is usually referred as secondary and the most common causes are chronic obstructive pulmonary disease, cystic fibrosis, infectious diseases, and cancer. Traumatic pneumothorax can be consequence of chest injury or invasive medical procedures (mechanical ventilation, central venous catheter placement, thoracentesis).
- Pleural effusion is classified as transudates or exudates, mainly based on protein content. Transudates are typically bilateral and the increase in systemic capillary pressure is due to increased filtered fluid in the presence of preserved endothelium. Exudates occur when a protein rich fluid is collected for an altered mesothelial barrier permeability.

Introduction

The pleural cavity is a virtual space delimited by the pleura and contains a thin layer of fluid pivotal for the mechanical coupling of the respiratory system. Collection of air (pneumothorax) and excess fluid (pleural effusion) impair the function of the respiratory system and are common in critically-ill patients, occurring in up to 15 and 60% of patients admitted to intensive care unit, respectively [1,2].

Anatomy

The pleural cavity is a closed space bordered by the pleura, a serous membrane consisting of a parietal leaflet that covers the internal surface of the thoracic cage, the diaphragm and the mediastinum, and a visceral leaflet that coats the external surface of the lung. The upper limit of the pleural space, occupied by the dome of the lung, extends 2–3 cm above the first rib and behind the sternocleidomastoid muscle. The inferior limit follows the border between the diaphragm and the chest wall, corresponding to the sixth rib anteriorly and just below the twelfth rib posteriorly. The visceral pleura is adherent to the lung surface from which it is not separable, ensuring a homogenous transmission of the forces. Both pleura are constituted by a single line of mesothelial cells, that are joined by tight junctions, such as endothelial cells, and have intracellular synthesis capability and active trans-cellular transport [3]. Mesothelial cells are provided with microvilli on the luminal side, a major density characterizes the visceral pleura and caudal lung regions. The parietal pleura is distinguished by the presence of stomata, round holes opening between cells which provide communication between the pleural space and lymphatic vessels of submesothelial tissue [3]. Blood supply is from systemic circulation for both pleura, the visceral one drains into the pulmonary vein system. Regarding innervation, the parietal pleura is provided by the intercostal and phrenic nerves, which entail a mark sensibility to pain, while the visceral pleura has an autonomic innervation and it is insensible to painful stimuli. However, nerve terminals with neurochemical characteristics of mechanosensory/nociceptive terminals could be involved in the pathogenesis of dyspnoea associated to pleural diseases [4].

Pleural cavity and respiratory system mechanics

The two pleural leaflets are separate by a thin layer of liquid that must be kept at the minimum needed to ensure the mechanical coupling between the lung and the chest wall. Lung and chest wall resting positions are different, so that at functional residual capacity (FRC) lung inward recoil is counterbalanced by chest wall outward tendency. These opposite recoil forces, which tend to separate the visceral and parietal pleura, are the major determinants of pleural pressure (P_{pl}). Pleural surface is exposed to a negative (subatmospheric) pressure that prevents lung collapsing and allows the lung and chest wall to move together. In clinical practice the oesophageal pressure (P_{es}) is the only available surrogate of P_{pl} and P_{es} variations are reliable of P_{pl} changes [5]. Moreover, P_{pl} is not equal along the whole lung height, but there is a vertical gradient, roughly 0.25 cmH_2O/cm, due to the lung weight [6]. Gravity exerts a uniform force on the lung, but its visco-elastic

nature and the presence of the supporting chest wall determines an inhomogeneous distribution. Consequently, P_{pl} is more negative at the top and tends to keep the lung open, whereas the bottom is compressed against the chest wall and the resulting P_{pl} is relatively higher. P_{pl} gradient is lower than the hydrostatic (1 cmH_2O/cm) because lung density is just one quarter the density of water. In the literature, two different models have been proposed for the pleural liquid pressure (P_{liq}). A theory proposes that Pliq is more negative than P_{pl} because of the presence of points of contact between the two pleural leaflets [7]. The other model states that lung and chest wall recoils are transmitted hydraulically through the pleural liquid, so that P_{liq} equals P_{pl} [8].

If air is collected into the pleural space, pleural pressure rises to atmospheric level causing the lung to collapse and the chest wall to expand, until a new equilibrium is reached. Pleural cavity has a high compliance, meaning that a large amount of fluid can be accumulated before P_{liq} begins to rise. Pleural effusion collects into the pleural cavity with a gravity distribution, altering P_{pl}. Above the pleural fluid P_{pl} gradient is normal, while below the gradient becomes hydrostatic with the consequence of a greater reduction of the transpulmonary pressure (P_L):

$$P_L = P_{aw} - P_{pl} \qquad \text{[eqn 1]}$$

where P_{aw} is the airway pressure. The consequence is the loss of aeration of the dependent lung zones. The displacement is not equally distributed between lung and chest wall, but it depends upon their own compliance. Thus, the volume of lung and chest wall are different, leading to the uncoupling of the respiratory system—the more compliant the chest wall, the more it accomplishes and the more compliant the lung, the greater the reduction in lung volume. Studies showed that pleural effusion entails a decrease in FRC of about one-third of the added volume, while the remainder is accepted by chest wall displacement. Moreover, regional lung volumes changed accordingly and the reduction of lung volume is mostly accounted for by the dependent regions with minimal changes in the upper lobes [9,10]. This distribution is in accordance with an altered P_{pl} and consequently P_L gradient. In another study, lung recruitment manoeuvres partially reversed the reduction in respiratory system compliance primarily due to the lung component, which can suggest that airway collapse can be an important mechanism involved [11].

Consistently, humans studies showed a small increase in lung volume after pleural effusion drainage compared with the volume removed, but a significant dyspnoea relief and more negative P_{es} [12,13]. A possible explanation is that the chest wall outward displacement determines a decrease in the length of the inspiratory muscles reducing their effectiveness [13]. Thoracentesis can restore the normal length and improve muscles efficacy with dyspnoea relief.

Pleural fluid dynamics

Normal pleural liquid volume is roughly 0.2 mL/kg, with a composition typical of plasma filtrate through a biological sieving membrane—protein content is low, 1–2 g/100 mL, and albumin is the major fraction [14]. The volume of pleural liquid is determined by the equilibrium of fluid turnover between in- and outflow, being equal to 0.2 mL/Kg/hour under physiological conditions [14,15]. Pleural fluid filters through the capillary of the parietal pleura and then is reabsorbed, mainly from stomata lymphatic system of the parietal pleura and, to a less extent, by solute-coupled transport and absorption into the capillaries of the visceral pleura. The three major determinants of this balance are the Starling forces, the lymphatic drainage, and the active transmembrane transport. Starling equation describes filtration across biological barriers (i.e., endothelium, as well as mesothelium):

$$If = Kf\left[\left(P_c - P_{liq}\right) - \sigma\left(\pi_c - \pi_{liq}\right)\right] \qquad \text{[eqn 2]}$$

where If refers to the net fluid movement across the compartments, Kf is the filtration coefficient, P is the hydrostatic pressure, π_c and π_{liq} the colloid–osmotic pressure in the sub-pleural capillaries and pleural liquid, respectively, and σ is the protein reflection coefficient of pleural mesothelium. If we consider as a whole the driving force between brackets, the eqn 2 simplifies to:

$$If = Kf \bullet \Delta Pf \qquad \text{[eqn 3]}$$

the transpleural liquid flow is dependent on the overall driving force (ΔPf) and on the Kf, that is equal to the product of the total surface (S) available for filtration and the water hydraulic permeability (Lp) (Kf = S·Lp). Lp (the coefficient defining water hydraulic permeability) is mostly dependent on the size and distribution of small aqueous channels, called pores, opening on the membrane. Studies suggests that mesothelial cells are also active in a solute-coupled liquid absorption and transcytosis based on morphological evidence of vesicular transport [14]. A similar equation can be written for the lymphatic drainage (Jl):

$$Jf = KI \bullet (P_{labs} = P_{liq}) \qquad \text{[eqn 4]}$$

where Kl is the conductance of the lymphatics, which is proportional to extension and is 10-fold greater than Kf, P_{labs} and P_{liq} are the absorption and the pleural liquid pressures, respectively. P_{labs} is rather negative, thus promoting reabsorption of pleural liquid. Lymphatic drainage is the main pathway limiting liquid accumulation and is essential for removing molecules and cells from the pleural space [14,15]. Pleural liquid turnover is polarized, filtration being greater in the upper regions of the cavity, whereas drainage is predominant at the diaphragmatic and mediastinal side [15]. Lymphatic flow seems the only way for draining cells back to blood circulation. Pleural fluid contains approximately 1500–2500 cells/mm^3, the majority are macrophages with fewer leucocytes, erythrocytes, and mesothelial cells [14].

Pneumothorax

Pneumothorax happens when air is introduced into the pleural cavity, causing chest wall displacement and lung collapse. Air can enter through the lung parenchyma or through chest wall injuries. Normally, air is not present into the pleural cavity, despite the negative pleural pressure, because the total of the partial pressure of gases dissolved in blood is less than one atmosphere (arterial blood 708 mmHg and venous blood 655 mmHg, breathing room air). This is essential for keeping the pleural cavity free of gases and reabsorption of collected air. Pneumothorax is classified in two groups based upon the aetiological mechanism–spontaneous

and traumatic (Table 123.1). Spontaneous pneumothorax can be secondary, i.e. associated to pulmonary diseases (mainly chronic obstructive pulmonary disease (COPD), cystic fibrosis, tuberculosis, cancer, interstitial lung diseases, and others). If no lung disease can be identified as a triggering factor, the pneumothorax is usually referred to as being primarily spontaneous, and is more frequent in young, thin, tall males. The classical theory is that it derives from the rupture of a subpleural bleb or bulla. Evidence to support this theory is derived by CT studies finding that 80% of patients with primary spontaneous pneumothorax show emphysema-like changes of lung parenchyma [16]. These alterations are often bilateral and mainly represented in the upper lobes. Some studies found a correlation with atmospheric pressure changes, loud music, height and smoking that seem to be a major risk factor [17].

A different model has been proposed for those patients without sign of emphysema-like changes or broken bulla during surgery. Visceral pleura show lesions of the mesothelial layer that is replaced by an inflammatory fibrotic tissue, alteration referred as 'pleural porosity,' and that can sustain the air leakage [17]. Both bullae and pleural porosity may be related to airway chronic inflammation, anatomy anomalies, connective tissue diseases, local ischaemia or malnutrition. Another possible scenario is the development of a haemopneumothorax, where the cause of bleeding is often an ectopic vessel enveloped into the pleural bulla.

On the other hand, traumatic pneumothoraxes can result from both penetrating and non-penetrating chest injuries, and can be divided into two major groups—iatrogenic or non-iatrogenic. The latter can be due to air leakage directly through the chest wall or visceral pleura wounds. Instead, alveolar rupture is a consequence of lung contusion or blast injuries. Iatrogenic pneumothorax is common and can be a complication of different medical procedures, such as transthoracic needle aspiration, thoracentesis, and the insertion of central intravenous catheters. Another important iatrogenic cause of pneumothorax in critically-ill patients is mechanical ventilation, referred to as barotrauma, and it is due to ventilation with high positive airway pressure, which determines high transpulmonary pressure (P_L) leading to alveoli over inflation or even rupture. Air leakage can be not only into the pleural cavity, but may even extend to mediastinum and body surface.

Table 123.1 Causes of pneumothorax

Type and causes of pneumothorax		
Spontaneous		
Primary		
Secondary	Emphysema	Lymphangioleiomyomatosis
	Asthma	Rheumatoid arthritis
	Cystic fibrosis	Sclerodermia
	Tuberculosis	Marfan's syndrome
	Pneumocistis carinii pneumonia	Ehlers–Danlos syndrome
	Idiopatic pulmonary fibrosis	Lung cancer
	Histocytosis X	Sarcoma
	Sarcoidosis	
Traumatic		
Non-iatrogenic	Penetrating or non-penetrating chest injury	
Iatrogenic	Transthoracic needle aspiration	Subclavian vein catheter
	Thoracentesis	Internal jugular vein catheter
	Transthoracic pleural biopsy	Mechanical ventilation

Pleural effusion

Pleural effusion is defined as any increase in pleural liquid volume sustained by an altered fluid turnover, depending on an increased filtration rate exceeding absorption compensatory mechanisms or caused by a primarily impaired drainage system. Enhanced filtration can be a consequence of increased filtration pressure, or altered mesothelial and endothelial permeability. The increase in pleural liquid promotes a change in the balance of fluid turnover toward a reduced filtration and enhanced absorption—a decrease in the net hydrostatic filtration pressure, an increase in lymphatic flow, and if the fluid has a low protein content, the oncotic pressure is still in favour of reabsorption. Parietal pleura lymphatic drainage is the main adapting mechanism facing fluid retention and can increase to 20 times its basal value [7]. Pleural effusion is classified as transudates or exudates, mainly based on protein content (Table 123.2). A pleural effusion is defined as exudates when the protein concentration is greater than 30 g/L or when the fluid to serum total protein ratio (C_{liq}/C_p) is higher than 0.5. Relaying only on this parameter, 15% of transudates and 10% of exudates are misclassified, thus Light's criteria can be used to better distinguish between the two types of pleural effusion with a sensibility of almost 100% for exudates [18,19]. Light's criteria take into account liquid and serum lactic dehydrogenases (LDH): pleural fluid to serum LDH ratio (LDH_{liq}/LDH_p) greater than 0.6, LDH_{liq} greater than two-thirds of the upper limit of serum reference and C_{liq}/C_p greater than 0.5 [20]. In the case of pleural effusion with a protein concentration between

Table 123.2 Causes of pleural effusion

Transudate	**Exudate**
Congestive heart failure	Pneumonia
Severe mitral stenosis	Neoplastic disease (lung, mesothelioma, metastatic)
Cirrhosis	Pulmonary thromboembolism
Nephrotic syndrome	Autoimmune diseases (rheumatoid arthritis, systemic lupus erythematosus)
Hypoalbuminaemia	Asbestos exposure
Pulmonary thromboembolism	Post-coronary artery bypass
Superior vena cava syndrome	Drug-induced
Peritoneal dialysis	Pancreatitis
Myxoedema	Chylothorax

25 and 35 g/L or in patients in therapy with diuretics, where C_{liq} can be misleading, a difference in serum and liquid protein greater than 31 g/L or an albumin concentration difference higher than 12 g/L suggest transudate [19]. This classification comprises different pathological mechanisms beneath the two kind of pleural effusion. In transudates, that are typically bilateral, the increase in systemic capillary pressure is due to the increased filtered fluid in the presence of preserved endothelium and mesothelium sieving properties, resulting in an acellular and low protein fluid. The most frequent conditions associated are heart diseases, chronic renal failure, hepatic cirrhosis, pleural fibrosis, and atelectasis. Isolated right heart failure rarely causes pleural effusion probably because the increased filtration can be matched by the enhanced lymphatic system. On the contrary, pleural effusion is common in case of biventricular or left ventricular failure where there is an increase in visceral pleura permeability leading to functional communication between the pleural and lung extravascular space (i.e., interstitial lung oedema) causing an excess of fluid filtration overwhelming compensatory mechanism. Systemic venous hypertension can be a rare cause of impaired lymphatic drainage. Then, renal and hepatic diseases may determine a decrease in protein content, with the result of a decreased colloid–osmotic pressure, as well as primary hypo-albuminaemia. Lastly, there may be direct transdiaphragmatic leak of ascitic fluid from the peritoneum. On the other hand, exudates occur when a protein rich fluid is collected for an altered mesothelial barrier permeability with cell and protein leak into the pleural space or for impaired lymphatic removal. The most common cause of exudates is inflammation; other conditions associated can be malignant neoplasms, primary of mesothelial cells or metastatic, tuberculosis, or asbestos-related diseases. The hallmark of pleural involvement in local or systemic inflammatory diseases is increased microvascular and mesothelial permeability, occurring with opening of new transcellular pathways and for direct mesothelial cell damage with loss of barrier selectivity [14,15]. One of the most frequent type of exudates is pleural effusion associated to pulmonary infection, parapneumonic effusion. Evidence shows that mesothelial cells are active elements in the immunity defence process—they can recognize the pathogens, and subsequently initiate and propagate the inflammatory response. Mesothelial cells have phagocytic properties and can release reactive oxygen species as first line defence mechanism. Mesothelial cells release also cytokines that are pivotal in the recruitment of native and acquired immunity cells [20]. Inflammation promotes a fibrin deposition upon damaged tissue and a fine balance between fibrin deposition and removal is essential to avoid the development of pleural fibrosis.

Haemothorax is defined as any pleural effusion with a haematocrit greater than 50% of peripheral blood. It is to remember that a haematic pleural effusion with a haematocrit >5% is visually indistinguishable from blood. Most cases are the result of chest trauma or invasive procedures. Other causes can be vascular rupture (aortic dissection or pulmonary vessel malformation), tumours, inherited or acquired coagulopathy, and anticoagulation therapy.

CHAPTER 124

Management of pneumothorax and bronchial fistulae

Wissam Abouzgheib and Raquel Nahra

Key points

- Observation is adequate in small pneumothorax.
- Small bore chest tubes are as effective as large ones and should be used initially.
- Ultrasound plays an important role in ruling out a pneumothorax.
- Suction is not always need in an air leak.
- One-way endobronchial valves may be used to treat prolonged air leaks.

Definition and classification of pneumothorax

Pneumothorax refers to the presence of air in the pleural space. The classification of pneumothorax includes spontaneous, traumatic, or iatrogenic. Spontaneous pneumothorax occurs without obvious cause, either primary without evidence of underlying lung disease or secondary with apparent underlying lung disease, often chronic obstructive pulmonary disease (COPD). Traumatic pneumothorax occurs after a blunt or penetrating trauma to the chest. Iatrogenic pneumothorax occurs after a diagnostic or therapeutic intervention, such as transthoracic lung biopsy, central line placement, or barotrauma due to mechanical ventilation. The incidence of pneumothorax, in patients receiving mechanical ventilation, ranges between 7 and 14% [1]. Patients with acute lung injury or ARDS are at high risk.

The clinical presentation ranges from asymptomatic to respiratory failure and prolonged bronchopleural fistulas (BPFs). Prompt diagnosis and management are crucial, especially in symptomatic and critically-ill patients requiring mechanical ventilation. This chapter discusses the diagnosis and management of pneumothorax and BPFs in general with a focus on critically-ill patients

Diagnosis

Clinical manifestations and presentations of pneumothorax are widely variable. Sometimes found incidentally on routine chest imaging, the presence of a pneumothorax is often clinically suspected with the appropriate clinical setting. Spontaneous pneumothorax is usually sought in patients between 20 and 40 years old presenting with sudden onset of dyspnoea and pleuritic chest pain. Secondary pneumothorax in patients with known underlying chronic lung diseases, presenting with more severe symptoms and iatrogenic or traumatic pneumothorax in patients with diagnostic/therapeutic interventions or preceding trauma. Symptoms vary, a small pneumothorax can be asymptomatic and self-limited, whereas a large pneumothorax can cause hypoventilation, hypoxaemia, and/or haemodynamic instability.

Tension pneumothorax represents a surgical emergency and requires emergent intervention. It may lead to respiratory failure requiring mechanical ventilation. It may also complicate pre-existing respiratory failure on positive pressure ventilation.

In intubated and sedated patients, a pneumothorax should be suspected with sudden and unexplained worsening respiratory failure, increased oxygen requirements, haemodynamic instability, and a sudden rise in peak and plateau pressures. It is ideally diagnosed based on clinical presentation, risk factors, and physical examination, and not by imaging followed by immediate emergent decompression.

The first-line imaging modality used to identify a pneumothorax is chest radiography.

A typical finding is the displacement of the white visceral pleural line from the chest wall on an upright chest X-ray. Contralateral shift of the trachea and mediastinum may also be present in spontaneous pneumothorax, but not necessarily suggestive of tension. The underlying lung parenchyma should be examined for the presence of underlying lung disease that would suggest a secondary spontaneous pneumothorax. In bedridden or ICU patients, care should be exercised in order to differentiate visceral pleural line from skin folds. Skin folds frequently extend beyond the rib cage, while blood vessels and lung parenchyma often extend beyond the skin fold. Their attenuation profile is also different, forming a negative black Mach band instead of the white visceral pleural line (Fig. 124.1)

Computed tomography (CT) is reserved for complicated or unclear situations. However, CT scans are more accurate in determining size of pneumothorax when compared to chest radiography [2].

Some investigators have reported using ultrasound to diagnose or rule out a pneumothorax [3], particularly in patients where it is needed urgently at the bedside, such as in ICU or for a trauma patient. The use of bedside ultrasonography has emerged in the past few years as the modality of choice in intensive care units (ICUs), where ultrasonography trained physicians are available. Bedside ultrasonography offers several advantages over chest radiography or CT scans, including rapid availability, lack of radiation, real time interpretation, and lower cost. It also offers the ability to immediately rule out a pneumothorax after an invasive procedure or in the

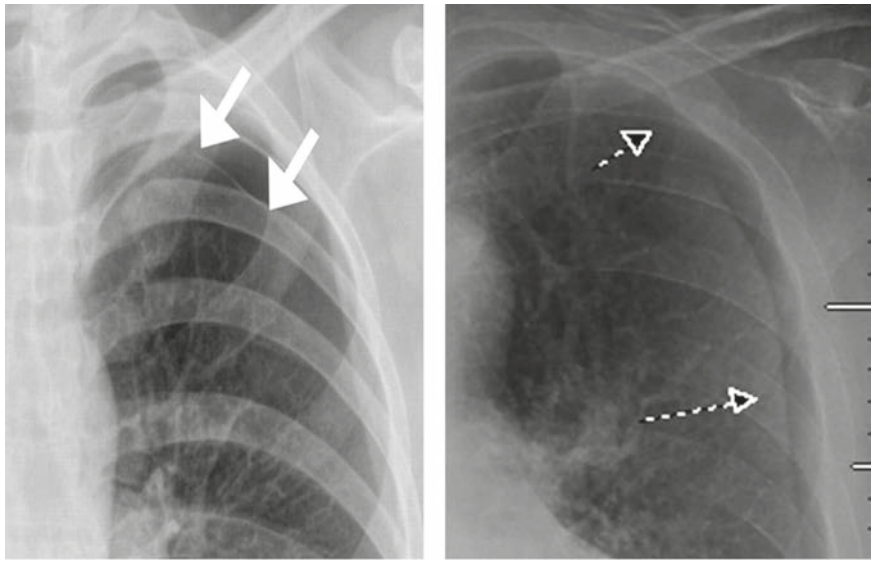

Fig. 124.1 (Left) White visceral pleural line in pneumothorax. (Right) Black Mach band in skin fold.

midst of a clinical deterioration. Two easily identifiable signs are needed to rule out pneumothorax. The sliding lung sign presents as shimmering of the visceral pleura when it moves relative to the parietal pleura during the respiratory cycle. The Comet tail artefacts (also called B-lines) are several echogenic lines that originate at the visceral–parietal pleural interface and extend to the bottom of the sonographic image (Fig. 124.2). The sensitivity and specificity of ultrasound for pneumothorax range from 86 to 98%, which is superior to supine chest radiograph (sensitivity 28 to 75%) [4,5]. Both techniques demonstrated high specificity.

Management of pneumothorax

Several parameters need to be considered in the management of a pneumothorax, such as type, size, severity of symptoms, first episode or recurrence, and patient preference. The British Thoracic Society guidelines define a pneumothorax as small if the distance from chest wall to the visceral pleural line is less than 2 cm or large if the distance is 2 cm or greater [6]. Some clinicians prefer 3 cm laterally and 4 cm apically as the threshold to distinguish small and large pneumothoraces.

Conservative approach: oxygen and observation

The first episode of spontaneous pneumothorax warrants a conservative approach when faced with small size pneumothorax and symptoms are absent or mild. Normal air re-absorption from the pleural space occurs at a rate of 1.25 % and it increases three- to four-fold when high flow (non-intubated patient) or high F_IO_2 (intubated patient) oxygen supplementation is instituted. Patients managed conservatively should be observed in the emergency department for 3–6 hours and discharged home if repeat chest imaging shows no progression.

Manual needle/catheter aspiration

Simple manual aspiration using an intercostal needle or small catheter is indicated in non-complicated patients presenting with a first episode spontaneous pneumothorax, large pneumothorax, or associated with symptoms. It consists of inserting a needle or catheter in the pleural space, and aspirating the pleural air followed by removal of the needle or catheter. The overall resolution

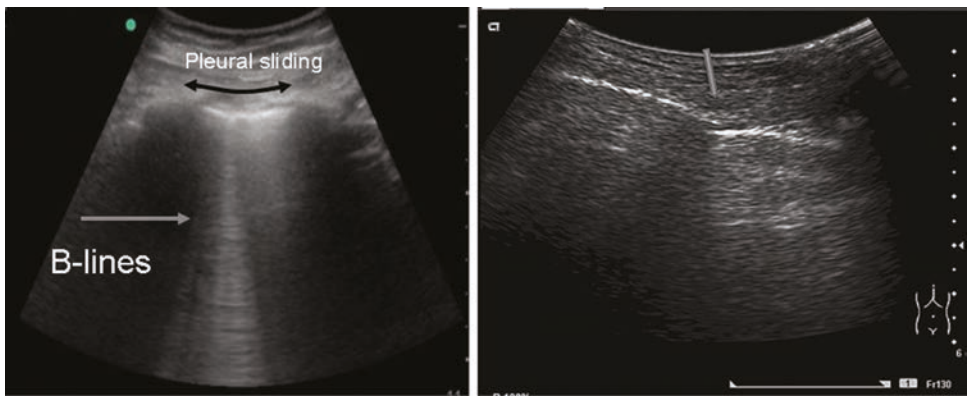

Fig. 124.2 Ultrasound. (Left) No pneumothorax. (Right) Pneumothorax: absence of pleural sliding or B-lines.

rate in spontaneous pneumothorax ranges between 59–83% of patients [7].

Tube thoracostomy: insertion and management

When simple aspiration is unsuccessful to keep the lung inflated, or when air leak is large or persistent, then a tube thoracostomy is indicated. Prior reflection on the magnitude of the underlying air leak, size of the pneumothorax, associated co-morbidities, and concurrent therapies may help when choosing tube thoracostomy size. There is no evidence that large tubes (20–24 F) are any better than small tubes (10–16 F) in the management of pneumothoraces. The initial use of large (20–24 F) intercostal tubes is not recommended, although it may become necessary to replace a small chest tube with a larger one if there is a large air leak preventing complete re-inflation of the lung [6].

The presence and degree of an air leak after chest tube placement, is also important and should be assessed daily to determine whether the tube can be removed. The number of chambers that are bubbling in a wet, suction-controlled, closed drainage provides a semi-quantitative measure of the severity of the leak. It does not indicate flow in any precise manner, but can provide an indication of any day-to-day increases or decreases in the degree of air leak.

Our recommended approach is, for patients who are not at risk for a large air leak, a smaller catheter (8–14 Fr) can be used in combination with a water seal or unidirectional flutter valve (i.e., Heimlich valve), which allows the patient to be mobile. These patients can be followed the next day with chest X-ray after clamping the chest tube for several hours for chest tube removal.

For patients with moderate size pneumothorax or possible moderate air leak, a 16–24 Fr chest tube is usually sufficient to maintain evacuation of the pleural space. The tube may initially be connected to a water seal, but if lung re-expansion does not occur then application of suction (–20 cmH_2O) is needed. Suction helps juxtapose the visceral and parietal pleura, which in theory leads to mechanical pressure on the bronchopleural fistula and potentially promotes healing.

A large surgical chest tube >24 Fr is needed in patients with large air leak, in mechanically-ventilated patients, and when smaller size tubes fail to re-expand the lung.

Small bore drains are as effective for air drainage as large bore drains and are more comfortable for patients. If there is associated blood, a large bore drain will be required. There are no large randomized, controlled trials directly comparing small and large bore drains.

The most common position for chest tube insertion is in the mid-axillary line, through the 'safe triangle'. This position minimizes risk to underlying structures, such as the viscera and internal mammary artery. A more posterior position may be chosen if suggested by the presence of a loculated collection. While this is relatively safe, it is not the preferred site, as it is more uncomfortable for the patient to lie on after insertion and there is more risk of the drain kinking.

For apical and large pneumothoraces extending to the apex, an antero-apical approach is favoured. It requires minimal positioning and rotation of a critically-ill patient. The second intercostal space in the mid-clavicular line is often chosen, two finger breadths from the lateral sternal border. The internal mammary vessels are at risk, but bedside ultrasound may be very helpful in choosing the optimal location, while avoiding vascular structures.

Once the lung has completely expanded and the air leak has resolved, the chest tube removal process begins. Applied suction should be discontinued first [7]. The chest tube should be clamped 6–12 hours after the last evidence of an air leak and a chest radiograph be performed 24 hours after the last evidence of an air leak [7]. If repeat chest X-ray shows resolution of pleural air, then chest tube removal is warranted.

In the case of clinical deterioration, such as worsening dyspnoea, hypoxaemia, subcutaneous emphysema, or signs of tension pneumothorax, the chest tube should be immediately unclamped and connected to suction.

When an air leak persists for more than 3–5 days then air leak management and recurrence prevention should be considered [8].

Bronchopleural fistula

A bronchopleural fistula (BPF) is a communication between the pleural space and the bronchial tree. It represents a significant clinical problem and generally occur after a spontaneous pneumothorax caused by underlying lung diseases, chest trauma, lung resection, or biopsy. The post-operative complication of pulmonary resection is the most common cause. It is also associated with increased costs and high morbidity and mortality [9].

When significant, a BPF may contribute to respiratory failure by increasing work of breathing. However, even when minimal, they can contribute to other complications related to prolonged bed rest or inactivity, such as atelectasis, deconditioning, nosocomial infections, and deep venous thrombosis [10].

The severity of the air leak is generally stratified depending on its frequency (intermittent or continuous) or its occurrence during respiratory cycles (inspiratory, expiratory, or both). Occasionally, it may be severe, leading to detectable differences in the inspired and expired tidal volumes in patients on mechanical ventilation.

When one or more large BPF occurs in a patient with acute respiratory distress syndrome (ARDS), management is extremely challenging. Ventilation is usually not a big problem since air exiting through the BPF has significant CO_2 and has contributed to CO_2 elimination. Oxygenation is the main problem, since it is difficult to maintain adequate positive end expiratory pressure (PEEP). In attempts to minimize leak and facilitate healing of the BPF, high frequency oscillatory ventilation may be useful.

Single lung ventilation may also be considered where large BPF's are present in the mechanically-ventilated patient. The strategy here would be to allow ventilation of the side without the BPF with more conventional ventilator settings, while using settings that minimize tidal volume and airway pressure on the side of the leak.

The initial management of a BPF is conservative for the first 3–5 days with tube thoracostomy, together with treatment of the underlying lung diseases. In patients receiving mechanical ventilation, reducing the air leak through ventilator adjustments to minimize the tidal volume and plateau airway pressure may also help. Ventilator settings should be adjusted to minimize both tidal volume and plateau airway pressure, which may lead to lesser alveolar distension and lower transpulmonary pressure gradient. Applying the least amount of chest tube suction necessary may also be beneficial, as well as weaning and extubating the patient as soon as possible. These strategies are not supported by high quality evidence, but elimination or reduction of contributing factors makes it less likely that a new pneumothorax will develop, or that the existing BPF will worsen and become physiologically significant.

When prolonged, current guidelines recommend early surgical consultation for possible thoracotomy or video-assisted

thoracoscopic surgery [7,8], although the American College of Chest Physicians favours the latter [7].

Surgical correction of BPFs has been associated with high success rate (80–95%) and low mortality rate. However, in critically-ill patients or those with poor performance status, surgical interventions may be too risky. Bronchoscopic management is a less invasive alternative in such situations and may be conducted at the bedside in the ICU. Various devices and sealing compounds have been tried and used with flexible bronchoscopy in the past, but with limited success [11–13], such as instillation of fibrin, acrylic glue, and tissue glue [14]. Also deployment of self-expandable metallic stents or watanabe spigots have been utilized [12].

One-way endobronchial valves, initially developed for bronchoscopic reduction surgery, became available more than a decade ago and have been successfully used in case series for the treatment of prolonged air leaks [15,16]. The airway leading the air leak is initially identified using intermittent balloon occlusion. The valve is then introduced to the desired airway loaded on a delivery catheter through the working channel of the bronchoscope. The valve is umbrella-shaped when deployed in the airway. It fully expands during inspiration and blocks the airflow distally, while it slightly collapses and allows for mucus clearance during expiration (Fig. 124.3). The valve is easily removable bronchoscopically several weeks after resolution of air leak.

Conclusion

Pneumothorax and bronchopleural fistula are frequently encountered in clinical practice. In critically-ill patients, they could represent a serious problem leading to significant co-morbidities. Rapid recognition and intervention are key elements. Bedside ultrasound in the ICU is a new diagnostic tool that facilitates the early diagnosis and treatment.

Surgical correction of BPFs remains the gold standard treatment, but in critically-ill patients, several bronchoscopic interventions may be offered. One-way endobronchial valves placement in the leaky airway is a very promising new strategy in poor surgical candidates.

CHAPTER 125

Management of pleural effusion and haemothorax

Davide Chiumello and Silvia Coppola

Key points

- The management of pleural effusion depends on type, stage, and underlying diseases.
- Primary treatment of non-malignant pleural effusions is directed to the underlying cause of pleural effusion.
- Parapneumonic effusions should be sampled by thoracentesis. A pleural fluid pH <7.2 is the single most powerful indicator to predict a need for chest tube drainage.
- The rate of re-accumulation of pleural effusion, the patient's prognosis and the severity of symptoms should guide the management of malignant pleural effusions.
- Thoracotomy is the procedure of choice for chest surgical exploration when massive haemothorax or persistent bleeding is present.

Introduction

The goal in the management of pleural effusions is to provide symptomatic relief removing fluid from pleural space and to treat underlying diseases. The management options depend on the type of pleural effusion, stage in the evolution, and underlying disease.

Diagnostic approach

Chest radiography remains the most important technique for the initial diagnosis of pleural effusion.

If an effusion is suspected, ultrasonography (US) should be performed since it is more reliable for detecting small pleural effusions in critical care setting. The major advantage of US over radiography is its ability to differentiate between free and loculated pleural effusion, then it is useful to guide thoracentesis. Computed tomography (CT) can be used to evaluate complex situations, where the anatomy cannot be fully assessed by radiography or US. Although history, physical examination, and radiographic studies may provide important clues to the cause of a pleural effusion diagnostic thoracentesis should be always performed [1–3].

The main step is to determine whether the fluid is a transudate or an exudate, using Light's Criteria [1]. If it is exudative, more diagnostic tests are required to determine the cause of the local disease—differential cell counts, smears and cultures for organisms, measurement of glucose and amylase levels, cytological analysis, and testing for a pleural fluid marker of tuberculosis. Generally, a transudate is considered as uncomplicated effusion that can be managed by conservative treatment or antibiotics alone. An exudative effusion or a large amount of loculated effusion, that is considered complicated effusion, should be managed by drainage. Complicated effusions include empyema, malignant effusion and haemothorax [2,4].

Management

Refractory non-malignant effusions

These effusions can be transudative (congestive heart failure, cirrhosis, nephrosis) or exudative (pancreatitis, connective tissue disease, endocrine dysfunction), uncomplicated or complicated.

Patients who have symptoms due to a pleural effusion that is refractory to primary treatment are candidates for additional therapies. Dyspnoea is the most common symptom that necessitates additional therapy.

Before proceeding with more invasive therapy, trapped lung should be excluded. Trapped lung refers to a fibrous pleural peel that encases the visceral pleura, while the visceral and parietal pleura are widely separated.

Bilateral symmetrical pleural effusions in a patient with congestive heart failure without fever or chest pain should be treated with diuretics before thoracentesis. However, if pleural effusion persists for more than 3 days, thoracentesis should be performed.

Repeated therapeutic thoracentesis are appropriate when the effusion re-accumulates slowly enough that repeated procedures do not become burdensome to the patient.

Additional management options for patients with non-malignant pleural effusions include in-dwelling pleural catheter for intermittent external drainage, pleuroperitoneal shunts for internal drainage, or surgical pleurectomy. These techniques have been applied in patients with non-malignant pleural effusions [3,4].

Parapneumonic effusions

Patients with severe pneumonia often develop parapneumonic effusions, with sometimes progression to empyema.

Parapneumonic pleural effusions are divided in three types:

- An **uncomplicated** effusion occurs when lung interstitial fluid increases and moves across the adjacent visceral pleural membrane.
- **Complicated** effusions occur when there is persistent bacterial invasion of the pleural space.

Table 125.1 Parapneumonic effusion characteristics and outcome

Volume of effusion	Bacteriology	Effusion pH	Outcome
From minimal to moderate free flowing effusion more than 10 mm, but <½ hemithorax	Unknown or negative culture and Gram stain results	Unknown or ≥7.20	Very low or low risk of poor outcome
Large, free flowing (≥½ hemithorax), loculated effusion	Positive culture or Gram stain or pus	<7.20	Moderate–high risk of poor outcome

For the moderate/high risk of poor outcome is sufficient that just only one of the three characteristics is present [7].

Data from Colice GL et al., (2000) 'Medical and Surgical Treatment of Parapneumonic Effusions An Evidence-Based Guideline', *Chest*, **118**, pp. 1158–71.

- An **empyema** is defined as the presence of pus in the pleural space [3].

A positive culture is not required for diagnosis since anaerobic organisms are difficult to culture or sampling is often performed after a patient has received antibiotics. Blood cultures should be performed in all patients with suspected pleural infection, although they are positive in only 14% of these patients. The usual presentation includes fever, cough, dyspnoea, chest pain, purulent sputum, leukocytosis, and new alveolar infiltrate on chest radiograph.

Radiographic and ultrasound imaging play a key role in the evaluation of parapneumonic effusions and empyema.

Optimal evaluation of empyema or loculated effusions requires chest CT scan with intravenous contrast because the pleural microbubbles may suggest that the fluid collection will be more resistant to chest tube drainage. It is clinically impossible to differentiate the presence of a complicated parapneumonic effusion requiring chest tube drainage from a simple effusion that may be resolved with antibiotics alone [5].

Pleural fluid sampling remains the most reliable diagnostic test to guide management and is recommended in all patients with a pleural effusion >10 mm depth associated to pneumonic illness or recent chest trauma or surgery. Small effusions (thickness <10 mm) usually resolve with antibiotics alone.

Pleural fluid pH should be assessed in all non-purulent effusions when pleural infection is suspected. A pleural fluid pH <7.2 is demonstrated as the single most powerful predictor for the need of chest tube drainage. Where pleural fluid pH measurement is not available, glucose and lactic dehydrogenases (LDH) should be measured: a pleural fluid glucose level <50 mg/dL may be used as an alternative marker to indicate a need for chest drain insertion [6,7].

According to the British Thoracic society, the **indications for pleural fluid drainage in pleural infection** are:

- A frankly purulent or turbid/cloudy pleural fluid or a loculated pleural collection
- The presence of organisms identified by Gram stain
- Pleural fluid pH <7.2 in patients with suspected pleural infection
- Poor clinical progress during treatment with antibiotics alone [6].

When the effusion is free-flowing, as demonstrated by lateral decubitus views or US and thoracentesis shows a non-purulent exudate with a glucose level greater than 60 mg/dL, LDH less than 1000 IU/L, and pH >7.20, the patient has a high likelihood of pleural fluid resolution with antibiotics alone over 7–14 days (uncomplicated effusion) [7,8].

Table 125.1 shows the risk of poor outcome in patients with parapneumonic effusions based on the volume of pleural effusion, pleural fluid bacteriology and pleural fluid pH, developed by an expert panel. The panel's consensus opinion suggests drainage for patients with moderate or high risk of poor outcome [7].

The choice of **antibiotic** should be based on the bacteriology. Virtually all antibiotics adequately penetrate the pleural space except aminoglycosides that may be inactivated at low pleural fluid pH. Empiric therapy should cover anaerobic organisms and include clindamycin, beta-lactam plus beta-lactamase inhibitors, and carbapenems. It is recommended that antibiotic therapy be continued until there is radiographic resolution of fluid, generally for 2–4 weeks following defervescence.

In addition to appropriate antibiotic therapy, some complicated parapneumonic effusions and all empyemas require **drainage** for resolution. Failure to improve after tube thoracostomy drainage may indicate that antibiotic coverage is not adequate or that a loculated area of empyema has developed.

Early thoracic **surgical consultation** is appropriate, as many patients require thoracoscopic, or open debridement and drainage. Proper management includes the sterilization of the empyema with appropriate systemic antibiotics (at least 4–6 weeks), the complete pleural fluid drainage, and the obliteration of the empyema cavity by adequate lung expansion.

Options for surgical solutions include open decortication and open thoracostomy. For patients who do not have good drainage of empyema from a well-placed chest tube, an intrapleural administration of fibrinolytic therapy is suggested. Continued failure of adequate pleural drainage should prompt thoracoscopy or thoracotomy to lyse adhesions, to completely drain the pleural space and optimize chest tube placement. The choice between thoracoscopic debridement and decortication depends on several factors; those favouring decortication include more adhesions, greater visceral pleural thickness and larger empyema cavity size [4,7,8].

Malignant effusions

Malignancy is the most common cause of exudative pleural effusions in patients aged >60 years [4].

Malignant pleural effusion implies disseminated disease and median survival depends upon the site and stage of the primary tumour. The decision to treat a malignant effusion depends upon the presence of symptoms and the underlying tumour type. Asymptomatic malignant pleural effusions (up to 25%) do not need to be treated as long as they attain a steady state and remain asymptomatic. Some tumour types may respond to chemotherapy with resolution of the effusion [9].

Symptomatic patients should initially undergo therapeutic thoracentesis to drain the fluid. The rate of re-accumulation of pleural effusion, patient's prognosis, and the severity of patient's symptoms

Table 125.2 Different options of management of malignant pleural effusions

Options	Clinical condition
Observation	Asymptomatic effusions (most will progress and require therapy)
Therapeutic thoracentesis	Relief of dyspnoea (most effusions can recur unless underlying tumour responds to chemo- or radiotherapy)
Chest catheter drainage	Most effusions will recur after catheter removal
Chest catheter drainage with chemical pleurodesis	Uncontrolled and recurrent symptomatic malignant effusions. 90% of patients seem to respond to talc pleurodesis
Thoracoscopy with talc insufflation	Uncontrolled and recurrent symptomatic malignant effusions. In more than 90% of patients effusion seem to be controlled
Pleurectomy	In patients who have failed chemical pleurodesis, but with reasonably long expected survival
Long-term in-dwelling pleural catheter	Symptomatic relief in patients who cannot tolerate a general anaesthesia or are not candidates for video thoracoscopy
Pleuroperitoneal shunt	When other options have failed

should guide the therapy. Patients whose malignant pleural effusion re-accumulates slowly (longer than 1 month) may be managed with therapeutic thoracentesis. Repeat pleural aspiration is recommended for the palliation of breathlessness in patients with a life expectancy <3 months [9,10].

A more aggressive intervention may be required if malignant pleural effusions recur rapidly (less than 1 month). Options include in-dwelling pleural catheter drainage, pleurodesis, pleurectomy, and pleuroperitoneal shunt. Placement of an in-dwelling pleural catheter for drainage is indicated when there is an irremediable lung entrapment or an endobronchial obstruction by tumour. This option is ideal when length of hospitalization has to be kept to a minimum because of the short duration of survival. Pleurodesis is a reasonable alternative for patients with an expected survival of few months. This therapy can be carried out in a single definitive procedure without the potential inconvenience of a long-term drainage catheter. In selected patients with trapped lung and large effusions refractory to chemical pleurodesis, pleuroperitoneal shunting is an acceptable palliative option [9,11].

A summary of the main different approaches to the management of malignant pleural effusions is shown in Table 125.2.

Haemothorax

Haemothorax needs to be differentiated from a haemorrhagic pleural effusion, as the latter can result from only few drops of blood in serous pleural fluid.

The definition of haemothorax is a pleural fluid to blood haematocrit ratio greater than 50%. Routine radiology cannot distinguish blood from other pleural effusions. CT scan helps to identify the precise location of blood. Massive haemothorax is diagnosed when 2 L drain from the chest. Blood removed from a probable haemothorax should be examined to establish its haematocrit and to exclude infection [12].

When a haemothorax is suspected, the essential management, together with appropriate resuscitation, is intercostal drainage. The only exception is the presence of clinical and radiological signs suggestive of aortic dissection or transection, because intercostal drainage can lead to rapid exsanguination.

Intercostal drainage in haemothorax achieves two objectives—to drain the pleural space allowing expansion of the lung and to allow assessment of rates of blood loss. The latter, along with the general clinical state of patient dictates further management.

Chest drains should be large enough to permit some clots to be evacuated (28–30G minimum) and should be placed at the base of the hemithorax. The ideal insertion point is the 6th intercostal space in the mid-axillary line. Lower spaces should be avoided; contraction of the hemithorax is frequently present because of pain and/or pulmonary collapse, and selection of too low space may cause iatrogenic intra-abdominal injury.

Chest tube drainage allows the monitoring of bleeding rate, may potentially tamponade bleeding, and evacuate the pleural space, thus decreasing the risk of developing empyema or a subsequent fibrothorax.

If pleural effusion persists despite tube thoracostomy, a diagnosis of clotted or retained haemothorax is made. The ideal management of clotted haemothorax is a matter of controversy. The placement of additional chest tubes can be ineffective because of the presence of clotted blood and loculations. Although thoracotomy is an effective procedure in the management of clotted haemothorax, video-assisted thoracoscopic surgery (VATS) is currently preferred to open thoracotomy [13].

One easily available and effective alternative to VATS is the use of intrapleural fibrinolysis. Recently, intrapleural streptokinase, has been shown to decrease pleural thickening and adhesion in experimental clotted haemothorax. However, more human trials are needed to confirm this finding [14].

Thoracotomy is the procedure of choice for surgical exploration of the chest when massive haemothorax or persistent bleeding is present.

Generally, indications for emergency or urgent thoracotomy in haemothorax are:

- Haemodynamic instability despite adequate resuscitation.
- Initial drainage >1500 mL.
- Continued bleeding >200 mL/hour for 3 consecutive hours.
- Continued bleeding >1500 mL/day.
- Radiographic evidence of significant retained clot (>1/3 of pleural space) [13,15].

Drainage techniques

Thoracentesis

Thoracentesis is the basic procedure not only to differentiate transudate from exudate, but also to remove the fluid in a patient with a large volume of effusion for symptomatic relief. The most common indication of diagnostic thoracentesis is fluid in the pleural space more than 10 mm in thickness on lateral decubitus chest radiograph with unknown aetiology [1,2,16]

Complications of thoracentesis include pneumothorax, haemothorax, re-expansion pulmonary oedema, and organ laceration. In general, removal of <1500 mL pleural effusion is recommended to avoid the risk of re-expansion pulmonary oedema.

Thoracentesis must be performed with care in mechanically-ventilated patients, because positive pressure ventilation increases the risk of tension pneumothorax. Thoracentesis as therapeutic procedure, may reduce respiratory distress in patients with large effusions [16].

However, Doelken et al. evaluated the effects of thoracentesis on respiratory function in mechanically-ventilated patients and did not find any significant changes in peak or plateau airway pressure or compliance of respiratory system after the procedure [17]. After fluid removal from the pleural space, changes in pulmonary gas volume and size of the thoracic cavity depend on the lung compliance compared with the chest wall compliance—the more compliant the lung is, the greater will be the increase in gas volume [16].

Thoracostomy drainage

Tube thoracostomy allows a continuous and large volume drainage of air or liquid from pleural space.

Specific indications include haemothorax, penetrating chest trauma, complicated parapneumonic effusion or empyema, chylothorax, and pleurodesis of symptomatic pleural effusions. In symptomatic or clinically unstable patients, there is no absolute contraindication to chest tube placement. The need for prophylactic antibiotics depends upon the clinical circumstances. The tube should be removed as soon as it is safe to do so. For the pleural effusions, the indications to remove the tube are when the lung is fully expanded or when the daily fluid output is less than about 100–300 mL/day. Pleurodesis should be considered for patients with uncontrolled and recurrent symptomatic malignant effusions via a tube thoracostomy or during thoracoscopy to produce a chemical serositis and subsequent fibrosis of the pleura. Pleural sclerosis should be attempted only if the lung expands fully after fluid removal. Pleurodesis failure is usually the result of suboptimal technique or inappropriate patient selection [2,4,18].

Surgical therapy

Video-assisted thoracoscopic surgery is very useful in managing incompletely drained parapneumonic effusions and clotted haemothorax. With thoracoscopy, the loculi in the pleura can be disrupted, the pleural space can be completely drained, and the chest tube can be optimally placed [4].

Radical total or subtotal pleurectomy and decortications should be reserved for patients who have failed chemical pleurodesis. Appropriate candidates must be good surgical candidates and have a reasonably long expected survival, as total radical pleurectomy/decortications is a major surgical procedure associated with some mortality [4,18].

Pleuroperitoneal shunts and in-dwelling external catheters

Pleuroperitoneal shunting is a rarely-used option for patients who have lung entrapment, malignant chylothorax, or failed pleurodesis.

In-dwelling catheters provide symptomatic relief in patients with malignant pleural effusions, who either cannot tolerate general anaesthesia or have a trapped lung that is not amenable to video-assisted thoracoscopy. The catheter is placed in the intrapleural space under local anaesthesia and drains externally when effusions are symptomatic. This drainage technique has the disadvantage of ongoing protein losses and increased risk of infection, and because of these side effects it is not used for non-malignant effusions [19].

Acknowledgements

The authors acknowledge R. Phillip Dellinger MD, Camden, USA for his guidance in the preparation of this manuscript.

PART 4.16

Haemoptysis

CHAPTER 126

Pathophysiology and causes of haemoptysis

Francesco Blasi and Paolo Tarsia

Key points

- Haemoptysis varies in intensity from a minor event to a life-threatening condition.
- Criteria for the definition of massive/life-threatening haemoptysis should be better defined.
- The epidemiology of haemoptysis has changed over time, particularly in industrialized countries, where bronchiectasis and lung cancer have surpassed tuberculosis as the most frequent causes.
- The lungs are furnished with a dual blood supply, the bronchial arteries and the pulmonary arteries. Although the former account for only about 1% of arterial supply to the lung, bronchial arteries are involved in approximately 90% of haemoptysis cases.
- The mechanisms leading to haemoptysis are being better elucidated, particularly in chronic inflammatory conditions, where release of angiogenic growth factors leads to neovascularization with thin-walled fragile new vessels that are prone to rupture into the airways.

Introduction

Haemoptysis is defined as the expectoration of blood or blood-streaked sputum from the lower respiratory tract. The term derives from the ancient Greek words *haima*, meaning blood, and *ptysis*, meaning spitting. The presence of haemoptysis, even in the case of minor events, is a frightening symptom for the patient. The clinical spectrum may vary from minor blood-stained sputum to major bleeding causing respiratory failure and haemodynamic instability. Underlying causes may vary from benign, self-limiting conditions to severe, potentially lethal diseases.

There is a lack of universal consensus on the quantification and severity of haemoptysis events. Haemoptysis is considered scant when involving <5 mL, mild when <20 mL, and moderate when >20 mL. Massive haemoptysis has been varyingly defined as 100 mL/24 hours to more than 1000 mL/24 hours. Most authors apply the term massive haemoptysis to bleeding >600 mL/24 hours or >25 mL/hour. The term exsanguinating haemoptysis refers to blood loss >1000 mL/24 hours (>150 mL/hour) or >300 mL for a single expectoration event [1]. Given the unreliability in both the patient's and physician's estimates of expectorated volume, and lack of consensus cut-off volume definition, other authors define haemoptysis as massive in the presence of clinical consequences, such as respiratory failure due to airway obstruction or haemodynamic instability [2]. It has been estimated that volumes of blood in the alveoli above 400 mL are sufficient to significantly alter gas exchange. However, it must be considered than, in many situations, haemoptysis arises in patients with underlying cardiorespiratory disease. These subjects may suffer considerable worsening of gaseous exchange even for smaller quantities of blood. It has been proposed that the term 'massive' haemoptysis be substituted with 'life-threatening.' Life-threatening haemoptysis may be defined as any haemoptysis that:

- Is >100 mL in 24 hours.
- Causes abnormal gas exchange/airway obstruction.
- Causes haemodynamic instability.

Independent of its definition, massive/life-threatening haemoptysis involves only a minority of clinical events (generally 5–10%), but related mortality may exceed 50% [1,2]. Mortality is generally more the result of airway compromise with asphyxiation, rather than exsanguination.

Causes

Haemoptysis may derive from a variety of very different conditions, such as infections, pulmonary diseases, neoplastic conditions, cardiovascular alterations, vasculitis, traumatic events, haematological derangements, and iatrogenic or drug-induced events (see Box 126.1). The relative importance of different causes of haemoptysis has changed over time. For centuries, haemoptysis was considered virtually pathognomonic for pulmonary tuberculosis. The following Hippocratic aphorism: 'The spitting of pus follows that spitting of blood, consumption follows the spitting of this and death follows consumption' shows how far rooted in history is the association between haemoptysis and tuberculosis. During the course of the last century, however, effective antimycobacterial treatment and the rise in prevalence of cigarette smoking have changed the epidemiology of haemoptysis. TB continues to be a leading cause of haemoptysis in the developing world, but in industrialized countries bronchial carcinoma and bronchiectasis are more commonly reported [3].

It has been estimated that in bronchogenic carcinoma, haemoptysis presents at some point in the natural history of the disease in up to 20% of patients. Conversely, haemoptysis may be the presenting symptom in only 7% of patients with lung malignancy [4]. Haemoptysis is more likely to occur, and may manifest earlier in

Box 126.1 Causes of haemoptysis

Infection
- Mycobacterial (tuberculosis and atypical mycobacteria).
- Fungal infections (including mycetoma).
- Necrotizing pneumonia.
- Lung abscess.
- Parasitic.
- Septic emboli.

Pulmonary
- Acute bronchitis.
- Chronic obstructive pulmonary disease.
- Bronchiectasis (including cystic fibrosis).
- Alveolar haemorrhage.
- Lymphangioleiomiomatosis.
- Sarcoidosis.
- Lung transplantation.

Neoplastic
- Bronchogenic carcinoma.
- Metastatic lung cancer.
- Endobronchial tumours (bronchial adenoma, carcinoid).

Cardiovascular
- Pulmonary embolism (lung infarct).
- Pulmonary hypertension.
- Pulmonary artery aneurysm.
- Bronchial artery aneurysm.
- Left ventricular heart failure.
- Mitral stenosis.
- Arteriovenous malformations.

Vasculitic
- Wegener's granulomatosis.
- Behçet's disease.
- Goodpasture syndrome.
- Systemic lupus erythematosus.
- Antiphospholipid syndrome.

Traumatic
- Foreign body aspiration.
- Blunt or penetrating chest injury.
- Aortic aneurysm.

Iatrogenic
- Bronchoscopy.
- Endobronchial procedures (brachytherapy, dilation, stent placement, laser).
- Lung biopsy.
- Pulmonary artery catheterization.

Drugs and toxins
- Bevacizumab.
- Solvents.
- Crack cocaine.
- Penicillamine.

Haematological
- Coagulopathy (congenital, acquired, or iatrogenic).
- Thrombocytopenia.
- Platelet dysfunction.

Miscellaneous
- Cryptogenetic.
- Endometriosis.
- Broncholitiasis.

the disease course, when carcinoma originates in a major bronchus compared with more peripheral sites.

Among mycobacteria, haemoptysis is mainly related to *Mycobacterium tuberculosis*, with few reports on the involvement of non-tuberculous mycobacteria. Haemoptysis may be the result of active tuberculosis, generally with small and chronic bouts of blood, although massive haemoptysis has also been described in this context. Inactive mycobacterial disease may be associated with bleeding arising from post-tuberculous thick-walled cavities or bronchiectasis. Rarely, peri-bronchial calcified lymph node may erode into or distort an adjacent bronchus. This condition is known as broncholithiasis and may be associated with symptoms such as cough, recurrent episodes of fever and purulent sputum, and sometimes massive haemoptysis [5].

Aspergilloma is a mycotic colonization of a pre-existing lung cavity or cyst. Post-tuberculous cavities or idiopathic pulmonary fibrosis cavities are examples of pre-existing lung disease conditions that may be prone to fungal colonization. *Aspergillus fumigatus* and *Aspergillus niger* are the most commonly encountered species. The reported incidence of haemoptysis in patients with aspergilloma ranges from 54 to 87.5%. Most patients will experience mild and recurrent episodes of haemoptysis, although roughly 10% may develop massive events [6]. Invasive pulmonary aspergillosis in immunocompromised subjects is also associated with haemoptysis events, although rarely fatal.

Cystic fibrosis, usually in the context of extensive bronchiectasis, has become an increasingly common aetiology of haemoptysis, probably due to the longer survival of affected patients into adulthood. Approximately 40% of patients with cystic fibrosis will develop an episode of haemoptysis during the course of their life, with an average annual incidence of 0.87% [7].

Necrotizing pneumonia, lung abscess, and lung gangrene caused by bacteria, such as *Klebsiella pneumoniae, Pseudomonas aeruginosa, Staphylococcus aureus, Streptococcus pneumoniae*, other *Streptococcus* spp. and *Actinomyces* spp. may be associated with haemoptysis in up to 15% of cases [8].

Bevacizumab is a monoclonal antibody that targets angiogenic factors and has been shown to be effective in the treatment of various forms of cancer. The use of this drug in patients with lung malignancy may be complicated by a high incidence of pulmonary haemorrhage, mainly in patients with squamous cell histology [9].

The event of pulmonary artery rupture during pulmonary artery catheterization (PAC) is relatively rare with an incidence of 0.01–0.47% [10]. However, when it does happen, associated mortality is considerable, being over 70%. Rupture may be due either to the catheter tip being directed into the vessel wall, or to catheter migration to a smaller calibre branch and subsequent rupturing during balloon inflation.

Pulmonary hypertension is reported as the underlying cause of haemoptysis in 0.2–4% of cases [11]. Conversely, in patients with Eisenmenger syndrome, haemoptysis is a more common finding.

In female patients with thoracic endometriosis haemoptysis represents an early clinical manifestation, occurring at an earlier age, whereas pneumothorax tends to manifest in more advanced disease. In over 80% of cases the right hemithorax is involved [12].

Diffuse alveolar haemorrhage is a rare cause of haemoptysis associated with disruption of the alveolar–capillary barrier. It should be suspected in case of haemoptysis, anaemia and bilateral infiltrates on the chest radiograph. The infiltrates are the result of distal inhalation of blood. Diffuse alveolar haemorrhage may be associated with Goodpasture's syndrome, where antibodies to type IV collagen are deposited along the alveolar and glomerular basement membranes, giving rise to haemoptysis. Diffuse alveolar haemorrhage is also associated with systemic vasculitis, such as Wegener's granulomatosis or microscopic polyangiitis. Less commonly, diffuse alveolar haemorrhage may be associated with other immunological conditions, such as systemic lupus erythematosus, Henoch–Schönlein purpura, IgA nephropathy, rheumatoid arthritis, Behçet's syndrome, and cryoglobulinaemia. Infectious processes, such as leptospirosis, malaria, and cytomegalovirus infection may present alveolar haemorrhage. A number of drugs are also associated with diffuse alveolar haemorrhage, such as propylthiouracil, carbimazole, and crack cocaine [13].

In a sizable number of cases, even after extensive diagnostic work-up, a definitive cause for haemoptosyis is not found. These cases are termed as cryptogentic haemoptysis. The incidence of cryptogenetic haemoptysis varies between different reports, with most being between 15 and 30% [14]. Most of these studies have, however, not systematically used CT evaluation on all patients. Wider availability and technical developments in CT imaging will likely result in reduced prevalence of unknown origin cases of haemoptysis in the future.

Pathophysiology

The lungs are furnished with a dual blood supply, the bronchial arteries and the pulmonary arteries. The former account for only about 1% of arterial supply to the lung and bring nutrients to the lung parenchyma, the bronchi, and vasa vasorum of the pulmonary arteries and veins. The bronchial arteries are a high-pressure circulation system. They have a variable anatomy in terms of origin and branching distribution. They generally originate from the descending thoracic aorta, at the level of the 3rd–8th thoracic vertebral body, more commonly between T5 and T6 (70–83.3% of cases) [15]. The right bronchial artery often arises together with the first aortic intercostal artery to form the intercostobronchial (ICBT) trunk, which usually branches off from the right lateral surface of the descending thoracic aorta. The left bronchial arteries conversely tend to arise from the more anterior surface of the descending thoracic aorta. The four most common bronchial artery branching patterns include type I with one right bronchial artery (rising from the ICBT) and two left bronchial arteries (present in 40.6% of cases), type 2 with one right (rising from the ICBT), and one left bronchial artery (21.3% of cases), type 3 with two right (only one rising from the ICBT), and two left bronchial arteries (20.6%), and type 4 with two right (only one rising from the ICBT), and one left bronchial artery (9.7% of cases) [15]. In approximately 20–30% of cases aberrant bronchial arteries branch off from other systemic arteries, such as the aortic arch, brachiocephalic artery, subclavian artery, internal mammary artery, inferior phrenic artery, or abdominal aorta. In addition, during chronic inflammatory processes collateral blood supply may be recruited from non-bronchial systemic arteries through transpleural vessels. These collateral non-bronchial vessels may derive from ramifications of subclavian, axillary, internal mammary arteries, as well as from subdiaphragmatic arteries. True bronchial arteries (both normal variants and aberrant) can be distinguished from these non-bronchial systemic arteries in that their trajectory into the pulmonary parenchyma parallels the bronchovascular axes. In contrast, non-bronchial systemic collateral vessels do not run parallel to the airways and have a more unpredictable origin from infradiaphragmatic arteries or from the supra-aortic great vessels or their branches, and enter the parenchyma through the inferior pulmonary ligament or through the adherent pleura; their course is not parallel to that of the bronchi.

The pulmonary arteries are a low-pressure circulation system that account for 99% of the arterial supply to the lungs and are responsible for gas exchange. The bronchial and pulmonary systems are in close proximity at the level of the vasa vasorum where they are interconnected by numerous anastomoses. These communications cause a physiological right-to-left shunt that involves approximately 5% of the total cardiac output.

Bleeding in the lungs may originate from bronchial arteries, pulmonary arteries, bronchial capillaries, and alveolar capillaries. Bronchial arteries are the most common site of bleeding causing haemoptysis, being involved in approximately 90% of cases [16]. In only 5% of cases does haemoptysis origin from the pulmonary vessels. In the remaining 5% of cases bleeding arises from ectopic bronchial arteries or other non-bronchial systemic arteries (including the aorta).

Bleeding from the pulmonary artery circulation may be found in disease processes, such as tuberculosis, mycetoma, cavitating lung carcinoma, lymphoma, Behçet disease, pulmonary arteriovenous malformations, and trauma during right heart catheterization. The most common cause of bleeding from the pulmonary circulation is Rasmussens's aneurysm. In the walls of cavitary lesions, bronchial or pulmonary arteries may be subject to deformation causing pear-shaped dilatations, which are, in truth, pseudo-aneurysmatic lesions, which may be eroded due to chronic inflammatory derangement. These aneurysms are traditionally considered responsible for haemoptysis in TB patients. However, the development of hypervascularized, dilated, tortuous bronchial vessels, often anastomotic with the pulmonary circulation, in the absence of true aneurysms, may be equally involved in these patients.

In certain situations, the thin-walled capillary communications between the high-pressure systemic bronchial arterial system, and the lower pressure pulmonary arterial system can vasodilate and enlarge. Conditions causing reduced pulmonary arterial perfusion, such as chronic thromboembolic disease and vasculitic disorders, in which there is a reduction in pulmonary arterial supply distal to the emboli, can lead to a gradual increase in the bronchial arterial contribution [3], thereby increasing the importance of bronchial-to-pulmonary artery anastomoses in regions of the lung that are deprived of their pulmonary arterial blood flow. Experimental studies have suggested that the increased bronchial arterial blood flow is due to neovascularization [3]. The anastomotic vessels, which are subjected to increased systemic arterial pressure, are often thin-walled, and prone to rupture into the alveoli or bronchial airways, giving rise to haemoptysis. During acute or chronic tracheobronchitic events, inflammation of the mucosa with vascular engorgement, desquamation, atrophy, and erosion, may lead to bleeding. Infective agents, such as *Aspergillus* spp. may release fungal endotoxins that exert haemolytic activity. Inflammatory processes release angiogenic growth factors, thus promoting neo-angiogenesis and recruitment of collateral supplies from adjacent vessels and increased anastomoses between bronchial and pulmonary arterial systems [17]. Similar mechanisms are in play in haemoptysis caused by lung cancer. Cancer growth requires new vessel formation derived from pro-angiogenic tumour-secreted cytokines becoming dominant over naturally-occurring angiogenesis inhibitors. Most common factors involved are vascular endothelial growth factor (VEGF), angiopoietin 1, fibroblast growth factor, hepatocyte growth factor, transforming growth factors α and β, platelet-derived growth factor (PDGF), tumour necrosis factor-α, and interleukin-8 [18]. Furthermore, there is evidence that VEGF elevation correlates significantly with the presence of haemoptysis in patients with pulmonary aspergilloma [19]. The hypoxic micro-environment associated with tumour growth causes cellular activation of hypoxia-inducible factor (HIF). HIF up-regulation promotes transcription of pro-angiogenic cytokines [20]. Hypoxaemia-induced angiopoietin 2 release plays an important role in initiating vessel sprouting in concert with VEGF. In contrast with angiopoietin-1, which stabilizes blood vessels, angiopoietin 2 destabilizes blood vessels, thus favouring bleeding. The new vessels associated with chronic inflammatory or tumoural pro-angiogenesis are usually thin-walled and fragile, and thus prone to rupture into the airways, therefore causing haemoptysis.

Other specific mechanisms may be involved in generating haemoptysis, in particular disease conditions. In patients with depressed left ventricular ejection fraction or mitral stenosis elevated pulmonary intravascular pressure may cause rupture of pulmonary veins or capillaries, resulting in blood-stained sputum. In patients with Goodpasture's syndrome, deposition of antibodies directed against the alveolar–capillary basement membrane disrupts capillary integrity leading to bleeding.

CHAPTER 127

Therapeutic approach in haemoptysis

Francesco Blasi and Paolo Tarsia

Key points

- The diagnostic work-up involves the complementary use of CT scan, bronchoscopy, and pulmonary angiography.
- Current multidetector CT angiography is currently considered superior and less time-consuming than traditional pulmonary angiography in identifying the artery causing bleeding.
- The priority in management of massive haemoptysis involves prompt resuscitation and airway protection with patient stabilization, followed by medical and endoscopic temporary procedures.
- Super selective bronchial artery embolization (BAE) is now considered the treatment of choice in most patients with massive haemoptysis.
- In cases of recurrent haemoptysis following BAE, particularly in particular conditions such as mycetoma, surgery may still be considered a desirable option, provided the patient is sufficiently fit.

Diagnostic work-up

The aim of diagnostic studies in patients with haemoptysis is two-fold—locate the source of bleeding, and identify the underlying cause. In investigating a patient with haemoptysis, it is important to ascertain that the blood arises from the lower airways and exclude haematemesis from the gastrointestinal tract or epistaxis from the nasopharynx. Alkaline pH (using pH indicator paper), foaminess, and the presence of pus are useful bedside signs that may indicate the lungs are the source of bleeding prior to diagnostic investigation.

Complete past history regarding respiratory and cardiac diseases should be recorded. A history of co-existent haematuria may suggest the presence of diseases such as Wegener's granulomatosis and Goodpasture's syndrome. Current medications, particularly anticoagulant therapy should also be noted. The patient should undergo detailed respiratory and cardiac examination, and nutritional status should be assessed. Additional important signs include finger clubbing, presence of palpable lymph nodes, and signs of skin or mucosal bleeding.

Blood tests should evaluate clotting profile, platelet count, and haemoglobin levels. Repeat testing may be necessary to better quantify the entity of blood loss. Blood gas analysis is essential to assess gas exchange. Sputum testing should be performed for bacteria, mycobacteria and fungi, and malignant cells, particularly in long-term smokers.

Chest X-ray

In most cases, this is the first radiographic investigation performed, and may be informative regarding a number of conditions involving the lung parenchyma, pulmonary vasculature, or the heart. Both a posterior–anterior and a lateral film should be obtained. Pulmonary masses, cavitary lesions, pneumonia, chronic pulmonary disease, or atelectasis may be visualized. Even though the true nature of the disease may not be immediately apparent, a chest radiograph may identify and localize the site of bleeding to one lung or a single lobe in 33–82% of cases [1,2], allowing more focused additional testing. In approximately 20–40% of cases, initial chest X-ray may be normal or non-informative (showing chronic or unchanged abnormalities) [3]. A normal chest radiograph is not sufficient to stop investigations for identifying the condition underlying the haemoptysis, as additional testing such as CT scan may reveal conditions such as pulmonary emboli, pulmonary hypertension, bronchiectasis, or initial interstitial disease, not detectable by a plain chest radiograph. Furthermore, it has been reported that between 5 and 6% of patients with haemoptysis, and a normal chest radiograph, a lung cancer is eventually identified [4].

Chest CT scan

Chest CT scan may allow correct localization of the bleeding site in 65–100% of cases [1,5,6]. Several studies demonstrate that CT is at least equal if not superior to bronchoscopy in identifying the cause of haemoptysis [5,6]. The site of haemorrhage may be localized due to detection of liquefied material within bronchi or ground glass infiltrates in the lung parenchyma. Recently, multidetector computed tomography (MDCT) techniques allow scans of the whole thorax in a single breath hold (little more than 10 seconds), with slice thickness approaching 1 mm. Contrast-enhanced MDCT with both two- and three-dimensional volumetric imaging allow high resolution angiographic studies [7]. MDCT angiography is particularly useful to interventional radiologists prior to planning bronchial arterial embolization.

In a study comparing traditional invasive angiography with CT angiography, the latter allowed more precise demonstration of both bronchial and non-bronchial systemic arteries [8]. Multidetector CT has also proven effective in identifying haemoptysis deriving from the pulmonary artery circulation [9].

CT scans also present some limitations. In severe unstable patients or in cases with active bleeding that requires airway management, shifting the patient to the radiology department may be problematic and bedside bronchoscopy is often preferred in this context.

Bronchoscopy

This procedure may be of help in a number of ways following or during haemoptysis events. It may allow identification of the lung or lobe causing the bleeding, identify the underlying cause, it may help clear the airways from blood clots favouring gas exchange, and finally it may be a means by which therapeutic manoeuvres to stop the bleeding are put in place. It also allows airway sampling, thus obtaining specimens for identification of bacterial, fungal, mycobacterial, or tumoural causes of haemoptysis. Bronchoscopy allows identification of bleeding up to the fifth or sixth generation of bronchi.

Optimal timing for bronchoscopy is still a matter of debate. Bronchoscopy is often performed 'early' (within the first 12–18 hours) due to the fact that bleeding may increase with time rendering later visualization of the airways less effective. This may be more pertinent for clinically stable patients or when bleeding has stopped. On the other hand, in patients with massive haemoptysis it is now possible to perform MDCT angiography or traditional invasive angiography with immediate embolization of culprit bronchial arteries within a very short time span. In these patients, bronchoscopy may be performed 'late' as an aid to identify the underlying cause of haemoptysis, and allowing microbiological and cytological analysis. There is, as yet, no definitive proof that 'early' bronchoscopy is associated with better outcomes.

Rigid bronchoscopy was the procedure of choice in the past. The procedure allows aspiration of large quantities of blood, use of therapeutic manoeuvres, while ensuring adequate ventilation [10]. One drawback of rigid bronchoscopy is the more limited capacity to explore the peripheral bronchial tree and the upper lobes compared with flexible bronchoscopy. Flexible bronchoscopy has now become the most common procedure in patients with haemoptysis, as it may be performed at the patient's bedside and allows visualization of segmental and subsegmental bronchi [11]. Due to the limited size of its operational channel, flexible bronchoscopy has a more limited suctioning capacity compared with rigid bronchoscopy. Fibre optic bronchoscopy identifies the site of bleeding in 73–93% of cases [11], with a lower diagnostic yield recorded in cases of mild-to-moderate haemoptysis.

Within the diagnostic framework of haemoptysis, bronchoscopy, and CT scan should not be considered as alternative procedures, but rather as complementary, each allowing specific information regarding site and cause identification.

Pulmonary angiography

Diagnostic pulmonary angiography was traditionally considered the procedure of choice to identify the source of bleeding. Moreover, it allows bronchial artery embolization during the same procedure. However, given the variability of the bronchial artery supply, complete angiographic investigation of orthoptic and ectopic bronchial arteries to identify the origin of bleeding may be quite time consuming. If CT, bronchoscopy, or both are performed prior to angiography, a better definition of the site of bleeding allows considerable shortening of procedure time. During angiography, signs that may be used to determine the site of bleeding include vessel size, vascular blush, focal hypervascularization, and presence of vascular shunts.

Over the last decade, it has become apparent that diagnostic angiography is less effective than MDCT angiography in detecting the site of bleeding [8].

Therapeutic approach

Treatment of haemoptysis may vary considerably, ranging from outpatient management to intensive care unit admittance. Choice of optimal management depends on the intensity of bleeding, degree of respiratory compromise, and severity of underlying cardiorespiratory status. Mild haemoptysis may be handled on an outpatient basis with antibiotics and symptomatic treatment, such as antitussives. For more severe cases, hospitalization is required for diagnostic and therapeutic work-up. Blood abnormalities must be corrected with corresponding blood products. Tranexamic acid is an antifibrinolytic agent that acts by inhibiting plasminogen activation. Oral or intravenous formulations of this agent have been employed in patients with mild-to-moderate haemoptysis. Intravenous vasopressors do not seem to have a role in the routine management of haemoptysis due to concerns in patients with co-existing coronary artery disease or hypertension. It has been suggested that bronchodilator use may best be limited in patients with haemoptysis as these drugs may exert vasodilator effects, thus facilitating bleeding recurrence [8].

Important steps in the management of patients with massive haemoptysis include:

- Resuscitation, airway protection, and patient stabilization as the priority.
- Subsequent localization of the site of bleeding.
- Specific interventions to stop the bleeding and prevent recurrence.

Intubation may be required with a large bore tube (preferably size 8 or more) to facilitate airway suctioning. A double-lumen endotracheal tube may be used when diseased side isolation is required in order to protect the unaffected lung. The left-sided tube is easier to place compared with the right-sided tube. The latter carries a higher risk of obstructing the right upper lobe bronchus, given that it originates rather proximally along the right main bronchus. Initial management also includes volume resuscitation, and correction of underlying coagulation disorders. If the site of bleeding includes only one lung, the affected side should be kept dependent in lateral decubitus in order to prevent aspiration to the contralateral side. The true clinical validity of this theoretical consideration has not been test in controlled trials.

Bronchoscopic treatment

As discussed earlier, bronchoscopy may be of use in a number of ways in patients with haemoptysis, allowing site of bleeding identification, sampling of the lower airways, airway clearing, and institution of therapeutic manoeuvres. The relative advantages and disadvantages of rigid versus fibre optic bronchoscopy that have been discussed regarding the diagnostic use of bronchoscopy, apply to the therapeutic aspects of the technique also.

Instillation of different types of substances has been used in the treatment of patients with haemoptysis. Cold saline lavage may be performed with 50-mL aliquots of refrigerated (4°C) saline,

instilling roughly 500 mL overall volume. This technique may be effective in stopping bleeding [11]. A rigid bronchoscope is generally preferred due to better suction capacity compared with fibre optic bronchoscopy.

Topical vasoconstrictive agents have been tested, mainly in cases of bronchoscopy-induced airway bleeding. Adrenaline (1:20,000) [11], or antidiuretic hormone derivatives, such as terlipressin (0.5 mg) and ornipressin (5 IU) have been used [12], but their efficacy in massive haemoptysis is debated since the drugs are easily diluted and washed away. Likewise, endoscopic instillation of fibrinogen-thrombin or thrombin has been evaluated, but efficacy has not been convincingly demonstrated [13]. Endobronchial application of tranexamic acid (500–1000 mg) may be used in mild-to-moderate cases. Temporary endobronchial tamponade with a balloon catheter is a commonly employed procedure. 4 Fr 80-cm long Fogarty catheters can be inserted through a flexible bronchoscope and ensure emergency control of bleeding while awaiting bronchial artery embolization or surgery [14]. Alternatively, Freitag et al. [15] developed a 6 Fr 170-cm long double lumen balloon catheter. The second lumen facilitates instillation of cold saline or topical agents. A detachable valve at the proximal end of the catheter allows easy removal of the bronchoscope with minimal risk of balloon displacement. The prolonged use of balloon catheter tamponade is discouraged as ischaemic mucosal injury and post-obstructive pneumonia may ensue.

A number of endobronchial materials or procedures have been used to facilitate temporary bleeding interruption, such as airway stents, silicone spigots, oxidized regenerated cellulose mesh, sealing glues, Nd-YAG laser, cryotherapy, and brachytherapy, particularly in the context of haemoptysis caused by endobronchial carcinoma [11].

Bronchoscopy treatment strategies may allow temporary control of bleeding, buying time while patients' conditions are stabilized. In some instances, the procedures may provide long-lasting haemostatic effects, but in many cases of massive haemoptysis provides temporary relief while awaiting more definitive treatment, such as bronchial artery embolization or surgery.

Bronchial artery embolization

Bronchial artery embolization (BAE) is performed during pulmonary angiography by occluding systemic vessels and blocking arterial blood flow to fragile vessels within diseased tissue. Non-selective BAE was associated with a greater rate of inadvertent occlusion of spinal arteries. More recently, microcatheter superselective bronchial artery catheterization has allowed more stable positioning within the bronchial tree and more distal cannulation avoiding spinal artery embolization.

BAE is now considered the procedure of choice in patients with persistent haemoptysis following medical management, massive haemoptysis, recurrence of haemoptysis, in candidates deemed unfit for surgery, or as an emergency procedure to temporarily control bleeding, while awaiting surgery. Embolizing materials include gelfoam, polyvinyl alcohol (PVA) particles, dextran microspheres, or steel coils. PVA particles, available in a variety of particulate sizes (generally measuring between 350–500 μm in diameter) are the most commonly used agents. These non-absorbable particles prevent recanalization. Metal coils tend to occlude more proximal vessels and render subsequent embolization virtually impossible, but are the material of choice in pulmonary artery aneurysms and in pulmonary arteriovenous malformations. With BAE, immediate control of bleeding may be obtained in 70–95% of patients. Recurrence has been reported in 10–30% of cases [16]. However, the procedure may be repeated safely over time. Recurrence may be due to non-optimal embolization of bronchial arteries, collateral vessel formation, origin of the bleeding from the pulmonary artery circulation, and presence of non-bronchial systemic arteries. Early recurrence (within weeks) of bleeding is generally caused by incomplete embolization, whereas late rebleeding is more likely due to recanalization of embolized vessels or collateral circulation due to progression of the underlying disease condition. Some lung cavitary conditions, such as mycetoma are more prone to recurrence than others and are ultimately best managed by surgery. Persistent recurrence may also be associated with within bleeding arising from the pulmonary artery circulation.

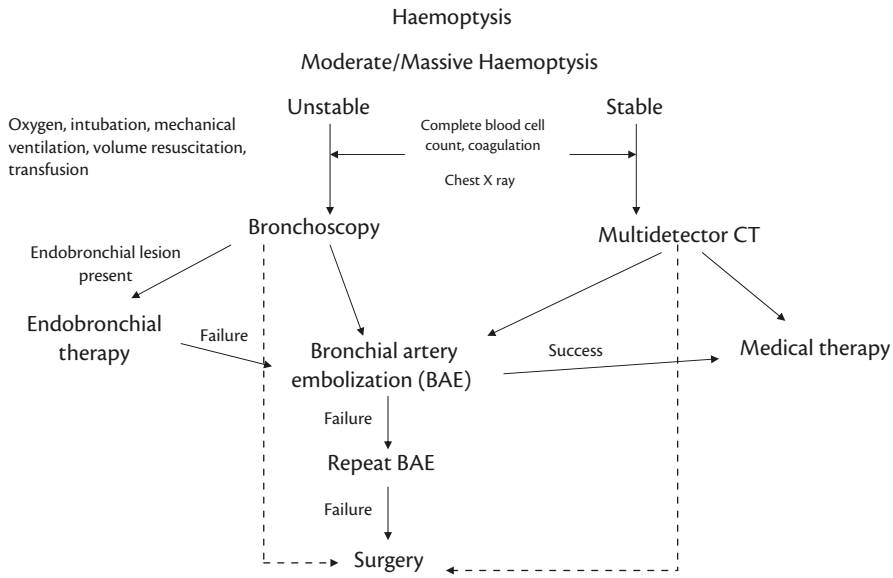

Fig. 127.1 Treatment algorithm for the management of haemoptysis.

Common complications following BAE include fever, dysphagia (present in 1–18% of cases), and chest or back pain (in 24–91% of cases) [17]. These side effects are generally transitory and are probably the result of the occlusion of vessels supplying the oesophagus, and diaphragmatic and pleural visceral pleura. The most feared complication is paraplegia derived from occlusion of spinal arteries that arise from bronchial or intercostal arteries. Use of superselective microcatheters has currently reduce the rate of this complication to <1%. In patients with massive haemoptysis the death rate following BAE is between 7 and 18% [18].

Surgery

Prior to BAE, surgery was considered to be the most effective method of controlling massive haemoptysis. Surgical mortality may be as high as 40% in the emergency setting, with additional morbidity in another 25–50% [19]. Mortality is considerably greater in emergency situations than in elective surgery. Moreover, most case series are now over 20 years old, and mortality has probably dropped considerably over the last decade due to improved surgical techniques and expertise.

Surgery is still considered the strategy of choice in conditions known to exhibit poor response to BAE, such as mycetoma. Additional situations where surgery is still indicated are complex arteriovenous malformations, iatrogenic pulmonary artery rupture, localized bronchiectasis and tuberculosis scars. Radiation therapy is a further option in patients with mycetoma or vascular tumours with massive recurrent haemoptysis [20]. Its effects are mediated through necrosis of feeding blood vessels and vascular thrombosis due to perivascular oedema.

Haemoptysis treatment algorithm

Haemoptysis, particularly massive haemoptysis, may present as a clinical emergency. Prompt patient stabilization, diagnostic testing, and therapeutic management are best obtained through multidisciplinary activation of intensivists, pulmonologists, radiologists, and thoracic surgeons. Fig. 127.1 presents a treatment algorithm that summarizes diagnostic and therapeutic options available for patients with massive haemoptysis.

SECTION 5

The cardiovascular system

PART 5.1

Physiology

CHAPTER 128

Normal physiology of the cardiovascular system

Hugh Montgomery and Rónan Astin

Key points

- Central venous pressure is not a good guide to preload, or a good predictor of the response to a volume challenge.
- Assessment of the dynamic response of pulse pressure or stroke volume to altered preload identifies fluid responsiveness.
- Afterload is influenced by factors other than simple peripheral vascular resistance.
- Ill-judged peripheral vasoconstriction can lead to decreased cardiac output in the setting of poor left ventricle function and/or hypovolaemia.
- Global cardiac output must be maintained at a level that can support the metabolic demands of the body, but within a range of arterial pressures commensurate with the limits imposed by the autoregulation of individual organ perfusion.

Introduction to the normal physiology of the cardiovascular system

The cardiovascular system (CVS) serves an essential 'delivery' service to every cell. This is not simply restricted to the supply of oxygen from the lung and nutrients from the gut and visceral stores, but of water, hormones and electrolytes. Likewise, it must remove waste products of metabolism such as carbon dioxide, water, and acids, from cells. The CVS also transports heat (e.g. from exercising muscle to the skin), playing a key role in thermoregulation. In performing such roles, the CVS needs to be both redistributive and responsive, being able to change both the scale of its global (macrovascular) and local (microvascular/regional) convective function.

Cardiac performance

Alongside venous compression by skeletal muscle contraction, and respiratory muscle generation of negative intrathoracic pressure (*vis a fronte*), cardiac contraction makes the greatest contribution to the hydraulic work that drives blood flow within the human circulation.

All cardiac chambers are composed of cardiomyocytes, the force (and velocity) generated by which depend upon their size, intrinsic contractile properties, and state of health, response to neurohormonal facilitators (such as tri-iodothyronine) and inotropic stimuli (sympathetic efferent activity, circulating catecholamines), biochemical factors (such as oxygen availability and electrolyte balance) and crucially, loading conditions (stretch or preload). The force generated by any cardiac chamber thus depends upon the same factors that influence the contraction of the myocytes of which the chamber is composed, as well as by the number and orientations of those cells.

Preload

Consider a heart facing constant resistance to efferent flow (afterload), and an unchanging biochemical and neurohormonal milieu. In this state, the force generated by the contracting chamber (the left ventricle (LV), for example) will depend upon the degree to which its constituent cardiomyocytes are stretched. This, in turn, will depend upon the chamber volume (end-diastolic volume (EDV)). This relationship is described by the Frank–Starling curve—with increasing LV preload, stroke volume (SV) rises until a plateau is reached (see Fig. 128.1).

The position of the curve is also affected by ventricular compliance (or distensibility). Because the right ventricle (RV) is generally thinner and more compliant than the LV, its Frank–Starling curve lies upwards and to the left of that for the LV. For any given stroke volume, left ventricular end-diastolic pressure (LVEDP) is thus normally higher than right ventricular EDP (RVEDP).

Compliance is also affected by disease. A left ventricle exposed to lifelong pressure overload may have an increased wall thickness and altered wall composition (with substantial deposits of collagen), meaning that high end-diastolic volumes may yield high intracavity pressures, but have limited capacity to stretch individual myocytes (see Fig. 128.1).

Nonetheless, for any given ventricle at any time, end-diastolic volume is a good measure of preload. In clinical practice, the relationship between EDV and cardiac work is hard to discern, due to difficulties in the direct measurement of hydraulic work and cardiac volume. SV is thus often used erroneously as a surrogate for cardiac work, and end-diastolic pressure (EDP) for cardiac volume.

The flaws with this approach are obvious. First, stroke volume may vary over time quite independently of work, for instance, with changes in afterload or inotropic status. Secondly, EDP depends upon both EDV and ventricular **compliance** ($\Delta EDV/\Delta EDP$), which varies greatly between individuals (as mentioned previously). A high EDP may occur in the presence of a low EDV when compliance is poor. The stretch 'perceived' by the myocyte may be lower still. Furthermore, the relationship between EDV and EDP is not linear, especially at higher volumes, meaning that changes in EDV in response to a fluid challenge become increasingly hard

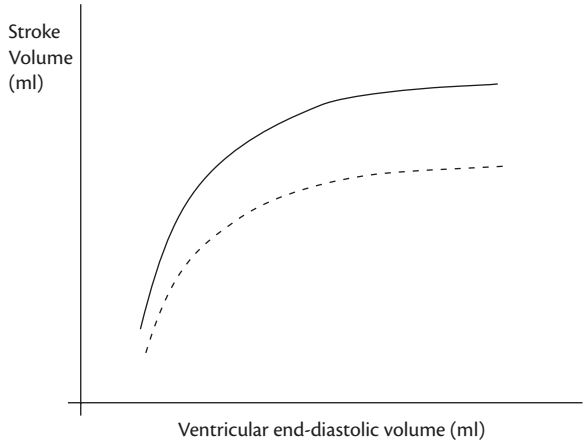

Fig 128.1 The Frank–Starling curve in a healthy ventricle (solid line). As ventricular volume (preload) rises, so too does cardiac work. Under constant conditions of afterload and inotropic drive, this is reflected by a rise in stroke volume towards a plateau. Stroke volume (and ejection fraction) can be increased by a reduction in afterload (such as that induced by vasodilatation), causing the curve to shift upwards and to the left. This does not reflect an inotropic response—the 'stroke work versus EDV' curve is unaffected. The dotted line represents a diseased ventricle. The curve has moved downwards and to the right such that, at any given preload, stroke work (and volume) are reduced. Thus, end-diastolic volume (and with it, pressure) will need to rise if SV is to remain unchanged. The same holds true if ventricular compliance is reduced.

to infer as intravascular volume expands. Compliance may also change over shorter timescales, given that diastolic relaxation is partly an active process.

While left ventricular end-diastolic pressure can be inferred from measurement of pulmonary artery occlusion pressure, pulmonary artery flotation catheters are now infrequently used in routine clinical practice. As a result, central venous pressure (CVP) is taken to infer RV end-diastolic pressure, while changes in RVEDP are also used to infer **left** ventricular EDP. CVP estimates right atrial pressure, and this is often used as an index of right ventricular filling. However, CVP changes in response to alterations in intrathoracic pressure and these changes only influence preload if they are incompletely transmitted across the vessel wall. The degree to which this is true cannot be readily determined. Changes in ventricular compliance and venous tone compound such effects, making CVP a poor guide to RVEDP (and thus LVEDP).

Static measures of CVP (and even of RVEDP) thus provide little insight into the patient's position on the 'Starling curve' and thus their capacity to increase SV in response to a volume challenge ('volume-responsiveness') [1]. This fact is of some importance, given that only half of haemodynamically-unstable intensive care unit patients are responsive in this manner [2]. Instead, dynamic assessment of the SV response to altered preload is required, for which a number of methods are currently used.

Ventricular loading changes during the **positive pressure** ventilatory cycle. The inspiratory phase decreases venous return and thus RV preload, but increases RV afterload. Right ventricular SV thus falls, as does LV filling and, a short while later, SV—usually during expiration [3]. The effects are greatest when both ventricles are operating on the steep portion of the Starling curve. Respiratory cycle-associated changes in SV (or pulse pressure) >12% predict the response to volume loading. Of note, such predictive power is dependent upon the use of tidal volumes of at least 8 mL/kg, and is invalidated by any spontaneous breathing or arrhythmias [4].

Changes in loading can be actively induced to predict volume responsiveness. A 5% increase in SV in response to a 15-second end-expiratory hold is strongly predictive [5]. Lower limb elevation to 45° while rendering of the trunk supine from a 45° position will volume load the RV from the leg and abdominal compartments. This also has value in predicting the response to an exogenous fluid challenge [6].

Afterload

Once ventricular systole has been initiated, the contractile work performed by the heart must be converted into flow. **Afterload**, the contractile tension across the ventricular wall (**wall tension**, T), represents the force to be overcome before the cardiac muscle can shorten and thus start ejecting blood. For a ventricle, Tt = Pr, where the product of contractile wall tension (T) and average wall thickness (t) matches the product of transmural pressure (P) and chamber radius (r) at end-diastole. Thus,

$$T = Pr/t. \qquad \text{[eqn 1]}$$

Increases in afterload reduce the volume of blood expelled for any given amount of cardiac contractile work and can result from various factors. First, afterload varies with wall thickness. More dynamically, chamber radius increases as a function of ventricular filling as EDV rises. Meanwhile, increased impediment (**impedance**) to the flow of ejected blood will also increase afterload. Impedance, in turn, rises if the **resistance** to average flow rises, or if there is limitation to the rate of change of flow through changes in vascular **compliance**—a less stiff vessel will more readily accept ejected blood. In clinical practice, compliance is not monitored, while resistance is derived from measurements of flow and pressure. Ohm's Law relates the constant flow of electric current (I) around an electrical circuit of resistance 'R' to the motive force (voltage, V) driving that flow:

$$V = IR, \text{ or } I = V / R \qquad \text{[eqn 2]}$$

Similarly, continuous flow of blood around a biological circuit (as seen in the microvasculature) is also determined by the ratio of the motive force (the pressure gradient across that vascular bed) and the resistance to flow that the bed offers. Thus, for the systemic circulation:

$$CO = \left(MAP - CVP\right) / SVR \qquad \text{[eqn 3]}$$

where CO represents cardiac output, MAP is mean arterial pressure, CVP is central venous pressure, and SVR systemic vascular resistance.

If pressures are measured in mmHg and flow in mL/sec, resistance can be expressed in mmHg per mL/sec which, when multiplied by 1333, yields the more familiar dynes/sec/cm^5. One dyne represents the force required to accelerate 1 g at a rate of 1 cm/sec^2. Such units are not readily amenable to simple mental calculation at the bedside, where MAP and CVP, and cardiac output, are presented in units of mmHg and L/min, respectively. Using these, SVR can be calculated in Wood's units, where a 'normal range' generally lies between 10 and 20.

In the absence of a substantial shunt, pulmonary blood flow should match systemic cardiac output. If mean pulmonary arterial pressure (PAP) and LVEDP are known, then pulmonary vascular resistance (PVR) can be calculated:

$$PVR = (PAP - LVEDP) / CO \quad \text{[eqn 4]}$$

Finally, one should not forget that afterload is the tension **across** the ventricular wall. As such, it will be influenced by **pleural pressure**. Large negative pleural pressures thus increase afterload and reduce cardiac output. This effect is most readily observed in the asthmatic where cardiac output (and with it, blood pressure (BP)) falls during inspiration, while perhaps being augmented by forceful expiration against resistance. The resultant drop in inspiratory blood pressure is recognized as '***pulsus paradoxus***', an exaggeration of the effect seen during normal breathing.

Vascular flow

As described in 'Afterload' the rate of constant flow through rigid tubes is determined by the ratio of the driving pressure gradient to the resistance (R) to flow. R is, in turn, determined by the radius (r) and length (L) of the tube, and the viscosity of the flowing fluid (η), so that:

$$R = \pi r^4 / (8 \eta L) \quad \text{[eqn 5]}$$

Blood viscosity is influenced most strongly by red cell concentration. A normal haematocrit is associated with a total blood viscosity some three-fold higher than the surrounding plasma alone. However, in critical care, resistance is more generally determined (and modified) by changes in arteriolar cross-sectional area.

As the larger arteries subdivide, the total cross-sectional area of the vasculature increases. The velocity of flow through each vessel thus falls, allowing time for exchange by diffusion. Even small reductions in arteriolar diameter (driven by circulating vasopressor agents such as vasopressin or norepinephrine, or increases in sympathetic efferent output), produces dramatic increases in resistance. If overall cardiac output remains constant, flow velocity through these arterioles rises, while BP (the product of flow and resistance) increases. Alternatively, such increases in afterload may be associated with reductions in flow if cardiac work cannot be augmented sufficiently. In the patient suffering progressive and significant hypovolaemia, a rising resistance initially compensates for a falling cardiac output to maintain the BP. Ultimately, however, such compensation fails and pressures fall. Similarly, the poorly judged use of vasoconstrictor agents in a patient with poor ventricular function (and relatively 'fixed' cardiac work) will 'convert' this work from flow to pressure: a rise in BP will be associated with a reciprocal fall in cardiac output. This is especially true if this scenario occurs in the context of relative hypovolaemia.

Pressure versus flow

For life to be sustained, perfusion must be maintained. While maintenance of adequate global blood flow (cardiac output) can be achieved across a wide range of different pressure/resistance combinations, this is not universally true when specific organs are considered. The phenomenon of **autoregulation** of flow describes the ability of different vascular beds to maintain constant regional flow across a restricted range of different pressures by adjustment of local resistance. Thus, a combination of metabolic and arteriolar myogenic/neurogenic mechanisms maintain constant cerebral blood flow (CBF) across MAP values ranging from approximately 60 to 140 mmHg. This range is influenced by various neuroendocrine and biochemical factors, and by disease states. The same is true of the renal vasculature, where a combination of myogenic mechanisms and tubuloglomerular feedback maintain constant flows until MAP falls below approximately 70 mmHg.

The minimum arterial pressures required for normal global organ function will vary with the individual, and must be judged on that basis. The longstanding hypertensive is likely to have reset their autoregulation to higher ranges, while local (occult) macrovascular stenoses may reduce effective organ perfusion pressure below that which is recorded systemically.

PART 5.2

Cardiovascular monitoring

CHAPTER 129

ECG monitoring in the ICU

Sanjay Gandhi and William R. Lewis

Key points

- Cardiac monitoring with early defibrillation reduces mortality in patients with confirmed myocardial infarction.
- Key goals of monitoring include detection of arrhythmia, identification of myocardial ischaemia and monitoring of the QT interval in the patient at risk for adverse cardiac events.
- Up to 20% of ICU patient develop arrhythmias detectable by ECG monitoring.
- Significant improvements in technology allow for increased automation and improved accuracy of the monitoring equipment.
- Trained personnel are required to interpret, and respond to telemetry alarms and initiate appropriate treatment.

Introduction

Electrocardiographic (ECG) monitoring is routinely used in hospitals for patients with a wide range of cardiac and non-cardiac diagnoses. Besides simple monitoring of heart rate and detection of life-threatening arrhythmias, the goals of ECG monitoring include detection of myocardial ischaemia, diagnosis of complex arrhythmia, and identification of a prolonged QT interval. The ECG remains a cornerstone in diagnosis and management of patients with coronary ischaemia. Over the past decade there has been an increase in the number and complexity of electrophysiological interventions, including complex ablations, biventricular pacing and insertion of implantable defibrillators. ECG monitoring in these patients can serve both a protective and diagnostic purpose—they detect life-threatening arrhythmias and double up as in-patient Holter monitors. Unfortunately, there are no randomized controlled trials of in-hospital cardiac monitoring, expert opinions based on clinical experience and published research in the field of electrocardiography form the basis of current guidelines [1].

Specific indications

Broadly, the indications for ECG monitoring can be categorized into three subgroups, with some degree of overlap—monitoring arrhythmia, detection of myocardial ischaemia, and identification of a prolonged QT interval.

Detection of arrhythmia

Lawrie et al. [2] showed that a 20% reduction in mortality from acute myocardial infarction could be achieved by early detection of ventricular fibrillation in this population. The highest risk of ventricular fibrillation after myocardial infarction is in the first 24 hours [2]. The typical duration of monitoring is 48–72 hours following an uncomplicated myocardial infarction. In the current era, aggressive mechanical and pharmacological interventions have reduced the mortality and incidence of malignant arrhythmia in patients with acute coronary syndromes. However, despite these advances, in a study of 6355 patients with non-ST elevation acute coronary syndrome undergoing Holter monitoring for 7 days, 20% had ventricular tachycardia, 14.7% had myocardial ischaemia, and 5.3% had both [3]. Having both conditions was associated with poor cardiovascular outcomes at 1 year. ECG monitoring is indicated in patients in the early phase of acute coronary syndromes and after complicated percutaneous coronary interventions. ECG monitoring is also used after placement of an intra-aortic balloon pump, both for monitoring for arrhythmia, but also to use the ECG as a trigger for the balloon pump.

ECG monitoring is also recommended in patients resuscitated from in- or outpatient cardiac arrest, due to a high risk for recurrence. Patients with high-grade conduction blocks, long QT interval, syncope, status epilepticus post-implantable cardioverter defibrillator (post-ICD) or pacemaker placement, or complex electrophysiological ablation also benefit from ECG monitoring.

Patients undergoing cardiac surgery are at high risk of ventricular and supraventricular arrhythmias, and an especially high incidence of post-operative atrial fibrillation [4]. These patients are monitored for a minimum of 48–72 hours post-operatively. Atrial epicardial leads can be monitored in these patients for improved accuracy of post-operative tachycardia.

In the intensive care setting, patients with major trauma, respiratory failure, sepsis, acute pulmonary embolism, after non-cardiac surgery, severe electrolyte abnormalities, acute heart failure, acute stroke, and drug overdose are routinely monitored. Twenty per cent of these patients develop significant arrhythmia, most commonly atrial fibrillation and ventricular tachycardia [5].

ST segment ischaemia monitoring

Asymptomatic ischaemic events, as detected by ECG monitoring, occur in 80–90% of patients with unstable angina and are associated with adverse short- and long-term outcomes [1]. However, no randomized clinical trials have demonstrated that addition of computerized ST monitoring improves patient outcomes in these patients. Computerized ST segment monitoring, while available on current generation of ECG monitors, is therefore underutilized [6]. Current guidelines recommend the use of continuous ST segment monitoring for a minimum of 24 hours in patients with acute

coronary syndromes. In addition, continuous ST segment monitoring is also recommended for 8–12 hours, in combination with serial biomarkers, to triage patients who present to the emergency department for evaluation of chest pain syndromes. Baseline ST segment changes should be taken into consideration when interpreting the results of ST segment monitoring for a given patient. Furthermore, in patients with baseline left bundle branch block, a ventricular paced rhythm of other confounding arrhythmia (e.g. atrial flutter), ST segment monitoring is not helpful.

QT interval monitoring

A corrected QT interval (QTc) >500 milliseconds is associated with a higher risk of torsades de pointes and mortality in acutely ill patients [7]. Risk factors for prolonged QT include female sex, electrolyte abnormalities, QT interval prolonging drugs, ischaemia, and acute neurological events. As the T wave is often obscure, most current cardiac monitors do not have algorithms to measure QT interval so manual measurements are required. Serial QT interval measurements should be done in the same lead for comparison. Current guidelines recommend the use of QT interval monitoring in patients who are prescribed anti-arrhythmic and other pro-arrhythmic drugs known to cause torsades de pointes, patients with new onset bradyarrhythmia, severe electrolyte abnormalities, and patients with acute neurological events.

Monitoring system and staffing

Lead systems

Unlike a standard 12-lead ECG, the electrodes for monitoring are placed on the torso to avoid motion artefact. The conventional bipolar three electrode system has the capability to monitor leads I, II, III, or a modified chest lead. This allows for single lead monitoring at any given time. While this may be adequate to monitor heart rate, it is limited in its ability to diagnose complex arrhythmias or to allow ST segment monitoring. More commonly, a five-electrode system, with four limb electrodes and a chest electrode, is used to provide data from six limb leads and any one of the chest leads, typically V1. These monitors also typically provide two channels, usually one limb lead and one chest lead. Multiple lead displays also minimize data loss due to noise. While more elaborate 6–10 electrode systems with the capability to provide a derived 12-lead ECG are available, they are not routinely used. Detection algorithms developed by various manufacturers are tested against standardized rhythm databases according to protocols established by Association for the Advancement of Medical Instrumentation. In post-cardiac surgery patients, an atrial electrocardiogram can be obtained by attaching any one of the electrodes to the atrial epicardial wire.

Attention should be paid to proper lead placement and careful skin preparation to acquire high quality data.

Staffing

The technology for cardiac monitoring has improved significantly since 1967 with increased automation of arrhythmia and ischaemia detection, remote alarms, and the ability to store and display a large amount of digitized data. However, alarms must still be triaged, interpreted, and acted upon to translate the clinical benefit of monitoring. In the National Survey of Continuous Electrocardiographic monitoring, 55% of US hospitals employed a monitor watcher in their 'step down' or telemetry unit [8]. Monitor watchers can immediately review any alarms, may detect subtle changes that do not trigger alarm, assure high quality tracings, and can free nurses for clinical care of the patients. Employing monitor watchers has been shown to increase accuracy of arrhythmia detection and reduce the incidence of sustained ventricular tachycardia [9]. However, as monitoring devices have now improved in their accuracy, in units with a good nurse-to-patient ratio the role of monitor watcher may be somewhat redundant. In a study by Funk et al. there was no difference in mortality, frequency of transfer to the ICU, or life- threatening arrhythmia in 2383 patients on the same cardiac unit with and without a monitor watcher over a period of 9 months [10]. While combined monitoring of several units with a single remote monitor watcher can be considered, it is preferable to have monitoring responsibility at the level of the monitored step-down or telemetry unit.

More importantly, the nursing staff or monitor watcher should be well trained with both didactic and hands-on practice. Physician and nursing leadership should establish staff training standards, define individual roles and responsibilities regarding cardiac monitoring, and establish protocols for documentation and response to monitor alarms. Appropriate life support systems, including defibrillators, temporary pacemakers, and medications, are required to treat serious arrhythmia and should be readily available in these units.

Conclusion

ECG monitoring has become the standard of care in patients at risk for cardiac arrhythmia or ischaemia. There has been a significant improvement in monitoring equipment over the past several decades. Highly-trained personnel are still required to identify serious arrhythmias and carry out appropriate corrective interventions in a timely fashion for better patient outcomes. Finally, in the age of optimum utilization and increased emphasis on cost and efficiency, care patient selection for ICU, and telemetry monitoring units are essential.

CHAPTER 130

Arterial and venous cannulation in the ICU

Ronan O'Leary and Andrew R. Bodenham

Key points

- Vascular access is a core skill and all practitioners should be confident with a variety of techniques. High-quality training is essential.
- Choice of site, techniques, and devices follows careful consideration of the indication, probable duration of therapy, concomitant pathologies, and potential for complications.
- Ultrasound guidance is the standard technique for central venous access, and is also increasingly used for peripheral venous and arterial cannulation.
- All cannulae should be inserted aseptically. Cannulation sites must be regularly inspected for signs of infection and lines removed promptly if indicated.
- Always consider catheter-related complications, especially sepsis, in unexpectedly deteriorating patients.

Introduction

Despite being almost ubiquitous within the critically-ill population, vascular access remains a frequent cause of iatrogenic injury, manifested as both procedural complications, and later events such as infection and thrombosis. Untoward events are minimized by expert tuition and meticulous practical technique. Consensus guidelines on vascular access are shown in Table 130.1. This chapter covers vascular access during in critical illness and discusses the development of more advanced techniques.

Vascular access, particularly central venous catheterization, should not be undertaken lightly. Can a patient be managed without vascular access or can the number of vascular access devices be rationalized? Other routes for drug and fluid administration exist, particularly enterally during the recovery phase.

General principles

These principles apply to all interventions within the ICU and elsewhere in the hospital. Only when life is threatened should vascular access be hurried. Otherwise, practitioners should observe meticulous aseptic technique, and provide adequate anaesthesia and sedation. Central venous access should mimic operative infection control practices.

- **Planning**: consider optimal choice of device, insertion site, duration of therapy, and co-existing pathology. Consider the probable demands on the operator and whether there is sufficient time to complete a complicated task.
- **Explanation and consent**: informed consent should be documented if practicable. If not, the indication with an analysis of risks and benefits should be recorded.
- **Asepsis**: clearly essential for insertion and aftercare, and an area of increasing medico-legal scrutiny. Checklists derived from work at Michigan [1] provide a framework (Fig. 130.1).
- **Anaesthesia and analgesia**: all but the smallest devices should be inserted under local anaesthesia in both awake and sedated patients.
- **Post-insertion**: confirm position by successful aspiration and flushing of the catheter, pressure measurements and waveform display, with X-ray, electrocardiographic, or ultrasound verification. Appropriate anchorage is essential to avoid dislodgement, with conscientious aftercare to reduce infection.

Peripheral venous cannulae

This core skill may be performed poorly, is not risk-free, and the dexterity required in challenging cases is often underestimated. Recently developed aids to visualization, including transillumination tools and infrared devices, although intuitively attractive have yet to demonstrate a clear-cut clinical benefit.

Cannulae of variable sizes and flow rates are available, including longer length devices. Common insertion sites include the dorsum of hand and forearm. The ante-cubital fossa and other joint flexures should be avoided. Less obvious sites include the scalp in infants, upper arm, chest wall in adults, and the external jugular vein. Discomfort may be minimized by using the smallest gauge appropriate device, and local anaesthetic for larger cannulae. Once inserted and secured, vigilance must be maintained for signs of infection and phlebitis.

Ultrasound aids cannulation of larger peripheral veins, particularly in children [2,3]. It allows visualization of the vessel, while the needle/cannula is introduced at a steep angle to the skin until flashback is seen, and then advanced until imaged within the vein. The needle is then flattened and the cannula passed over the needle into the vein. Agitated saline can confirm patency and location, which is otherwise difficult with deeper veins.

Checklist for Prevention of Central Line Associated Blood Stream Infections

Based on 2011 CDC guideline for prevention of intravascular catheter-associated bloodstream infections:
http://www.cdc.gov/hicpac/pdf/guidelines/bsi-guidelines-2011.pdf

For Clinicians:

Promptly remove unnecessary central lines

- ☐ Perform daily audits to assess whether each central line is still needed

Follow proper insertion practices

- ☐ Perform hand hygiene before insertion
- ☐ Adhere to aseptic technique
- ☐ Use maximal sterile barrier precautions (i.e., mask, cap, gown, sterile gloves, and sterile full-body drape)
- ☐ Perform skin antisepsis with >0.5% chlorhexidine with alcohol
- ☐ Choose the best site to minimize infections and mechanical complications
  - Avoid femoral site in adult patients
- ☐ Cover the site with sterile gauze or sterile, transparent, semipermeable dressings

Handle and maintain central lines appropriately

- ☐ Comply with hand hygiene requirements
- ☐ Scrub the access port or hub immediately prior to each use with an appropriate antiseptic (e.g., chlorhexidine, povidone iodine, an iodophor, or 70% alcohol)
- ☐ Access catheters only with sterile devices
- ☐ Replace dressings that are wet, soiled, or dislodged
- ☐ Perform dressing changes under aseptic technique using clean or sterile gloves

For Facilities:

- ☐ Empower staff to stop non-emergent insertion if proper procedures are not followed
- ☐ "Bundle" supplies (e.g., in a kit) to ensure items are readily available for use
- ☐ Provide the checklist above to clinicians, to ensure all insertion practices are followed
- ☐ Ensure efficient access to hand hygiene
- ☐ Monitor and provide prompt feedback for adherence to hand hygiene
  http://www.cdc.gov/handhygiene/Measurement.html
- ☐ Provide recurring education sessions on central line insertion, handling and maintenance

Supplemental strategies for consideration:

- 2% Chlorhexidine bathing
- Antimicrobial/Antiseptic-impregnated catheters
- Chlorhexidine-impregnated dressings

National Center for Emerging and Zoonotic Infectious Diseases
Division of Healthcare Quality Promotion

CDC

Peripherally inserted central venous catheters

A long catheter (with up to three lumens) may be inserted into a peripheral vein, usually in the arm, and passed into central veins where it may remain for prolonged periods. ECG guidance is increasingly used. With practice they are easy and safe to insert, associated with low rates of complications, and are useful for parenteral nutrition or antibiotics during the convalescent phase of illness. Peripherally-inserted central venous catheters (PICCs) can be inserted via antecubital veins or, preferably, using ultrasound to identify deeper upper arm veins away from joint flexures. For ease of passage, the basilic or brachial vein should be used as the cephalic vein runs a more tortuous course. Power-injectable PICC devices allow liquids, e.g. radiological contrast solution, to be injected under high pressure (up to 325 psi). Midlines catheters utilize a similar technique with a shorter catheter whose tip lies in axillary/subclavian vein.

Arterial access

These are typically used for haemodynamic monitoring and sampling, with larger cannulae used for extracorporeal circuits and radiological interventions. Serious complications are uncommon with the former, but not the latter, in particular the femoral cannulae used for extracorporeal membrane oxygenation circuits. Seldinger-type insertion kits are increasingly used for all devices. Ultrasound guidance is useful in the arteriopath, or where oedema and multiple previous cannulations combine to make access difficult, and to access superficial or deeper non-palpable arteries (e.g. mid-forearm) [8].

Site selection is important, even on first cannulation. Consider the risk-benefit ratio of multiple attempts at poor distal vessels, versus a finite risk of successfully cannulating an end-artery more proximally. Peripheral cannulation is typically performed via the radial artery of the non-dominant arm at the wrist. A patent ulnar artery implies the radial is not an end-artery so, if occluded, tissue loss should not occur. Allen's test (compression of radial/ulnar artery, while assessing hand perfusion), while attractive conceptually, does not reliably predict safe cannulation. The brachial artery may be used but, being an end-artery, there is a risk of distal limb occlusion although this has not been demonstrated in retrospective case series [9,10]. Avoid repeated peripheral attempts in hypotensive, vasoconstricted patients, and consider ultrasound early in difficult patients.

The femoral artery is a valuable access site widely used for diagnostic and interventional procedures, but carries increased risks of infection and thrombosis with prolonged catheterization. The superficial femoral artery is often more palpable than the common, but partially overlies the vein and is more likely to be diseased with atheroma. Proximal puncture above the inguinal ligament can lead to occult haemorrhage into the retroperitoneal space which may be life-threatening. Ultrasound should be used to assess patency and guide cannulation (Fig. 130.2).

Catheter removal should be done aseptically. Firm pressure should be applied to the site for at least 10 minutes. Occasionally, persistent bleeding from a superficial artery may require a fine skin suture or tissue glue. Pressure dressings are rarely helpful when a deeper arterial cannulation site continues to bleed. Radiological occlusion devices or surgical closure are required for devices larger than 9 Fr, in the presence of severe coagulopathy, or in areas where pressure cannot be applied. Large, tense haematomas may need surgical drainage, irrespective of vessel closure.

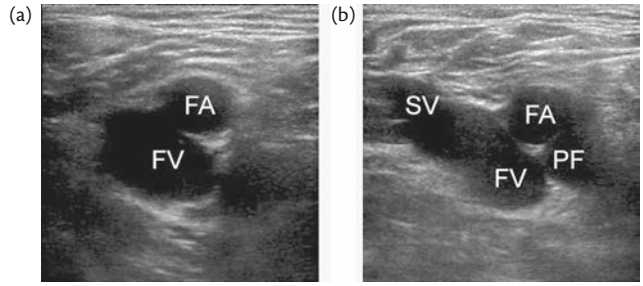

Fig. 130.2 Ultrasound anatomy of the femoral region which may be complex and variable. Left side as viewed from below. (a)Vessels close to the inguinal ligament with common femoral artery (FA) partially overlying the femoral vein. (b) Lower in the groin the superficial artery (SFA) overlaps the FV and profunda femoral artery (PFA). The long saphenous vein (SV) is joining the FV.

Central venous catheters

Central venous access is essential in the management of critically-ill patients and few patients cannot be successfully cannulated centrally, even if only temporarily. Even so, always consider whether peripheral access may be more appropriate, and remove lines inserted under emergency and prehospital conditions as soon as possible. The roles and indications for these devices is widening, while the scrutiny of their complications is increasing [11,12]. Insertion of central venous catheters (CVCs) should closely adhere to institutional or national infection prevention guidance. Infections can be minimized by careful site selection, ultrasound guidance, strict asepsis, insertion packs, and checklists, and frequent monitoring [13].

The internal jugular vein (IJV) is probably the most common site of cannulation. The right IJV approach has the lowest rate of procedural complications and catheter tip misplacement, but an increased risk of infection compared with infraclavicular subclavian routes probably arising from oropharyngeal or tracheostomy contamination. Cannulae sited in the IJV are awkward to dress and awake patients find the site uncomfortable. Many landmark approaches to the IJV have been described. The development of higher-resolution ultrasound equipment has revealed vulnerable and less well appreciated vessels, and other structures near to common insertion sites.

The axillary vein runs from the apex of the axilla, behind the posterior border of the clavicle, and across the first rib to join the subclavian vein and then the IJV forming the brachiocephalic vein behind the sternoclavicular joint. Landmark approaches were traditionally associated with an increased complication rate compared with the IJV, particularly pneumothorax and incorrect tip placement, but recent studies have challenged this (add ref 16 see end). It is, however, a more comfortable site, and easier to dress and keep clean. Ultrasound guidance is associated with safer and more successful techniques for cannulation of the subclavian (via infraclavicular or supraclavicular approaches), or axillary vein (Table 130.2).

Table 130.2 Selected studies employing ultrasound for vascular access

Site	Study population	Comments	Year	Ref.
Internal jugular	Critical care	RCT comparing ultrasound- with landmark-guided cannulation of the IJV Success, time to cannulation and number of attempts all significantly lower in ultrasound group. All complications were lower in ultrasound group, but reported rate of complications higher than expected in a modern critical care setting	2006	[17]
Internal jugular	Elective patients undergoing long-term catheterization	>98% Success on first attempt No cases of pneumothorax No cases of significant haemorrhage	2010	[18]
Subclavian	Critical care	RCT comparing landmark subclavian with ultrasound-guided subclavian/axillary vein. Higher rates of success, reduction in time to cannulation and complications in the ultrasound group	2011	[19]
Infraclavicular axillary vein	1923 Elective patients undergoing long term catheterization	Rate of all major complications >1% in a complex heterogenous group. High rate of success in patients previously cannulated	2012	[20]

Data from various studies. See references.

The femoral vein has the highest rate of infections and thrombosis, and can be associated with occult retroperitoneal haemorrhage. It is uncomfortable for awake and mobile patients (especially with large, stiff catheters), and difficult to keep clean and dress. However, it is often indispensible during life-threatening emergencies, and some extracorporeal circuits are best sited using femoral vessels. The anatomy is more complicated than the side-to-side orientation of vein and artery typically depicted. As with all central sites, ultrasound guidance is recommended.

Tip positioning

The importance of tip position in the superior vena cava (SVC) requires anatomical knowledge. The SVC is a confluence of the two brachiocephalic veins formed behind the first right costal cartilage, is approximately 2 cm wide and 7 cm long with no valves, and descends to the right atrium (RA). Its lateral right border is partially visible on anteroposterior chest X-rays, but it can be difficult to see where the right atrium begins, but this can be estimated from a distance of two vertebral bodies plus discs (verterbral body units) below the carina. Its upper right border bulges into the right pleural space so a tear here risks major haemorrhage into the low-pressure pleural environment.

The catheter tip should lie in the long axis of the SVC or the upper RA, and should not abut the vein wall at an angle. The apparent position of a central venous line on an anteroposterior X-ray may be misleading [15]. Several structures project over an approximate catheter path in the SVC and RA (e.g. ascending aorta, pleura, mediastinum, internal mammary vessels), further difficulties occur if the film is suboptimal or there is distorting pathology.

Catheter misplacement within the venous system is common, either to the neck veins, contralateral side or down an arm—these are generally obvious on X-ray. Catheters outside the venous system are of greater concern so careful assessment is needed before using or removing such catheters. Rare patients have congenital variants e.g. a left sided or a bilateral SVC. Increasing numbers of patients who have had long term CVCs (e.g. for dialysis, cancer, cystic fibrosis) will have central vein narrowing or blockage, with implications for new CVC placement.

Complications

Any anatomical structure adjacent or connected to the vascular tree may be damaged during needle, catheter and guide wire insertion, or later due to thrombosis, perforation and infection. Certain procedural complications are recognized as potentially life-threatening and a cause for high-value legal claims (e.g. haemothorax from great vessel damage, inadvertent carotid cannulation with stroke, and cardiac tamponade [16]).

The most flexible and narrowest gauge catheter possible should be used to reduce insertion trauma and vein irritation. Vessel diameter can be measured ultrasonically and compared with the catheter diameter. A catheter occupying more than one-third of the vein diameter increases the risk of thrombosis. Large-bore cannulae for massive transfusion or dialysis/haemofiltration do not traverse corners easily so the right IJV or femoral veins should be used where possible. The risk of extravasation with peripheral cannulae used for large-volume pressurized fluid infusions should be balanced against those of large-bore central venous catheters, the latter being generally safer if the right expertise and equipment are available.

Guide wires should pass centrally without resistance, but may go astray; without X-ray screening there is no certainty of excluding misplacement. Dilators and catheters passed over a guide wire will enlarge the tract to their diameter, but when inserted over a kinked or excessively angulated guide wire may tear the vein and exit into adjacent structures. The guide wire should be repeatedly checked to ensure free movement to confirm no distortion or false passage.

Poor catheter tip position increases risks of thrombosis, arrhythmias, perforation, and longer-term stenosis. Catheter tips (particularly from the left) can perforate the vein wall and cause a hydrothorax when fluids are infused. The lower half of the SVC is within the fibrous pericardium, where a perforation followed by infusion may cause pericardial tamponade. Ideally, an adequate length of the distal catheter should lie in the SVC long axis with its tip above the pericardial reflection (approximately level with the carina on X-ray). However, this is frequently not achievable, particularly with left-sided catheters; the tip may need to lie within

the pericardial reflection or in the upper right atrium, or as a short-term measure in the left brachiocephalic vein.

Removal

Central catheters should be removed once they are no longer required in a head-down position to avoid air entrainment. Anchorage devices should be removed first, Pressure should be applied for a few minutes and the site covered with an occlusive dressing. Prolonged pressure should be avoided over the carotid artery when removing jugular lines.

Ultrasound-guided central venous access

Ultrasound-guided access allows direct vessel visualization, optimal target site identification, and examination for. thrombosis, valves, dissection, atheroma, or other anatomic abnormalities. Used via the IJV and other routes, it reduces complications, number of attempts and time to successful cannulation, and is recommended by national bodies (Table 130.1). Evidence is accumulating that confirms utility at a variety of sites (Table 130.2). A typical sequence is shown in Fig. 130.3.

Ultrasound is evolving with developments in advanced imaging and needle visualization techniques. These have the potential to advance safety and efficacy in more challenging patients and access sites. For example, compound imaging techniques and the use of multi-modal sensors may accurately identify needle position within a 2D ultrasound image.

Key principles aid successful ultrasound-guided cannulation:

- Position the display opposite to the operator, and orientate the image anatomically as seen from the side of the operator. The display orientation marker is matched to a palpable probe marker.
- Veins are easily compressible. Larger central veins show respiratory fluctuation, and valves may be visible. Arteries are pulsatile, round and not easily compressible. Peripheral arteries typically have characteristic double vena comitantes. Colour Doppler differentiates pulsatile arterial flow from the more continuous venous flow pattern.
- Vessels may be viewed in short axis (out of plane) or long axis (in plane). It is common to use the short axis during needle insertion, but it takes practice to maintain constant needle-tip visualization as the tip may inadvertently pass through the beam and the shaft be mistaken for the tip. Alternatively, the vein may be imaged longitudinally or transversely, and the needle inserted in the long axis. This gives superior needle/wire views, but may not provide concurrent images of surrounding structures and is more challenging to learn.

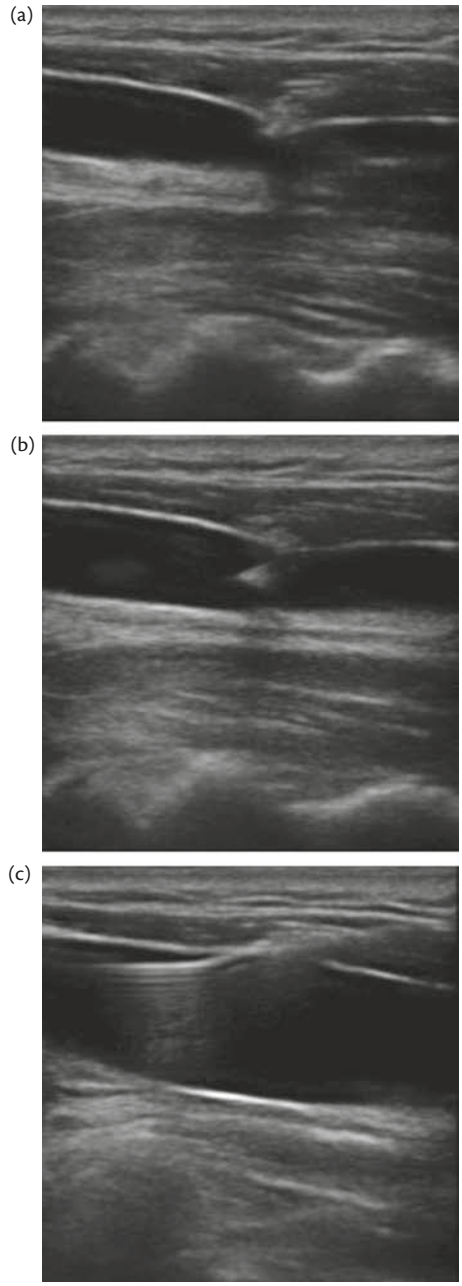

Fig. 130.3 Ultrasound-guided insertion of needle and guide wire to internal jugular vein. The needle tip is identified throughout its path from skin to vein lumen (a). This requires precise positioning as the needle shaft may be confused with the tip. Once the needle tip is visualized within the lumen (b), the guide wire is passed and confirmed to lie within the vein (c).

Conclusion

Vascular access is a key element of critical care and should be practised to an advanced level by all critical care practitioners. It requires comprehensive structured tuition, detailed understanding of anatomy, and thorough post-insertion care. Procedural complications can be reduced by ultrasound and other aids. Vascular catheters act as a potential reservoir and route of transmission for nosocomial infection; this necessitates meticulous attention to insertion technique and monitoring for infection. The future is likely to bring organizational changes to the teaching and assessment of vascular access, including high-fidelity simulation, international guidelines and position statements, standardized advanced equipment and greater scrutiny of complications.

CHAPTER 131

Blood pressure monitoring in the ICU

Stefano Romagnoli and Giovanni Zagli

Key points

- The dynamic response of the pressure transducer, which is derived from the relationship between the cardiovascular system and the transducer itself, is dynamic and may change over time when one or more variables alter.
- Satisfactory performance of an arterial pressure transducer can be obtained if the natural frequency and the damping coefficient have suitable values. Both can be measured at the bedside.
- To limit underdamping, the operator should use short, stiff, non-compliant tubing and limit the number of stopcocks. Extra stopcocks and extension lines should be avoided. To avoid overdamping, the cannula and tubing must be kink-free, and clear of clots and air bubbles.
- The clinician must compare his/her own interpretation of the arterial waveform with the systolic and diastolic values delivered by the monitor to confirm the validity of the data. Comparison between invasive and non-invasive BP monitoring is a useful means of artefact detection due to inadequate damping. This should be confirmed with a fast-flush test.
- Considerable haemodynamic information (i.e. preload responsiveness, afterload, vascular tone, and stroke volume) can be obtained from a careful observation and analysis of arterial pressure waves and components. This may help the health care provider to make inferences about the circulation and establish the most appropriate treatment.

Introduction

As a tightly-regulated variable, monitoring of arterial blood pressure (BP) is mandatory in critically-ill patients. The components of BP, such as systolic, diastolic and pulse pressure, and the waveform itself may also help evaluation of the clinical situation. Two systems are mainly used for measuring BP—the indirect cuff method and direct arterial cannulation. The automated intermittent oscillometric technique for non-invasive arterial pressure monitoring is reliable in stable conditions. However, in high-risk situations or in the critically ill, various clinical conditions may contribute to unreliable measurement, e.g. arrhythmias, cardiogenic shock, high-dose vasopressors. Therefore, in conditions of haemodynamic instability resulting from disease and/or surgery in intensive care units (ICUs), operating theatres, emergency departments, and coronary care units, a more accurate beat-to-beat measurement and tracing check of blood pressure is necessary. Faithful reproduction of the arterial waveform then becomes the main purpose of the monitoring device, converting the force into a reliable electrical signal.

Technical aspects, accuracy, and artefacts

The components of an invasive BP monitoring system include an intravascular catheter, a precalibrated pressure transducer, fluid-filled non-compliant tubing to connect the catheter to the transducer, flush devices, stopcocks and, finally, a monitor for amplification, display, and storage of the pressure waveforms. After the system is zeroed at the phlebostatic axis (mid-axillary line at the fourth intercostal space), the pressure waveform of the arterial pulse is transmitted via the column of fluid to the pressure transducer, which converts it into an electrical signal. The signal is then processed, amplified, and converted into a graphic representation by a microprocessor.

Although intra-arterial measurement is considered the gold standard of BP monitoring, accuracy and precision are often invalidated by artefacts that should be recognized and corrected. An understanding of the physical principles involved in pressure transduction is important to recognize the two main artefacts that most frequently compromise accuracy:

- Resonant amplification due to underdamping.
- Overdamping.

Understanding the physical causes of these artefacts is a key factor in avoiding the misinterpretation of arterial pressure and, therefore, inappropriate therapies [1].

BP is a regulated variable integrating various determinants from the cardiovascular system. This system has, in turn, a number of static and dynamic (highly variable over time) characteristics—heart rate, contractility, stroke volume, ejection time, diastolic time, large and small artery stiffness, and vascular tone. All these physical properties interact to generate a pressure wave that is influenced by characteristics such as elasticity, stiffness, length, and calibre. An additional interaction with the transduction system depends on two fundamental characteristics of the transducer:

- Natural frequency (or resonance frequency).
- Damping coefficient.

The natural frequency is the frequency at which a system (e.g. the components of a pressure transducer) naturally vibrates once it

has been set into motion. In other words, it is the number of times (frequency) a system oscillates (moves back and forth) between its original position and its displaced position if there is no outside interference (e.g. frictional forces).

The damping coefficient quantifies the frictional forces that act on the oscillating system and determine how rapidly it comes to rest. Thus, friction reduces the amplitude of oscillations within an oscillatory system.

The relationships between the frequencies delivered by the cardiovascular system (driving force), natural frequency and damping coefficient define the dynamic response, and whether that response is adequate (i.e. without distortion) or not (i.e. distorted due to over- or underdamping).

The frequencies at which the cardiovascular system transfers signals to the transducer can be analysed in detail by breaking down a complex pressure waveform into basic sine waves by means of a Fourier analysis or transformation (see Fig. 131.1) [2]. In a Fourier transformation, each complex pressure wave can be viewed as the sum of fundamental sine waves characterized by its amplitude and period (frequency). The first wave (fundamental frequency or first harmonic) corresponds to the heart rate and is measured in Hertz (cycles per second, Hz). For instance, 60 beats/minute corresponds to 1 cycle/second, equalling 1 Hz. The other waves (second, third harmonic, etc.) are multiples of the fundamental wave, and these contain the 'information' regarding that pressure wave (e.g. dicrotic notch, reflected waves, etc.). At least 6–10 harmonics are required to provide a faithful reproduction of a pressure waveform. For a system to reproduce a distortion-free arterial pressure waveform, with faithful reproduction of detail, when the heart rate is 120 beats/min, the transducer should be able to transmit a frequency of at least 12–20 Hz (120 beats/min = 2 Hz).

If the natural frequency lies close to the frequency of one of the component harmonics, the system oscillates at its maximum amplitude causing resonation. This oscillation produces an amplified pressure wave that, in turn, amplifies the waveform components. In such conditions, the system is underdamped, and the resulting artefact is known as underdamping, resonance, overshoot, or ringing.

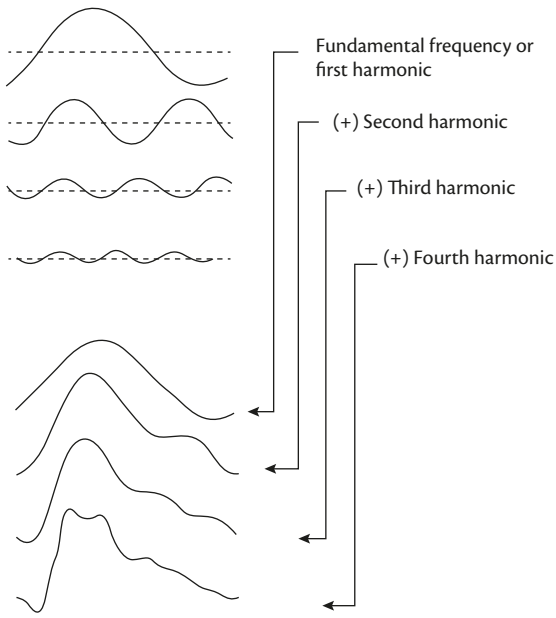

Fig. 131.1 Fourier analysis of an arterial pressure. Three basic sine waves (fundamental, second, and third harmonic) are summed, resulting in the fourth complex wave.

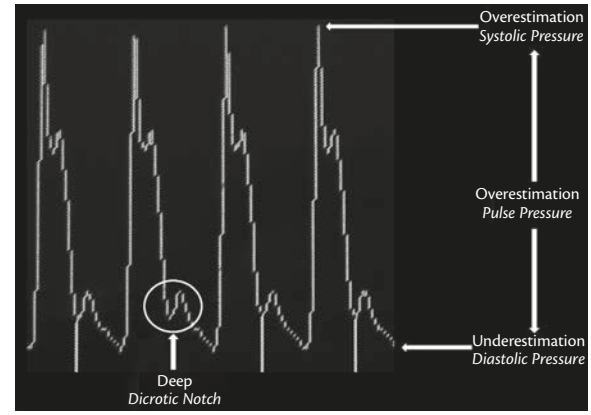

Fig. 131.2 A typical resonant underdamped arterial pressure waveform. All images reproducing arterial pressure traces are from MostCare™, Vygon, Italy, a high fidelity haemodynamic monitoring system.

In the following situations, the resultant waveform will differ from its true counterpart (see Fig. 131.2):

- Systolic BP overestimation (up to 80 mmHg) [3] or systolic pressure overshoot (narrow peak).
- Diastolic BP underestimation.
- Pulse pressure (systolic minus diastolic pressure) overestimation.
- Deep dicrotic notch.
- Non-physiological oscillations during the diastolic phase.

Optimal systems should have a resonant frequency as high as possible to transmit very high frequencies (e.g. high heart rates with steep systolic upstrokes) faithfully without amplification of the signal. The system should also have an adequate damping coefficient low enough to avoid overdamping. Damping is anything that limits the number and amplitude of oscillations in an oscillating system (e.g. friction in the fluid pathway). Some degree of damping is required (see Fig. 131.2), but excessive damping will result in an overdamped signal. Thus, high-frequency sine waves will not be transmitted, resulting in a loss of information. The characteristics of an overdamped wave are as follows (see Fig. 131.3):

- Underestimation of systolic pressure.
- Overestimation of diastolic pressure.
- Underestimation of pulse pressure.
- Slurred upstroke.
- Absent dicrotic notch.
- General loss of detail.

The main reasons for overdamping are air bubbles in the circuit, blood clots, or kinking of the cannula.

In both over- and under-damping, the mean BP approximates to the actual mean BP.

To reduce the likelihood of underdamping, the operator should use short, stiff, non-compliant tubing and limit the number of stopcocks. If these precautions are insufficient, the Accudynamic®

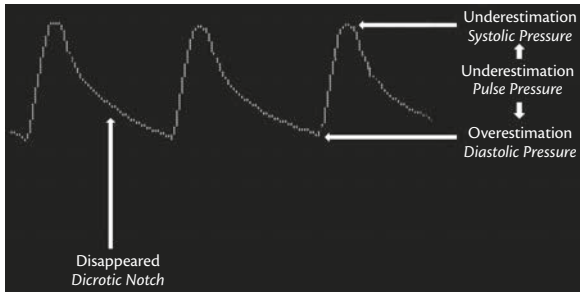

Fig. 131.3 A typical overdamped arterial pressure waveform.

System (ICU Medical, San Clemente, CA, USA), a manufactured tool specifically aimed at increasing the damping coefficient, can be used. To reduce the occurrence of overdamping, the line should always be unkinked and free of air and clot.

When a signal is suspected to be resonating, the operator should perform the following steps:

- Compare the systolic blood pressure measured with the invasive system with that measured by the non-invasive system.
- Perform a fast-flush (square wave) test.

The dynamic response of a transducer can be measured at the bedside using a 'fast-flush' test [4,5], with the BP tracing being recorded onto a paper sheet. The valve of the continuous flush system must be pulled to generate a square wave on the output tracing. By releasing the valve, a variable number of undershoot and overshoot waves can be observed that will decay exponentially in accordance with the damping coefficient. Two measures are necessary (see Fig. 131.4):

- The natural frequency is measured by calculating the distance between successive peaks and applying the following formula:

$$\text{Natural frequency} = \text{Paper speed (mm / sec)} / \text{distance between peaks (mm)} \quad \text{[eqn 1]}$$

e.g. 25 (mm/sec)/1.7 mm = 14.7 Hz

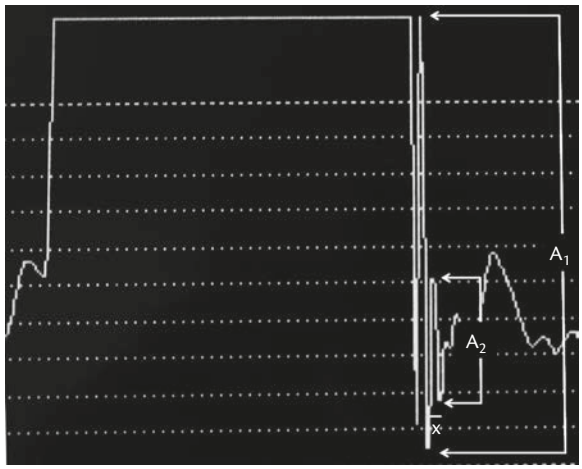

Fig. 131.4 Example of a catheter transducer system response to a fast-flush test. Amplitude ratio is calculated by dividing A2/A1 and resonant frequency by dividing 25 (mm/sec)/x.

- The damping coefficient can be derived by calculating the amplitude ratio (dividing the amplitude of the second oscillation by the first), e.g. 16 mm/22 mm = 0.72.

The calculated values should be plotted onto a graph (see Fig. 131.5), with the interactions between the values allowing the system to be categorized into one of three types—adequate, over- or under-damping.

Haemodynamic information from the waveform

Careful interrogation of the arterial pressure components may assist in analysis of the circulation and to establish the most appropriate therapy. Information regarding preload responsiveness (circulating volume), afterload, vascular tone, and stroke volume can be obtained from understanding the waveform morphology.

The normal components of the arterial pressure waveform are shown in Fig. 131.6 (see also Fig. 131.7).

Changes in the arterial pulse contour are usually due to changes in vascular properties resulting from changes in the amplitude and timing of wave reflections. These are generated by the impact of the pulse against the bifurcations of the arterial tree and against high-resistance arteriolar vessels (the main site of reflection). Changes in arterial pressure with ageing have been widely studied—an increased pulse wave velocity, due to increased stiffness of the arterial system, causes wave reflections to travel very quickly, thus merging the incident early phase of the systolic pressure with its reflective wave (see Fig. 131.7).

Vasoconstriction

The effects of endogenous and external catecholamines are characterized by increases in both systolic (reduced arterial system compliance) and diastolic (reduced peripheral run-off) pressure. Moreover, the dicrotic notch and successive pressure wave rises are progressively earlier (proximal to the systolic peak) as a consequence of rapid equilibrium between aortic and ventricular pressures. The opposite phenomenon—delayed and low dicrotic notch plus reduced systolic and diastolic pressures—is frequently observed in severe vasodilatation (e.g. sepsis, vasovagal reflex, nitrate administration) as a longer time is needed for aortic pressure to exceed ventricular pressure.

Shock

In shock states, except during acute inflammation, diastolic waves are often increased when hypotension is compensated by peripheral vasoconstriction. Thus, arterial waveform observations may help distinguish hypotension due to reduced blood volume from that due to vasodilatation.

Aortic valve stenosis

The duration of ventricular ejection is prolonged, and the systolic upstroke is less steep than in normal left ventricle outflow (*pulsus tardus*) with slow amplitude changes (*pulsus parvus*). The dicrotic notch is usually less evident.

Aortic regurgitation

The waveform is characterized by a steep rise of the systolic upstroke, low diastolic, and wide pulse pressure.

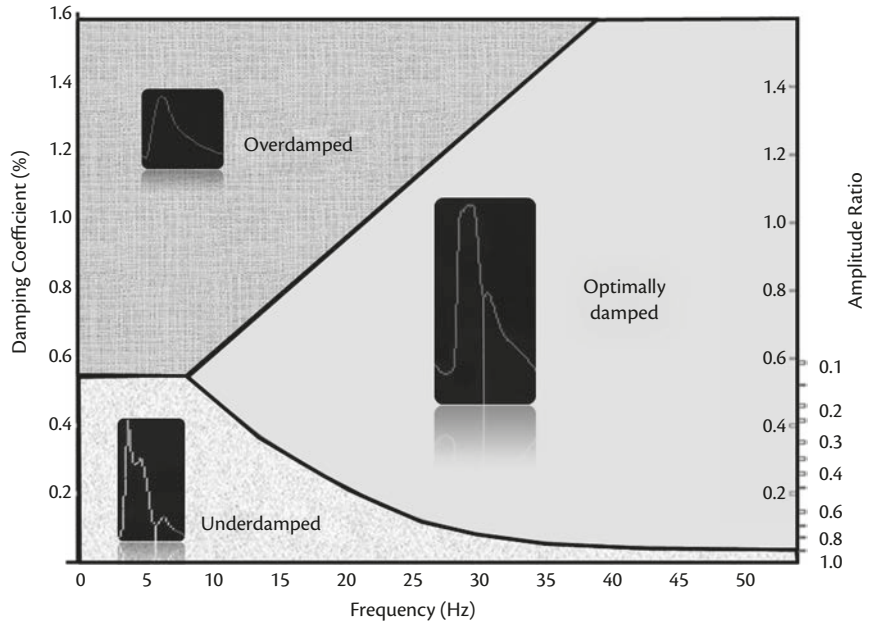

Fig. 131.5 Results from a fast-flush test identify the three main causes of damping. Systolic BP overestimation (up to 80 mmHg) or systolic pressure overshoot (narrow peak).
 Data from Romagnoli S et al., 'Dynamic response of liquid-filled catheter systems for measurement of blood pressure: precision of measurements and reliability of the Pressure Recording Analytical Method with different disposable systems', *Journal of Critical Care*, 2011, **26**, pp. 415–22.

Left ventricular dysfunction (*pulsus alternans*)

This alternation of beats with higher and lower pulse pressures is indicative of severe left ventricular dysfunction. As pulse pressure is proportional to stroke volume, those beats with higher pulse pressures are the result of increased preload remaining from the previous ejection.

Cardiac tamponade (*pulsus paradoxus*)

This is an evident increase and decrease in pulse pressure determined by inspiration and expiration that results from a large dependence of the preload on intrathoracic pressure modifications. *Pulsus paradoxus* is characteristic of cardiac tamponade and all other causes of deep oscillations in thoracic pressure (i.e. bronchospasm, airway obstruction, dyspnoea).

Hypovolaemia: circulating volume and dynamic indices of fluid responsiveness

The effects of positive pressure mechanical ventilation on heart-lung interaction are as follows:

- **During inspiration**:
  - Displacement of pulmonary venous blood into the left heart chambers (increase in left ventricular preload).
  - Decrease in left ventricular afterload (reduction in left ventricular transmural pressure).
  - Increase in left ventricular stroke volume → increase in systolic BP and pulse pressure.
  - Increase in right ventricular afterload (increase in pulmonary vascular resistance).
  - Decrease in the gradient for venous return (mean systemic filling pressure minus right atrial pressure) [6] → decrease in right ventricular stroke volume
- **During expiration**:
  - Pulmonary engorgement of blood → reduction in left ventricular stroke volume.
  - Reduction in stroke volume → reduction in systolic blood pressure.
  - Reduction in pulse pressure.

a) Systolic upstroke
b) Systolic peak
c) Systolic decline
d) Small pulse of reflected pressure wave (frequent)
e) Dicrotic notch (in the central aorta, indicates aortic valve closure (incisura))
f) Diastolic run-off
g) End-diastolic pressure

Fig. 131.6 The normal components of the arterial pressure waveform.

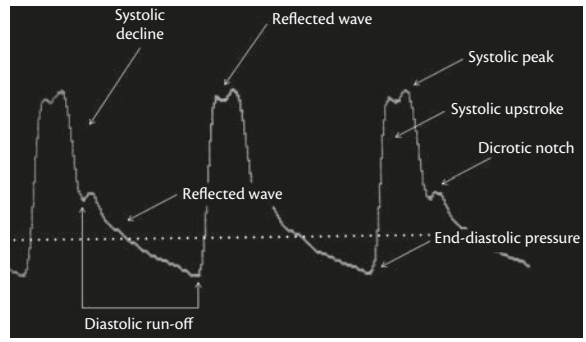

Fig. 131.7 Components of an arterial pressure waveform from an elderly patient undergoing vascular surgery. Note that the peak systolic pressure wave is followed by a small pulse of a reflected pressure wave, suggesting a high grade of arterial stiffness.

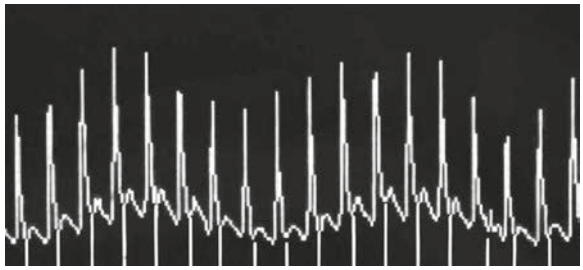

Fig. 131.8 Effect of heart–lung interaction in a hypovolaemic patient.

The greater the variation in BP tracing during the mechanical ventilation respiratory cycle, the greater the reduction in left ventricular preload. Several studies have demonstrated that a systolic pressure variation (SPV) or pulse pressure variation (PPV) >10–15% during the respiratory cycle indicate a high likelihood that patients will be fluid responsive, i.e. increase their stroke volume ≥15% following a fluid challenge (see Fig. 131.8) [7]. In hypovolaemic conditions, the area under the pressure curve appears to be globally reduced with a narrow systolic shape, a lower systolic peak and higher diastolic pressure (in case of vasoconstriction). All are consequences of a smaller left ventricular stroke volume. Moreover, the contribution from reflected waves usually disappears for the same reason.

Conclusion

Invasive arterial pressure is invaluable in diagnostic and therapeutic processes during critical care and major surgery. Pathophysiological mechanisms involved in arterial pressure waveform determination are complex and change rapidly over time. Nonetheless, observation of each component of the arterial wave may provide useful haemodynamic information, but very common artefacts must be recognized and corrected to avoid dangerously inaccurate haemodynamic data interpretation.

CHAPTER 132

Central venous pressure monitoring in the ICU

Sheldon Magder

Key points

- CVP is determined by the interaction of cardiac function and return function.
- The range of clinically important values is small so measurements must be carefully made.
- Pressure measurements with fluid-filled systems are relative to an arbitrary reference value.
- CVP is best used in the negative sense, i.e. a high CVP suggests the subject is unlikely to be fluid responsive.
- CVP is most effective when combined with measurement of cardiac output.

Introduction to central venous pressure monitoring

Although the usefulness of central venous pressure (CVP) monitoring is much maligned, it can be useful in the hands of the astute clinician who understands both measurement pitfalls and the physiology behind its determination. CVP is a low-technology, readily available measure that can be assessed by bedside examination of jugular venous distension above the sternal angle, by using a fluid-filled manometer or, more commonly, an electronic transducer connected to a centrally-placed catheter.

Physiological basis

Two interacting functions determine cardiac output (Fig. 132.1) [1,2]. One is heart function, as indicated by the Starling relationship that relates cardiac output (CO) to preload. Preload is defined as the final tension on a muscle before the onset of contraction. Right heart preload is given by the right atrial pressure (RAP) just before the onset of systole. Each cardiac function curve assumes constant afterload, contractility, and heart rate. The second function that determines CO is venous return, the return of blood to the right heart from the systemic venous circulation. The determinants of return function are mean systemic filling pressure (MSFP), i.e. the pressure in small veins and venules, the downstream RAP, and the resistance between them [3]. MSFP is determined by the volume distending the small veins and venules, and their wall 'stretchiness' (compliance). RAP is common to both functions and provides an indication of their interaction. Under most conditions, flow resistance in the major vessels is trivial so CVP equals RAP. Unless there is tricuspid stenosis, during diastole RAP is equivalent to ventricular diastolic pressure.

CVP does not indicate blood volume and, without consideration of CO, does not indicate heart function. Similarly, it does not indicate the magnitude of left atrial pressure. A single value of CVP does not indicate whether a patient is likely to be fluid-responsive or not. However, CVP measurement can be useful in interpreting responses to fluid boluses, while the pattern of change with a change in CO can indicate whether a falling BP is due to a decrease in cardiac function or in venous return function. Furthermore, the CVP waveform pattern can also be of diagnostic value.

Basis of measurement

Clinically significant values of CVP only occur over a narrow range (~10 mmHg) so small errors in measurement can have a large effect on decisions [4]. It is thus essential to understand the principles behind measurements made with fluid-filled devices. Pressures are measured relative to a reference value. Since the body is surrounded by atmospheric pressure, it is reasonable to set the zero value at atmospheric, and to then determine deviations from this pressure. Thus, a CVP of 0 mmHg is actually ~760 mmHg. However, this creates a problem. The stretch of an elastic structure is determined by the difference in pressure between the inside and outside of the structure (transmural pressure). The heart is within the chest and surrounded by pleural pressure. When chest wall muscles are relaxed, pleural pressure is normally subatmospheric because of inward elastic recoil of the lungs and outward recoil of the chest wall. During the ventilatory cycle, the difference between pleural and atmospheric pressure varies. Pleural pressure falls with spontaneous inspiration and rises with mechanical breaths. When positive pressure is applied to the airways, pleural pressure is always greater than atmospheric pressure. Pleural pressure can also be increased by contraction of chest and abdominal muscles during expiration. During these phases, CVP measured relative to atmospheric pressure does not indicate true transmural pressure of the heart, and thus the force distending intravascular structures and true preload. Ideally, cardiac pressures should be referenced to pleural pressure, but this is generally impractical. To minimize the error produced by not having the correct reference value, cardiac pressures are obtained at end-expiration when pleural pressure is closest to atmospheric.

A second problem with fluid-filled systems is that placement of the measuring device becomes an important factor as the mass of fluid within the device creates a gravitational force, which is then

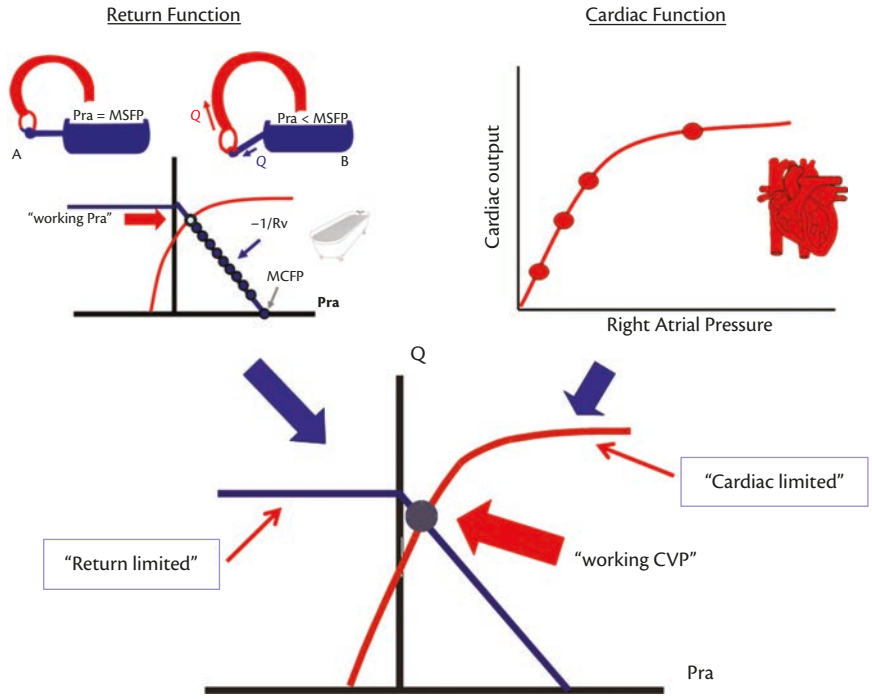

Fig. 132.1 Determinants of cardiac output and the central position of CVP. Cardiac output is determined by the intersection of venous return function, which is a set of venous returns at given right atrial pressures (Pra) (upper left), and cardiac function which is a set of cardiac outputs at a given Pra (upper right). When these two functions are graphed together, their intersection point occurs at the 'working CVP' and working cardiac output, which are the values in the person at that time.
Q, flow (equivalent to cardiac output); MSFP, mean systemic filling pressure; Rv, venous resistance.

included in the measurement. For physiological purposes, the consensus reference level is the right atrial mid-point; this is where blood returns to the heart and is pumped out again. A good approximation of this point is a vertical distance below the sternal angle, where the second rib meets the sternum. This level is valid whether the subject is supine or sitting up at a 60° angle as the right atrium is a round anterior structure; thus its centre remains at a constant distance from the sternal angle. This level is recommended for clinical evaluation of CVP from the jugular distension above this point. When using a transducer, the level is set by siting the stopcock on the transducer set, which opens to air at 5 cm below the sternal angle. More often, the transducer is levelled to the mid-thoracic position as a levelling device is not needed to identify this position. This results in values ~3 mmHg higher than those based on the sternal angle, the precise difference varying with chest size.

If the measuring device has appropriate fidelity, the CVP tracing has three distinguishable upward waves—'a' produced by atrial contraction, 'c' by backward buckling of the tricuspid valve at the onset of systole, and 'v' by atrial filling during ventricular systole (Figs 132.2 and 132.3). There are two downward waves, the 'x' descent due to atrial relaxation, and 'y' due to atrial emptying during the early phase of diastole. The 'a' and 'v' waves are often large. In Fig. 132.2, the bottom of the tracing is 0–1 mmHg, whereas the top is 9–10 mmHg. Fluid therapy is less likely with the latter. Measurement at the base of the 'c' wave gives the final pressure within the ventricle before the onset of systole; in Fig. 132.2 it is 2 mmHg. If the 'c' wave cannot be seen, the base of the 'a' wave usually substitutes adequately. The 'c' position can also be identified by drawing a vertical line from the end of the QRS wave for the ECG; depending on the monitor, some adjustment may be needed for the difference between the ECG electrical signal and the slower fluid signal for pressure through the catheter (Fig. 132.3).

Diagnostic use of CVP

CVP by itself is not a useful guide for fluid management. It must be put in context by measuring CO or, at least, a surrogate of tissue

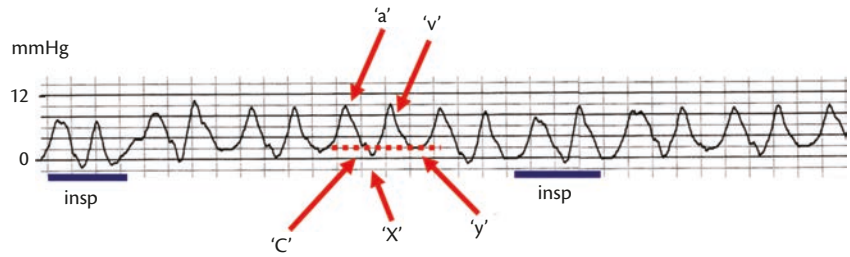

Fig. 132.2 Central venous pressure tracing with labelled individual waves. The dark line and 'insp' indicate inspiration. The dotted line indicates the appropriate place to make the measurement, which is at the bottom of the 'c' wave. The CVP in this example is 2 mmHg.

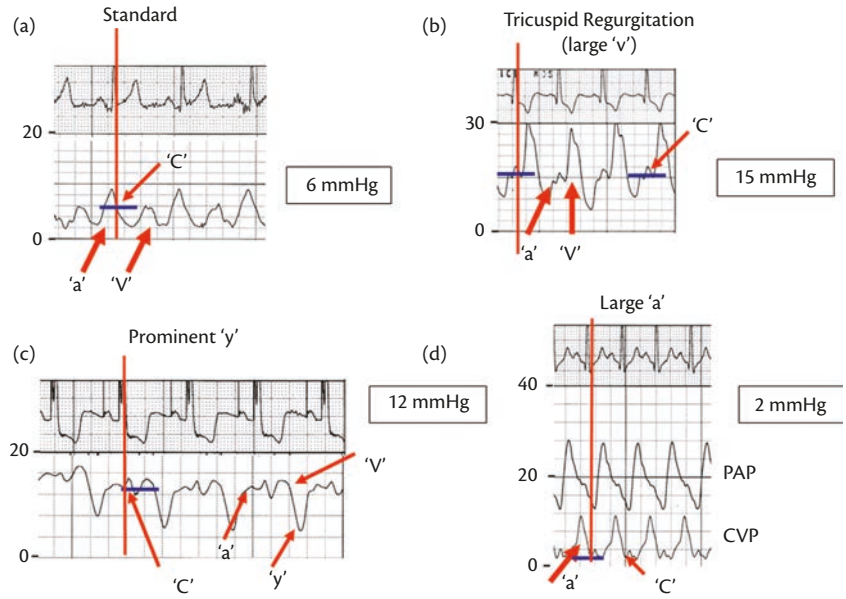

Fig. 132.3 Examples of CVP tracings and appropriate measurements. (a) Normal tracing with the 'a' wave greater than the 'v'. The vertical line indicates the use of the QRS on the ECG to mark the 'c' wave. (b) Example of tricuspid regurgitation with a prominent 'c-v' wave (they run into each other) and prominent 'y' descent. (c) Example of prominent 'y' descent; the 'a' wave is small and the patient has an atrial pacemaker (note the spike in front of the p wave on the ECG). (d) Example of a large 'a' wave; a pulmonary artery tracing (PAP) can also be used to identify the onset of systole.

perfusion [5]. A parallel is trying to interpret PCO_2 without measuring pH. In normal sitting subjects, CVP is sub-atmospheric yet there is no need to give fluid. This similarly applies to a patient with normal sensorium, colour, blood pressure and renal function, and a low CVP.

The utility of CVP measurement arises when fluid is being considered to support BP or oliguria in an unstable clinical situation. If the principal diagnosis is hypovolaemic shock, the CVP will probably be very low so jugular venous pulsations should not be evident with the patient's head raised to 30°. If the diagnosis is right ventricular failure, whether due to right ventricular dysfunction or obstruction (e.g. pulmonary embolism), the CVP should be elevated. These two processes can occur concurrently, e.g. pulmonary embolism and hypovolaemia. If so, fluid should improve the situation or elevate CVP without any restoration of BP.

The value of CVP by itself is most useful in the negative sense. A high CVP indicates that fluid boluses are unlikely to be helpful because the heart is likely functioning on the flat part of the cardiac function curve. Furthermore, even if the person does respond to volume loading, there will be a price to pay for the high CVP, including liver congestion and possible deterioration of renal function. Other treatment approaches might be considered [6].

What is a high CVP? The plateau of the cardiac function curve usually occurs at values <10 mmHg (13–14 mmHg if using mid-thoracic level). Without any measure of CO, it is thus reasonable to target a CVP of 10 mmHg, as recommended in early goal-directed resuscitation protocols. An important limitation is the presence of primarily left ventricular dysfunction (e.g. coronary artery disease or valvular disorders) where left atrial pressure can be markedly elevated without any elevation in CVP. A chest X-ray may provide useful clues.

Blood pressure approximately equals the product of CO and systemic vascular resistance (SVR). A fall in BP may be due to a fall in either. This can be differentiated by examining concurrent changes in CO. If this is maintained or rises, the primary problem is a fall in SVR. Although increasing CO might help, primary treatment should be aimed at the fall in resistance. If both BP and CO fall, the fall in output (due to a decrease in cardiac function or in return function) is the primary problem. If the CVP also falls, the primary problem is a decrease in return function—giving more volume is likely the best treatment choice. However, if CO falls yet CVP rises, treatment should be aimed at improving pump function.

CVP measurements can assist in assessing the response to a fluid challenge. Fluid boluses increase CO by increasing preload. Preload does not have to change much to produce a substantial increase in CO. A measurable rise in CVP and no change in CO implies that the heart is likely functioning on the flat, non-responsive part of the cardiac function curve and further volume loading will not help. This use of the CVP is in the negative sense, i.e. a rise in CVP without a rise in cardiac output means that volume loading will be unlikely to help. The caution here is that some colloid solutions appear to produce a rise in CO without much of a rise in CVP. This suggests they might be actually improving cardiac function in a 'pharmacological' sense, rather than by increasing preload alone. For practical purposes, the increase in CVP should be ≥2 mmHg as this can be readily identified on a monitor.

Respiratory variation in CVP

The heart is surrounded by pleural pressure. Accordingly, pressure measured with a transducer outside the chest and relative to atmospheric pressure, will fluctuate during the ventilatory cycle (Fig. 132.4). Typically, CVP falls with spontaneous inspiration yet right heart volume actually increases. This occurs because the fall in pleural pressure lowers pressure in the heart relative to atmospheric pressure, thereby increasing the gradient for venous

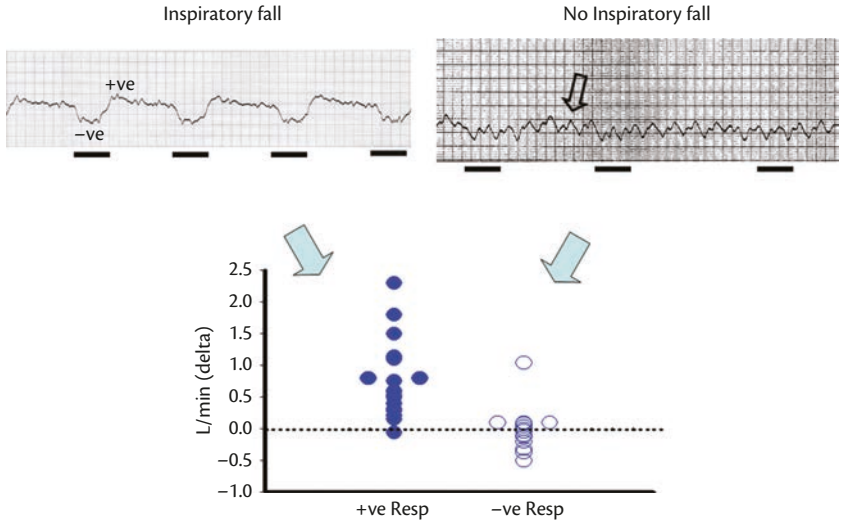

Fig. 132.4 Use of inspiratory variations in CVP to predict fluid responsiveness. In the upper left tracing there is an inspiratory fall in CVP (–ve) indicating the patient would likely respond to fluids. In the upper right tracing, there is no inspiratory fall in CVP, indicating the patient would not be fluid-responsive. The arrow indicates that after the first inspiration there is a small rise in CVP during expiration; the following dip should not be mistaken for an inspiratory fall. The bottom graph shows what happened in 33 patients. +ve indicates an inspiratory fall in CVP and –ve indicates this did not happen. The *y*-axis gives the change in cardiac output with a fluid bolus that was sufficient to raise the CVP by 2 mmHg.

return. Placing the transducer in the pleural space would have seen pressure rise as expected with the increase in right heart volume. However, when the heart is functioning on the flat part of the cardiac function curve, CVP does not fall during inspiration as heart filling is limited. Although transmural pressure increases, end-diastolic volume, and thus stroke volume, does not change. This principle can be used to predict fluid responsiveness. Patients with an inspiratory fall in CVP are likely to increase CO with a volume infusion. However, if the heart is functioning close to the plateau of its function curve, the increase in CO may not be significant. Again, the test is best used in the negative sense. If there is no inspiratory fall in CVP, it is unlikely that the patient will be fluid-responsive. Caveats include a spontaneous inspiratory effort that must be sufficient to decrease pleural pressure enough to affect cardiac filling, even in mechanically-ventilated patients. A fall in CVP during inspiration should be excluded, as this is due to release of active expiratory muscle, rather than a fall in pleural pressure.

Clinical information can also be gained from the magnitude of respiratory swing in CVP. A large inspiratory fall indicates large inspiratory efforts; underlying reasons should be sought, such as increased airway resistance, decreased lung compliance, or increased drive. A large inspiratory rise in CVP in a mechanically-ventilated patient is suggestive of decreased thoracic compliance, which also includes high abdominal pressure. Large expiratory increases in CVP indicate active recruitment of expiratory muscles (Fig. 132.5). These can occur in a pattern in which the CVP rises during expiration; here, the CVP at end-expiration is no longer appropriate for assessing cardiac preload as the measurement includes the rise in pleural pressure. In the second pattern, the CVP can rise at the beginning of expiration and then gradually decrease. Here, the proper place to measure CVP is on a breath with a plateau in the CVP tracing, otherwise the pressure will be overestimated.

Use of CVP waveforms

Clinical information can also be gained from components of the CVP trace (Fig. 132.3). Tall 'v' or 'c-v' waves are suggestive of tricuspid regurgitation. In severe regurgitation, the CVP can even look like a right ventricular pressure tracing. Prominent 'y' descents indicate restriction to cardiac filling, making it is less likely that the

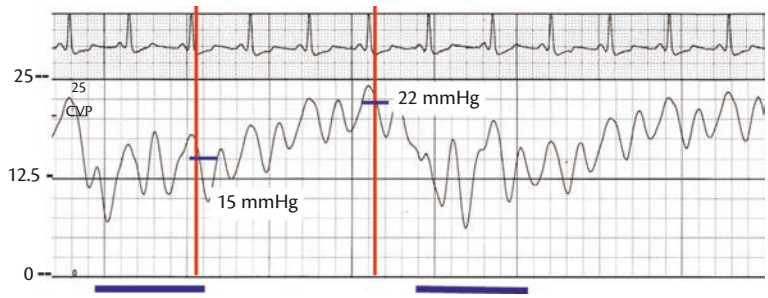

Fig. 132.5 Example of a patient with active use of expiratory muscles. The dark horizontal line indicates inspiration. There is a progressive increase in CVP during expiration that only occurs with recruitment of expiratory muscles. Here, the best measure of CVP is at the beginning rather than the end of expiration, as usually recommended. The appropriate value is 15 mmHg.

patient will be fluid-responsive bolus. The loss of a 'y' descent in a hypotensive patient can be an important indicator that cardiac tamponade is present. A prominent 'a' wave indicates either tricuspid valve stenosis or decreased right ventricular diastolic compliance.

Conclusion

CVP is readily assessable at the bedside. With an understanding of the principles of its measurement and determinants, the CVP can help clinicians distinguish whether a hypotensive state is due to a decrease in SVR or CO. The CVP can then be used to distinguish a decrease in CO due to a decrease in pump function or a problem with the return function, especially when changes in CVP are combined with changes in CO (or a surrogate thereof). CVP and CO measurements also provide a good guide to understanding whether or not further volume boluses will be of use, and thus help avoid excessive volume use. Finally, with experience, the CVP waveform can be used to help predict both cardiac and pulmonary abnormalities.

CHAPTER 133

Pulmonary artery catheterization in the ICU

Efrat Orenbuch-Harroch and Charles L. Sprung

Key points

- Although there is limited evidence of favourable outcomes from the use of the pulmonary artery catheter, it remains an important diagnostic tool in the management of critically-ill patients, specifically when knowledge of intracardiac pressures and oxygenation parameters is considered to be particularly important.
- The pulmonary artery wedge pressure (PAWP) reflects left atrial pressure, and thus left ventricular end-diastolic pressure (LVEDP), assuming that continuity of the circulation is preserved.
- PAWP should be measured at the end-expiratory phase of ventilation.
- When measuring cardiac output by the manual thermodilution method, at least three measurements should be obtained and averaged to overcome the between-measurement variability.
- Complications occur in 10–15% of pulmonary artery catheter insertion and are related to insertion, passage of the catheter and maintenance of the catheter in the pulmonary artery.

Introduction

Haemodynamic monitoring is a significant component in the management of the critically-ill patient, allowing for evaluation of the aetiology, severity, and response to treatment, and complementing clinical assessment. Flow-directed pulmonary artery catheters (PAC) were introduced in 1970 by Swan and Ganz [1] as a simple and rapid technique for measuring several continuous or intermittent circulatory variables. Initially, the PAC was introduced into clinical practice without substantial supporting evidence; however, subsequent observational trials and more recent randomized controlled trials failed to demonstrate positive outcome benefits [2–4]. As a consequence, the use of the PAC has significantly declined in the last two decades [5]. It remains controversial as to whether an outcome benefit is required prior to using a diagnostic tool. Such a benefit can only be demonstrated when data are interpreted correctly and effective therapy is available after the diagnosis is made. Given its overall safety record, the pulmonary artery catheter still has a valid role in both diagnosing haemodynamic abnormalities and monitoring therapeutic interventions. It should thus be considered for use in appropriate patients for the proper indication.

Indications

The major indications for PAC use are detailed in Box 133.1. The PAC was initially used to guide therapy following complicated acute myocardial infarction where measurements of cardiac output and PAWP could distinguish between cardiogenic and non-cardiogenic mechanisms and guide therapeutic strategy. PAC use also helps to differentiate between cardiogenic and non-cardiogenic pulmonary oedema, and to establish the cause of mechanical complications following myocardial infarction. For example, a >5% rise in right ventricular oxygen saturation over the right atrial value is seen in acute ventricular septal defect. During acute mitral regurgitation a large 'v' wave appears in the PAWP tracing. Cardiac tamponade is characterized by elevation and diastolic equalization of the right atrial (RA), right ventricular end-diastolic (RVEDP) and pulmonary artery wedge (PAWP) pressures, and by the absence of the 'y' descent on the RA tracing. The PAC is also helpful for monitoring the impact of therapeutic interventions in these conditions.

Patients with severe congestive heart failure refractory to aggressive medical management may benefit from PAC-derived information, especially systemic vascular resistance and PAWP, thereby allowing specific therapy to be tailored. The ESCAPE trial [2], however, failed to demonstrate any benefit in mortality or length of hospitalization from PAC use in patients with congestive heart failure.

Traditionally, PACs have been used in high-risk patients undergoing elective or emergent non-cardiac surgery. However, in a large multicentre, randomized controlled trial, no benefit was achieved in either in-hospital mortality or 1-year survival [6]. PACs are believed to benefit cardiac surgery patients with haemodynamic risks, including those with ejection fractions <30%, impaired right ventricular systolic function, left ventricular diastolic dysfunction, acute ventricular septal defects, and patients with left ventricular assist devices [7]. In a randomized trial of patients undergoing elective cardiac surgery, those assigned to receive PAC-directed protocolized therapy to increase their oxygen delivery had shorter ICU and hospital lengths of stay [8]. Although a clinical rationale exists for using the PAC in haemodynamically-unstable patients, several randomized controlled trials in the critically ill have not shown clear outcome benefits [2–4]. One observational study showed a decrease in the mortality rate associated with PAC use in the most severely ill, but an increase in a lower illness severity population [9]. To summarize, there is no absolute indication at present for PAC

Box 133.1 Indications for pulmonary artery catheterization

- **Acute myocardial infarction:**
  - Hypotension.
  - Congestive heart failure.
  - Acute mitral regurgitation.
  - Ventricular septal defect.
  - Right ventricular infarction.
  - Cardiac tamponade.
- **Congestive heart failure:** titrate vasodilator therapy
- **Acute pulmonary embolism.**
- **Shock:**
  - Sepsis.
  - Massive haemorrhage.
- **Respiratory failure:**
  - Non-cardiogenic (acute respiratory distress syndrome).
  - Cardiogenic.
  - Unknown causes.
- **Assess volume status:**
  - Renal failure.
  - Cirrhosis.
- **Surgical patients:**
  - Intra- and post-operative monitoring of high risk surgical patients.
  - Surgical procedures involving massive volume shifts.

insertion. They should be carefully considered on a patient-by-patient basis, especially in the most severely ill.

Insertion and interpretation of tracing

The most common insertion sites are the internal jugular, subclavian, and femoral veins, but any large vein, including the external jugular and antecubital veins, can be used. Choice of site depends on patient characteristics and operator experience. The right internal jugular and left subclavian veins are favoured because the catheter easily passes through to the pulmonary artery, and have lower rates of infections compared with the femoral vein site.

Puncture is performed with strict adherence to aseptic technique. Access is obtained using a modified Seldinger technique [10]. In brief, the desired vein is located by a needle through which a guide wire is then passed into the vein. The original needle is removed and an introducer sheath is threaded over the guide wire which is then removed The PAC, connected to a calibrated pressure transducer, is then inserted through the introducer sheath and the integral balloon near the tip of the PAC is subsequently inflated with 1.5 ml of air.

The catheter is advanced ('floated') until the right ventricle (RV) tracing is obtained on the monitor and the systolic pressure increases (Fig. 133.1). The catheter is then advanced an additional 5-15 cm, across the pulmonary valve and into the pulmonary artery (PA). Here, the pressure tracing is characterized by a higher diastolic pressure than the RV, and the appearance of a dicrotic notch (Fig. 133.1). Not more than 15 cm of catheter should be introduced into the RV to avoid catheter knotting. Failure to obtain a PA waveform indicates that the catheter is probably curling within the RV. In this situation deflation of the balloon, followed by catheter withdrawal and reinsertion is required.

Finally, the catheter is advanced to the 'wedge' position. The PAWP is identified by a decrease in pressure combined with a characteristic change in the waveform. The balloon should then be deflated and the PA tracing should reappear. If the PAWP tracing persists or there is any uncertainty about whether the tracing is a PAWP or PA tracing, then the catheter should be withdrawn until a definitive PA tracing is identified otherwise the patient is at risk of a pulmonary infarction. The PAWP trace should be obtained on inflation of the balloon with at least 1.25 ml of air. The position of the PAC should always be confirmed with a chest X-ray.

Direct measurements and derived calculations

The pulmonary artery catheter must be appropriately calibrated and zeroed to atmospheric pressure to obtain accurate diagnostic information. Variables that can be measured or derived using the pulmonary artery catheter are detailed in Table 133.1.

Central venous pressure

Central venous pressure (CVP) equals right atrial pressure and right ventricular diastolic pressure. CVP is influenced not only by ventricular function and compliance, but also by intravascular volume, venous return, systemic venous tone, and pulmonary vascular resistance. CVP does not increase until the RVEDP rises. Therefore, left ventricular failure and pulmonary congestion may be present with a normal CVP. CVP is most commonly elevated in the setting of biventricular heart failure, tricuspid regurgitation, or stenosis, pulmonary hypertension, volume overload, constrictive pericarditis, and cardiac tamponade.

Pulmonary artery pressure

Pulmonary artery pressure (PAP) is measured continuously from the distal port of the PAC when the tip of the catheter lies freely in the vascular lumen, beyond the pulmonary valve. PAP is elevated in some high-flow states (hypervolaemia), left ventricular failure, and high-resistance states including pulmonary hypertension, as well as in common conditions that increase pulmonary vascular resistance

Table 133.1 Variables measured or derived using the pulmonary artery catheter

Variable	Formula	Normal range	Units
Measured variables:			
◆ Cardiac output (CO)		4–7	L/min
◆ Mean pulmonary artery pressure (MPAP)		9–16	mmHg
◆ Pulmonary artery wedge pressure (PAWP)		2–12	mmHg
◆ Central venous pressure (CVP)		0–8	mmHg
◆ Mixed venous oxygen saturation		75	%
Derived variables:			
◆ Stroke volume (SV)	CO/HR	60–100	mL/beat
◆ Stroke index (SI)	SV/BSA	30–65	mL/beat/m^2
◆ Cardiac index (CI)	CO/BSA	2.8–4.2	L/min/m^2
◆ Systemic vascular resistance (SVR)	[(MAP-CVP)/CO] × 80	900–1400	dyne/sec/cm^5
◆ Pulmonary vascular resistance (PVR)	[(MPAP-PAWP)/CO] × 80	150–250	dyne/sec/cm^5
◆ Left ventricular stroke work	SI(MAP-PAWP) × 0.0136	43–61	g/m^2
◆ Right ventricular stroke work	SI(MPAP-CVP) × 0.0136	7–12	g/m^2
◆ Oxygen delivery	Cao_2 × CO × 10	640–1400	ml O_2/min
◆ Oxygen consumption	(Cao_2-Cvo_2) × CO × 10	180–280	ml O_2/min
◆ Oxygen extraction utilization ratio	$avDO_2/CaO_2$	0.22–0.3	%

HR, heart rate; BSA, body surface area; Cao_2, arterial oxygen content; Cvo_2, mixed venous oxygen content; $avDO_2$, arteriovenous oxygen content difference ($CaO_2 - CvO_2$).

in the intensive care unit (ICU) setting (hypoxaemia, thrombosis, fibrosis, sepsis).

Pulmonary artery wedge pressure

The PAWP is obtained by inflating the catheter balloon, encouraging flow-directed movement of the catheter until a branch of the PA is obstructed. Once obstruction occurs, a continuous static column of fluid is created from the catheter tip to the left atrium, provided there is no intervening venous or alveolar obstruction. This fluid column is also continuous with the left ventricle (LV) when the mitral valve is open. Thus, during diastole and in the absence of major mitral valve disease, the PAWP represents the left ventricular end-diastolic pressure (LVEDP) and reflects left ventricular preload. It may not, however, reflect left ventricular end-diastolic volume, since left ventricular distensibility may vary between patients with different clinical situations.

There are several situations in which PAWP and LVEDP are discordant. Reduced left ventricular compliance (due to ischaemia or hypertrophy) and severe aortic insufficiency may cause LVEDP to exceed PAWP due to premature closure of the mitral valve. The LAP also does not reflect LVEDP in mitral stenosis. Furthermore, PAWP exceeds LVEDP if PAWP fails to accurately reflect left atrial pressure (LAP) during pulmonary venous hypertension, respiratory failure, or when the catheter tip sits in either West's Zones I or II (i.e. a non-Zone III position) within the lung where mean alveolar pressure exceeds mean pulmonary venous pressure. In this situation, PAWP is influenced more by alveolar pressure than intravascular pressure. This most commonly occurs during positive pressure ventilation in hypovolaemic patients. Placement of the catheter in a correct zone III position can usually be confirmed by the presence of the catheter tip below the level of the left atrium on a chest X-ray.

Once the PAWP tracing has been obtained, one must ensure that a correct value is recorded. The most common sources of error for PAWP measurement include catheter placement in a non-Zone III lung position, and failure to correctly identify end-expiration when determining PAWP [11]. During positive pressure ventilation, as opposed to spontaneous ventilation, intrathoracic pressures increase during inspiration and decrease during expiration. Such changes affect pulmonary artery pressure and PAWP measurements. Therefore, the proper phase in the ventilatory cycle to judge the PAWP regardless of the mode of ventilation is at end-expiration, when air flow is zero, and intrathoracic and atmospheric pressures are equal. Identification of end-expiration may be particularly difficult with tachypnoea or marked fluctuations in pressure during respiration, and the automated computations of the mean pressure may not accurately reflect pressures at end-expiration. Hence, manual measurement from a graphic recording of the pressure waveform at end-expiration is preferable.

Cardiac output

Cardiac output (CO) is measured with the PAC by thermodilution. This method is based upon conservation of thermal energy over a few consecutive beats. Thermal indicator (cooled fluid) is injected quickly through the central venous port and the change in temperature is registered by a thermistor at the tip of the catheter in the pulmonary artery. The indicator used is a small amount (e.g. 10 mL) of 5% glucose that is cooler than blood, thus slightly lowering its temperature. The degree of change in temperature is inversely proportional to the cardiac output. The thermistor records the temperature change over time and a temperature–time curve is created. The area under the curve is integrated and is inversely proportional to the flow rate or CO, in the absence of an intracardiac shunt or tricuspid regurgitation. The thermodilution method has been

well-validated [12]. It is safe and easily performed at the bedside. However, variations in the amount and rate of injection, or in the phase of the respiratory cycle in which the measurement is taken, may cause large variations in CO measurements. During mechanical ventilation, there may be large swings in intrathoracic pressure caused by many factors, including alterations in venous return, in respiratory pattern or rate. There remains some controversy regarding the optimal time when the thermal indicator should be injected. Therefore, three measurements falling within 10% of each other are obtained and averaged for the estimation of CO [13].

Other sources of error include conditions in which incomplete forward ejection of the indicator exists. Tricuspid regurgitation, a relatively frequent condition among critically ill, will result in under-estimation of CO. Intracardiac shunts, however, cause over-estimation due to dilution of the indicator with left-to-right shunt, or shunting of the indicator to the left heart with a right-to-left shunt. The accuracy of thermodilution is lower with very high or very low values of CO. 'Continuous' thermodilution CO measurement is available in newer catheters. This is based on a warm indicator method, whereby irregular pulses of heat are emitted by a 10-cm thermal filament sited on the catheter at the level of the right ventricle. The resulting thermal signal is measured by a thermistor at the catheter tip at 3-minute intervals, creating a semi-continuous measurement. *In vivo* studies found good accuracy, but with a trend toward overestimation [14]. Doppler-equipped PACs have been developed for continuous measurement of blood flow and cardiac output, but their accuracy depends on correct placement of the Doppler transducers inside the main pulmonary artery. Newer catheter designs incorporate continuous oximetric monitoring of pulmonary artery oxygen saturation by reflectance spectrophotometry, thereby enabling continuous estimation of cardiac output. This technology has acceptable accuracy and correlation compared with mixed venous oxygen saturation [15] and bolus thermodilution cardiac output techniques [16].

Box 133.2 Contraindications to pulmonary artery catheter insertion

Absolute

- Tricuspid or pulmonary valve stenosis.
- Mechanical tricuspid (or pulmonary) valve prosthesis.
- Right atrial or right ventricular mass (tumour or thrombus).
- Tricuspid or pulmonary valve endocarditis.
- Tetralogy of Fallot.

Relative

- Coagulopathy.
- Neutropenia.
- Arrhythmias.
- Left bundle branch block.
- Recent implantation of permanent pacemaker or cardioverter–defibrillator.
- Bioprosthetic tricuspid (or pulmonary) valve.
- Electrolyte abnormalities.
- Digoxin toxicity.

Contraindications

Absolute and relative contraindications for PAC insertion are listed in Box 133.2. The absolute contraindications are rare and include conditions in which catheter advancement may be interrupted or harmful. Coagulopathy should be corrected if possible. In cases of major coagulopathy, which cannot be corrected, the subclavian approach should be avoided. Hypoxaemia, acidosis, electrolyte abnormalities, and digoxin toxicity should also be corrected if possible prior to insertion because of the increased risk of arrhythmias [17].

Complications

Complications occur in about 10–15% of pulmonary artery catheterization, and may rarely be fatal [2–3]. They can be divided to two main categories:

- Complications related to catheter insertion and passage.
- Complications related to catheter use and maintenance.

The first category includes complications of venous access (arterial puncture, haematoma, pneumothorax, and haemothorax), as well as problems associated with trauma to the vessels and heart caused by the passage of the catheter. Various types of arrhythmias related to PAC placement have been described, and include ectopic atrial and ventricular beats, atrial and ventricular tachycardias, and conduction abnormalities. Ventricular arrhythmias during passage of the catheter occur in 13–68% of the patients [18], but mortality related to this complication is low and most of the cases have a benign self-limiting course. Critically-ill patients in the ICU are more prone to developing arrhythmias because of the presence of arrhythmogenic conditions as myocardial ischaemia, electrolyte disturbances, acidosis, hypoxaemia, and elevated endogenous and exogenous catecholamine levels. The development of right-bundle branch block (RBBB) is estimated to occur in 3–6% of catheterizations. In the presence of pre-existing left-bundle branch block, the development of RBBB can lead to complete heart block, but the incidence of this complication is not higher than the incidence of RBBB in patients without underlying conduction defects [19].

Complications associated with the use and maintenance of the catheter include pulmonary artery rupture, pulmonary infarction, thromboembolic events, and catheter-related infections. Pulmonary artery rupture is the most serious complication with a high mortality rate. It should be considered in cases of haemoptysis, dyspnoea, anxiety, and hypotension. Risk factors include age >60 years, pulmonary hypertension, improper balloon inflation, improper catheter positioning, cardiopulmonary bypass, and anticoagulation [18]. In most cases, emergent thoracotomy is needed. The risk of infectious complications increases with duration of catheterization. Most data suggest that the risk of infection increases significantly when catheters remain for more than 3–4 days [20], therefore catheter necessity should be evaluated on a daily basis.

CHAPTER 134

Mixed and central venous oxygen saturation monitoring in the ICU

Frank Bloos and Konrad Reinhart

Key points

- Venous oximetry is performed either by blood gas analysis or continuously by fibre optics inserted within the intravascular catheter.
- Mixed venous oxygen saturation (SvO_2) is obtained from the pulmonary artery via a pulmonary artery catheter, while central venous oxygen saturation ($ScvO_2$) is obtained from the superior vena cava via a central venous catheter.
- In critically-ill patients, $ScvO_2$ values <70% are associated with unfavourable outcomes. In septic shock and in peri-operative high-risk patients, a treatment goal of $ScvO_2$ >70% (SvO_2 >65%) should be targeted.
- $ScvO_2$ values >90% indicate reduced O_2 extraction and identifies patients with an increased risk of death.
- Other measures of tissue oxygenation such as serum lactate and organ function need to be monitored in parallel to venous oximetry to increase the sensitivity for detection of a mismatch between O_2 delivery and tissue O_2 need.

Introduction

Extended monitoring techniques, such as pulmonary artery catheterization, pulse wave analysis, or echocardiography are available for assessment of haemodynamic status, particularly in patients with impaired cardiocirculatory function. However, evidence is still lacking as to whether such techniques truly alter outcomes. In this context, achieving fixed targets of haemodynamic parameters, such as supranormal O_2 delivery did not prove beneficial for critically-ill patients. On the other hand, early restoration of a sufficient circulation may prevent the development of multi-organ dysfunction. It therefore seems reasonable that haemodynamic resuscitation should target goals that reflect tissue oxygen needs of an individual patient. Venous oximetry may be such a tool.

Physiological background

The pulmonary artery contains venous blood from the whole body, i.e. a mixture draining from superior and inferior venae cavae. The oxygen saturation of blood in the pulmonary artery is therefore referred to as 'mixed venous oxygen saturation' (SvO_2). This is a marker for whole body oxygen extraction and can be measured with a pulmonary artery catheter. In health, changes in tissue oxygen needs are usually covered by corresponding changes in oxygen delivery. Thus, oxygen extraction and SvO_2 generally remain constant. Oxygen extraction increases and SvO_2 decreases if the cardiovascular system cannot compensate for increased O_2 needs. Thus, a drop in SvO_2 indicates a mismatch between O_2 supply and demand [1].

Changes in SvO_2 result from changes in the relationship between O_2 delivery and need (Table 134.1). A fall in SvO_2 may be due to a decrease in O_2 delivery, such as a drop in arterial O_2 content (i.e. hypoxaemia, anaemia) or cardiac output (i.e. cardiogenic shock). It may also reflect an increase in O_2 need such as fever, shivering, and pain, which would otherwise remain uncovered by a matched increase in O_2 delivery [1].

Insertion of a pulmonary artery catheter is invasive and its clinical utility is a matter of discussion [2]. Central venous catheters (CVC) are frequently used in critically-ill patients. Measurement of oxygen saturation in the blood obtained from a CVC is referred to as 'central venous oxygen saturation' ($ScvO_2$). In general, the physiological principles of SvO_2 can also be applied to $ScvO_2$. However, both values are not identical since a catheter placed within the superior vena cava only represents venous blood draining the upper body. Oxygen extraction by different organs differs according to their varying oxygen needs and deliveries. The corresponding veins therefore hold highly variable oxygen saturations (Fig. 134.1) [4].

Table 134.1 Changes in SvO_2 result from changes in the relationship between O_2 delivery and need

Decrease in SvO_2 or $ScvO_2$	
Increase O_2 consumption	*Decrease O_2 delivery*
Stress Pain Fever Shivering	Drop in arterial oxygen content (i.e. anaemia, hypoxaemia) Drop in cardiac output
Increase in SvO_2 or $ScvO_2$	
Decrease O_2 consumption	*Increase O_2 delivery*
Analgesia Sedation Mechanical ventilation Hypothermia	Increase in arterial oxygen content Increase in cardiac output

Thus, under physiological conditions, $ScvO_2$ is lower than SvO_2 by 2–3%. This relationship is reversed in critically ill patients under analgo-sedation or in shock. While it is not possible in the clinical setting to predict SvO_2 from $ScvO_2$, changes in SvO_2 are adequately mirrored by changes in $ScvO_2$ [3].

Technique of venous oximetry

Oxygen saturation can be measured either discontinuously by blood gas analysis, or by continuous fibre optic monitoring. For blood gas analysis, blood is obtained from the distal lumen of a pulmonary artery catheter for SvO_2, and from the distal lumen of a CVC placed into the superior vena cava for $ScvO_2$. As all clinical studies addressing $ScvO_2$ were undertaken with CVCs in the superior vena cava, therapeutic goals derived from such studies cannot be transferred to femoral vein CVCs since oxygen saturations in the superior and inferior venae cavae differ (Fig. 134.1).

Continuous venous oximetry is achieved using reflection spectrophotometry via fibre optics integrated into the CVC for $ScvO_2$ or the PA catheter for SvO_2. Oxygen saturation is displayed on an external monitor. While continuous venous oximetry is more expensive than blood gas analysis because of the higher costs of the catheters, frequent blood gas analyses may add up to a significant cost and time expenditure.

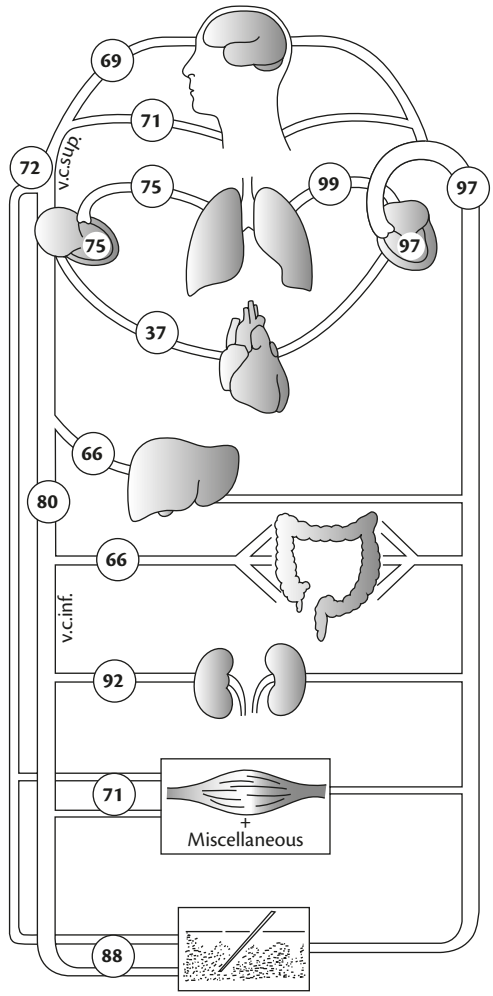

Fig. 134.1 Venous oxygen saturation in different venous systems. Individual oxygen saturations differ according to the different oxygen extraction of specific organs.
Reproduced from *Clinical Aspects of O_2 Transport and Tissue Oxygenation*, 1989, 'Monitoring O_2 transport and tissue oxygenation in critically ill patients', Reinhart K, Eyrich K (eds), with permission from Springer Science and Business Media.

Clinical application

In a large study in critically-ill patients, a treatment goal targeting SvO_2 values >70% did not improve survival rates [5]. However, this treatment goal was only achieved in 66.7% of protocolized patients, the interventions took place late in the course of the disease, and no treatment algorithm was specified for haemodynamically unstable patients. More recent studies in septic shock and in perioperative patients showed that $ScvO_2$-guided treatment algorithms can impact upon outcomes [6,7].

$ScvO_2$ monitoring during surgery

Avoidance or prompt reversal of hypoperfusion during extended surgery may prevent perioperative morbidity and shorten the ICU length of stay. Indeed, patients undergoing intra-abdominal surgery experienced complications more often if a drop in $ScvO_2$ was observed during surgery [8]. A goal-orientated treatment algorithm consisting of hourly $ScvO_2$ measurements reduced the occurrence of organ dysfunction and the duration of hospital stay [6]. This study used O_2 extraction ratio (O_2ER) as a treatment goal, calculated as $(SaO_2 - ScvO_2)/SaO_2$. An intervention was induced if the O_2ER dropped <27%. Fluid was administered when central venous pressures (CVPs) were low, otherwise dobutamine was given until O_2ER was >27%. This goal approximates to $ScvO_2$ values of 70–73% when arterial oxygenation is in the normal range (see Fig. 134.2).

Post-operative $ScvO_2$ monitoring

The occurrence of a low $ScvO_2$ after surgery is associated with increased morbidity [8,9]. Similarly, patients admitted to intensive

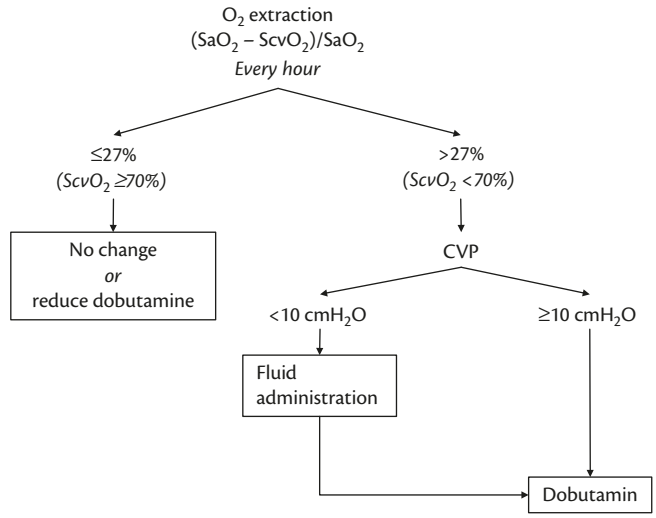

Fig. 134.2 Goal-directed therapy as applied during surgery.
CVP, central venous pressure; SaO_2, arterial oxygen saturation; $ScvO_2$, central venous oxygen saturation.
Data from Donati A et al., 'Goal-directed intraoperative therapy reduces morbidity and length of hospital stay in high-risk surgical patients', *Chest*, 2007, **132**, pp. 1817–24.

care with a low $ScvO_2$ have a higher risk of dying than those with normal $ScvO_2$ values [10]. However, it is unknown for how long a patient should be monitored. Patients after cardiac surgery may also profit from venous oximetry though only data from small studies are available. Low SvO_2 and $ScvO_2$ values are both associated with a higher morbidity in these patients [11]. A small study demonstrated some outcome advantage when haemodynamic stabilization included a $ScvO_2$ target >70% [12]. These data point to the fact that venous oximetry is a rational option in high-risk patients after surgery.

Septic shock

Septic shock is characterized by hypovolemia, arterial hypotension, myocardial depression and microcirculatory dysfunction. A low $ScvO_2$ is associated with an unfavourable prognosis in these patients [13].

Early goal-directed therapy (EGDT) combines several haemodynamic goals into a treatment algorithm (Fig. 134.3) with CVP, mean arterial pressure and $ScvO_2$ targets. Compared with a control group, EGDT resulted in patients being given more fluid, dobutamine and blood transfusions within the first 6 hours following admission to an emergency department [7]. This was associated with an improvement in 28-day mortality from 46.5% to 30.5% ($p = 0.009$). However, three large multicentre trials did not reproduce the beneficial effect of EGDT on outcome [14-16]. Thus, current data do not support the systematic use of this protocolized approach in the haemodynamic resuscitation of patients with septic shock. Whether this limitation also holds true for venous oximetry in unclear since $ScvO_2$ targets in patients with sepsis were always investigated in the frame of EGDT. As in other clinical applications of venous oximetry, $ScvO_2$ and SvO_2 targets should be assessed in the clinical context of the patient.

Currently, international guidelines for the treatment of septic shock have still adopted the concept of EGDT and recommend a $ScvO_2$ >70% [17]. Likewise, a treatment goal >65% is recommended for SvO_2, although EGDT using the pulmonary artery catheter has never been formally tested in septic shock patients.

Importantly, EGDT, and thus the treatment goals for venous oximetry, have been designed for the initial resuscitation of septic shock. Although the treatment goals for SvO_2 or $ScvO_2$ appear reasonable beyond the initial resuscitation phase, this has never been formally studied. Implementation of the Surviving Sepsis Campaign guidelines [17] has been studied in a large Spanish study [18]. Compliance with guidelines was associated with a better survival. Survivors received more fluids and vasopressors, and a $ScvO_2$ >70% was more frequently achieved.

Other clinical applications

Although the pulmonary artery catheter has a recognized role in the management in decompensated heart failure, a venous oximetry value has never been formally studied as a treatment goal. As SvO_2 is tightly correlated with cardiac output, a drop in SvO_2 is a reliable early marker of cardiac deterioration [19]. Patients with congestive heart failure and a low $ScvO_2$ require a more aggressive management approach than those with normal values of $ScvO_2$. Venous oximetry has also been applied in other patient groups in the emergency department, including those sustaining major trauma. However, no study has yet investigated the validity of venous oximetry in aiding haemodynamic stabilization in polytraumatized patients.

Limitations of venous oximetry

Venous oximetry mirrors the adequacy of tissue oxygenation of the whole body. It is not possible using this technique to identify an inadequate oxygen supply in single organs. Thus, a normal value of mixed or central venous oxygen saturation does not always exclude tissue hypoxia. A limitation of the utility of this technique is reached if organ dysfunction progresses or serum lactate increases despite normal, or even increased, venous oximetry [20].

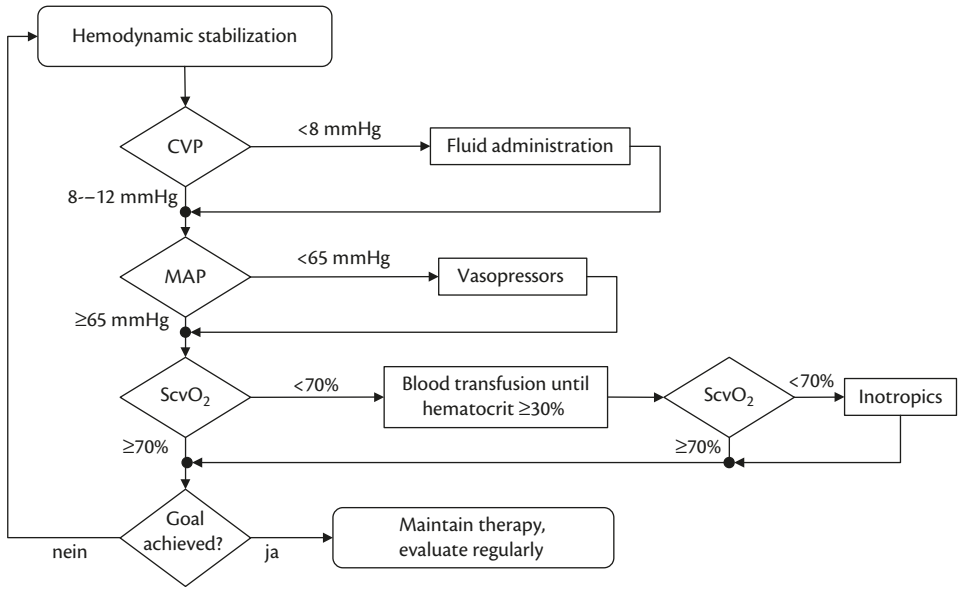

Fig. 134.3 Early goal-directed therapy for patients with septic shock.

CVP, central venous pressure; MAP, mean arterial pressure; $ScvO_2$, central venous oxygen saturation.

Data from Rivers E et al., 'Early goal-directed therapy in the treatment of severe sepsis and septic shock', *New England Journal of Medicine*, 2001, **345**, pp. 1368–77.

This may be related to a decrease in cellular utilization of oxygen due to mitochondrial dysfunction and/or an increase in vascular shunt. Venous oximetry thus only represents the adequacy of tissue oxygenation if the tissues can extract oxygen from the capillary blood. This function may be impaired in severely damaged tissues. Venous hyperoxia is seen under this condition and is associated with an unfavourable outcome. Patients with congestive heart failure frequently have $ScvO_2$ values of approximately 50%, since these patients with low O_2 deliveries need to respond to changes in O_2 need by increasing O_2ER. It is in general unreasonable to attempt to reach a $ScvO_2$ goal of ≥70% in these patients.

CHAPTER 135

Right ventricular function in the ICU

Antoine Vieillard-Baron

Key points

- In normal situations, the right ventricle (RV) virtually acts as a passive conduit.
- In the intensive care unit, RV function is key to treatment optimization and prognostic assessment.
- RV function monitoring is strongly recommended in critically-ill patients.
- Echocardiography, by a transthoracic or transoesophageal route, is probably the best technique for this purpose.
- Alterations in respiratory mechanics or in ventilator settings may significantly impact upon RV function.

Introduction

The right ventricle (RV) has long been considered 'useless' because of its intrinsic properties. In normal conditions, it virtually acts as a passive conduit [1]. Unlike the left ventricle, its iso-volumetric contraction pressure is negligible and there is no iso-volumetric relaxation period as it continues to eject blood long after the beginning of its relaxation. Indeed, the pressure within the pulmonary circulation is low in healthy subjects. Thus, the RV is very sensitive to any acute alterations in its afterload, and its ability to adapt acutely is limited. However, in critically-ill patients, there are many clinical situations where there is uncoupling between the RV and the pulmonary circulation, leading to RV systolic dysfunction and, ultimately, failure. Uncoupling means either that pulmonary vascular resistance and RV afterload are too high with respect to RV contractility, as occurs in pulmonary embolism (PE) and the acute respiratory distress syndrome (ARDS), or that RV contractility is too low with respect to slight increases in its afterload, as may occur in patients with septic shock or RV infarction who require mechanical ventilation. Indeed, mechanical ventilation may decrease RV preload, but also significantly increases RV afterload [2].

Uncoupling usually leads to acute cor pulmonale, the reported incidence of which is up to 25% when protective mechanical ventilation is used in ARDS (Table 135.1) [3], and >60% with anatomically massive PE [4]. RV systolic function is key to the patient's haemodynamic profile and in managing their haemodynamic function. There are many important reasons for monitoring RV function in the critically ill. First, right ventricular failure is a major reason for non-responsiveness to fluid [5], in many situations, the right ventricle is preload-unresponsive, whereas the left ventricle

Table 135.1 Recent studies reporting incidence of RV dysfunction when protective ventilation is used in ALI/ARDS patients

	Number of patients	Population characteristics	Tool	Reported parameter of RV dysfunction	Incidence
Vieillard-Baron et al. 2001 [3]	75	ARDS	Ultrasound (TEE)	ACP	25%
Page et al. 2003 [14]	110	ARDS	Ultrasound (TEE)	ACP	24.5%
Osman et al. 2009 [15]	145	ARDS	PAC	CVP > PAOP	27%
Bull et al. 2010 [11]	475	ALI/ARDS	PAC	TPG ≥ 12 mmHg	73%
Brown et al. 2011 [16]	48	ALI/ARDS	Ultrasound (TTE)	ACP	30%
Mekontso-Dessap et al. 2011 [17]	203	ARDS	Ultrasound (TEE)	ACP	22%
Lhéritier G et al. 2013	200	ARDS	Ultrasound (TEE)	ACP	22.5%

PAC, pulmonary artery catheter; TTE, transthoracic echocardiography; TEE, transoesophageal echocardiography; CVP, central venous pressure; PAOP, pulmonary artery occlusion pressure; TPG, transpulmonary gradient; ARDS, acute respiratory distress syndrome; ALI, acute lung injury.

Data from various studies. See references.

remains responsive. Fluid infusion is then always deleterious and exacerbates venous congestion. Secondly, RV dysfunction per se is strongly associated with a poor prognosis in patients with ARDS, PE, and acute myocardial infarction. Finally, RV function also has a pivotal role in the prognosis of chronic disease, as in chronic pulmonary hypertension [6].

RV function monitoring

Table 135.2 summarizes the different devices used at the bedside to monitor RV function. Echocardiography, via transthoracic or transoesophageal routes, is probably the best compromise between clinical effectiveness and invasiveness. Devices based on transpulmonary thermodilution, e.g. the PiCCO system, are inadequate for evaluating RV function [7]. Computerized tomography can offer useful information, e.g. in suspected PE it allows visualization of the thrombus and an evaluation of RV function (Fig. 135.1) [8].

RV function is highly influenced by respiratory mechanics and respiratory settings in mechanically-ventilated patients. Both may impair the pulmonary circulation and so increase RV afterload in certain circumstances. RV function should always be interpreted and re-evaluated in the light of respiratory mechanics and respiratory settings: any change may instantly modify RV function. An example is given in Fig. 135.2.

Pulse pressure variation

In ventilated patients with haemodynamic compromise, blood pressure monitoring by an arterial catheter is strongly recommended. Visualization of a marked respiratory pulse pressure variation usually means that volume resuscitation can (or should) be optimized. However, in other situations, as in severe ARDS, such variations may instead reflect severe RV systolic dysfunction and so may serve as a warning to physicians to pay attention to the right ventricle (Fig. 135.3).

Pulmonary artery catheter

Use of the pulmonary artery catheter (PAC) has declined in recent years because of its limitations, such as its lack of proven impact on prognosis. However, those still using it should understand the parameters of RV dysfunction that should be monitored. Twenty years ago, RV systolic dysfunction was defined in a large series of ARDS patients as central venous pressure (CVP) exceeding the pulmonary artery occlusion pressure (PAOP) (Fig. 135.4) [9]. The pressure gradient between diastolic pulmonary artery pressure (DPAP) and PAOP (Fig. 135.4) [10], or between mean pulmonary artery pressure (MPAP) and PAOP, are likely to be more relevant. The latter gradient, called the transpulmonary gradient, was independently associated with mortality in a large series of ARDS patients [11]. These two pressure gradients do not directly reflect RV function, but rather the status of the pulmonary circulation.

Table 135.2 Main tools available for RV function monitoring

Tool	Parameters of RV dysfunction	Limitations
Arterial catheter	Pulse pressure variations	Non-specific
Pulmonary artery catheter	Central venous pressure >PAOP, elevated DPAP–PAOP gradient or MPAP–PAOP gradient, decreased right ventricular ejection fraction	Invasive, technical errors, transmission of airway pressures
Transpulmonary thermodilution	Inaccurate	Inaccurate
Echocardiography (transthoracic, transoesophageal)	Acute cor pulmonale, RV dilatation, paradoxical septal motion, biphasic pattern of pulmonary blood flow	Discontinuous, semi-invasive (transoesophageal echocardiography)

PAOP, pulmonary artery occlusion pressure; DPAP, diastolic pulmonary artery pressure; MPAP, mean pulmonary artery pressure.

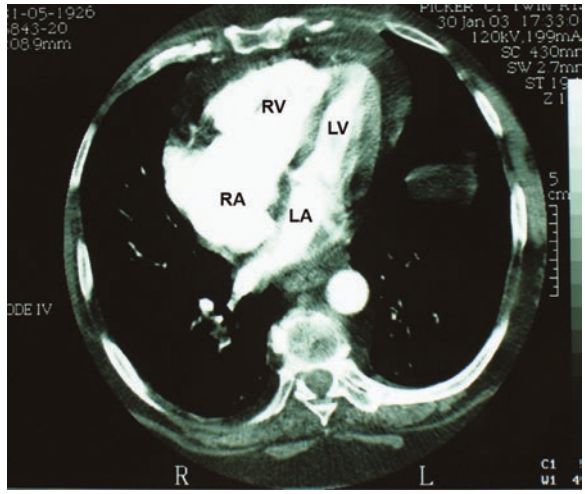

Fig. 135.1 Chest CT scan in a patient hospitalized with massive pulmonary embolism. Note the huge enlargement of the right ventricle.
RV, right ventricle; LV, left ventricle; RA, right atrium; LA, left atrium.

Right ventricle ejection fraction (RVEF) and pulmonary artery pressure (PAP) may be evaluated with a PAC. RVEF can be calculated from RV volume measurements using a fast-response catheter, as proposed many years ago in septic shock [12]. However, a 'low' RVEF may be observed in situations where coupling between the right ventricle and pulmonary circulation is optimal, whereas a 'normal' value may be poorly adapted to a huge increase in RV afterload and then associated with uncoupling. Thus, it is not particularly useful to evaluate RVEF, regardless of any adaptation of the right ventricle to load conditions. The same limitation applies to PAP. A patient may develop acute cor pulmonale, although PAP may be only slightly elevated, yet RV contraction is severely impaired. However, another patient may not do so, despite significant elevations in PAP, as the right ventricle has adapted well to its load conditions.

PAP measurement, if performed, has to be used differently. For instance, it can be used to monitor treatment-related effects (e.g. nitric oxide inhalation should decrease pulmonary hypertension, if beneficial), or to distinguish between acute and chronic RV dysfunction as a systolic PAP remaining below 60 mmHg is highly suggestive of an acute phenomenon (a previously normal RV cannot generate a higher pressure), whereas systolic PAP values >60 mmHg is very suggestive of pre-existing disease with a hypertrophied right ventricle.

Echocardiography

This is probably the best technique for evaluation and monitoring of RV function at the bedside in the critically ill. This objective is served by simple and focused echocardiographic parameters—RV size, interventricular septum movement, and the pattern of RV

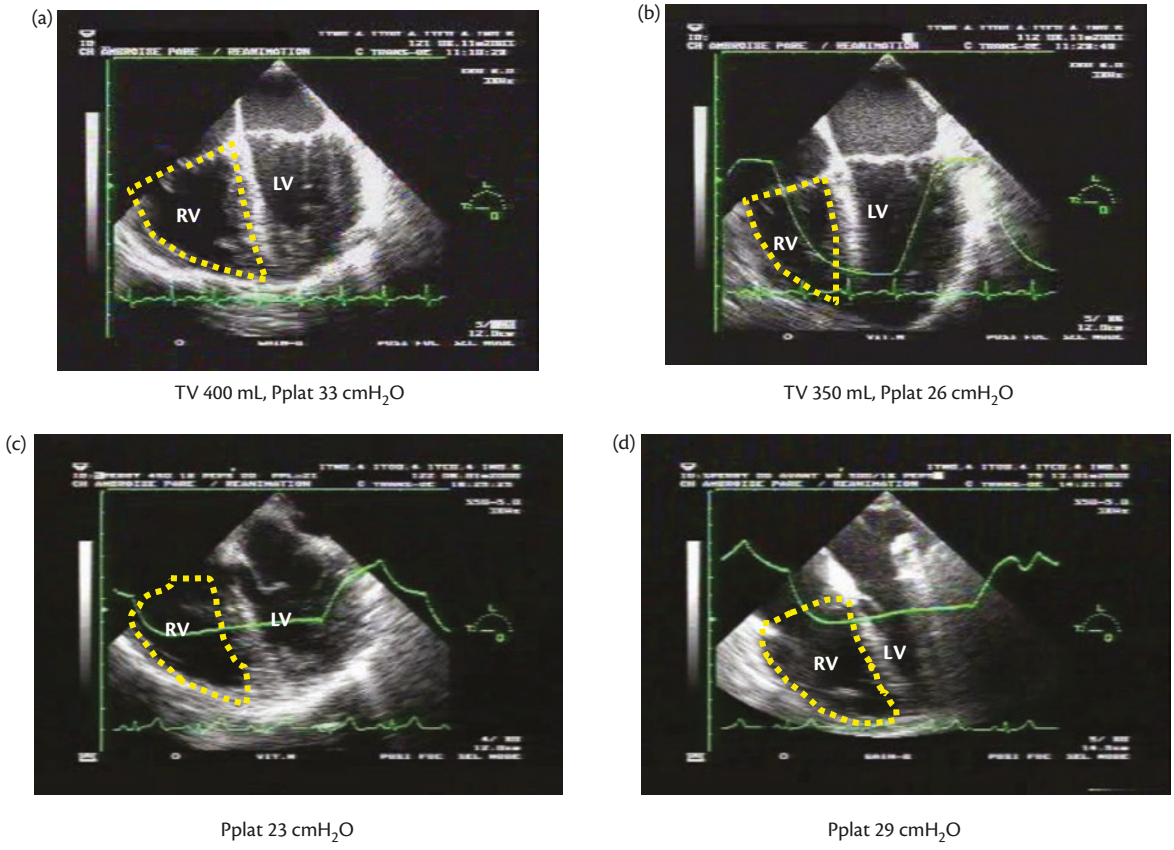

Fig. 135.2 Long-axis view of the left ventricle by transoesophageal echocardiography (TEE) in patients mechanically-ventilated for severe ARDS. (a) Here, TEE demonstrates acute cor pulmonale (note the significant RV dilatation). After reduction of tidal volume and plateau pressure, RV size was normalized (b). In patient 2, note the deterioration of RV function related to the decrease in compliance and increase in plateau pressure from 23 (c) to 29 cmH_2O (d).

TV, tidal volume; Pplat, plateau pressure; RV, right ventricle; LV, left ventricle.

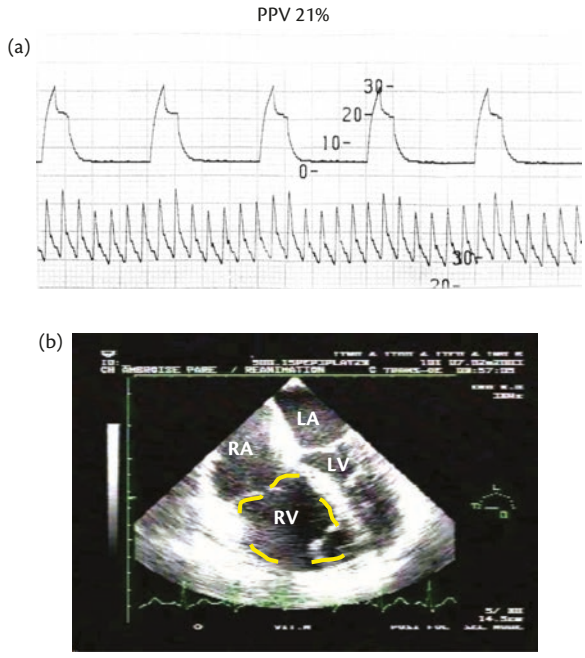

Fig. 135.3 Pulse pressure variations related to acute cor pulmonale in a patient ventilated for ARDS (a). Note the huge increase in RV size with compression of the left ventricle (b).

PPV, pulse pressure variation; RV, right ventricle; LV, left ventricle; RA, right atrium; LA: left atrium.

ejection flow using pulsed Doppler. Acute cor pulmonale is defined by the combination of RV dilatation with paradoxical septal motion during systole (Fig. 135.5) [13]. RV dilatation reflects diastolic overload, whereas paradoxical septal motion in systole indicates systolic overload. A biphasic pattern of ejection flow is highly suggestive of an obstruction in the pulmonary circulation (proximal in PE, distal in ARDS) (Fig. 135.5) [13]. Echocardiography also enables

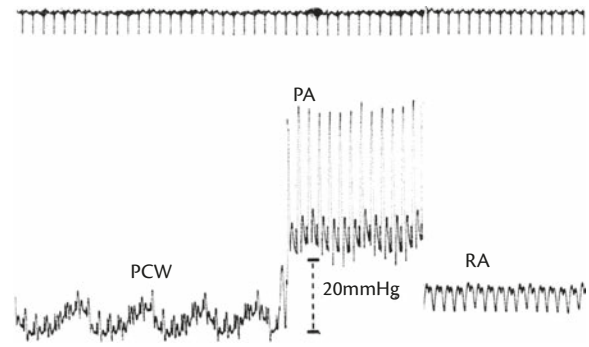

Fig. 135.4 Pulmonary artery catheter in a patient with ARDS. Note that RA pressure was higher than pulmonary capillary wedge (PCW) pressure and, secondly, that the gradient between the diastolic pulmonary artery pressure and the PCW pressure was abnormally elevated.

PA, pulmonary artery pressure; RA, right atrial pressure; PCW, pulmonary capillary wedge pressure.

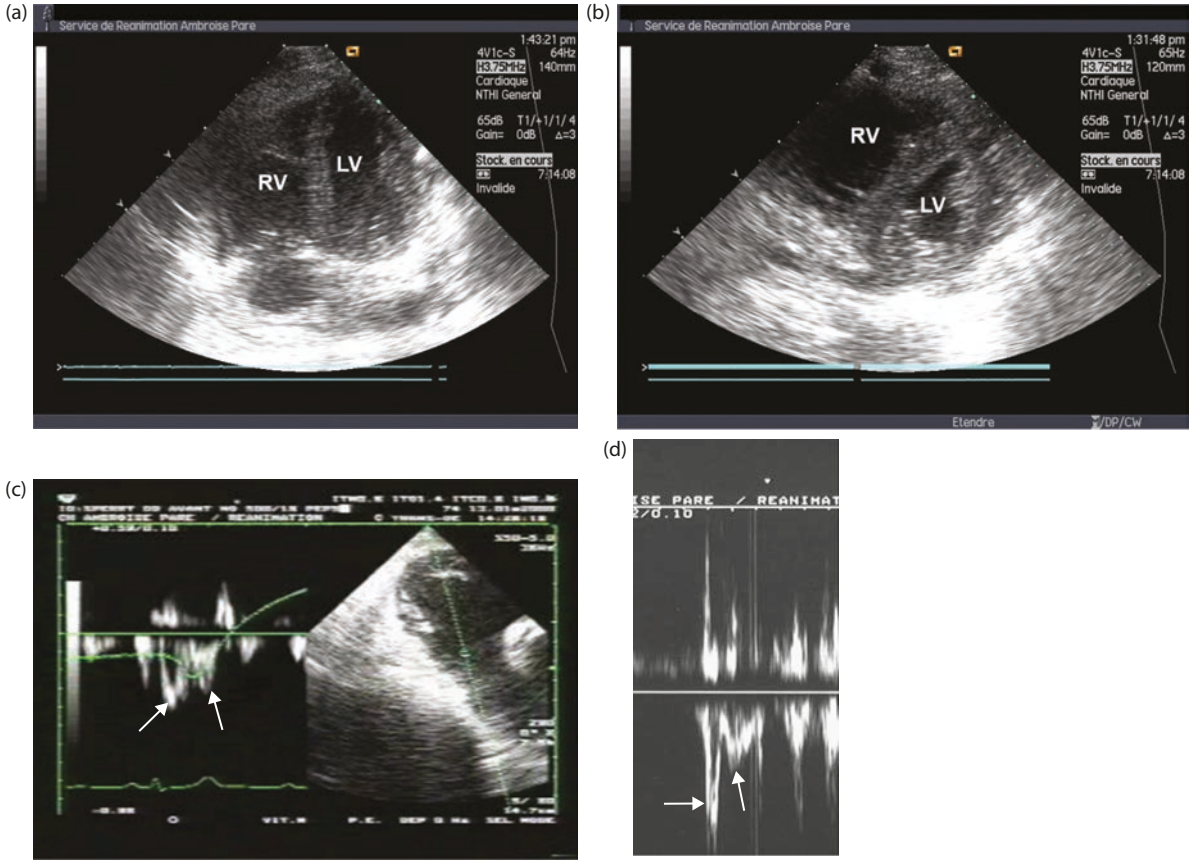

Fig. 135.5 Typical pattern of acute cor pulmonale. (a) and (b) acute cor pulmonale in a patient with ARDS related to influenza. The apical four-chamber view demonstrated RV dilatation (a), whereas the parasternal short-axis view demonstrated paradoxical septal motion (b). In another patient with acute cor pulmonale related to ARDS, note the biphasic pattern of the pulmonary flow (c) (arrows). The same pattern was also seen in a patient with a massive pulmonary embolism (d).
RV, right ventricle; LV,: left ventricle.

an evaluation of RV preload by visualizing the inferior vena cava (IVC). A virtual IVC is suggestive of a preload problem (and the need for fluid in the context of shock), whereas a congested IVC reflects RV diastolic overload.

As reiterated in Table 135.2, a limitation of echocardiography is its inability to monitor haemodynamics continuously, especially RV function. Thus, it should be routinely combined with other systems in the most severely ill patients, such as invasive monitoring of BP.

In conclusion, RV function monitoring is strongly recommended in many situations encountered in the ICU, such as ARDS, septic shock, and PE. Many devices are available, but echocardiography probably constitutes the best compromise between accuracy and invasiveness. Whatever the device used, intensivists must be aware of its limitations, and understand how respiratory mechanics and ventilator settings may impact on RV function.

CHAPTER 136

Cardiac output assessment in the ICU

Nishkantha Arulkumaran and Maurizio Cecconi

Key points

- Haemodynamic monitoring itself does not improve patient outcome. This is dependent on the acquisition of accurate data, appropriate interpretation, and suitable management decisions. Any value derived from CO monitoring must be interpreted in the context of other clinical data, in particular, markers of tissue perfusion.
- The best method of CO monitoring depends upon patient's needs, the clinical scenario, and the experience of the treating physician in relation to the monitoring device itself.
- Although many treatment algorithms have 'targets' validated for specific populations of patients, there is no ideal set of values for an individual patient.
- Cardiac output is estimated, not measured. Values of haemodynamic parameters derived from different CO monitoring devices may not, therefore, be directly comparable.
- The trend or change in haemodynamic parameters is at least as important as the absolute values. This is particularly important when any intervention to augment CO is undertaken. Continuous CO monitoring is therefore preferable to intermittent assessment as it allows trends to be more readily determined.

Introduction

Cardiac output (CO) monitoring devices can be used to detect and monitor haemodynamic changes, and guide therapy. In addition to tracking CO, several of these monitors provide additional parameters, such as dynamic indices of preload (including pulse pressure variation (PPV) and stroke volume variation (SVV)), or volumetric indices (including intrathoracic blood volume index (ITBVI) and extravascular lung water index (EVLWI)) (Fig. 136.1). The different methods of CO monitoring each have their own merits and limitations. Here, we will present the rationale for CO monitoring, and describe some of the devices available.

History

CO monitoring was conceived by Adolf Fick in 1870, who suggested cardiac output could be computed from the ratio of oxygen consumption to the difference in arteriovenous oxygen content.

$$CO = VO_2 / [(CaO_2 - CvO_2) \times 10] \quad \text{[eqn 1]}$$

where VO_2 is oxygen consumption, CaO_2 is arterial O_2 content, and CvO_2 is venous O_2 content.

The indicator dilution method involves injection of an indicator dye into the central circulation with its concentration measured downstream. Cardiac output is derived from the area under the dilution curve (a function of the diluted dye over time), as described by the Stewart–Hamilton equation [1]:

$$\text{Cardiac output} = [V(T_B - T_I) \times K_1K_2] / [T_B(t)dt] \quad \text{[eqn 2]}$$

where V is the volume of injectate, T_B is the temperature of blood, T_I is the temperature of injectate, K_1 and K_2 are computational constants, and $T_B(t)dt$ is the integral of blood temperature change.

Following on from earlier work published by Bradley and Branthwaite [2], in 1970 Swan and Ganz reported their flow-directed balloon-tipped, multi-lumen pulmonary artery catheter (PAC) [3]. This enabled clinicians to float the catheter through the right heart into the pulmonary artery and measure cardiac output by transpulmonary indicator dilution at the bedside. The use of cold 5% glucose as the 'indicator' (thermodilution) replaced the use of indocyanine green dye. The PAC has been utilized in various clinical settings, and represents the gold standard against which other CO monitoring devices have been traditionally compared.

Despite numerous clinical trials and validation studies, there are no conclusive data to suggest that one technique is superior to another. Not all devices have been validated against the same set of criteria and in the same clinical settings. There are no reference criteria for acceptance thresholds for the performance of CO monitors, and various reference techniques are used [4]. Clinical data and specific patient issues should be considered when deciding which device to use and how to accurately interpret the data provided. In this chapter, we describe the different options available, features and limitations, and evidence for use in clinical practice.

Methods of cardiac output estimation

Pulmonary artery catheter

Intermittent CO measurement is achieved by injecting a bolus of glucose, preferably cooled to 4°C, into the superior vena cava/right atrium via a proximal port of the catheter and measuring the change in blood temperature at a thermistor sited at the catheter tip 30 cm distally. Cardiac output is calculated from the rate of change in temperature using a modified Stewart–Hamilton equation. The addition of a thermal filament that sends heat pulses into the blood

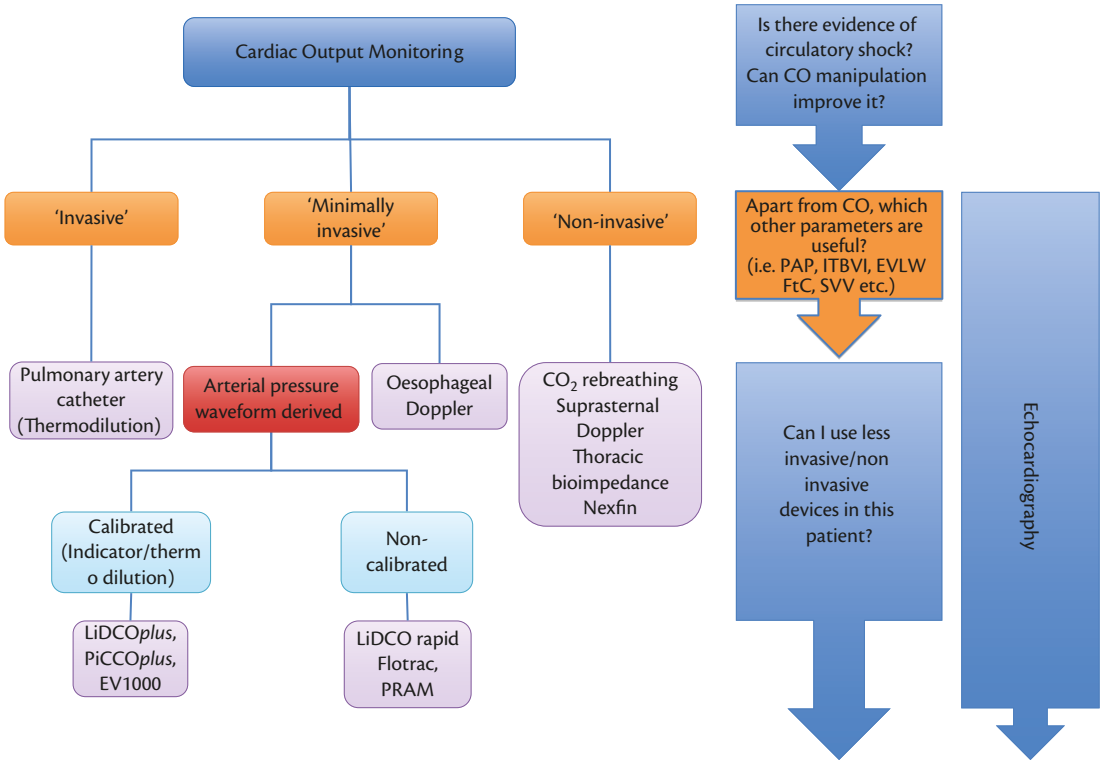

Fig. 136.1 A classification of cardiac output monitors, based on how they work and the level of invasiveness. Several of these monitors provide additional haemodynamic parameters, such as dynamic indices of preload (including pulse pressure variation (PPV) and stroke volume variation (SVV)) or volumetric indices (including intrathoracic blood volume index (ITBVI) and extravascular lung water index (EVLWI)).

within the superior vena cava/right atrium enables estimation of CO averaged over the previous 5–10 minutes. This method is semi-continuous, rather than continuous, and alterations in CO are not detected rapidly.

The main advantage of the PAC over other CO monitoring devices is the ability to directly measure pulmonary artery pressures, right- and left-sided filling pressures, and mixed venous saturations. Measurements derived from thermodilution are relatively accurate, and are comparable with direct Fick and dye dilution methods. As measurements vary with the phase of the respiratory cycle, the average of 3–4 replicate injectates spread over the cycle is usually taken as the CO measurement.

Inaccuracies may arise due to the presence of intracardiac shunts, tricuspid valve pathology, and the simultaneous infusion of cold fluid. As the coefficient of variation for CO measurement is approximately 6–7%, a change of 12–15% in CO between two serial measurements is needed to suggest true clinical significance, other than a chance finding related to the inherent variability of the technique [5].

Observational data suggested PAC use was associated with higher mortality rates and increased use of resources [6]. However, subsequent randomized controlled trials in critically failed to demonstrate either outcome benefit or harm [7,8]. Due to concerns regarding complications related to insertion or use, less invasive CO monitoring devices have superseded the PAC in most clinical scenarios [9].

Pulse pressure analysis monitors

Here, stroke volume is derived from the arterial pressure waveform transduced from an in-dwelling arterial catheter. Such devices use predefined algorithms based on pulse pressure analysis [10]. Each algorithm makes specific assumptions for the estimation of cardiac output and their accuracy depends on the clinical situation. The devices estimate the impedance of the cardiovascular system, based on an assessment of compliance and resistance. This is derived from an online analysis of the arterial pressure waveform, which transforms a pressure over time function into a volume over time function.

There are various clinical situations where the algorithms cannot transform the signal properly, resulting in unreliable CO measurements. These include aortic valve pathology and significant distortions of the arterial waveform (severe arrhythmias, use of vasopressors, multiple ectopics, and the use of intra-aortic balloon counterpulsation) resulting in changes in vascular compliance. Optimization of the input signal is therefore crucial, and calibration may be required prior to use. Patients with atrial fibrillation though with a controlled ventricular rate can have stroke volume (SV) and CO monitored with these devices.

The PiCCO®, LiDCO™, VolumeView™, and COstatus® devices offer cardiac output monitoring from a combination of transpulmonary thermodilution and arterial pressure waveform analysis, e.g. pulse contour (PiCCO) and pulse pressure (e.g. LiDCO). The PiCCO and VolumeView devices require a femoral or brachial arterial catheter in addition to a central venous catheter, whereas the LiDCO requires peripheral arterial and venous access. The PiCCO and VolumeView devices use ice-cold fluid as the indicator, whereas the LiDCO device uses lithium as the indicator 'dye'. The COstatus device requires central venous and peripheral arterial catheters to measure CO and other haemodynamic parameters by measuring changes in blood ultrasound velocity following injection of a warm saline bolus.

The pressure waveform is initially calibrated using the transpulmonary dilution method, allowing data to be monitored

continually. Repeat calibration is required at regular intervals or where any change in vascular system compliance occurs. Although absolute values of haemodynamic parameters cannot be accurately determined without calibration, relative changes in stroke volume in response to a fluid challenge (functional haemodynamic monitoring) are still possible without calibration. These monitors have been used with goal-directed therapy protocols to reduce morbidity in high-risk surgical patients undergoing peri-operative care, based on protocols for fluid and inotrope management.

Some devices, e.g. Vigileo™, MostCare®, and LiDCOrapid® do not use calibration prior to estimation of arterial waveform-derived stroke volume, but these are prone to error with significant changes in vascular compliance. In medical/mixed ICU populations the accuracy of arterial pressure waveform monitoring is highly dependent upon a good calibration [11].

Variations in intrathoracic pressure during mechanical-ventilation result in changes in right atrial pressure, the magnitude of which correlates inversely with intravascular volume. Therefore, mechanically-ventilated patients who are intravascular volume-deficient have a greater variation in pulse pressure and stroke volume. PPV and SVV are thus dynamic indices of preload, with values >10–15% indicative of probable responsiveness to a fluid challenge [12]. Pulse pressure analysis monitors record beat-to-beat variations in PPV and SVV. The PPV to SSV ratio increases with increased vascular tone and can be used to identify vasopressor need in hypotensive patients [13]. The utility of PPV and SVV has limitations in spontaneously ventilating patients, in those with arrhythmias, right heart failure, and those being ventilated with tidal volumes <8 mL/kg. Clinical outcomes associated with the use of PPV and SVV require more rigorous validation, and need to be interpreted within their physiological remits.

Doppler monitoring devices

The oesophageal Doppler monitor uses a disposable flexible 7-mm diameter probe with two D-shaped transducers positioned at the tip. The probe is inserted approximately 35 cm into the oesophagus to the mid-thoracic level at which point aorta and oesophagus run both close and parallel to each other. The probe is orientated to detect blood flow in the centre of the descending thoracic aorta. One transducer emits 4 MHz continuous Doppler, which is reflected off blood corpuscles moving down the descending thoracic aorta resulting in a Doppler frequency shift (f_d) detected by the receiving transducer:

$$f_d = 2(f_o \cdot v \cdot \cos\theta) / c \qquad \text{[eqn 3]}$$

where v is blood flow velocity, f_o is transmitting Doppler ultrasound frequency, and θ is the angle between ultrasound beam and aortic blood flow.

The Doppler frequency shifts undergo fast Fourier transform analysis enabling blood flow velocity within the descending thoracic aorta to be measured in real time. The flow velocity waveforms are displayed on an integral monitor, with the area under the triangular waveform representing the stroke distance, i.e. the distance travelled by a column of blood down the aorta per heartbeat [14]. A nomogram based on the patient's age, height, and weight translates stroke distance into an estimate of total left ventricular stroke volume.

Other measures derived from the oesophageal Doppler include peak velocity (a surrogate of left ventricular contractility) and the corrected flow time (FTc). Peak velocity declines with age, ranging from 90–120 cm/sec in a healthy 20-year-old to 50–80 cm/sec in a 70-year-old. The FTc is the systolic flow time, or the duration of forward flow time, corrected for heart rate by dividing the flow time by the square root of the cardiac cycle time. FTc is inversely related to systemic vascular resistance with a normal range of 330–360 ms in a healthy individual [15]. An increased FTc is seen with a vasodilated circulation, whereas a reduction in FTc is a consequence of any pathology that impairs left ventricular filling or emptying with a resulting vasoconstriction. Such conditions include hypovolaemia, mitral stenosis, pulmonary embolus, or pericardial tamponade, and excessive peripheral vasoconstriction, e.g. due to vasopressors or hypothermia. A rise in FTc with a fluid challenge is used as a dynamic marker of preload and fluid responsiveness.

Accuracy depends on an adequate quality signal from correct placement. This may be difficult to achieve in the ICU patient with minimal or no sedation, or sometimes due to patient positioning. This device has limitations in specific situations. As it measures blood flow in the descending thoracic aorta, which represents 70% of total blood flow in health, this will be affected acutely by aortic cross-clamping. With epidural use, pregnancy and coarctation of the aorta, the proportion of descending aortic to total blood flow to the lower body will alter. Here, absolute values may be inaccurate, although trends can still be followed. Aortic cross-sectional area varies between systole and diastole, especially in younger people with a more elastic aorta, but the area remains relatively fixed through systole. The aortic cross-sectional area in systole is affected by thoracic aneurysms and, to a much lesser extent, by alterations in vascular tone. An intra-aortic balloon pump causes turbulent flow, affecting signal quality. Mindful of the above cautions, cardiac output values correlate reasonably well with the PAC, and can follow trends accurately [16]. Studies have demonstrated reduced morbidity and length of stay in high-risk surgical patients undergoing peri-operative oesophageal Doppler-guided fluid management protocols [17].

The transthoracic Doppler cardiac output monitor (USCOM™, Sydney, Australia) is completely non-invasive. Here, a probe sited in the suprasternal notch is directed towards the ascending aorta. It cannot at present offer continuous monitoring and clinical data demonstrating its utility are awaited.

CO_2 rebreathing/NICO system

The Fick principle has been applied to the NICO system of carbon dioxide (CO_2) rebreathing, where cardiac output is proportional to the difference in arterial and venous CO_2 concentrations. A mainstream infrared sensor for CO_2 measurement is incorporated into the endotracheal tube allowing arterial CO_2 content to be estimated from the end-tidal CO_2 ($ETCO_2$) value and its corresponding dissociation curve. To estimate venous CO_2, a disposable rebreathing circuit is used to allow partial CO_2 rebreathing for a period of time. Every 3 minutes, the rebreathing valve opens to create an additional 150 mL of dead space, thereby increasing $ETCO_2$. CO_2 production is calculated as the product of CO_2 concentration and airflow during this re-breathing cycle. CO_2 produced over a defined period of time is proportional to CO_2 delivery to the lungs.

Alterations in the mode of ventilation, intrapulmonary shunts, increase in dead space, and rapid alterations in haemodynamic variables lead to inaccuracies in measurements and limits its use in critically-ill patients. At present, this technique is at a stage of

infancy and may only be applied in a precisely-defined clinical setting to mechanically-ventilated patients.

Thoracic bioimpedance and thoracic bioreactance

Thoracic bioimpedance (TEB) allows non-invasive and continuous estimation of cardiac output. Impedance is the resistance to a high-frequency, low-amplitude current transmitted between two electrodes. Bioimpedance measures the amplitude of the voltage change across the thorax. TEB works on the principle of the thorax being a cavity containing a volume of fluid (blood) that has a specific resistance. A small current is transmitted between electrodes placed on the neck and the lower thorax, and the voltage is measured. Impedance, which is derived from the voltage, is inversely proportional to the volume of fluid (i.e. aortic blood flow) within the thorax. Thus, an increase in intrathoracic blood volume results in lower impedance. This occurs during systole when aortic blood volume increases. Stroke volume is derived from a formula based on the resistivity of blood, distance between electrodes, ventricular ejection time, and the measured mean thoracic impedance between electrodes.

Various technical and physiological factors affect the accuracy of TEB. Alterations in extravascular lung water and respiratory cycle-dependent alterations in venous blood flow need to be 'filtered' out. Interference from the mechanical ventilator and electrode movement may impair the electrical signal, while increased aortic stiffness also results in decreased accuracy. Data on the validity of TEB in relation to thermodilution-measured CO have been conflicting [18,19]. Serial measurements may be useful to follow trends in CO, although further refinements in this technique are required.

Thoracic bioreactance analyses beat-to-beat changes in electrical currents across the thorax. The size of the phase shifts between electrical currents is proportional to the stroke volume. As its ability to accurately measure phase shifts is less dependent on external noise and electrical interference, thoracic biorectance is more refined than TEB. Early data comparing biorectance (NICOM system, Cheetah) to thermodilution techniques suggest that the methods are comparable [20]. Further studies are required to validate the utility of biorectance and bioimpedance in specific patient populations.

Echocardiography

Transoesophageal echocardiography (TEE) has the clear advantage of providing information on the structure of the heart and proximal aorta in addition to haemodynamic parameters. As such, it has an integral role in the management of the cardiac surgical patient. As an immediate point-of-care assessment of acute haemodynamic change, the role of TEE in the intensive care unit (ICU) is expanding. A miniaturized, disposable biplane TEE probe (ClariTEE®, ImaCor Inc., Garden City, New York, USA) can provide qualitative assessment of cardiac function, although the results from ongoing validation studies are pending. The main disadvantages to TEE are the level of training required to obtain and evaluate images, and the inability to provide continuous cardiac output monitoring.

Conclusion

Novel minimally-invasive monitors that track cardiac output reliably have largely superseded the pulmonary artery catheter. Robust and sensitive methods of validating these devices are required. Selection of the cardiac output monitor and subsequent data interpretation should consider the merits and limitations of the device in respect to the clinical scenario. Ultimately, the best patient outcome can only be achieved with acquisition of accurate data, suitable interpretation of that data, and appropriate management decisions.

CHAPTER 137

Oxygen transport in the critically ill

Stephan M. Jakob and Jukka Takala

Key points

- Tissue oxygen supply cannot be precisely evaluated clinically, since neither systemic blood flow nor arterial oxygen content can be estimated reliably.
- Pulmonary artery catheterization allows measurement of oxygen delivery and demands.
- Mixed venous oxygen saturation is directly correlated with arterial oxygenation, cardiac output, and haemoglobin, and inversely correlated with systemic oxygen consumption.
- Mixed venous oxygen saturation reflects the global adequacy of oxygen delivery, but lower normal limits are individual. Concomitant assessment of blood lactate levels is useful.
- Central venous oxygen saturation and its response to treatment does not necessarily represent mixed venous oxygen saturation and its changes.

Introduction

The cardiovascular system should deliver adequate amounts of oxygen and nutrients to the tissues, and remove their waste products. Measurement of blood pressures, heart rate or cardiac output does not reflect oxygen transport; both oxygen delivery and oxygen demands should be assessed.

Monitoring components of oxygen delivery facilitates early detection of the cause of its deterioration. A sufficient level of oxygen delivery varies widely in individual patients and diseases. Monitoring the adequacy of oxygen transport to the tissues can be particularly important in conditions where blood flow redistribution reduces oxygen delivery inhomogeneously, or when oxygen is used inefficiently. The latter may occur in sepsis [1], in patients with primary mitochondrial diseases, or when drugs affect mitochondrial function [2].

Oxygen in mixed and central venous blood reflects the oxygen reserve, i.e. the amount of oxygen that is delivered, but not extracted. Obviously, arterial oxygen saturation is also a determinant of mixed venous oxygen saturation. The impact of mixed venous oxygen saturation on arterial saturation depends on several factors, the most important being intrapulmonary shunt.

Arterial lactate concentration is an indicator of the adequacy of oxygen delivered in relation to its use for ATP production.

Monitoring oxygen transport within the cardiovascular system

Oxygen delivery to tissues is the product of blood flow and oxygen content:

$$\begin{aligned} DO_2(mL/min/m^2) &= CI(L/min/m^2) \times CaO_2(mL/L) \\ &= CI(L/min/m^2) \times [1.34 \times Hb(g/L) \\ &\quad \times SaO_2 + 0.2325 \times PaO_2(kPa)] \end{aligned} \quad \text{[eqn 1]}$$

Tissue oxygen supply cannot be precisely evaluated clinically, since neither systemic blood flow nor arterial oxygen content can be estimated reliably. Monitoring of global oxygen delivery is, however, possible if cardiac output is monitored. Pulmonary artery catheters (PAC) use thermodilution for cardiac output measurement and monitoring. Measurement of cardiac output using a built-in thermofilament is semi-continuous, but lags several minutes behind the actual changes. Cardiac output can also be monitored with less invasive means, e.g. by ultrasound [3] or pulse contour analysis [4]. Pulse contour analysis needs calibration with an invasive method. Newer uncalibrated devices have been developed, however their performance has been questioned [5]. The advantage of the PAC is the simultaneous monitoring of intravascular pressures and mixed venous oxygen saturation, which helps to evaluate the adequacy of oxygen transport and the causes of insufficient oxygen delivery.

Monitoring oxygen uptake

Oxygen uptake (VO_2) from arterial blood reflects oxygen being consumed by various metabolic processes in the tissues. The fraction of oxygen uptake from oxygen delivery (DO_2) is the oxygen extraction ratio:

$$O_2 \text{ extraction ratio} = VO_2 / DO_2 \quad \text{[eqn 2]}$$

Different tissues have varying oxygen extraction capabilities. When oxygen extraction reaches its maximum (always <100%) during a decrease in DO_2, VO_2 becomes delivery-dependent. As a consequence, a tissue oxygen debt emerges, and anaerobic metabolism with increased lactate production ensues. Tissues may adapt to the low DO_2 by reducing their metabolism and function.

The adequacy of DO_2 may be assessed by instituting a rapid increase and then measuring accompanying changes in VO_2. An

increase in VO_2 >15–20% suggests DO_2 inadequacy. Measuring VO_2 is also useful when evaluating the causes of arterial hypoxemia: in the presence of increased pulmonary shunt (venous admixture), VO_2 can have a substantial impact on arterial oxygenation.

Oxygen consumption can be calculated from data obtained by the PAC using arterial and mixed venous blood samples [6], or can be measured from expiratory gas. Gas exchange monitors, either as stand-alone devices or integrated into patient monitors or ventilators, enable continuous bedside measurement of VO_2. Under conditions of correct calibration and control of measurement conditions, VO_2 can be measured with high accuracy and reproducibility [7,8]. Gas exchange monitors lose their ability to accurately measure VO_2 at FIO_2 >0.60–0.70.

VO_2 can also be calculated using the Fick principle as the product of cardiac output and arterial-mixed venous oxygen content difference:

$$VO_2 = CO \times (CaO_2 - CvO_2) \quad \text{[eqn 3]}$$

However, this approach results in less accuracy and higher variability than VO_2 measurement using gas exchange monitors [6].

Monitoring mixed and central venous oxygenation

Mixed venous oxygen saturation represents the oxygen reserve once blood has passed through the capillaries of the various systemic vascular beds. It is acknowledged as a global indicator of DO_2 adequacy. Because fractions of systemic blood flow delivered to different tissues and their oxygen extraction vary, a normal mixed venous oxygen saturation (SvO_2) does not necessarily guarantee adequate oxygen delivery to all tissues. Nevertheless, in most clinical conditions where tissue hypoxia is present, the mixed venous oxygen content and its changes reflect DO_2 adequacy [9].

Transforming the Fick equation for VO_2 can aid interpretation of mixed venous oxygen saturation:

$$VO_2 = CO \times (CaO_2 - CvO_2) \quad \text{[eqn 4]}$$

$$CvO_2 = CaO_2 - VO_2 / CO \quad \text{[eqn 5]}$$

$$CvO_2 / CaO_2 = 1 - VO_2 / (CaO_2 \times CO) = 1 - VO_2 / DO_2 \quad \text{[eqn 6]}$$

In most clinical conditions, the effect of dissolved oxygen on arterial and venous oxygen content is negligible, and the equations for arterial and mixed venous oxygen content can be simplified as follows:

$$CaO_2\,(mL/L) = 1.34 \times Hb\,(g/L) \times SaO_2 \quad \text{[eqn 7]}$$

$$CvO_2\,(mL/L) = 1.34 \times Hb\,(g/L) \times SvO_2 \quad \text{[eqn 8]}$$

The equations for mixed venous oxygenation can then be simplified further:

$$SvO_2 / SaO_2 = 1 - VO_2 / DO_2 \quad \text{[eqn 9]}$$

$$SvO_2 = SaO_2 - VO_2 / 1.34 \times Hb \times CO \quad \text{[eqn 10]}$$

The last equation demonstrates that SvO_2 will decrease if VO_2 increases and/or if haemoglobin, cardiac output or arterial oxygenation decreases.

The relationship between SvO_2 and CO, VO_2 and haemoglobin is displayed in Fig. 137.1.

Lower limits for 'safe' SvO_2 do not exist. In patients with chronic heart failure, who have adapted to a low cardiac output, SvO_2 saturations <50% are often well tolerated. Conversely, in critically-ill patients, insufficient perfusion with a risk of tissue hypoxia may develop at SvO_2 levels >60% [9]. SvO_2 values <65% should thus be considered as a warning sign of insufficient tissue perfusion in the acutely ill.

Changes in SvO_2, rather than single values, are useful in evaluating responses to therapeutic interventions, since they reflect changes in the oxygen supply/demand relationship [9]. SvO_2 can be monitored on-line using a fibre optic PAC that utilizes reflectance spectrophotometry to measure the mixed venous blood saturation; these have to be first calibrated against co-oximetry [10]. Central venous oxygen saturation ($ScvO_2$) has been used as a surrogate for SvO_2 [11]; however, the two may not necessarily correspond to each other. Changes in $ScvO_2$ in response to treatment may also not correspond to changes in SvO_2 [12].

Relationship between arterial and mixed venous oxygenation

In normal lungs, venous oxygen content has practically no effect on arterial oxygen content, since venous admixture (physiological shunt, Qs/Qt) is negligible. However, the impact of changes in CvO_2 on CaO_2 increases when Qs/Qt becomes larger. In the presence of a large shunt, an increase in VO_2 and/or a reduction

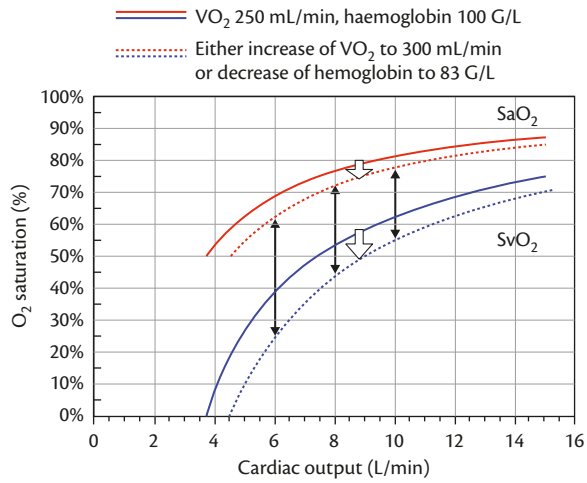

Fig. 137.1 Effect of oxygen consumption and haemoglobin on arterial (red) and mixed venous (blue) oxygenation. A constant physiologic shunt of 50% has been assumed. A similar proportional increase in oxygen consumption and decrease in haemoglobin have identical effects: in both cases the arterial (red dotted line) and mixed venous (blue dotted line) saturation curves shift downwards (open arrows) and the arterial–venous saturation difference widens (solid arrows).

of cardiac output and haemoglobin will cause substantial arterial hypoxaemia. This is evident from the shunt equation:

$$Qs / Qt = (CcO_2 - CaO_2) / (CcO_2 - CvO_2), \quad \text{[eqn 11]}$$

where CcO_2 is the pulmonary venous capillary oxygen content in normally ventilated and perfused alveoli. This can be rearranged as:

$$CaO_2 = CcO_2 \times (1 - Qs / Qt) + CvO_2 \times Qs / Qt \quad \text{[eqn 12]}$$

According to the Fick equation, VO_2 is the product of cardiac output and arterial-mixed venous oxygen content difference. This can be rewritten as:

$$CvO_2 = CaO_2 - VO_2 / CO \quad \text{[eqn 13]}$$

By combining eqns 12 and 13:

$$CaO_2 = CcO_2 - (VO_2 / CO) \times (Qs / Qt) / (1 - Qs / Qt) \quad \text{[eqn 14]}$$

If the dissolved oxygen is ignored, eqn 14 can be written as:

$$SaO_2 = 1 - (VO_2 / CO \times Hb \times 1.34) \times (Qs / Qt) / (1 - Qs / Qt) \quad \text{[eqn 15]}$$

Equation 15 indicates the direct relationship between arterial oxygenation (SaO_2) and cardiac output and haemoglobin, and an inverse relationship with VO_2 (Figs 137.1 and 137.2).

Monitoring the delivery of oxygen to the alveoli

While the amount of oxygen that can be used is dependent on the amount delivered to the tissues, the latter is not only a function of cardiac output and haemoglobin, but also of the amount of oxygen delivered to the blood in the lungs.

Alveolar partial pressure of oxygen (PAO_2) is dependent on barometric pressure (pB), inspired fraction of oxygen (FIO_2), partial pressure of fully saturated water vapour at body temperature (PH_2O; at 37°C, 47 mmHg), alveolar partial pressure of carbon dioxide ($PACO_2$)—estimated as the arterial PCO_2 ($PaCO_2$)—and the respiratory quotient (RQ):

$$PAO_2 = FIO_2 \times (pB - pH_2O) - PaCO_2 \times [1 - FIO_2 \times (1 - RQ)] / RQ. \quad \text{[eqn 16]}$$

Accordingly, oxygen delivery to the alveoli can be monitored using the FIO_2 provided adequate ventilation has been verified either clinically, by monitoring end-tidal CO_2, or by $PaCO_2$ measurement by blood gas analysis. The effect of $PaCO_2$ on PAO_2 becomes smaller when FIO_2 increases. This implies that patients receiving even modest supplementary oxygen can become severely hypercapnic with normal arterial oxygenation.

Monitoring oxygenation of arterial blood

Arterial oxygenation, although most easy to monitor, only partially reflects blood oxygen content. The CaO_2 is a function of haemoglobin (Hb), haemoglobin oxygen saturation (SaO_2), and oxygen dissolved in plasma, which depends on the partial pressure of arterial oxygen (PaO_2):

$$CaO_2 = 1.34 \times Hb \times SaO_2 + 0.2325 \times PaO_2 \quad \text{[eqn 17]}$$

As evident from the equation, haemoglobin concentration and oxygen saturation have the most important impacts on arterial oxygen content.

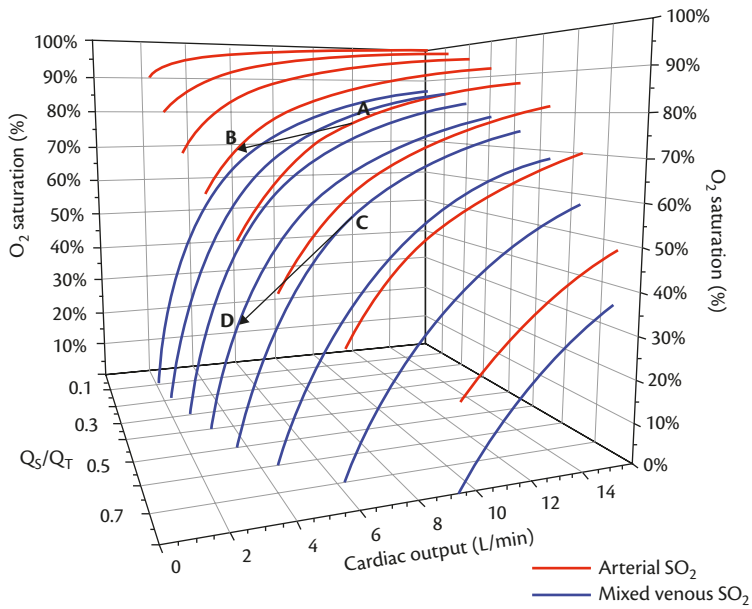

Fig. 137.2 The relationship between venous admixture (Qs/Qt), arterial and mixed venous saturation, and cardiac output. For the calculations, dissolved oxygen has been ignored, and a haemoglobin of 100 g/L and oxygen consumption of 250 mL/min have been assumed. Points A and B represent the effects of cardiac output decreasing from 8 L/min to 4 L/min. The venous admixture is likely to decrease, here from 0.50 to 0.40. Since the decrease in cardiac output is accompanied by increased oxygen extraction, the SvO_2 decreases substantially (points C and D), and the net effect is worsened arterial hypoxaemia.

For monitoring arterial blood oxygenation, blood gas analysis (for PaO_2 and saturation measurement) or pulse oximetry can be used [13]. As detectability of a capillary pulse is a prerequisite for pulse oximetry, monitoring cannot be performed during severe vasoconstriction. Pulse oximetry measures the percentage of oxygenated normal haemoglobin and does not take into account fractions of met- or carboxyhaemoglobin. The percentage of oxyhaemoglobin in total haemoglobin will therefore be overestimated [14].

Tissue oximetry

Oxygen saturation and PO_2 can also be measured directly at the tissue level. Most frequently, these are measured in the brain (PtO_2) and peripheral muscles (StO_2). In the brain, a modified Clark electrode system is most frequently used, with the aim of maintaining brain PO_2 ≥20 mmHg [15]. Brain PO_2 monitoring is mostly used in patients with traumatic brain injury or severe subarachnoid haemorrhage. Low PO_2 values have been associated with increased mortality after traumatic brain injury [16]. Increasing the inspired fraction of oxygen, cerebral perfusion pressure, and/or sedation can help to reverse low PO_2. If they do, survival is improved [17].

Near-infrared spectroscopy has been employed for the assessment of tissue oxygen saturation of the extremities. It correlates with vasoconstriction [18], while low StO_2 and abnormal StO_2-related variables are associated with organ dysfunction and mortality in sepsis [19]. However, the general use of StO_2 monitoring has not yet been established.

Arterial lactate concentration and evaluation of the adequacy of tissue oxygenation

Increased lactate concentrations in tissue hypoxia are due to increased lactate production and/or decreased lactate clearance. Hyperlactataemia is associated with increased morbidity and mortality in various conditions. Mortality can be reduced by therapy guided by lactate levels [20]. Hyperlactataemia can occur secondary to enhanced glucose turnover with increased, rather than decreased oxygen consumption (e.g. during adrenaline treatment), or may be the result of pyruvate dehydrogenase inhibition or isolated reduction of metabolic lactate clearance as a consequence of liver dysfunction. In any case, tissue hypoxia should be excluded when blood lactate is increased. Evaluation of DO_2 adequacy in the critically-ill patient should be based on the combined evaluation of direct and indirect signs of tissue hypoxia. Clinical examination should confirm the absence of hypovolaemia, and circulatory and respiratory failure. Sufficient cardiac output, perfusion pressure, and arterial oxygen content are prerequisites for an adequate DO_2.

CHAPTER 138

Tissue perfusion monitoring in the ICU

Eric Kipnis and Benoit Vallet

Key points

- Monitoring the adequate delivery of oxygen relative to demand is essential during resuscitation and for monitoring of vital functions.
- Although tissue oxygenation seems the best endpoint, it can only be directly measured locally in a limited area of a given tissue.
- Assessment of global oxygenation by central ($ScvO_2$) or mixed (SvO_2) venous oxygen saturation is indicative of inadequate oxygen delivery relative to demand when $ScvO_2$ (or SvO_2) is low. However, 'normal' or high values may be truly normal, may 'miss' local perfusion disorders, or may reflect mitochondrial dysfunction in the late stages of sepsis.
- Inadequate tissue oxygenation may also be monitored indirectly through resulting metabolic imbalances that may be either local (increased tissue lactate levels/decreased tissue lactate clearance, increased tissue-to-arterial PCO_2 gradients, or shift in tissue redox state towards a reduced NADH) or global (increased blood lactate/decreased blood lactate clearance, increased veno-arterial PCO_2 difference).
- Blood flow, as well as microcirculatory characteristics, while useful in investigating perfusion, can only be assessed locally in limited areas of accessible tissues.

Introduction

The endpoint of perfusion is an adequate oxygen delivery to mitochondria in order to maintain production of ATP relative to metabolic demand. Any failure in lung, myocardial, or macro/microcirculatory function may lead to inadequate oxygen delivery, eventually compounded by impaired mitochondrial oxygen utilization, ultimately resulting in cell death, organ dysfunction, and failure. This inadequate oxygen delivery relative to demand is the physiological definition of shock regardless of mechanism or aetiology. Therefore, tissue perfusion and oxygenation cannot be dissociated in any approach to resuscitation or monitoring. Throughout this chapter, tissue perfusion monitoring will be considered as monitoring tissue perfusion, ensuring adequate oxygen delivery relative to demand.

Monitoring perfusion through oxygenation

From these considerations, it becomes apparent that routine parameters such as mean arterial pressure (MAP) or central venous pressure (CVP) do not address the question, and that tissue oxygenation seems the best marker of perfusion. It follows that a major issue is the difference between monitoring oxygen locally, in a very limited area of tissue or globally, in blood. To date, there is no means of monitoring oxygen in patients in all or even several tissues simultaneously.

Tissue oxygenation

Tissue oxygenation can be directly monitored. The gold standard is the Clark electrode, which is based upon oxygen reduction of a silver/silver chloride electrode generating a proportional electrical current, as used in blood gas analysers. Other methods have emerged, such as phosphorescence quenching, which measures the oxygen-related decay in phosphorescence of a phosphor after light excitation. All have been developed into microelectrodes that can be transcutaneously inserted into tissues, or incorporated into intravascular in-dwelling catheters for the assessment of either local or global oxygenation.

Indirect, non-invasive spectrophotometric measurements of oxygen saturation are based upon the different red/infrared light absorption characteristics of oxygenated/deoxygenated haemoglobin. The most widespread is routine capillary pulse oximetry, which provides information on oxygenation (SpO_2), but also perfusion through ratios between pulsatile and non-pulsatile signals (perfusion index). Near-infrared spectroscopy (NIRS) also uses haemoglobin saturation to monitor tissue oxygenation (StO_2), most often in the muscle microvasculature, but limb occlusion tests are required to provide perfusion information [1].

Assessment of local tissue oxygenation has found its major clinical use in monitoring oxygenation of the most critical of tissues, the brain, using either microelectrodes small enough to allow insertion into the brain without injury, or NIRS-based non-invasive methods such as StO_2 [2].

Non-invasive techniques such as pulse oximetry or StO_2 are mainly used as routine 'alert' and/or screening for decreased tissue oxygenation in emergency, peri-operative or critical care settings [1].

The main advantage is that tissue oxygenation is a crucial endpoint immediately providing information concerning inadequate oxygen delivery. Aside from the invasive nature of some devices, the main disadvantage is that local tissue oxygenation can only be monitored in a very limited area at any given time.

Global oxygenation

Global tissue oxygenation can only be appraised indirectly through measuring the net result between the oxygen available for delivery

in arterial blood and oxygen uptake by the tissues. Oxygen saturation measured in venous blood downstream from any further uptake, i.e. in the pulmonary artery sampled by a pulmonary artery catheter (SvO_2) or in the superior vena cava sampled by a central venous catheter ($ScvO_2$), should reflect this net balance between global oxygen delivery and uptake. $ScvO_2$ may overestimate SvO_2 by 3–8% leading to accepted thresholds of 70% for $ScvO_2$ and 65% for SvO_2. It seems logical that $ScvO_2$ monitoring would be useful in shock characterized by inadequate delivery relative to demand. Indeed, in a landmark study, Rivers et al. showed that using a $ScvO_2$ endpoint >70% to judge sequential steps for early management of patients with severe sepsis decreased mortality compared with standard therapy [3]. Patients thus managed received more fluids, and were resuscitated to higher mean arterial pressures than patients receiving standard care. $ScvO_2$ has since been incorporated as a resuscitation endpoint in guidelines for the management of severe sepsis and septic shock.

$ScvO_2$ can be obtained either intermittently through blood gas analysis of venous blood obtained from a central venous line inserted in the superior cava, or monitored continuously through central lines that include an oxygen probe. Another advantage is that a 'low' $ScvO_2$ alerts the healthcare practitioner to situations of inadequate oxygen delivery, which may not be apparent using measures such as MAP or CVP. Such alerts must, however, lead to fully exploring and managing all aspects of oxygen delivery, with re-evaluation through the $ScvO_2$ response.

The obvious drawback to $ScvO_2$ measurement is that normal/high values cannot discriminate whether delivery is adequate/in excess of demand, or whether demand is pathologically decreased in injured tissues. In fact, normal/high $ScvO_2$ values are considered a hallmark in persisting or worsening septic shock due to septic mitochondrial dysfunction impeding oxygen extraction and utilization. However, such situations mostly arise in the later stages of critical illness so a normal $ScvO_2$ value remains a reliable target in the early management of sepsis.

A less evident and more problematic limitation stems from how global an indicator it is. Since $ScvO_2$ is measured downstream from tissues, if a given tissue receives inadequate oxygen delivery, the resulting low **local** venous oxygen saturation may be 'masked' by admixture with highly saturated venous blood from tissues with better oxygen delivery/perfusion, resulting overall in normal or perhaps even high $ScvO_2$ values (Fig. 138.1b).

Therefore, while $ScvO_2$ will not miss any global oxygen delivery disorder (Fig. 138.1c), it may remain 'blind' to local perfusion disorders that abound in sepsis due to an impaired microcirculation.

Metabolic markers of adequate tissue perfusion

Metabolic monitoring of tissue perfusion relies on biochemical and enzymatic reactions occurring in cells, and in organelles (mitochondria) that produce the energy needed for organ function. Under adequate oxygenation/perfusion conditions, glucose is the substrate for glycolysis, leading to the formation of pyruvate. This is oxidized into acetyl-CoA, which enters the citric acid (Krebs') cycle inside the mitochondrial matrix, where it is oxidized into CO_2 while reducing NAD^+ to NADH and FAD to $FADH_2$ (Fig. 138.2). NADH and $FADH_2$ are oxidized by the mitochondrial electron transport chain. Their electrons are transferred down the chain to oxygen and, in

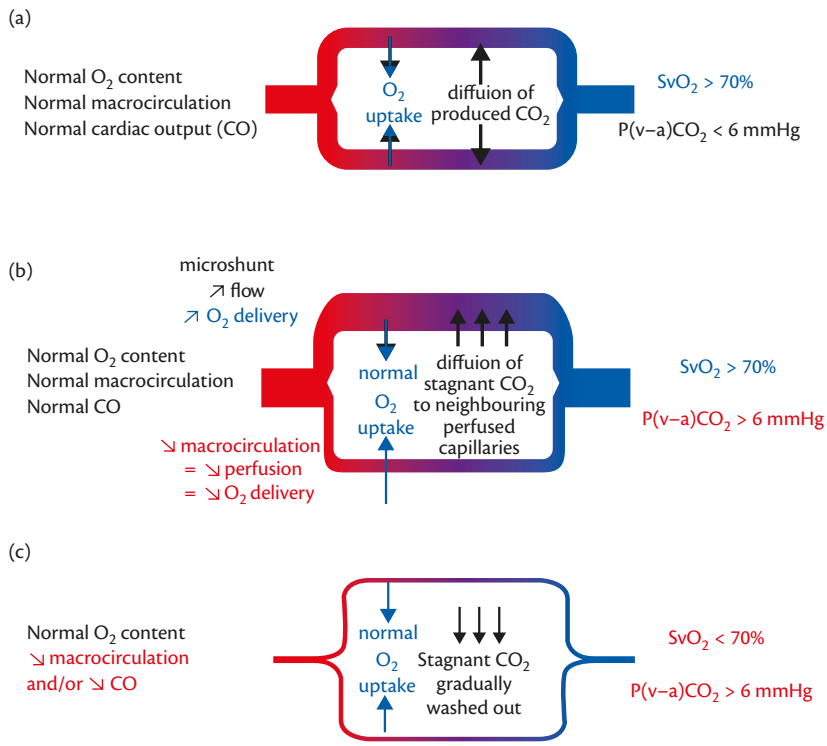

Fig. 138.1 Detection of local or global perfusion disorders with SvO2 or $P(v\text{-}a)CO_2$. (a) Normal. (b) Heterogenous altered microcirculation. (c) Decreased global flow.

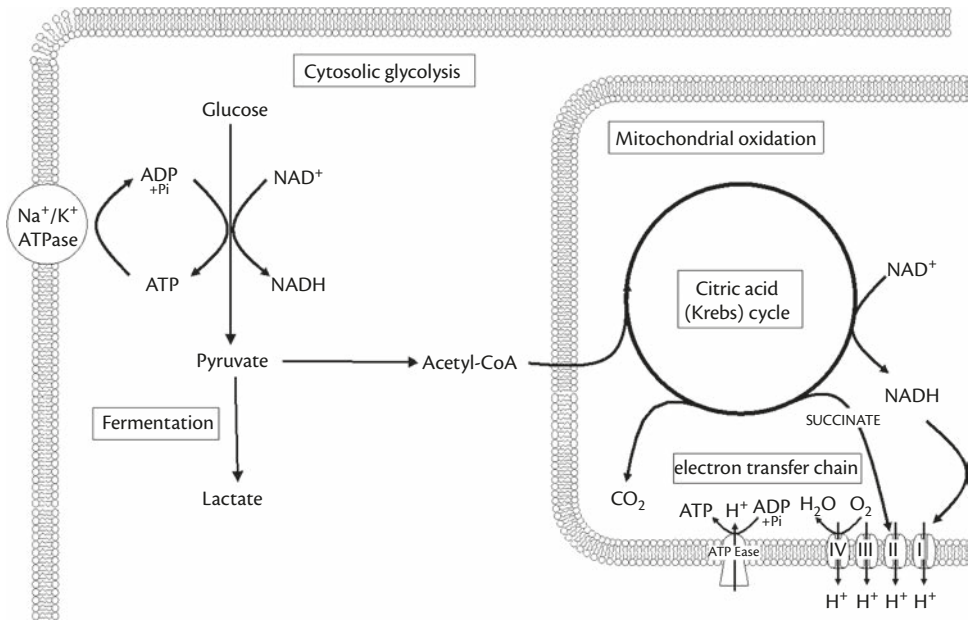

Fig. 138.2 Metabolic parameters of cellular oxygenation/perfusion.

doing so, generates the proton motive force necessary to phosphorylate ADP to the high energy carrier, ATP (Fig. 138.2).

Lactate

Pyruvate can also undergo anaerobic fermentation into lactate. A common misconception is that lactate is only produced in the absence of oxygen. Increased cellular metabolism requiring active Na^+/K^+-ATPase transport uses ATP and may 'drive' glycolysis into producing massive amounts of pyruvate in excess of mitochondrial oxidative capacity (Fig. 138.2). This therefore leads to lactate formation, even in the presence of adequate amounts of oxygen. Such situations may arise from intense physical effort during sport, but has also been demonstrated in sepsis due to endogenous and exogenous catecholamines. This has led to a controversy on the use of lactate as a marker of inadequate cellular oxygenation [4].

However, even given this limitation, lactate has been extensively used and studied in assessing adequate tissue oxygenation/perfusion. Lactate is measured through routine biochemical methods either in blood or using microdialysis probes in tissues. Lactate levels can be considered in terms of its concentration, the lactate-to-pyruvate ratios, or its clearance over time. The body of evidence surrounding lactate has led most guidelines to incorporate increased blood lactate concentrations as diagnostic criteria for impaired perfusion in severe sepsis, septic shock, and severe trauma. As an illustrative example, a multicentre study compared $ScvO_2$ with lactate as resuscitation endpoints, and found that both performed similarly [5]. Furthermore, reaching both $ScvO_2$ and lactate clearance endpoints in septic shock was shown to be superior to $ScvO_2$ alone [6,7]. This suggests that lactate clearance may detect perfusion disorders that $ScvO_2$ cannot.

PCO_2

The production of CO_2, also a by-product of cellular metabolism, is related to oxygen uptake. CO_2 produced by cells is highly diffusible and is 'washed out' from tissues by adequate perfusion, into the pulmonary circulation where its diffusibility allows easy elimination by the lungs. When perfusion is impaired, CO_2 stagnates and increases in tissues. Tonometric methods such as gastric tonometry and sublingual capnography allow CO_2 recovery from accessible mucosal surfaces. These methods allow an approximation of CO_2 production after subtracting the arterial PCO_2 from the tissue partial pressure, i.e. a P(tissue–arterial)CO_2 gradient. Such tissue-to-arterial PCO_2 gradients have been studied as markers of increased tissue CO_2 due to decreased washout through decreased perfusion. Inherently, these local methods only provide information on sublingual and splanchnic perfusion, respectively, and these are variably associated with widespread impaired perfusion. Another drawback is that CO_2 sampling catheters may move and provide inconsistent readings.

Globally-produced CO_2 can be expressed as the difference between the partial pressure of CO_2 downstream from most tissues in the venous system, and CO_2 in arterial blood arriving to the tissues, i.e. the veno-arterial difference or gap: P(v-a)CO_2. Since CO_2 is readily eliminated by the lung, an increase in P(v-a)CO_2 above the normal threshold of 6 mmHg reflects intense CO_2 stagnation in tissues either through local or global perfusion disorders. Indeed, CO_2 is so diffusible that in tissues with decreased or even no perfusion, stagnating CO_2 will diffuse to neighbouring tissues, which remain perfused, increasing venous $PvCO_2$ and, consequently, P(v-a)CO_2 to > 6 mmHg (Fig 138.1b).

Another main determinant of P(v-a)CO_2 is global flow/cardiac output. There must be sufficient cardiac output to wash out CO_2 into the venous, and then pulmonary circulation without it stagnating and increasing. Indeed, in situations of low cardiac output, P(v-a)CO_2 may rise independently of any specific tissue hypoperfusion (Fig. 138.1c). Therefore, P(v-a)CO_2 does not just assess local tissue perfusion but, rather, the adequacy of cardiac output relative to tissue perfusion.

P(v-a)CO_2, like lactate, was compared with $ScvO_2$ in optimization during high-risk surgery; both low $ScvO_2$ and high P(v-a)CO_2

were associated with post-operative complications. However, complications that remained undetected by 'normal' $ScvO_2$ values (>70%) were detected by increases in $P(v\text{-}a)CO_2$ [8]. This suggests that, like lactate, $P(v\text{-}a)CO_2$ may also detect perfusion disorders 'ignored' by the $ScvO_2$.

Redox state

The function of the mitochondrial respiratory chain is to transfer electrons from NADH produced by the citric acid cycle to O_2, driving the ATP production necessary to allow normal cell activity. An increase in cellular activity, provided oxygen delivery remains adequate, will shift the redox state of NADH towards the oxidized form (NAD^+). Inadequate oxygen delivery will result in an increase in NADH. This activity of the respiratory chain *in vivo* can be monitored through this mitochondrial NADH oxidation-reduction (redox) state. The reduced form, NADH, absorbs light and emits fluorescence at different wavelengths, allowing mitochondrial redox state monitoring by measuring UV absorbance or NADH fluorescence. Since absorption is limited by tissue thickness, fluorescence spectrophotometry of NADH has been employed in various in vitro and in vivo models. Devices based upon NADH fluorescence have undergone limited clinical testing [9]. However, the same limitations apply as for other local monitoring systems: they may only detect local disorders and signal quality depends on contact with the explored tissue, which may be inconsistent when, for example, mounted in a Foley catheter.

Blood flow

Rather than assessing metabolic consequences, it is possible to assess blood flow adequacy in surface tissues such as sublingual tissue. Several methods allow either measurement or visualization of erythrocyte movement in tissue capillaries [10].

Laser Doppler flowmetry (LDF) applies the Doppler principle to measuring the velocity shift in refracted light from moving erythrocytes transilluminated by a laser source. Its main advantage is that it provides a quantitative measure of flow (flux). The main disadvantages are the absence of structure visualization, the sampling of a variable area and mix of arterioles–capillaries–venules, and the inability to assess capillary density and/or heterogeneity.

The two major methods of capillary flow visualization are based upon the principles of recovering light from moving erythrocytes in transilluminated tissue, while filtering out light from static structures. In orthogonal polarized spectral (OPS) imaging, this is achieved by light polarization, while sidestream dark field (SDF) imaging uses pulsed lateral transillumination. The main advantage of either approach is visualization, allowing the assessment of capillary density, heterogeneity, and recruitment. However, these parameters can only be assessed qualitatively or semi-quantitatively, and assessment can only be carried out manually off-line.

Flow assessment also has the advantage of being non-invasive, but with the disadvantage of only accessing limited areas of superficial tissue, such as skin or sublingual tissue.

Conclusion

Tissue perfusion monitoring is already part of the routine clinical assessment of critically-ill patients, particularly in sepsis. Several methods described here are recommended in various guidelines. Future use of tissue perfusion monitoring should focus on the hierarchical organization of global tissue oxygenation/perfusion monitoring through sequential use of $ScvO_2$, $P(v\text{-}a)CO_2$, and lactate clearance, and on the development of multimodal local monitoring of flow, oxygenation, and mitochondrial redox status.

CHAPTER 139

Lactate monitoring in the ICU

Tim C. Jansen and Jan Bakker

Key points

- Hyperlactataemia is common in the intensive care unit and an important prognostic marker for morbidity and mortality.
- Hyperlactataemia is caused by both anaerobic and aerobic mechanisms of production and clearance.
- A number of drugs used in critical care cause hyperlactataemia.
- The use of lactate monitoring in goal-directed therapy has clinical benefit.
- Lactate generally increases the ability to predict non-survival, both in the ED and ICU settings.

Aetiology

Lactic acid is >99% dissociated into lactate anions and protons (H^+) at physiological pH. It has two optical isomers, L- and D-lactate. In the ICU situation there is more interest in L-lactate as D-lactate formation is caused by overgrowth of intestinal flora. L-lactate is produced from pyruvate by lactate dehydrogenase (LDH) (Figure 139.1).

Blood lactate was first measured in human blood by the German physician-chemist Johann Joseph Scherer in 1843, when he described a lethal case of fulminant septic shock due to puerperal fever [1]. Nowadays, lactate is frequently measured in critically-ill patients, usually with the aim of detecting tissue hypoxia. However, this is an oversimplification as aerobic processes can also result in increased lactate levels (Box 139.1).

Anaerobic lactate

If cellular oxygen is lacking, more lactate is produced by anaerobic glycolysis, resulting in hyperlactataemia. The corresponding lactic acidosis is the 'type A' according to the classification of Cohen et al. [2]). Experimental studies have confirmed this by reducing the components of systemic oxygen delivery (haemoglobin level, oxygen saturation, and cardiac output) until oxygen demands could no longer be met. Below this critical level of oxygen delivery, oxygen consumption becomes limited by oxygen delivery and this coincides

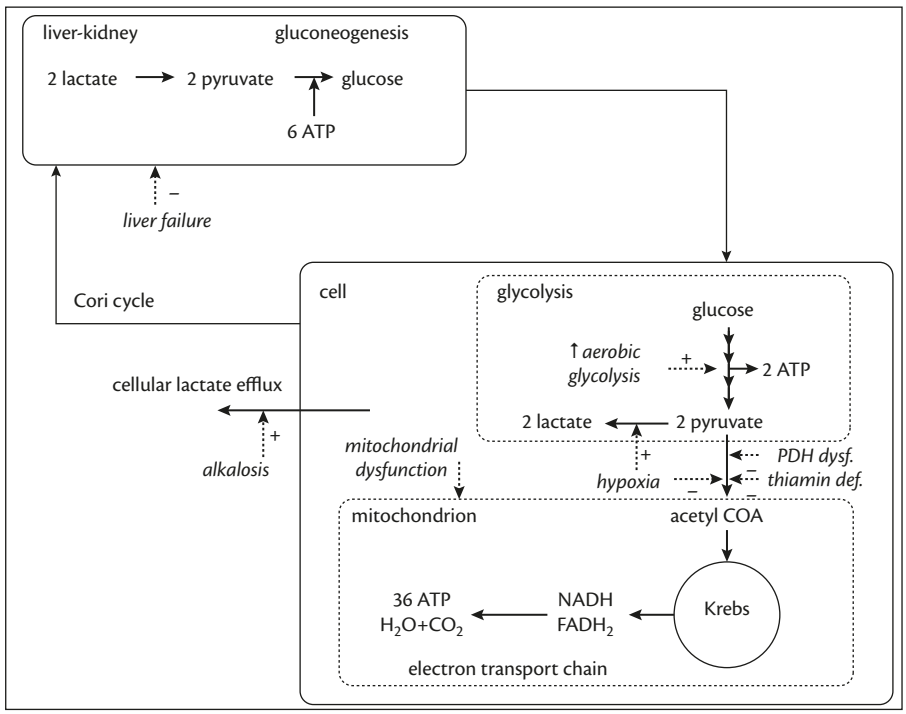

Fig. 139.1 Lactate metabolism: the process of glycolysis, the Krebs' cycle, electron transport chain and gluconeogenesis. Dotted arrows depict the point of action of the various mechanisms causing hyperlactataemia: – inhibitory effect, + excitatory effect.

ATP, adenosine triphosphate; NADH, nicotinamide adenine dinucleotide; $FADH_2$, flavin adenosine dinucleotide; PDH, pyruvate dehydrogenase; dysf, dysfunction; def, deficiency.

with a sharp increase in lactate levels. Similarly, when life support was withdrawn in critically-ill patients in a terminal state of disease, a sharp increase in lactate occurred at the moment that oxygen demands could no longer be met by increased oxygen extraction [3].

In addition to a low **systemic** oxygen delivery, microcirculatory processes that hamper oxygen utilization at the tissue level may also cause lactate levels to rise. Particularly in sepsis, microcirculatory derangements or shunting may lead to insufficient oxygen being delivered to the cell, thereby increasing lactate levels. This is indirectly illustrated by the observation that improving capillary perfusion correlated with a reduction in lactate levels in patients with septic shock, independent of changes in systemic haemodynamic variables [4].

Finally, although hyperlactataemia has often been attributed to intestinal ischaemia, serum lactate is an non-specific marker and probably undergoes significant elevation only after advanced mesenteric damage ([5].

Aerobic lactate

Despite optimal correction of tissue oxygenation, hyperlactataemia may still persist. Thus, cellular hypoxia is not present in 'stress' or 'type B' hyperlactataemia. Other mechanisms account for the production of lactate, namely:

- **Increased aerobic glycolysis**: resulting in elevated concentrations of pyruvate that exceed the capacity of pyruvate dehydrogenase that converts pyruvate into acetyl CoA. Such enhanced glycolysis can be triggered by cytokine-mediated uptake of glucose or catecholamine-stimulated Na^+–K^+-pump activity [6].
- **Mitochondrial dysfunction** [7].
- **Impaired activity of pyruvate dehydrogenase** (PDH): this enzyme is inhibited in septic conditions and increasing its activity with dichloroacetate significantly reduced blood lactate levels [8]. Thiamine deficiency (beriberi disease) also inhibits PDH activity and can cause severe hyperlactataemia .
- **Reduced lactate clearance in liver dysfunction [9] and liver surgery**: decreased clearance has also been reported following cardiac surgery and during sepsis.
- **The lung can be an important source of lactate** [10]: both in pulmonary and extra-pulmonary disease. This probably reflects metabolic adaptations in response to inflammatory mediators rather than tissue hypoxia.
- **Alkalosis** [11]: as an H^+-linked carrier mechanism is involved in transport of lactate across the cell membrane, thereby increasing lactate efflux.
- **The Warburg effect**: with lactate production by malignant cells, even under aerobic conditions [12].
- **Grand mal seizures**.
- **Congenital metabolic diseases**.
- **Drugs and poisons**: epinephrine and $beta_2$ agonists (by increasing glycogenolysis, glycolysis and Na^+–K^+-pump activity), corticosteroids, and a variety of agents causing mitochondrial cytopathy or inhibition of oxidative phosphorylation including metformin (particularly in the presence of renal dysfunction), propofol (propofol infusion syndrome), nucleoside reverse transcriptase inhibitors used in HIV treatment, carbon monoxide poisoning (also reduces the oxygen-carrying capacity of haemoglobin), methanol (through production of formic acid), and cyanide.

A high lactate level found when using a point of care device that is not confirmed using a standard laboratory technique can be used as a diagnostic test for ethylene glycol poisoning. This occurs due to an artefactual reaction with the lactate electrode.

Technique of lactate measurement

Blood lactate levels can be measured by central hospital laboratory machines, point-of-care blood gas analysers or hand-held devices. Generally, all have reported small biases with clinically acceptable limits of agreement. Most investigators report satisfactory agreement

Box 139.1 Aetiology of hyperlactataemia

Anaerobic causes

- Macrocirculatory shock.
- Microcirculatory shunting.
- Carbon monoxide poisoning (carboxyhaemoglobin).

Aerobic causes

- Increased aerobic glycolysis:
  - Catecholamine-stimulated increased Na^+–K^+-pump activity.
  - Cytokine-mediated glucose uptake.
- Mitochondrial dysfunction.
- Pyruvate dehydrogenase dysfunction:
  - Sepsis.
  - Thiamine deficiency.
- Reduced clearance:
  - Liver insufficiency/surgery.
  - Sepsis.
- Alkalosis.
- Malignancy (Warburg effect).
- Epileptic seizure (grand mal).
- Congenital metabolic diseases.
- Drugs and intoxications:
  - Nucleoside reverse transcriptase inhibitors.
  - Epinephrine.
  - Metformin.
  - Propofol (propofol infusion syndrome).
  - Corticosteroids.
  - Cyanide.
  - Ethylene glycol.
  - Methanol.
  - Carbon monoxide poisoning (inhibition of cytochrome oxidase).

comparing capillary, venous, or central/mixed venous levels with arterial levels. Ongoing *in vitro* glycolysis may occur after blood sampling, resulting in erroneous elevation of lactate levels, particularly in cases of leukocytosis or high haematocrit. Analysis within 15 minutes, storage at <4°C, or use of fluoride oxalate tubes are thus recommended. Infusion of Ringer's lactate solution does not hamper measurement accuracy. While renal replacement therapy eliminates only negligible amounts of lactate, the use of lactate-containing buffer solutions can induce transient hyperlactataemia .

Prognosis

In a recent systematic review, all available studies addressing the prognostic value of lactate in the emergency department (ED) or intensive care unit (ICU) were identified [13]. In the ED setting, the area under the receiver operating characteristic curve (AUROC) for mortality varied from 0.67 to 0.98, indicating a moderate to excellent capability to discriminate non-survivors from survivors. In the ICU setting, AUROC varied from 0.53 to 0.86. The positive predictive value or post-test probability for mortality was very low (4–15%) in some studies. However, comparison of pretest probability (population mortality rate) with post-test probability ultimately determines its value in risk stratification. From available studies, lactate generally increases the ability to predict non-survival, both in the ED and ICU settings. The consistency of this finding confirms a role for lactate in the risk stratification of critically-ill patients.

Risk of hyperlactataemia

While hyperlactataemia is associated with worse outcomes, lactate itself is not harmful. It is regularly administered to patients as Ringer's lactate or in lactate-containing buffer solutions for renal

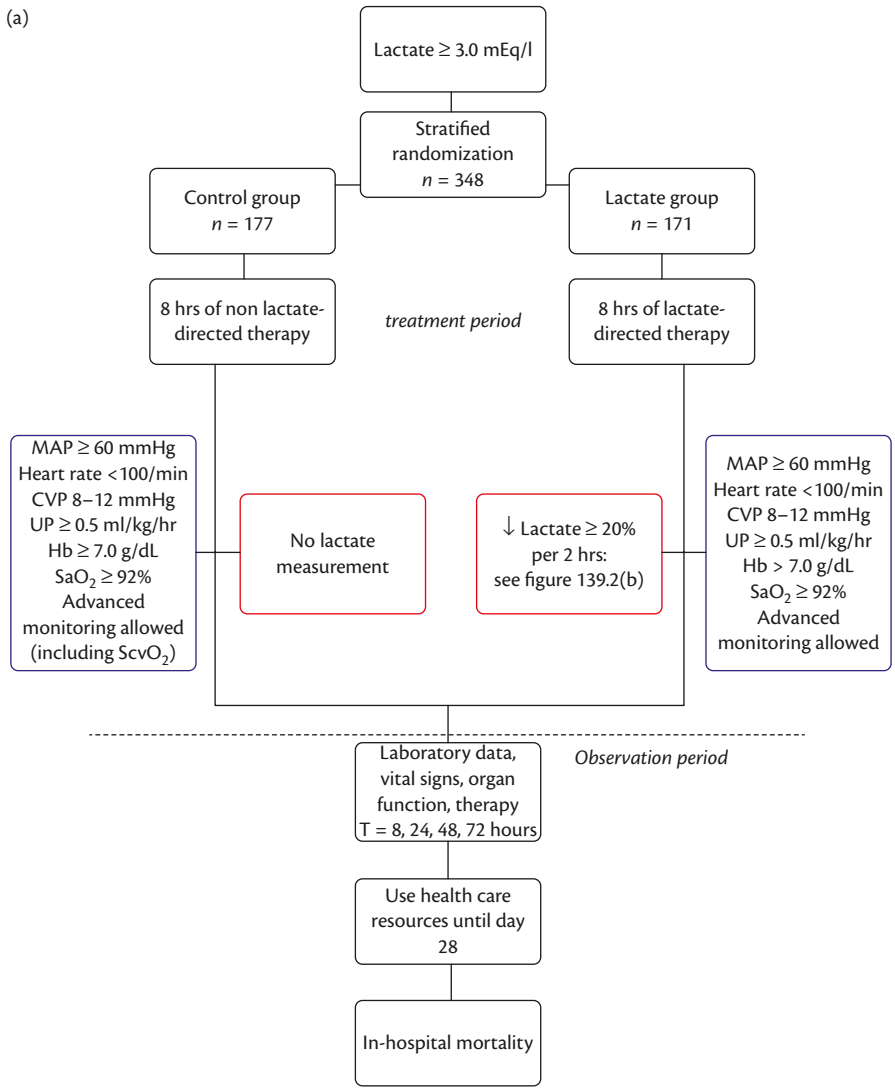

Fig. 139.2 (a) Study of early lactate-guided therapy in ICU patients. Treatment algorithm of control and lactate groups. The CVP target was 12–15 mmHg in mechanically-ventilated patients. CVP was also used as a dynamic safety limit during fluid challenges. The haemoglobin target was 10 g/dL in patients with cardiac ischaemia. (b) Additional treatment algorithm lactate group. If lactate fell ≤2 mmol/L, no further decrease was required. Fluid responsiveness was assessed by 200 mL fluid challenges targeting an increase in MAP, $ScvO_2$ or stroke volume, or a decrease in heart rate.

NTG, nitroglycerine; RBC, red blood cell transfusion.

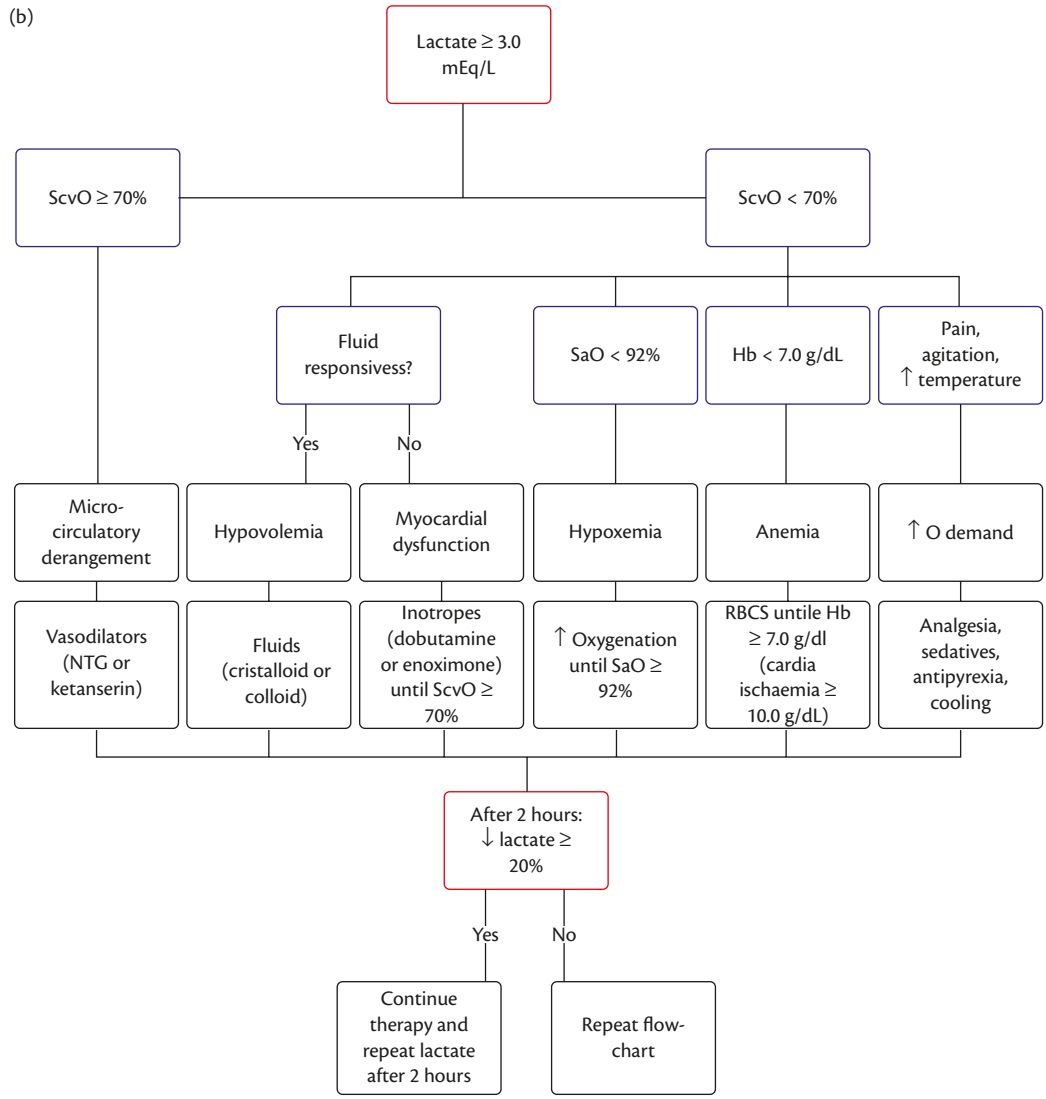

Fig. 139.2 Continued

replacement therapy. Reducing lactate levels by administration of dichloroacetate offered no clinical benefit [8] while lactate is a key metabolite in many tissues [14].

Benefit of lactate monitoring

Lactate monitoring may improve outcomes when hyperlactataemia triggers goal-directed DO_2 therapy. A single-centre trial in post-cardiac surgery patients showed a reduced length of stay [15]. In 2010, a three-centre, open-label US study randomized 300 patients to test non-inferiority between lactate clearance ≥10% and central venous oxygen saturation ($ScvO_2$) ≥70% as goals of early resuscitation in patients presenting to the ED with severe sepsis or septic shock [16]. The intervention lasted until all goals were achieved or for a maximum duration of 6 hours. There were no differences in treatments administered during the first 72 hours and in-hospital mortality rates were similar. This study has some limitations, in particular as $S(c)vO_2$ can be a valuable tool to differentiate anaerobic from aerobic hyperlactataemia, which often requires different treatment. It also seems questionable whether the targeted 10% reduction in lactate levels by 6 hours is sufficient to guarantee adequate resuscitation. Furthermore, only 10% of patients received either dobutamine or a red blood cell transfusion. As fluids and vasopressors were guided by central venous and arterial pressures in both groups, the potential difference in protocol actions directly attributable to either lactate or $ScvO_2$ was small. This complicates interpretation of the study findings as, in retrospect, it seems implausible that a change in resuscitation target could increase mortality by 10%, the non-inferiority margin selected for the trial [17].

A four centre, open-label, randomized controlled trial in the Netherlands [18] randomly allocated 348 patients to either lactate-guided monitoring (lactate group) or a control group during the first eight hours of their ICU stay (Fig 139.2a). In the lactate group, treatment was guided by lactate levels with the objective of decreasing lactate by ≥20% every 2 hours (Fig 139.2b); in the control group the treating clinicians had no knowledge of lactate levels (except for the admission value) over the first 8 hours. This resulted in more fluid and vasodilator administration in the lactate group. A 9.6% absolute mortality reduction was found in the unadjusted primary outcome analysis ($p = 0.067$). This was consistent with a significant mortality reduction in the pre-defined

multivariable analysis (p = 0.006) and with secondary outcome measures. However, despite the outcome benefit, the evolution of lactate levels was similar between groups, suggesting no causal relationship between the resuscitation therapy and hyperlactataemia. Instead, lactate might be an epiphenomenon of disease severity, with clinicians interpreting hyperlactataemia as a warning signal of non-improvement or even deterioration in the presence of stable haemodynamic variables. This could have triggered intensified resuscitation or attention to causes other than inadequate tissue perfusion, e.g. a non-controlled septic focus. Additionally, $ScvO_2$ monitoring, which was mandatory in the lactate group and optional in the control group, may also have had an impact on observed outcomes.

To summarize, these two recent studies show that lactate-directed resuscitation therapy offers clinical benefit for critically-ill patients, although responsible mechanisms remain uncertain. Lactate measurement should probably be accompanied by venous saturation monitoring to guide decision-making and therapy.

Conclusion

Both anaerobic and aerobic mechanisms of lactate production and clearance are important for the correct interpretation of hyperlactataemia . Despite this broad differential diagnosis and acknowledging that the prognostic value of lactate can vary considerably depending on the patient population, a rising lactate generally increases the ability to predict non-survival. Two recent multi-centre trials have confirmed that use of lactate levels in goal-directed therapy improves clinical outcome. These findings suggest that lactate monitoring is beneficial for ICU patients and should be incorporated into early resuscitation strategies.

CHAPTER 140

Measurement of extravascular lung water in the ICU

Danny F. McAuley and Thelma Rose Craig

Key points

- Extravascular lung water (EVLW) is associated with increased morbidity and mortality in critically-ill patients.
- The single indicator transpulmonary thermodilution technique is an available bedside technique to measure EVLW.
- There are no clear guidelines as to what constitutes a normal 'EVLW' value.
- Indexing EVLW to predicted body weight, rather than actual body weight is a better predictor of ICU mortality.
- EVLW estimation may be inaccurate in children and, in certain situations, including lung resection and abdominal aortic aneurysm.

Methods of quantifying extravascular lung water

For several decades there has been a comprehensive quest to find a reliable and reproducible technique to measure extravascular lung water (EVLW) in critically-ill patients. The chest radiograph is routinely used to identify pulmonary oedema, but is ineffective in estimating changes in EVLW when compared with a thermodilution technique [1]. EVLW estimation can also be performed by quantitative computed tomography (CT). Measurements of pulmonary oedema by thermodilution techniques show good correlation with those of quantitative CT [2]. However, CT is disadvantaged by radiation exposure, risks of transfer outside the ICU, expense, and difficulties with making serial measurements.

The reference gold standard method of calculating lung water is the gravimetric method [3]. This is based on comparing wet and dry lung weights. The lungs are weighed and then dried until a constant dry weight is achieved. Blood volume is estimated using a spectrophotometer. The EVLW is the amount of water contained in the lungs outside the pulmonary vasculature. This model has an obvious limitation as it can only be performed post-mortem. Serial measurements are obviously not possible and it is uncertain how lung removal affects EVLW quantification.

The transpulmonary thermodilution technique

There has been greater interest in developing bedside techniques to measure EVLW. Transpulmonary thermodilution is a reliable method used in haemodynamic monitoring of critically-ill patients. Earlier work focused on a double indicator dilution technique, which involves simultaneous injection of a freely diffusible 'cold' indicator and a plasma-bound indicator, such as indocyanine green (ICG) [4]. The diffusible constituent enters both the intra- and extravascular compartments, while the ICG enters the intravascular component only. EVLW accounts for the difference between the compartments. However, this method is expensive, cumbersome, time-consuming, and is now no longer available.

The need for a more straightforward technique that could be easily performed at the bedside led to the development of the single indicator transpulmonary thermodilution technique. This involves injection of a bolus of cold saline into a central venous line with the thermodilution curve being measured via a thermistor device sited within an arterial catheter. This is currently only available using the PiCCO system (Pulsion Medical, Munich, Germany). EVLW estimation using this method requires arterial and central venous catheters. The injectate sensor is attached to the central venous catheter. Following calibration, a bolus of 0.9% normal saline at 4°C is injected into the central venous catheter. The thermodilution curve is measured in the descending aorta (Fig. 140.1). The volume of distribution of the cold saline is calculated from these curves and EVLW calculated. This system heavily relies on the derivation of certain variables.

The volume of distribution of an indicator is the product of cardiac output and mean transit time (intrathoracic thermal volume, ITTV).

$$ITTV = CO \times MTT$$

$$CO = HR \times SV \text{ (HR heart rate, SV stroke volume)} \qquad \text{[eqn 1]}$$

where mean transit time (MTT) is time it takes from injection to half the indicator has passed the detection point

The pulmonary thermal volume (PTV), the largest mixing chamber of the cold indicator, is defined as the product of cardiac output and the exponential downslope time of the thermodilution curve:

$$PTV = CO \times DSt \qquad \text{[eqn 2]}$$

where DSt is exponential downslope time (see Figure 140.2)).
DSt = Down Slope time = Linear decay function of the indicator. Means how fast does the concentration of the indicator pass the detection point

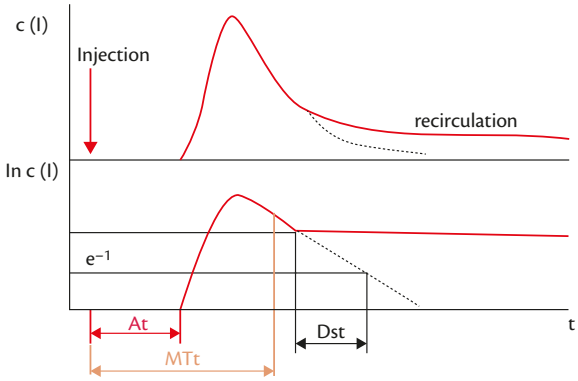

Fig. 140.1 Thermodilution curve.
At, appearance time; MTt, mean transit time; DSt, exponential downslope time.
Reproduced with permission from Pulsion Medical Systems.

The global end-diastolic volume (GEDV) is the difference between ITTV and PTV:

$$GEDV = ITTV - PTV \quad \text{[eqn 3]}$$

This technique assumes a linear relationship between GEDV and intrathoracic blood volume (ITBV). This relationship in humans has been determined by Sakka et al. [5] to equate to:

$$ITBV = 1.25 \times GEDV \quad \text{[eqn 4]}$$

The difference between ITBV and ITTV is EVLW:

$$EVLW = ITTV - ITBV \quad \text{[eqn 5]}$$

(see Figure 140.2)).

The single indicator transpulmonary thermodilution technique has been validated against the gold standard method of gravimetric analysis, and compared with the double indicator technique [6] demonstrating good reproducibility and close agreement.

Measurement of EVLW in a paediatric population can be problematic. Correlation between transpulmonary thermodilution estimation of EVLW and chest X-ray (CXR) quantification of pulmonary oedema is poor [7]. Measurement of EVLW in smaller children (age <10 years) may be inaccurate regardless of the technique used to estimate EVLW. In addition, the physiological principles regarding the relationship between GEDV and ITBV may not apply in a paediatric population. There may also be technical issues, for example, the need to use a femoral venous catheter or the arterial catheter size relative to the child's size may limit measurement of EVLW in young children [8].

Other techniques

Measurement of EVLW using the transpulmonary lithium indicator technique using the LiDCO system (LiDCO Ltd, Cambridge, UK) has also been investigated. Here, a small dose of lithium chloride is injected into a peripheral or central venous access. The resultant arterial lithium concentration time curve is recorded by withdrawing blood past a lithium sensor attached to the patient's in-dwelling arterial line. Only a small concentration of lithium is required, and this is considered non-toxic and pharmacologically inert. However, comparison of EVLW measurements between the double and single thermodilution techniques, and the lithium indicator technique

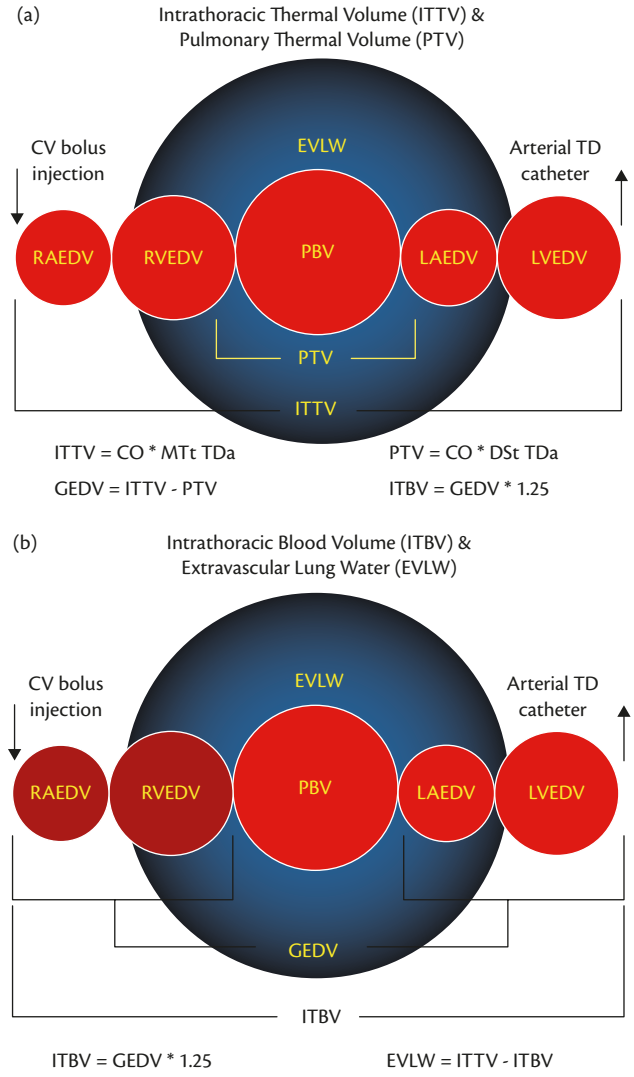

Fig. 140.2 (a) Calculation of ITTV and PTV by the single indicator dilution technique. (b) Calculation of EVLW from ITBV and GEDV.
RAEDV, right atrium end-diastolic volume; RVEDV, right ventricle end-diastolic volume; PBV; pulmonary blood volume; LAEDV, left atrium end-diastolic volume; LVEDV, left ventricle end-diastolic volume; TD, thermodilution.

in patients post-cardiac surgery suggest that the lithium indicator technique is not a reliable measure of EVLW [9]. In this study, the single and double indictor transpulmonary thermodilution techniques demonstrated an acceptable degree of bias, but poor limits of agreement.

Clinical uses

There remains no agreed definition as what constitutes a 'normal' EVLW. Some studies consider <7 mL/kg to be normal [10], whereas others consider values <10 mL/kg as within normal physiological limits [11].

EVLW is traditionally indexed to actual body weight, but since lung volumes are dependent on gender and height, not weight, indexing to predicted body weight has gained favour as it reduces falsely low EVLW measurements in obese patients. This may help to explain why EVLW has been misinterpreted as 'normal' in some

patients with ARDS. EVLW measured within 48 hours of fulfilling ARDS criteria, irrespective of aetiology, when indexed to predicted body weight is a predictor of ICU mortality after adjusting for severity of illness and other important covariates [12]. In this study, the odds ratio for ICU death was 4.3 per standard deviation increase in EVLW.

In a recent systematic review of 11 studies comprising 607 patients, EVLW was significantly higher in non-survivors compared with survivors in critically-ill patients, with a mean difference of 5 ml/kg [13]. The cut-off values differed across studies, which showed significant heterogeneity and ranged from 6.3 to 16 mL/kg. Two studies have suggested that a cut-off value of 16 mL/kg in patients with ARDS is associated with increased mortality [12,14]. A recent study of 200 consecutive subjects found EVLW was an independent risk factor for 28-day mortality in ARDS patients [15].

Measuring EVLW to guide fluid management in patients with pulmonary oedema may reduce the duration of mechanical ventilation and length of ICU stay [16]. EVLW can be pharmacologically manipulated in both animal models [17] and in patients with ARDS [18] suggesting EVLW is adequately sensitive to detect clinically important changes in pulmonary oedema. Measurement of EVLW using the transpulmonary thermodilution technique has been used as a primary endpoint in randomized controlled clinical trials [18,19], and appears to be able to detect clinically significant differences in pulmonary oedema.

Potential pitfalls in EVLW estimation

The accuracy of EVLW quantification relies on two assumptions. First, the downslope time of the thermodilution curve multiplied by the cardiac output gives the pulmonary thermal volume and thus an estimate of GEDV. Secondly, the ratio between GEDV and pulmonary blood volume equates to 4:1. There are other limitations to indicator dilution measurements of EVLW [20]. The most serious problem associated with any indicator dilution measurement of compartmental volumes is the potential failure of the injected indicator to reach all portions of the compartment in the given time period. There are also potential concerns regarding assumptions made on the recirculation of indicator. Comparisons between the single indicator method overestimated EVLW when compared with the gravimetric analysis in animal models [11]. This may be accounted for by the equilibration with the myocardium and surrounding vessels, and by recirculation of the indicator leading to an elevated EVLW.

Several clinical situations, including valve insufficiency, can lead to inaccuracy in CO calculation and, hence, EVLW assessment. An abdominal aortic aneurysm may raise GEDV and ITBV if the indicator passes through the aneurysm. The accuracy of transpulmonary thermodilution is affected by lung resection as pulmonary blood volume will be decreased and affect the GEDV/ITBV ratio.

Regardless, the measurement of EVLW is a potential technique to advance research into the underlying mechanisms of pulmonary oedema, as well as predict clinical outcomes and assess future potential therapies.

CHAPTER 141

Doppler echocardiography in the ICU

Julien Maizel and Michel Slama

Key points

- Echocardiography provides the most complete and safest examination of haemodynamic status in the intensive care unit patient.
- Echocardiography can identify most cardiac causes of shock in ICU patients.
- Intensivists should acquire competencies in echocardiography.
- Echocardiography aids understanding of mechanisms leading to haemodynamic instability.
- Echocardiography can assess the effects of prescribed treatments.

Introduction

The use of echocardiography in the intensive care unit (ICU) has steadily grown in parallel with a decreasing use of right heart catheterization for which multiple studies showed no outcome benefit. Although echocardiography has never shown any positive impact on ICU patient outcomes, its capacity to non-invasively identify the major causes of circulatory failure has made it increasingly popular. Initially focused on stroke volume and cardiac output measurement, echocardiography is being progressively used for more complex and comprehensive haemodynamic assessments. As with ultrasound, ICU physicians should acquire their own echocardiography skills to complement those of the cardiologist. This requires educational programmes to generate sufficient trained operators in every ICU [1].

General principles

Ultrasound is defined as a frequency >20 kHz. In clinical echocardiography the probe usually emits ultrasound frequencies between 2–4 MHz for transthoracic echocardiography (TTE) and 5-8 MHz for transoesophageal echocardiography (TEE). Higher frequencies provide better picture resolution, but cannot reach deep tissue. Lower frequencies provide deeper structure visualization, but with weaker resolution. The propagation velocity of the ultrasound wave depends on the composition of the medium from 300 m/sec in air to 1540 m/sec in human soft tissue. Air interposed between the probe and the structure of interest will dramatically decrease echogenicity.

While TTE has the big advantage of being non-invasive, the impact of lung air and chest wall dressing or tubes in producing poor-quality images can be a real concern. Nonetheless, the reported percentage of anechoic ICU patients using TTE is <10%. As this approach allows delineation of haemodynamic status in most ICU patients, it is generally recommended before TEE. However, if the patient is anechoic, or when posterior structures of the heart (superior vena cava, valvular systems, auricles, thoracic aorta, pulmonary veins) need to be visualized, the use of TEE becomes more appropriate (Table 141.1). TEE is usually considered a semi-invasive procedure with an overall reported complication rate between 2 and 3%, mostly due to transient hypo- or hypertension [2]. Major complications include orogastric perforation, gastrointestinal bleeding, arrhythmias, and respiratory complications (e.g. hypoxaemia, accidental extubation, laryngospasm, bronchospasm) do not exceed 2% of all procedures [2,3]. No related mortality was reported in a series of 2508 ICU procedures [4]. Table 141.2 displays absolute and relative contraindications of TEE.

Haemodynamic evaluation

Cardiac performance in shocked patients is a key point in therapeutic support decision-making. TTE could prospectively identify most cardiac causes in a study of 100 ICU shocked patients, impacting on management in half [5].

Left ventricular systolic function and cardiac output

Determining systolic function is an integral part of the TTE examination. Both ventricles should always be examined.

Table 141.1 Particular advantages of transthoracic and transoesophageal echocardiographic approaches

Transthoracic echocardiography	Transoesophageal echocardiography
Visualization of the IVC	Visualization of SVC
Examination of the pericardium	Examination of atria and auricules (thrombus)
Examination of the LV apex (thrombus, myocardial infarction)	Evaluation of native and prosthetic valve function (endocarditis, regurgitation)
Evaluation of pulmonary artery pressure via the degree of tricuspid regurgitation	Visualization of thoracic aorta (dissection, trauma)
LV tract outflow obstruction	Visualization of pulmonary artery (trauma, thrombus, embolism)
	Examination of proximal coronary flow

LV, left ventricle; RV, right ventricle; IVC, inferior vena cava; SVC, superior vena cava.

Table 141.2 Absolute and relative contraindications for transoesophageal echocardiography

Absolute contraindications	Relative contraindications
Mediastinal irradiation	Oesophageal varices
Unstable cervical trauma	Symptomatic hiatal hernia
Oesophageal tumour	Non-intubated patient with respiratory distress or a full stomach
Oropharyngeal tumour	Agitation
Oesophagectomy	
Active or recent gastrointestinal bleeding	

Echocardiography is the only device that separately analyses right and left ventricular performance. This is particularly important as right ventricular dysfunction requires specific management of fluid, drugs, and ventilator settings.

Several methods quantify left ventricle (LV) contractility, e.g. LV maximal systolic elastance, tissue Doppler, fractional shortening. However, from a practical viewpoint, measurement of left ventricular ejection fraction (LVEF) combined with cardiac output is usually sufficient. LVEF can be assessed by visual estimation or Simpson's method. Visual estimation by an experienced echocardiographer could detect systolic dysfunction with high feasibility and reproducibility (compared with Simpson's method) [6], and with clinical utility in ICU patients [7]. Systolic function can also be evaluated by TEE using LVEF in a longitudinal four-chamber view or LV fractional area contraction in a transgastric short-axis view.

Cardiac output (CO) is considered a cornerstone in haemodynamic evaluation. For both TTE and TEE, the most reliable method consists of measuring (in the same position) both LV outflow tract diameter and the aortic flow velocity-time integral (VTI) recorded with Doppler ultrasound. Stroke volume is computed as aortic cross-sectional area multiplied by VTI, and CO as the product of stroke volume and heart rate. Excellent agreement has been demonstrated with the thermodilution technique in ICU patients.

Left ventricular diastolic function and filling pressure

Evaluation of diastolic function provides important information [8]. In patients with a steep LV pressure-volume relationship (impaired LV relaxation), infusion of small fluid volumes may increase LV diastolic pressure and precipitate acute pulmonary oedema. It is crucial to consider differences between diastolic dysfunction and increased LV filling pressure. Diastolic dysfunction is the alteration of LV properties marked by decreased LV relaxation and increased stiffness. Diastolic dysfunction is seen in diastolic heart failure, but also in heart failure patients with systolic dysfunction. LV filing pressure, or end-diastolic pressure (LVEDD), is not necessarily increased with diastolic (or systolic) dysfunction in the absence of congestive heart failure.

Several variables can be used to explore diastolic function—mitral inflow, early septal and lateral mitral annular systolic velocities, left atrial volume, pulmonary venous return flow, and the Valsalva manoeuvre. Some are difficult to obtain in an ICU patient (e.g. Valsalva manoeuvre) or require TEE (e.g. pulmonary venous flow). For ICU patients we can reasonably recommend focusing upon mitral inflow, the early mitral annular systolic velocity in tissue Doppler mode, and pulmonary venous return flow if TEE is used (Figs 141.1, 141.2, and 141.3). Three grades of diastolic dysfunction have been identified—mild (grade I), moderate (grade II), and severe (grade III). This classification strongly prognosticates all-cause mortality in a general population. Grade II dysfunction represents impaired relaxation and moderate elevations of LV filling pressure, whereas Grade III denotes a restrictive LV filling pattern with high LV filling pressures that could revert to impaired relaxation (grade II or I) after successful therapy. However, this grading presents some limitations. In patients over 60 years old it is not rare to find a grade I pattern (E/A ratio <1 and deceleration time >200 ms) without diastolic dysfunction. Here, a history of cardiovascular disease or the presence of left ventricular hypertrophy will confirm the existence of diastolic dysfunction. Athlete's heart can present with an increased left atrial size (≥34 mL/m^2) but the presence of normal septal and lateral E' velocities confirms the absence of diastolic dysfunction.

Despite these limitations this classification does provides useful information for ICU practice. For example, determining LV filling pressure helps to establish a cardiac origin of acute respiratory failure. Many Doppler indices derived from mitral flow E/A ratio (the ratio between early (E) and late (A) mitral inflows recorded with pulsed Doppler), pulmonary venous flow (D wave deceleration time and systolic fraction) and tissue Doppler E/E' ratio (the ratio between early (E) mitral inflow recorded with pulsed Doppler and the early diastolic velocity (E') recorded from Doppler tissue

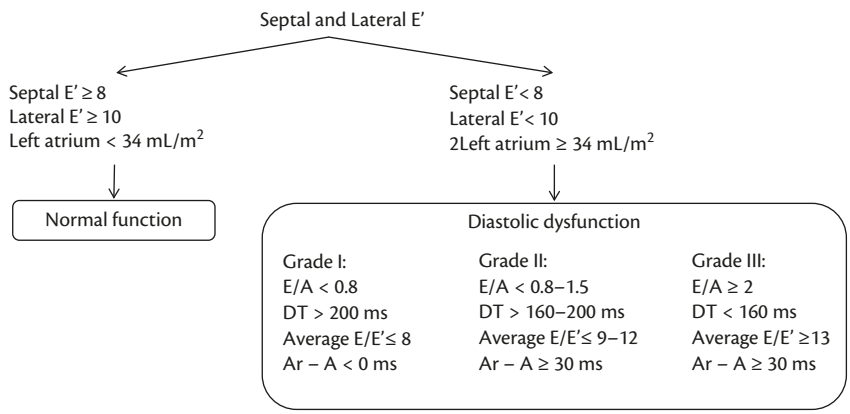

Fig. 141.1 Left ventricular diastolic function assessment.

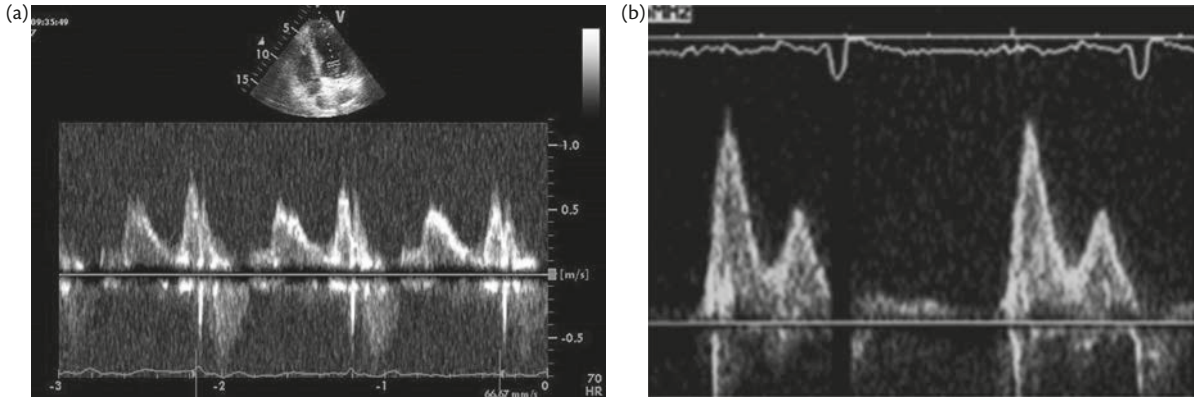

Fig. 141.2 Mitral flow recorded using pulsed wave Doppler. (a) Diastolic dysfunction grade 1. (b) Grade 3.

imaging with the sample cursor placed in the lateral or medial mitral annulus) can help to further explore LV filling pressures (Table 141.3). These parameters have been validated against pulmonary artery occlusion pressure in mechanically-ventilated ICU patients. Data are lacking for spontaneously breathing ICU patients and are therefore extrapolated from the catheter laboratory. However, each parameter has its limitations. The E/A ratio offers better diagnostic value in patients with depressed systolic function (Fig. 141.2), while the E/E' threshold differs (particularly in cases of myocardial ischemia) depending on whether E' is recorded in the lateral or medial junction of the mitral annulus. Both should thus be recorded (Fig. 141.3). Pulmonary artery flow generally necessitates the use of TEE. Estimation of LV filling pressures in ICU patients requires several parameters, rather than just one. For systolic dysfunction, E/A or E/E' should be measured [9].

Right ventricular function

Right ventricle (RV) assessment should be systematically performed when evaluating critically-ill patients. The RV's role is to aid venous return and eject it into the low-pressure pulmonary circulation. Most RV dysfunction in ICU patients is secondary to an increased RV afterload related to elevations in pulmonary vascular resistance (PVR). Bronchospasm, acute respiratory distress syndrome, pulmonary embolism, and mechanical ventilation are potential aetiologies. RV dysfunction may also result from volume overload or myocardial dysfunction including RV infarction, contusion, and sepsis.

In the ICU setting, RV examination includes assessment of size, thickness, contractility (including paradoxical septal movement), and an estimation of pulmonary pressures. RV dimensions are recorded in apical or subxiphoid four-chamber views. The ratio between RV and LV end-diastolic diameters (or areas) defines the presence of RV dilatation. The ratio is normally <0.6, whereas moderate dilatation is defined by ratios between 0.6–1, and severe dilatation by ratios ≥1. The presence of RV dilatation should be complemented by measuring RV wall thickness at the level of the mid-lateral free wall (excluding any papillary muscle or epicardial fat tissue). Thickness ≥7 mm (normal <4 mm) suggests chronic, rather than acute RV pressure overload [10]. RV systolic function may be assessed using the ejection fraction method

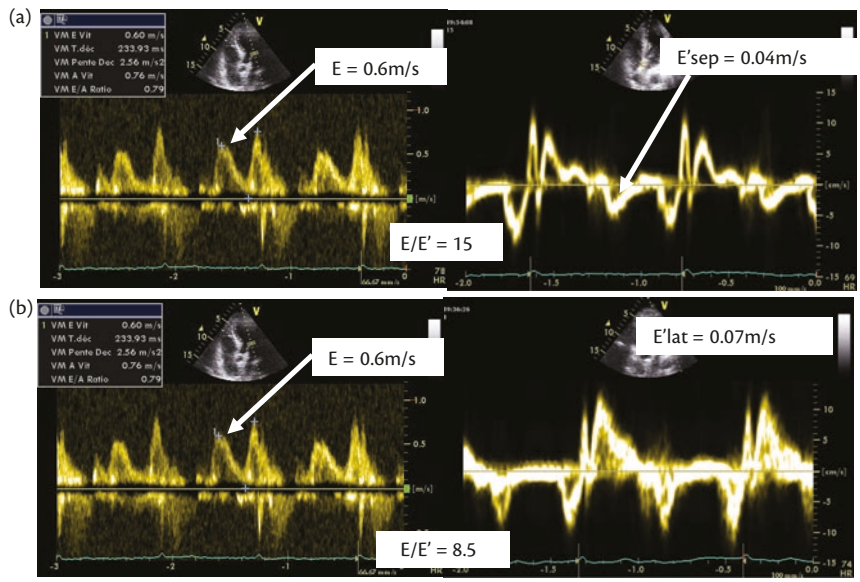

Fig. 141.3 E/E' ratio at the septal level (a) and the lateral wall (b).

DDT, D wave deceleration time (pulmonary venous flow); TTE, transoesophageal echocardiography; systolic fraction (%) = VTI systolic wave/VTI systolic + diastolic waves of pulmonary venous flow.

in a four-chamber view. This can be problematic due to RV shape complexity and a lack of standardized methods for calculating RV volumes.

RV fractional area change (normal >35%) can also assess systolic function. End-systolic and diastolic RV areas are measured in the apical four-chamber view using TTE, or in the transgastric short-axis mid-papillary view with TEE. Displacement of the tricuspid annulus recorded in M-mode (TAPSE) analyses anterior movement during systole. Normally between 17–30 mm, TAPSE <16 mm suggests RV systolic dysfunction. A systolic velocity of the free wall tricuspid annulus recorded in tissue Doppler mode (S wave) <10 cm/sec likewise suggests RV systolic dysfunction [10]. The right and left ventricles are closely related, sharing the interventricular septum. During RV dysfunction, septal motion is shifted towards the LV during either systole (pressure overload) or diastole (volume overload). This can be observed in M mode parasternal longitudinal view (TTE) or in transventricular short-axis view (TTE or TEE). This phenomenon of paradoxical septal movement can be quantified by the eccentric index in a transventricular short-axis view. This is the ratio between two diameters, one of which bisects and the second being perpendicular to the septum (Fig. 141.4). This ratio is normally 1 (round shape of the LV), but becomes >1 (D-shaped) with a paradoxical septum.

Modifications in RV and interventricular septal morphology are associated with increases in pulmonary arterial and right atrial pressures. When evaluating right atrial pressure (RAP) one must recognize the impact of mechanical ventilation. In spontaneously breathing patients, an end-expiratory inferior vena cava (IVC) diameter (measured in subxiphoid transverse M-mode view perpendicular to the long axis and 1–3 cm proximal to the right atrial ostium) ≤2 cm predicts RAP <10 mmHg. Collapsibility <40% during inspiration (maximum diameter – minimum diameter/maximum diameter × 100) also predicts RAP <10 mmHg [11]. In mechanically-ventilated patients, an end-expiratory IVC diameter <12 mm also predicted RAP <10 mmHg, but respiratory variations in diameter were not predictive [12]. Pulmonary artery systolic pressures can be evaluated non-invasively from the maximal velocity of the tricuspid regurgitant jet (Fig. 141.5). This should be carefully interpreted as it also depends on stroke volume and can be easily underestimated due to a weak regurgitant Doppler signal in mechanically-ventilated patients.

Pericardium

The pericardial space is a virtual cavity, but blood, fluid, pus, or air can occasionally be responsible for an effusion and dramatically affect cardiac performance with tamponade. TTE combining parasternal, apical, and subxiphoid views is usually sufficient to exclude an effusion. With poor echogenicity or after recent cardiac surgery, TEE may be required to visualize behind the atria and exclude any confined compressive clot. Echocardiography can help to quantify the effusion (circumferential or partial, measuring also its thickness in end-diastole) and to assess any consequences

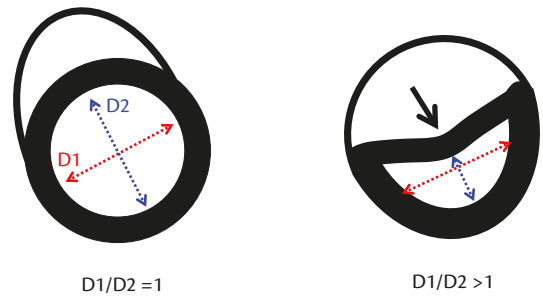

Fig. 141.4 Left ventricular short-axis view. Eccentric index assessment.

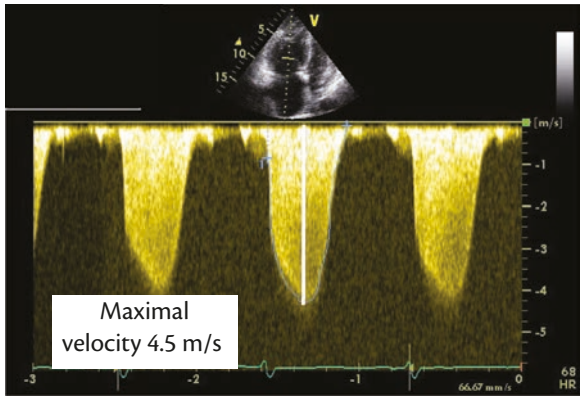

Fig. 141.5 Tricuspid regurgitation recorded using continuous wave Doppler. Pulmonary artery systolic pressure (SPAP) is calculated as 4× (Maximal velocity)^2 + right atrial pressure. In this patient RAP = 9 mmHg and SPAP = 80 mmHg.

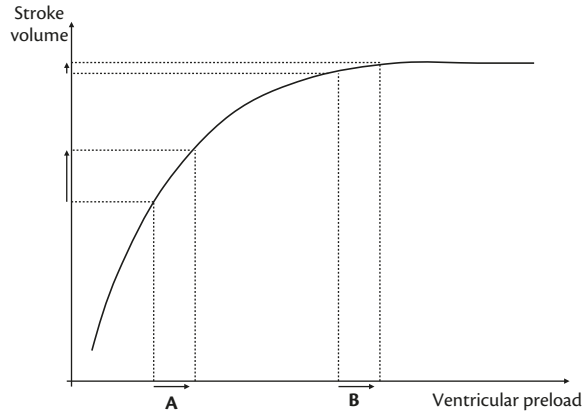

Fig. 141.7 Frank—Starling relationship.

on right-heart cavities. Tamponade represents circulatory failure due to RV and/or right atrium (RA) diastolic collapse related to compression. More than just size alone, the risk of tamponade relates to the rapidity of formation. Tamponade does not necessarily require a large-sized effusion. Movement of the RV free wall (apex and mid portions) and the RA wall during diastole should be carefully analysed to detect the presence of a compressive effusion (Fig. 141.6). Another indirect, but non-specific sign of compression is a congested IVC. Respiratory variations in tricuspid Doppler signals can aid in detecting compression in spontaneously breathing patients, but not during mechanical ventilation. During spontaneous inspiration physiological acceleration of the tricuspid velocity is considerably increased (+80%) and mitral velocity deceleration decreased (–40%). Echocardiography also guides the physician during pericardiocentesis.

Fluid responsiveness

Management of circulatory failure usually requires fluid administration to improve cardiac output and oxygen supply. An excessive fluid input can be deleterious, provoking congestive heart failure and pulmonary oedema. It is therefore important to predict the efficacy of a fluid challenge and avoid futile increases in left ventricular end-diastolic pressure. Fluid only increases stroke volume if both ventricles are working on the steep part of the Frank–Starling curve. Otherwise, fluid will simply increase preload without any significant increase in stroke volume (Fig. 141.7). In the ICU, except for obvious situations (active bleeding, burns, trauma), clinical findings do not predict fluid responsiveness [13] so complementary information should therefore be used. Static and dynamic measures can predict fluid responsiveness. Static parameters evaluate left ventricular filling pressure or RAP under one loading condition, assuming the lower the preload the higher the probability of a response to volume expansion. A virtual end-systolic LV area <4 cm^2 in the short-axis view also predicts likely fluid responsiveness [14]. However, except for this extreme situation, no cut-off value exists to predict fluid responsiveness because of the wide variety of LV dimensions. Other static parameters described include Doppler parameters listed previously and in Table 141.3.

Dynamic parameters are clearly superior to static. These are described as dynamic as they try to determine whether the patient is situated on the ascending portion of the Frank–Starling curve where any preload variation affects stroke volume (i.e. preload-dependent), or on the plateau portion where preload variations are not accompanied by variations in stroke volume, i.e. preload-independent (Fig. 141.4).

Many criteria have been described using loading modifications generated by mechanical ventilation, fluid challenge or passive leg-raising (Table 141.4). Tidal ventilation generates a positive intrathoracic pressure during inspiration, decreasing venous return, increasing resistance in the pulmonary capillaries, decreasing LV preload a few cardiac cycles later and, finally, decreasing stroke volume if both right and left ventricles are functioning on the ascending portion of the Frank–Starling curve. Variations in stroke volume >13%, in Ao VTI >20%, or in Ao maximal velocity >12% predict fluid responsiveness. This can be used only in sedated, mechanically-ventilated, non-spontaneously breathing patients in sinus rhythm. The positive pressure generated by the ventilator during inspiration will also generate cyclic modifications in superior and inferior vena caval diameters recorded by TTE (IVC) or TEE (SVC) (Table 141.4).

Muller et al. recently tested the accuracy of a 100 mL 'mini-fluid' challenge given over a minute to predict fluid responsiveness in mechanically ventilated critically-ill patients [15]. An increase >10% in Aortic velocity-time integral (Ao VTI) predicted fluid responsiveness with

*Controlled ventilation, adapted to the ventilator and an absence of any arrhythmia.

**Fluid challenge consisting of 100 mL of hetastarch given over 1 minute.

MV, mechanical ventilation; ΔVTI Ao, Respiratory variations of the aortic flow time velocity integral; ΔAo Vel, respiratory variations of the maximal aortic blood velocity; IVC, inferior vena cava; SVC, superior vena cava; dIVC = $(IVC_{max} - IVC_{min})/IVC_{min}$; ΔIVC= $(IVC_{max} - IVC_{min}) \div (IVC_{max}+IVC_{min}/2)$; SVC collapsibility = $(SVC_{min} - SVC_{max})/SVC_{min}$; ABF: aortic blood flow recorded with oesophageal Doppler; dVTI Ao = (VTI Ao post-PLR – VTI Ao pre-PLR)/VTI Ao pre-PLR. (PLR = passive leg raising).

95% sensitivity and 78% specificity. Passive leg-raising is probably one of the safest and most accurate tools to predict fluid responsiveness in both mechanically- and spontaneously-breathing patients [16]. By mobilizing venous blood from the legs and lower abdomen, this provides a transient 300 mL blood infusion into the right heart. Its reversibility avoids any futile increase in LV filling pressure. In mechanically-ventilated patients (with or without spontaneous breathing activity) an increase in aortic blood flow measured by oesophageal Doppler after passive leg-raising also predicts preload responsiveness [17]. Nonetheless, an elevation in intra-abdominal pressure alters the diagnostic accuracy of passive leg-raising with a higher risk of false positives [18]. In non-intubated ICU patients, an increase in aortic VTI >12% is currently the only reliable echocardiographic parameter to predict fluid responsiveness [16].

Conclusion

The use of echocardiography in the ICU has considerably increased in recent years to become a central device to detect and understand the complexity of circulatory and respiratory failure. Clinicians should be aware of the benefits and limitations of the numerous parameters provided by echocardiography in order to correctly interpret the examination and appropriately adapt patient management.

CHAPTER 142

Monitoring the microcirculation in the ICU

Can Ince and Alexandre Lima

Key points

- The microcirculation is the final destination of the cardiovascular system responsible for delivering oxygen to the respiring tissue cells so that they can perform their functional activities to sustain organ function.
- The microcirculation consists of microvessels <100 μm in diameter and are composed of arterioles, capillaries, and venules. The capillaries are the smallest (±5 μm) vessels and the predominant site where oxygen leaves the circulation by passive diffusion to tissue cells. They are also the most vulnerable component of the microcirculation.
- The ability of the microcirculation to deliver oxygen to cells depends on its convective capacity (red blood cell flow delivery) and diffusive capacity (the distance oxygen has to travel from capillaries to cells. This is quantified by the functional capillary density that can only be measured by observing the microcirculation.
- Shock is defined as a condition in which cells need more oxygen to sustain their functional activity than is being supplied by the microcirculation. In critical illness, distributive shock defines the condition where shunting denies oxygen transport to these vulnerable areas causing tissue hypoxia in the presence of normalized systemic variables. Such a condition requires therapy to recruit such shunted microcirculatory units.
- Orthogonal polarization spectral (OPS), sidestream darkfield (SDF) and other imaging techniques have allowed microcirculatory imaging to be accomplished, but are cumbersome to use as clinical tools. Recent imaging techniques based on computer-controlled sensors and Cytocam-incident darkfield (IDF) imaging suggest the possibility of integrating this crucial physiological compartment into conventional haemodynamic monitoring.

Introduction

The microcirculation is the key physiological compartment of the cardiovascular system, where oxygen is delivered by convection and diffusion to respiring parenchymal cells to support cellular, and thereby organ, function. The microcirculation consists of microvessels less than 100 μm in diameter consisting of arterioles, capillaries, and venules. The smallest vessels (<6 μm) are the capillaries where most oxygen leaves the circulation by passive diffusion to cells. The critical role of the microcirculation has long been recognized, but only recently has it been possible to image its function at the bedside, thus making it a clinically important compartment to monitor. Prior to this type of monitoring, peripheral perfusion was used as a surrogate before more advanced optical techniques were developed to image microcirculatory function, both non-invasively and at the bedside. Here, we provide a brief overview of microcirculatory assessment.

Clinical assessment of peripheral perfusion

The rationale of monitoring peripheral perfusion is based on the phenomenon that the sympathetic neurohumoral response decreases skin perfusion (and thereby temperature) during hypotension to maintain central blood pressure. Thus, toe temperature has been used since the 1960s as an indicator of the severity of circulatory shock [1]. Although reduced peripheral temperature is associated with different shock states, such abnormalities are not always related to microcirculatory alterations, especially in septic shock. Subjective assessment of peripheral perfusion can be accomplished by assessment of skin temperature or by measuring capillary refill time. This physical examination can identify patients at high risk of circulatory complications, as well as otherwise haemodynamically stable patients who have organ dysfunction [2]. More quantitative assessment of peripheral perfusion can be accomplished by use of the pulse oximetry signal where the ratio between pulsatile and non-pulsatile components of the signal can be used to calculate a peripheral perfusion index. This index can be used to assess the effects of therapeutic interventions on peripheral perfusion in critically-ill patients [3].

Imaging of microcirculatory morphology and haemodynamics

In the late 1990s hand-held video microscopes were introduced by Ince and co-workers to image the microcirculation at the bedside using orthogonal polarization spectral (OPS) imaging [4,5]. They were also the first to image the human brain microcirculation during surgery [4,6]. Direct video observation of flowing red blood cells (RBC) in the microcirculation is accomplished by illumination of the microcirculation. This technique utilizes green light that is absorbed by haemoglobin within the RBC, making them visible as flowing dark globules under microscopic magnification. This illumination is combined with optical modalities that filter

out surface reflections of light so that microcirculatory structures below the tissue surface can be visualized. Such optical modalities (orthogonal polarization spectral (OPS) imaging and its successor, sidestream dark field (SDF) imaging) had previously been developed for intravital microscopy, but were incorporated into hand-held microscopes [5]. Over the last decade, clinical investigations using these techniques in intensive care patients have shown that microcirculatory dysfunction plays a key role in the development of complications and can be used for prognostication [7–10].

Microcirculatory alterations in critically-ill patients have been predominantly measured sublingually. This readily accessible location is also a clinically relevant compartment due to its vascularization originating from the external carotid artery. Sublingual microcirculatory monitoring is the most sensitive haemodynamic marker of adverse outcomes in both adult and paediatric critically-ill patients [e.g. 8,9]. Early goal-directed therapy that could successfully resuscitate the microcirculation was associated with improved organ function assessed 24 hours later [10]. Intestinal and rectal microcirculatory measurements have also been undertaken in critically ill patients [e.g. 11].

The microcirculatory effects of numerous therapies have been studied in critically-ill patients, including blood transfusions, vasoactive drugs, and steroids [e.g. 12–14]. Its monitoring is considered especially relevant to the diagnosis of hypovolaemia and its treatment with fluid [15,16]. Microcirculatory imaging techniques have also been used to measure other cellular structures important to microcirculatory function, such as leukocyte adherence and endothelial cell glycocalyx alterations. The glycocalyx is a gel-like layer lining endothelial cells and is central in the control of vascular homeostasis. Its compromise is associated with leukocyte activation and a collapse of (micro)vascular integrity. Monitoring of glycocalyx function could potentially provide important clinical data regarding the function of the cardiovascular system.

Studies using bedside microcirculatory imaging have shown that different pathophysiological insults can have different effects on microcirculation perfusion patterns. For example, haemodilution during on-pump surgery reduces the density of RBC-filled capillaries. This results in a fall in oxygen extraction capacity through increasing the diffusion distances over which oxygen has to travel. Heart failure with reduced pump function on the other hand results in a decrease in capillary convective blood flow. Thus, convective failure can be caused by hypotension, arterial obstruction, or cardiogenic failure.

In critical illness, especially during sepsis with concurrent shock, microcirculatory dysfunction is further characterized by heterogeneous flow abnormalities with some obstructed capillaries sitting alongside others that exhibit normal- or even hyper-flow [8,10,14]. These heterogenous abnormalities define the nature of distributive shock seen in sepsis, within the classification scheme of circulatory shock types defined by Weil and Shubin [17]. Such heterogeneity can occur in the presence of a normal or even elevated cardiac output. It results in patchy areas of tissue hypoxia caused by shunting of vulnerable microcirculatory areas within the organs that can occur despite normal or even elevated venous saturation levels [18]. This explains, at least in part, the clinical finding of an oxygen extraction deficit in sepsis. Thus, microcirculatory observations offer valuable insights into the nature of the circulatory defect seen in different shock states and warrant incorporation into routine haemodynamic monitoring.

To describe the functional status of the microcirculation, the following parameters need to be quantified—microcirculatory flow (convective capacity, quantified for the different size of microvessels) and functional capillary density (diffusive capacity of the microcirculation) [5]. The latter is an important parameter for oxygen transport that can only be determined by imaging techniques. A measure of heterogeneous microcirculatory convective flow is also needed to identify microcirculatory alterations associated specifically with sepsis. To date, these parameters can only be determined by time-consuming off-line analyses of recorded microcirculatory movies.

Although OPS and SDF imaging have provided important insights into the microcirculation, several technical limitations hamper the integration of microcirculatory microscopy into the routine clinical monitoring environment [19]. Current OPS and SDF imaging devices can be regarded as first- and second-generation devices, respectively, employing relatively low-resolution analogue camera technology, and requiring recording and off-line analysis for image quantification. Recently, a third generation hand-held microcirculatory imaging device based on incident dark field (IDF)) imaging has been introduced called Cytocam-IDF device with a computer-controlled, high-resolution sensor, and illumination unit [20]. This new device provides the hardware requirements necessary to allow instant online analysis of microcirculatory images for bedside clinical decision-making in order to guide (microcirculatory-targeted) therapies.

Conclusion

Assessment of the microcirculation is a valuable adjunct in haemodynamic monitoring during critical illness, providing direct insights into the nature of the underlying disease and the response to therapy at the level of an essential physiological compartment. It enables a functional haemodynamic evaluation of the circulation, assessing its ability to transport oxygen to the tissues at the level of its cellular components. Its integration into conventional haemodynamic monitoring offers a more integrated evaluation of the cardiovascular system in different critical illness conditions. Recent technological advancements allow this technology to potentially advance from a research tool to a routine clinical device.

CHAPTER 143

Imaging the cardiovascular system in the ICU

Richard Paul and Susanna Price

Key points

- Imaging must be interpreted in the clinical context of the patient.
- Interpretation is highly practitioner-dependent—'the eye only sees what it is trained to look for'.
- The risk–benefit ratio of each investigation should be evaluated on an individual patient basis.
- The specific diagnostic question should be discussed directly with the imager/interpreter.
- Despite improved CT performance, the gold standard investigation for suspected endocarditis remains transoesophageal echocardiography.

Introduction

Cardiac imaging in the critically-ill patient can be challenging. Many modalities remain poorly validated, while most imaging specialists are unfamiliar with critical care. Applying first principles and interpreting findings in the clinical context are mandatory, demanding knowledge of cardiovascular pathophysiology in critical care, the range of investigations available, their sensitivity and specificity, and the potentially complementary roles of imaging techniques.

Chest X-ray

The utility of daily portable anterior-posterior (AP) chest X-ray (CXR) in the ICU is debated. New, relevant findings are reported in up to 20% of plain films [1], but use remains widespread in cardiothoracic intensive care units (ICUs). Routine CXR should be performed following placement/removal of lines/drains to minimize exposure to ionizing radiation, and compared with previous images.

An AP-CXR helps to exclude or diagnose complications of in-dwelling catheters and may indicate some causes of haemodynamic instability. Cardiomegaly and valve-related calcification should be investigated further using echocardiography. Pericardial collections may be suggested by 'cardiomegaly' and/or apparent migration of venous lines/pacing wires in serial films. Pericardial calcification may indicate tuberculosis and/or constrictive pericarditis. The central venous catheter (CVC) tip should lie in the superior vena cava—up to 30% are incorrectly positioned and an atypical CVC path may suggest abnormal venous connections (i.e. persistent left superior vena cava), knowledge of which will influence the insertion site for a pulmonary artery catheter or pacing wire. Pulmonary vascular markings provide information regarding pulmonary blood flow distribution, but may be misleading in supine films. CXR is unhelpful in excluding pulmonary embolus, but tension haemothorax or pneumothorax is usually obvious. Lung collapse or severe atelectasis can cause haemodynamic instability in patients with poor right ventricular function or univentricular circulation, see Table 143.1.

CT pulmonary angiography

Pulmonary embolism should be suspected in patients with disproportionate hypoxaemia and pulmonary hypertension. Isotope scans are frequently non-diagnostic in the critically ill [2], therefore multislice CT pulmonary angiography is recommended, enabling visualization of emboli in subsegmental branches of the pulmonary arteries (>85% sensitivity, 90% specificity).

CT coronary angiography

Increasingly used in the outpatient population, multislice, electrocardiogram-gated systems provide an accuracy of up to 95%, and a negative predictive value approaching 100% in detection of coronary stenosis [3]. It represents a useful non-invasive tool in the low-to-intermediate risk population before progressing to invasive angiography. CT coronary angiography can evaluate coronary stent and graft patency, arterial wall morphology, coronary artery dissection [4], and can identify extra-mural/non-stenotic plaques that pass undiagnosed by conventional angiography. While modern equipment has an equal diagnostic yield for coronary artery disease in patients with either slow atrial fibrillation or sinus rhythm [5], there is less evidence for its use in faster, less stable tachyarrhythmias where motion artefact renders the images suboptimal. Little evidence supports its use in the critically ill where coronary angiography (with potential for immediate intervention) remains the investigation of choice.

CT thorax

This yields more information (Table 143.2) than CXR, but requires patient transportation, a not insignificant dose of radiation and potentially harmful contrast administration for studies of the aortic and pulmonary vasculature. It is useful in chest trauma, aortic

Table 143.1 Potential radiographic findings on CXR

Clinical context	Radiography	Notes
Elevated LAP	Increased vascular pedicle width Upper lobe blood vessel dilation Increased cardiothoracic ratio. Thickened interlobular septae Alveolar oedema	Reasonable correlation [20] Care with supine films. Specific chamber dilatation should be identified Not specific—may be due to increased permeability
Chest trauma	Widened mediastinum Pleural effusion Oesophageal/LMB displacement	Suggests aortic trauma
Pneumothorax	Hypolucency Lung edge Absence of vascular markings Deep diaphragmatic sulcus	May not be apparent in anterior pneumothoraces Challenging in presence of bullous emphysema—USS and CT more sensitive

LMB; left main bronchus, USS; ultrasound, CT; computed tomography.

dissection, suspected pulmonary embolism, and for diagnosing and guiding drainage of anterior or loculated pneumothoraces.

CT can be useful in evaluating endocarditis, demonstrating complications (coronary artery occlusion, fistulae) and peripheral embolization [6]. Electrocardiogram-gated multidetector cardiac CT is potentially superior to transoesophageal echocardiography (TEE) in demonstrating prosthetic valve malfunction due to pannus/thrombus (particularly with multiple valve replacements), and in demonstrating paraprosthetic complications and vegetations [7]. A main advantage of CT over TEE is in the diagnosis of extracardiac endocarditis, with demonstration of systemic, pulmonary, and cerebral embolization [8] and mycotic aneurysm/abscess formation (Table 143.3). However, due to its better resolution, MRI may be required for diagnosis of micro-abscesses or infarcts [9]. As CT has limitations (e.g. failure to demonstrate leaflet perforations, lack of haemodynamic information, high radiation dosage for repeated studies), routine use for diagnosing endocarditis is not recommended, and TEE remains the investigation of choice.

Invasive catheterization

The ready availability of senior and experienced operators is essential for investigating and managing critically ill cardiac patients, providing the potential for immediate diagnosis and therapy.

Table 143.2 CT thorax in the critically ill

Clinical problem	Findings and notes	
Chest trauma	Aorta	Aortic tear, intimal flap, haematoma, haemomediastinum
	Lung	Consolidation. Pneumothorax, haematoma, pneumatocoele
	Chest wall	Vertebral, rib and sternal fracture 1st rib fracture—associated with vascular injury 9th, 10th, 11th rib fractures—associated hepatic/splenic injury

	Trachea/bronchi	Pneumothorax, pneumomediastinum
	Oesophagus	Pneumothorax, pneumomediastinum Pleural effusion/pleural fluid
Pneumothorax	Particularly useful in the diagnosis of anterior and loculated pneumothoraces—CT-guided drainage may reduce complication risk	
Pulmonary embolus	Spiral contrast CT pulmonary angiography has high sensitivity and specificity, and provides information regarding other potential diagnoses	
Occult infection	Diagnosis of sternal wound and mediastinal infection, empyema, and lung abscess	
ARDS/ALI	Assessment and diagnosis of coexisting problems, e.g. pleural effusions, anterior pneumothorax, lung abscess Differentiation from underlying interstitial lung disease/other pulmonary disease	
Pleural effusions	Useful in differentiating effusion, empyema and lung abscess, and guiding percutaneous drainage	
Pre-cardiac or aortic surgery	Assessment of aortic aneurysm/dissection Planning of re-sternotomy	
Diagnosis of pulmonary disease	Pneumonia, interstitial lung disease, neoplasm	

CT, computed tomography; ARDS, acute respiratory distress syndrome; ALI, acute lung injury.

Table 143.3 Strengths and weaknesses of echocardiography and CT for evaluation of endocarditis

	TEE	CT
Vegetations and perforations	◆ Excellent spatial and temporal resolution ◆ Challenging imaging in PVE ◆ Demonstration of leaflet perforation in aortic valve endocarditis challenging	◆ May miss vegetations <4 mm ◆ Possible superior performance in demonstration of prosthetic vegetations ◆ Probable inferior performance in demonstration of leaflet perforations
Haemodynamic effects	Well-validated technique for evaluation of haemodynamics, but may be difficult to assess when very severe acute lesions present	Limited predominantly to planimetry
Abscess cavities	◆ Highly operator dependent ◆ Challenging in early endocarditis ◆ Emerging data suggests possibly CT superior	◆ Excellent visualization of abscesses, aneurysms and pseudo-aneurysms ◆ Able to image whole of thorax ◆ Combination with PET may assist in diagnosis of root abscesses
Fistulae/abnormal connections	◆ Highly operator-dependent, but well demonstrated	◆ Excellent visualization
Coronary artery involvement	◆ Delineation of proximal coronary artery segments generally possible ◆ RCA may be difficult to image in the presence of AVR ◆ Anomalous coronary arteries in the presence of an enlarged aortic root may be difficult to image ◆ Inadequate for demonstration of anything other than ostial coronary artery stenosis ◆ Myocardial infarction and/or ischaemia may be suggested by new RWMA	◆ Excellent demonstration of coronary arteries with respect to cardiac anatomy ◆ Potential avoidance of pre-operative cardiac catheterization in high-risk cases
Extracardiac 'endocarditis' and peripheral embolization	◆ Intra-cardiac and ascending aorta (including previous cannulation sites) well visualized ◆ Peripheral embolization not visualized ◆ Extracardiac shunts challenging	◆ Well documented with respect to embolization (neurological, pulmonary and systemic) and abscess formation ◆ Extra-cardiac endocarditis (including extracardiac shunts) well visualized, but need additional imaging techniques to demonstrate infection

AVR, aortic valve replacement; PET, positron emission tomography; PVE, prosthetic valve endocarditis; RCA, right coronary artery; RWMA, regional wall motion abnormality; TEE, transoesophageal echocardiography; CT, computed tomography.

Left heart catheterization

Indications for coronary angiography in the critically ill are shown in Table 143.4. In patients where cardiac surgery has involved re-implantation/manipulation of the coronary arteries, instability should trigger a high index of suspicion of disruption to coronary flow. Prompt liaison with, and early re-exploration by, the surgical team is mandated, particularly if catheterization might lead to delayed intervention.

Right heart catheterization (RHC)

Formal RHC remains the gold standard for haemodynamic assessment of pulmonary hypertension, being required for diagnosis, classification, prognostication and vasoreactivity testing [10]. Further uses include differentiation of pericardial tamponade from constrictive pericarditis, diagnosis of intracardiac shunt [11], and evaluation of bronchial and pulmonary haemorrhage, and chronic thromboembolic disease [12].

Ultrasound

Ultrasound is widely used in the diagnosis, monitoring, and management of critically-ill patients. Its real-time diagnostic capabilities, together with the progressive miniaturization of devices, and increasing ease of use, has led to a rapid expansion of its applications outside cardiology [13]. Ultrasound is used for insertion of central, peripheral venous, and arterial cannulae, particularly where anatomy is abnormal or with multiple previous interventions, marked obesity, or oedema.

Echocardiography

Echocardiography has many roles in the ICU, ranging from use during cardiac arrest to more complex diagnostic applications. The first mode of choice is generally TTE, although this may be limited by patient issues (e.g. immobility, body habitus, pulmonary pathology), pathology (e.g. prosthetic valve endocarditis), or interventions (e.g. IPPV, dressings/drains), where TEE may be required. Intracardiac echocardiography provides high-resolution images, although its cost is prohibitive for routine ICU use.

Peri-arrest echocardiography

Ultrasound/echocardiography by appropriately-trained practitioners is recommended in current resuscitation guidelines as a supplement to advanced life support to determine the underlying diagnosis leading to the (peri-)arrest state, e.g. pericardial

Table 143.4 Indications for coronary angiography in the critically ill

Clinical features	Potential diagnosis	Potential causes	Other investigations
◆ Haemodynamic instability	◆ Myocardial ischaemia ◆ Myocardial infarction (types I–IV)	◆ Coronary obstruction ◆ Graft malfunction ◆ Coronary spasm	ECG Echocardiography Elevated biomarkers
◆ Ventricular arrhythmias	◆ Myocardial ischaemia ◆ Myocardial infarction (types I–IV)	◆ Coronary obstruction ◆ Coronary stenosis ◆ Graft malfunction ◆ Coronary spasm	ECG Echocardiography Elevated biomarkers
◆ Failure to wean from ventilator	Myocardial ischaemia	◆ Coronary obstruction ◆ Coronary stenosis ◆ Graft malfunction	Stress echo CXR
◆ Failure to wean from ventilator ◆ Haemodynamic instability	Dynamic MR	◆ Ischaemic heart disease ◆ Ventricular dilatation	Stress echo CXR RHC
◆ Clinical history ◆ Unequal pulses ◆ Haemodynamic instability	Aortic disruption	◆ Dissection ◆ Trauma	Echo CXR CT/CMR Aortography Coronary angiography

ECG, electrocardiogram; CXR, chest radiograph; MR, mitral regurgitation; RHC, right heart catheterization; CT, computed tomography; CMR, cardiac magnetic resonance.

tamponade, acute pulmonary embolism, hypovolaemia, right and/or left ventricular failure, and severe valvular pathology [14].

Echocardiography as a monitoring device

Echocardiography is widely used in the ICU for a non-invasive assessment of right and left heart filling status, to measure cardiac output and pulmonary arterial pressures [15], and to assess the response to therapeutic interventions, including the adjustment of ventilator settings to minimize the impact of IPPV on right ventricular performance. Although not ideal as a monitor (requiring multiple, repeated studies), useful haemodynamic information may be obtained rapidly and reliably, in addition to suggesting the underlying cause of the haemodynamic insufficiency [16].

Echocardiography as a diagnostic tool

Echocardiography may assist in the diagnosis and management of pathology commonly seen in the cardiothoracic ICU (see Table 143.5).

Lung ultrasound

Lung ultrasound in the ICU is frequently limited to detecting and drainage of pleural collections. Other potential applications include diagnosis and delineation of pneumothorax (particularly anteriorly in the supine position), lung abscess, interstitial fluid, and alveolar consolidation [13]. In some ICUs, the use of ultrasound has largely replaced routine CXR.

Other imaging modalities

Cardiac magnetic resonance scanning

The image quality of cardiac magnetic resonance scanning (CMR) makes it an attractive imaging modality, but there are particular considerations for ICU patients. All equipment must be MR-compatible, the transfer intensivist appropriately trained, piped oxygen should be used and intravenous infusion devices remain in the 'safe zone' beyond the 50 Gauss line, connected to the patient with long lines passed through a waveguide.

Positron emission (computed) tomography

Myocardial perfusion scintigraphy, using either single photon emission computed tomography (SPECT) or positron emission computed tomography (PET), is well established as a functional cardiac imaging technique in ischaemic heart disease [17]. SPECT is widely available, using multiplanar perfusion imaging of photon-emitting radionucleotides. Images are software-reconstructed and give an accurate assessment of myocardial perfusion and ventricular function. PET detects γ-rays from an injected radioactive tracer, the most useful cardiac tracers being ^{82}rubidium and the newer fluorine-18 fluorodeoxyglucose (^{18}F-FDG)—a glucose analogue and therefore highly suitable for the assessment of myocardial viability. PET has superior resolution and lower radiation usage, and carries high sensitivity and specificity for detecting coronary artery disease [18]; both methods can be used in the critically ill to determine ventricular wall motion and function, and the extent of ischaemia and infarction. Use is generally confined to circumstances where the diagnosis cannot be made using bedside imaging (e.g. echocardiography), or imaging that allows for potential intervention (e.g. angiography), or where it can be used as an adjunct to echocardiography in the diagnosis of endocarditis. Here, scintigraphy may be useful where cases are complicated by extracardiac infection (aortic cannulation sites, previous shunts in congenital heart disease), and where uncertainty persists over whether a lesion seen on echocardiography remains actively infected.

Table 143.5 Echocardiographic findings in the ICU

Clinical finding	Cardiac cause	Echocardiographic finding	Notes
1. Low cardiac output (unresponsive to inotropes)	Valvular disease	Any severe stenotic or regurgitant lesion	Difficult to assess in ICU. Sequential stenotic lesions may mask severity of individual lesions
	Intrinsic cardiac disease	HOCM/LVH with LVOTO Large VSD/ASD Severe LV/RV dysfunction	See text
	Extrinsic cardiac disease	Tamponade Pericardial effusion Pericardial disease	NB: Post-operative cardiac surgical patients (see text)
2. Oliguria	Underfilling	Low transmitral/tricuspid velocities Small ventricular volumes Apposition of LV papillary muscles in systole	If severe LVH papillary apposition may be unreliable sign
	Intrinsic cardiac disease	Poor LV function Severe AS	High LA pressure demonstrated
	Pericardial disease	Pericardial effusion Pericardial tamponade Pericardial constriction	NB. Post-operative cardiac surgical patients (see text)
3. Increased filling pressures (left-sided)	Impaired LV	Increased E > A ratio (corrected for age) Short IVRT	
	Mitral valve disease	Significant MS or MR	**MR: dynamic ventricle, increased forward velocities (>1 m/sec) Short duration and low velocity (<3 m/sec) regurgitant jet
4. Increased filling pressures (right-sided)	Secondary to left-sided disease	Significant AS, AR, MS, MR or LV disease	
	Impaired RV	Reduced RV LAX function	Any reduction in association with PHT is significant Mild impairment after CABG is normal
	Tricuspid regurgitation	Annular dilatation or endocarditis	If severe, RV dynamic with increased forward velocities (>1 m/sec) Short duration and low velocity regurgitant jet
5. Sepsis/SIRS	LV/RV dysfunction	Ventricular dilatation Systolic/diastolic dysfunction	Changes controversial and may be masked by inotropes
	Source of sepsis	Endocarditis	
6. Endocarditis	Native/prosthetic valve Pacemaker wires Extracardiac 'endocarditis'	Vegetations Paraprosthetic leaks Aortic root abscess	Vegetations rare in prosthetic valve endocarditis
7. Pulmonary hypertension	Acute PE	Dilated RV, severe TR	May rarely demonstrate intracardiac thrombus
	Post-pneumonectomy	Displaced heart Increased pulmonary acceleration time	Views often difficult even with TEE
	Mitral valve disease	Significant MS or MR (2D, PW, CW, and colour Doppler)	Severe MR in ICU may be difficult to diagnose (see text and **)
8. Failure to wean from ventilator	Intrinsic cardiac disease	Ischaemia Severe MR HOCM LV/RV dysfunction	Stress echo may be necessary to make diagnosis

9. CVA/embolic event	Intracardiac thrombus	LA appendage RA Apical LV thrombus Endocarditis	Exclude intracardiac shunt with contrast study
10. Cyanosis	Intracardiac shunting	Positive contrast study	Use agitated blood/saline. Perform Valsalva manoeuvre

HOCM, hypertrophic obstructive cardiomyopathy; LVH, left ventricular hypertrophy; VSD, ventricular septal defect; ASD, atrial septal defect; LV, left ventricle; RV, right ventricle; IVRT, isovolaemic relaxation time; MS, mitral stenosis; MR, mitral regurgitation; AS, aortic stenosis; AR, aortic regurgitation; LAX, long axis; PHT, pulmonary hypertension; CABG, coronary artery bypass grafting; SIRS, systemic inflammatory response syndrome; PE, pulmonary embolism; TR, tricuspid regurgitation TEE, transoesophageal echocardiography; PW, pulsed wave; CW, continuous wave; CVA, cerebrovascular accident; LA, left atrium.

Integration of PET with CT enables highly accurate coronary angiography and myocardial perfusion imaging in a single investigation. Dual-energy CT (DECT) also shows promising similar results when compared to SPECT [19], allowing faster acquisition of superior images, more suited to imaging of critically-ill patients in remote locations.

Conclusion

Undertaking cardiac imaging in the critically ill demands balancing the potential diagnostic benefit versus the risk of harm from invasive/remotely conducted investigations. Basic investigations remain valuable in intensive care, even if many are not validated in this population. Despite the risk of harm from the investigations themselves, the greatest risk to the patient remains misinterpretation; expert opinion should always be sought.

PART 5.3

Acute chest pain and coronary syndromes

CHAPTER 144

Causes and diagnosis of chest pain

Caroline Patterson and Derek Bell

Key points

- Differentiating life-threatening from benign causes of chest pain is a challenge, especially in the critical care setting, when symptoms and signs overlap, and patients may be unable to communicate fully.
- Achieving a prompt diagnosis is important in critically unwell patients, who typically have reduced cardiorespiratory reserve. A high index of suspicion is required for occult disease.
- After ensuring haemodynamic stability, it is imperative to rule out myocardial infarction in the first instance. Other life-threatening causes of chest pain to consider include aortic dissection, critical aortic stenosis, pulmonary embolism, tension pneumothorax, and oesophageal rupture. More benign causes include pleurisy, pericarditis, myocarditis, and rib fractures.
- ECG, chest X-ray, and routine observations are often non-diagnostic. Targeted investigations such as computed tomography, transthoracic or transoesophageal echocardiography may be indicated.
- Timely intervention optimizes survival benefit. Treatment may be commenced prior to confirmation of diagnosis, based on high clinical suspicion and risk scoring (e.g. GRACE score for myocardial ischaemia, Wells score for PE).

Introduction

Over 50% of patients questioned after admission to intensive care recall having significant pain [1–3], which is commonly localized to the thorax [1]. Chest pain in the critical care setting, more so than in the emergency department or acute assessment unit, is often an indicator of complex or life-threatening pathology, necessitating immediate assessment and management (see Table 144.1). Diagnosis is limited by difficulties patients have in communicating the severity or location of their pain [2]. The advantage of the critical care setting is that patients are intensively monitored within a resource-rich environment to aid timely investigation with prompt targeted interventions.

Initial assessment

The approach to the patient with chest pain or suspected chest pain should follow the standard airway, breathing, circulation algorithm. Immediate standard clinical observations plus a resting 12-lead electrocardiogram (ECG) and chest X-ray (CXR) are essential, supported by rapid examination, and a targeted or collateral history. Conditions such as ventricular arrhythmia and tension pneumothorax, which require immediate intervention, should be excluded.

The clinician should identify whether the chest pain is of new onset or a chronic problem and, if so, when the last episode occurred. History-taking should define the nature of the pain, the presence of any cardiovascular risk factors, prior investigations for chest pain, and prior coronary artery intervention. Pain can be defined by the 'PQRST' mnemonic (position, quality, radiation, severity, and timing, where timing includes the rate of onset, duration, and frequency of chest pain episodes). Exacerbating/relieving factors and additional symptoms should also be identified.

In mechanically-ventilated patients, head nodding and movements of the upper limbs are the most frequent means of patient communication and the clinician should be vigilant for these non-verbal cues [1]. Patients may be able to blink or point in response to a pain scale.

Physical examination should include inspection of the chest, looking for asymmetric expansion or chest wall deformity. Chest wall palpation should identify tenderness and crepitus. The clinician should assess pulse character, radio-radial delay and blood pressure in both arms. Auscultation should include the symmetry and quality of breath sounds, and listening for muffled heart sounds, murmurs, rubs, or gallops. A full clinical examination should be performed as soon as practically possible, but should not delay immediate treatment. Abdominal examination may reveal bruits or palpable aortic aneurysm. Lower limbs should be examined for asymmetry and tenderness suggestive of deep vein thrombosis (DVT).

Investigations

As always, investigation should be guided by history and examination. A CXR is mandatory, unless the patient is scheduled for imminent computed tomography (CT). CXR is useful to exclude complications of acute coronary syndrome (e.g. pulmonary oedema) and to identify alternative diagnoses (e.g. pneumothorax, pneumonia). CT imaging of the thorax, including CT angiography, supports the exclusion of non-cardiac diagnoses (e.g. aortic dissection, pulmonary embolism) and allows visualisation of the coronary anatomy. Transthoracic echocardiography is useful to identify significant valvular and myocardial pathology, pulmonary hypertension and to diagnose/exclude pericardial effusion.

Table 144.1 Causes of acute chest pain

Immediately life threatening	Other serious pathology
Acute coronary syndrome	Pneumonia/pleurisy
Aortic dissection	Pericarditis
Critical aortic stenosis	Oesophageal pathology
Pulmonary embolism	Sickle cell crisis
Pneumothorax	Neuralgia (herpes zoster)
Oesophageal rupture	Musculoskeletal pathology (fractured ribs)
Perforated viscus	

Transoesophageal echocardiography offers superior imaging of the aorta. Targeted biomarkers, such as cardiac troponin, D-dimer, and N-terminal pro-B type natriuretic peptide (NT-BNP) are useful adjuncts for diagnosis and risk stratification.

Life-threatening conditions

Acute coronary syndrome

Routine critical care unit surveillance has a sensitivity of only 12% for the detection of myocardial ischaemia [4]. In critical care patients with chest pain it is mandatory to rule out myocardial infarction in the first instance. Risk assessment should consider family history, hypertension, hyperlipidaemia, diabetes mellitus, and prior smoking history. GRACE and TIMI scores provide prognostic information.

Typical symptoms of myocardial ischaemia are retrosternal chest pain (and/or arm, back, or jaw pain) lasting several minutes, nausea, vomiting, sweating, or breathlessness. There may also be haemodynamic instability. Rarely, myocardial ischaemia mimics gastrointestinal disease with epigastric discomfort and belching. Atypical presentations are more common in women, ethnic minorities, and those of advancing age.

A 12-lead ECG is essential for diagnosis. Acute chest pain associated with ST-elevation lasting ≥20 minutes is associated with total coronary artery occlusion. Hence, persistent ST-elevation requires immediate treatment with the therapeutic objective of achieving rapid, complete, and sustained myocardial reperfusion by primary angioplasty or fibrinolytic therapy [5].

Patients without ST-elevation may have persistent or transient ST-segment depression or T-wave inversion, flattened T waves, or no ECG changes at all. The aim in these patients is to alleviate ischaemia and symptoms, while monitoring the patient with serial ECGs and markers of myocardial necrosis [5]. In patients where the changes appear dynamic, an urgent cardiology opinion should be sought.

Cardiac troponins are useful in differentiating between unstable angina and non-ST-elevation myocardial infarction, and in stratifying risk. An initial troponin rise occurs within 4 hours of myocardial ischaemia and the diagnostic cut-off for myocardial infarction is a troponin value exceeding the 99th percentile of a normal reference population. This can vary between laboratories and assays, therefore it is essential for the clinician to know their local normal range.

Aspirin should be given to all patients unless contraindicated. If the GRACE score suggests a 6-month mortality >1.5%, clopidogrel should also be given. Fondaparinux is recommended unless there is a high bleeding risk or angiography is planned within 24 hours. If angiography is likely or there is significant renal impairment, unfractionated heparin is preferred [6]. Critically unwell patients are at increased risk of bleeding. Nitrates, β-blockers, angiotensin-converting enzyme inhibitors and statins may be initiated in discussion with local cardiologists.

Thoracic aortic dissection

Aortic dissection should be considered in all patients with a history suggestive of myocardial infarction. The ECG may be normal, but, in some cases, dissection of the aortic root can cause right coronary occlusion with associated ECG changes. A higher degree of suspicion is necessary if there are risk factors for dissection, such as hypertension, prior cardiac surgery (e.g. aortic valve replacement) or aortic manipulation (e.g. angiography, stenting).

The pain of aortic dissection typically has an abrupt onset and with maximal severity at onset. The location of the pain can suggest the location of the dissection. In the Stanford classification, type A dissections involve the ascending aorta, whereas type B dissections do not. Anterior chest pain is often the result of aortic root or anterior arch involvement. Inter-scapular pain suggests involvement of the descending aorta and pain in this region is often described as tearing in nature. Around 10% of patients with dissection experience no pain. Presentation may be with dyspnoea and/or orthopnoea if there is cardiac failure secondary to aortic regurgitation or cardiac tamponade.

Clinical signs include the diastolic murmur of aortic regurgitation, and a pulse deficit/blood pressure differential between both arms. Horner's syndrome, syncope, and neurological compromise, mimicking cerebrovascular accident, are also recognized.

As described, ECG changes are usually non-specific, but may mimic inferior myocardial infarction. A negative D-dimer makes aortic dissection unlikely [7], while elevated D-dimer levels support dissection as a possible diagnosis. Around 80% of patients with acute dissection demonstrate widening of the aortic silhouette on CXR, but a normal film does not exclude the diagnosis [8]. CT aortography, transoesophageal echocardiography, and magnetic resonance imaging are all highly accurate in the diagnosis of aortic dissection.

Immediate management should focus on blood pressure reduction. Intravenous β-blockers are considered first-line therapy. Multiple blood pressure agents are commonly required. Emergency surgery is recommended for acute type A dissection, but all patients should undergo multidisciplinary evaluation involving cardiothoracic/vascular surgical specialists [9].

Pulmonary embolism

Critical care patients frequently have ≥1 predisposing factors for thromboembolism (e.g. surgical intervention, immobility, sedation, and paralysis). Despite the high frequency of deep vein thrombosis in these patients, concerns remain that pulmonary embolism (PE) is underdiagnosed [10].

In non-ventilated patients, around 90% of patients with PE report dyspnoea, chest pain, and syncope, either singly or in combination [11]. Chest pain is typically pleuritic in nature and occurs as a result of pleural irritation due to distal pulmonary infarction, mild pleural

effusion, and alveolar haemorrhage, which may be associated with haemoptysis. In massive PE, the pain may be central in nature, and associated with syncope or recurrent syncope.

The most common signs are tachypnoea, tachycardia, suspected deep vein thrombosis (more difficult to detect in critical care patients due to peripheral oedema), fever, and cyanosis [11]. In ventilated patients, PE may present as a sudden episode of hypotension, tachycardia, or desaturation, or contribute to difficulties in ventilator weaning [12].

The CXR is insensitive for the detection of pulmonary embolism. ECG demonstrates variable ST-segment changes, T wave inversion or right heart strain. Widening of the alveolar–arterial gradient is non-specific in critical care patients and there may be metabolic acidosis secondary to circulatory compromise. A normal D-dimer level has a strong negative predictive value, but a positive result is not diagnostic. The diagnosis should be confirmed, preferably by CT pulmonary angiography, as this is the most reliable test. However, echocardiography may be suggestive or show clot in the pulmonary artery, and ventilation–perfusion scanning may be useful in selected cases.

Patients with an intermediate to high probability of PE on Wells Score should be treated with heparin, even before the diagnosis is confirmed. Low molecular weight heparin is preferred to unfractionated heparin unless there is haemodynamic compromise or rapid reversal may be required. Thrombolysis is indicated if the patient is shocked or has a large clot burden with limited cardio-respiratory reserve. Placement of caval filters should be considered in critical care patients with significant lower limb venous thrombosis, especially if anticoagulation is contraindicated.

Pneumothorax

Barotrauma and invasive procedures (e.g. central venous catheter insertion, thoracocentesis) contribute to pneumothorax in around 3% of patients admitted to the intensive care setting[13]. Iatrogenic pneumothorax is more common in patients with adult immunodeficiency syndrome, acute respiratory distress syndrome, and cardiogenic pulmonary oedema. Prompt diagnosis helps reduce the risk of a simple pneumothorax becoming a tension pneumothorax. Risk assessment should include history of previous pneumothorax, underlying lung disease, and history of smoking.

Symptoms are typically of acute onset chest pain and dyspnoea. Pain is pleuritic in nature and often radiates to the ipsilateral shoulder tip. Secondary pneumothorax (i.e. in the presence of known risk factors) is generally less well tolerated due to reduced respiratory reserve.

Signs are reduced breath sounds on the affected side, hyper-resonant percussion note and pulsus paradoxus. In the ventilated patient there may be a sudden increase in airway pressures. In the event of tension pneumothorax there may be contralateral tracheal deviation, jugular venous distension, and sudden haemodynamic instability with tachycardia and hypotension.

CXR is the most common screening test for pneumothorax; however, bedside thoracic ultrasound is more sensitive than supine CXR (often used in critical care) [14]. A CT scan is the gold standard investigation and also differentiates pneumothorax from complex bullous lung disease.

If there is a suspicion of tension pneumothorax, diagnostic investigation should not delay treatment. Immediate needle decompression is indicated, followed by insertion of an intercostal drain. A simple pneumothorax causing symptoms or decreased gas exchange in a patient on positive pressure ventilation (invasive or non–invasive) requires intercostal drainage. In a non-ventilated patient, needle aspiration may suffice but should be followed by close patient monitoring and consideration of drainage [15].

Aortic stenosis

Angina, syncope, and dyspnoea occur with progressive aortic stenosis. Symptoms typically occur once the aortic valve area is <1.0 cm^2. Exertional chest pain is present in around two-thirds of patients with severe aortic stenosis, of whom half also have significant coronary artery disease. Pain occurs very rarely at rest. Risk factors for degenerative calcific aortic stenosis are similar to those for vascular atherosclerosis. Urgent echocardiography is the investigation of choice in the unwell patient with suspected aortic stenosis.

Clinical signs include a slow rising, low-volume pulse and a narrow pulse pressure. A low-volume carotid pulse and a soft S2 sound are considered the best clinical indicators. The typical crescendo–decrescendo systolic murmur of aortic stenosis is best heard in the aortic area, and may radiate to the carotids. As the left ventricle fails, flow through the stenotic valve is reduced and the murmur quietens. Pulsus alternans occurs most commonly in patients with severe left ventricular systolic dysfunction.

ECG evidence of left ventricular hypertrophy is present in 85% of individuals with severe aortic stenosis [16]. T-wave inversion and ST-segment depression become more common as hypertrophy progresses and there is a risk of pulseless electrical activity with cardiac arrest. CXR is usually unremarkable until left ventricular failure develops and then cardiac silhouette is increased in diameter. Echocardiography assesses the degree and impact of aortic stenosis by characterizing the anatomy of the aortic valve, grading the severity of stenosis severity and assessing left ventricular function.

In critically-ill patients, the definitive management is aortic valve surgery, providing the patient is fit for surgery. Peri-operative work-up should include coronary angiography. β-blockers, digoxin, diuretics, and angiotensin-converting enzyme inhibitors can help relieve chest pain and dyspnoea related to pulmonary congestion but these medications should be prescribed with caution.

Oesophageal rupture (Boerhaave's syndrome)

Although the classic features of oesophageal rupture are chest pain and cervical subcutaneous emphysema following an episode of vomiting (the Mackler triad), spontaneous rupture accounts for less than a third of cases. Most oesophageal rupture is iatrogenic, occurring after medical instrumentation (e.g. upper GI endoscopy, particularly dilation of the oesophagus). Oesophageal perforation from external blunt trauma is exceedingly rare, but well recognized in patients involved in high speed road traffic accidents.

Most patients present with pain (71%), fever (51%), dyspnoea (24%), and palpable crepitus (22%) [17]. Pain is localized to the neck, chest, epigastrium, or back, and may be referred to the shoulder tips. Gastrointestinal symptoms occur less commonly and include dysphagia, vomiting, haematemesis, melaena, and abdominal rigidity, particularly with distal perforation. Facial swelling, hoarseness, and dysphonia are recognized with perforation of the cervical oesophagus. Hamman's sign is a crunching sound, audible synchronous with the heartbeat, associated with pneumomediastinum.

CXR suggests the diagnosis in up to 90% of cases [18] with indirect markers of rupture including effusion (typically left-sided), hydropneumothorax, pneumothorax, pneumomediastinum and subcutaneous emphysema. Diagnosis is confirmed by water-soluble contrast studies (e.g. gastrografin swallow). Diagnostic pleural fluid findings are food debris, pH <6.0, or an elevated amylase level.

Prompt intervention is required to avoid mediastinitis, which is associated with a high mortality. Initial management is volume resuscitation, broad spectrum antibiotics, and analgesia. Patients should be kept nil by mouth and have a nasogastric tube inserted. Surgery is the treatment of choice and should be considered by the multidisciplinary team [19].

A perforated peptic ulcer, or other abdominal viscus, may also present with acute chest pain. The diagnosis may be identified by finding sub-diaphragmatic air on an erect CXR, but a CT scan of the abdomen may be necessary, particularly in ventilated patients.

Potentially serious pathologies causing chest pain

Although the origin of chest pain is not always immediately life-threatening, chest pain may reflect underlying serious illness, or illness that may lead to significant complications. Anxiety and somatisation disorders may also present as chest pain mimicking more serious conditions.

Pulmonary causes of chest pain

Pleuritic chest pain typically has a stabbing quality and worsens with inspiration. The most common cause in critical care patients is pneumonia, with chest pain occurring in around a third of cases. Pleuritic pain may also occur with tuberculosis, autoimmune diseases (e.g. systemic lupus erythematosus, rheumatoid arthritis), malignancy (e.g. mesothelioma), pulmonary embolism and chest trauma (e.g. post-operative). Airway diseases such as asthma and COPD may present with chest pain related to airway inflammation and bronchospasm.

Cardiovascular causes of chest pain

The pain of acute pericarditis occurs over the anterior chest, has a sudden onset, and is exacerbated by lying flat. Diagnosis is supported by signs of pericardial friction rub, pericardial effusion and widespread ST-elevation on ECG. In critically-unwell patients, the presence of pericarditis should prompt consideration of systemic inflammatory disease or uraemic complications in the presence of severe kidney injury. Myocarditis may coincide with pericarditis and presents across a spectrum of disease, from mild viral illness to acute cardiac failure. An elevated troponin suggests the presence of myocarditis.

Gastrointestinal causes of chest pain

Owing to the shared innervation of the heart and oesophagus, visceral pain from these organs can be similar in character. Oesophageal conditions causing chest pain include oesophagitis, gastro-oesophageal reflux, and dysmotility disorders (e.g. achalasia).

Sickle cell disease

Chest pain is common in sickle cell disease and may result from pneumonia, pulmonary infarction, myocardial ischemia, bone infarction, or a diffuse pain crisis. Acute chest syndrome is a vaso-occlusive crisis of the pulmonary vasculature, often precipitated by respiratory infection. Clinicians should be alert to the risk of hypoxaemia and the occasional need for endotracheal intubation and mechanical ventilation.

Neuralgia

In immunosuppressed or older patients the pain of herpes zoster may precede the rash. Post-herpetic and post-radiation neuralgia may also cause chest pain.

Musculoskeletal chest pain

Onset is often insidious and pain may last for hours to weeks. It is frequently sharp and well localized. Pain may be reproducible on palpation, positional, or movement-related. In critically unwell patients, particularly those with a history of trauma or falls, it is important to exclude rib fractures, which may lead to pneumothorax in some cases.

Conclusion

Chest pain should be treated seriously in all critically-unwell patients, especially when a history is not readily available. Causes of chest pain should be considered in the differential diagnosis, and investigated as indicated by clinical findings and available test results.

CHAPTER 145

Pathophysiology of coronary syndromes

Robert M. Bell

Key points

- A disease characterized by endothelial dysfunction and inflammation.
- It is a chronic disease process, with atheroma commencing at an early age, but with acute coronary syndrome (ACS) presenting in later life.
- Disease in vessels is dictated by haemodynamic flow characteristics within the coronary vessel.
- Non-thrombotic ACS is characterized by increased demand and thrombotic ACS by acute limitation of blood flow.
- Common risk factors, including hypercholesterolemia, hypertension, diabetes, and smoking, all impact upon endothelial function and nitric oxide bioavailability.

Introduction

Acute coronary syndromes (ACS), unstable angina, non-ST elevation myocardial infarction and ST-elevation myocardial infarction (MI) are characterized by an acute insufficiency of the coronary circulation. Downstream myocardium is rendered ischaemic and will undergo necrotic injury unless blood flow is speedily restored. The primary aetiology is coronary artery disease (CAD) in the form of coronary atherosclerosis. While there are other, much rarer causes of ACS (Box 145.1), for the purposes of this chapter, the pathogenesis of ACS and coronary atherosclerosis will be considered as synonymous.

The natural history of atherosclerosis in CAD

The natural history, derived from cadaveric examination at various ages, has been described for over 60 years [1]. From fatty streaks through intermediate lesions and the development of complex atheromatous plaques to potential culprit lesions with thin fibromuscular plaques prone to rupture, the process appears to commence from a young age. While aortic fatty streaks may be found in children in the first decade of life and are widely prevalent by the age of 3, they are found at the same frequency in all populations irrespective of cardiovascular risk and cannot be considered a reliable harbinger of future pathogenic coronary atherosclerotic disease [2]. More pathologically-relevant fatty streaks of the coronary vasculature become more evident in the second decade of life. By the third decade of life, advanced, raised coronary atherosclerotic lesions can be found, as witnessed in autopsy studies of soldiers (mean age 22 years) killed during the Korean war [3]. However, presentation of ACS typically occurs much later in life–for non-ST elevation ACS, the mean age of presentation is midway through the seventh decade [4]. Thus, prolonged exposure over many decades to pro-atherosclerotic factors is important to the clinical manifestation of the disease. It can be regarded as a disease of ageing, characterized by a slow, but progressive expansion of the intima, the normally thin layer of the coronary wall between endothelium and underlying smooth muscle, through invasion of lipid, inflammatory cells, and deposition of extracellular matrix (see Fig. 145.1) [5].

Shear stress and localization of coronary plaques

The location of atherosclerotic plaques within the coronary tree can largely be predicted by haemodynamic flow characteristics within the three main epicardial arteries. The crucial property of coronary flow that predisposes to atheromatous changes is areas of low or oscillatory shear stress, typically found on the inner curvature of the vessel wall or adjacent to vascular bifurcations [6]. Altered shear stress contributes to endothelial dysfunction, predisposing these areas of vessel wall to further injury and inflammation. Not only does low shear stress appear to predicate the location of

Box 145.1 Non-atheromatous causes of acute coronary syndrome presentation

Rare causes of spontaneous (type 1) myocardial infarction.

Causes

- Toxin-induced coronary vasospasm (e.g. cocaine).
- Allergic-induced vasospasm—Kounis syndrome.
- Spontaneous acute coronary dissection.
- Coronary embolization.
- Anomalous coronary vascular anatomy, myocardial bridging.
- Takotsubo syndrome.
- Coronary arteritis.

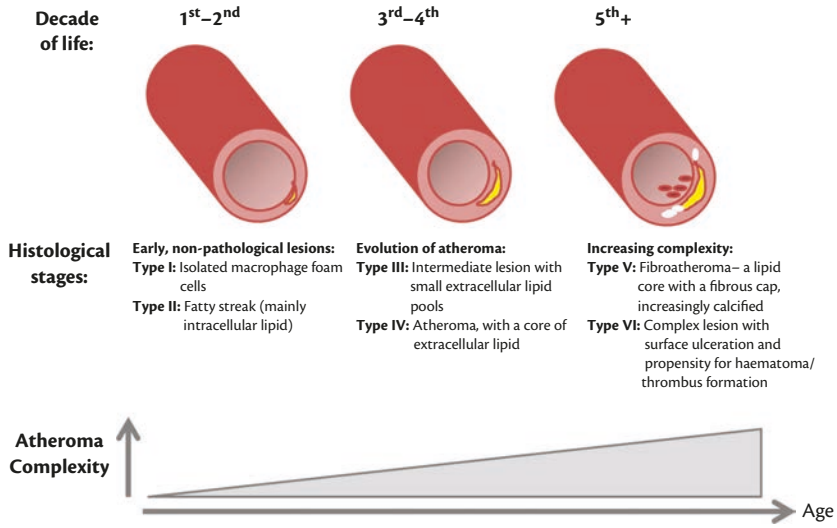

Fig. 145.1 Progression of the atherosclerotic plaque. Atherosclerosis starts with deposition of the inflammatory fatty streak. Over a period of a decade, this evolves into more complex atheromatous plaques. This may ultimately culminate in the development of a vulnerable plaque, susceptible to erosion or rupture, and intraluminal thrombosis, and the development of an acute coronary syndrome.

atherosclerotic plaques, but it may also play an important role in raised lesion progression [7].

Evolution of the coronary plaque

A key initiating event in the development of the fatty streak is oxidative modification and non-enzymatic glycation of both apolipoprotein B (Apo B) and lipid components of low density lipoprotein (LDL) in the extracellular matrix of the vascular intima. Accumulation of oxidized, modified LDL generates a pro-inflammatory/pro-atherosclerotic milieu [8]. Lipid deposition preferentially occurs in areas where the endothelium has already been primed in areas of low shear stress or injury, leading to altered endothelial function. The coronary vascular endothelium possesses important regulatory roles—modulating vascular tone and permeability, maintaining the blood–heart barrier, and preventing platelet–leukocyte adhesion, aggregation, and thrombosis. Disruption of endothelial function through the initiation of chronic inflammation thus leads to an adverse chain of events culminating with development of atheromatous lesions. Through endothelial expression of various chemokines (e.g. monocyte chemotactic protein-1 (MCP-1) and interleukin (IL)-8), and adhesion molecules (e.g. intercellular vascular adhesion molecules (VCAM-1), intercellular adhesion molecule-1 (ICAM-1) and P- and E-selectin), plus recruitment of the innate immune system with activation of monocytes, T- and B-lymphocytes and polymorphonuclear granulocytes [9], monocyte-derived macrophages are attracted and become adherent to the endothelium before migrating through the vascular wall into the tunica intima. Here, the macrophages take up modified LDL via scavenger receptors, leading to the characteristic intimal accumulation of cholesterol-laden macrophages that become the foam cell pathognomonic of the fatty streak and subsequently, the atherosclerotic plaque [8]. While phagocytic uptake of modified cholesterol is initially beneficial, the uptake of modified LDL into macrophages engages further inflammation and expression of endothelial adhesion molecules and chemoattractants to maintain a progressive inflammatory state, becoming an almost self-perpetuating cycle of pro-atheromatous inflammation and deposition. This deposition does not result in immediate narrowing of the vessel's lumen, but rather a slow, progressive thickening of the vascular wall in a process known as 'remodelling.' There is relative luminal diameter preservation until the plaque occupies >40% of the internal elastic luminal area [10]. Thereafter, the plaque starts to protrude into the vessel's lumen, altering flow characteristics and impacting upon shear-stress characteristics in the affected vessel wall.

Non-thrombotic CAD: coronary stenosis

ACS may occur where there is a stable, raised plaque, albeit one capable of resulting in significant blood flow limitation under high or extreme cardiovascular demand. Usually, these may be either effectively asymptomatic or result in stable exertional angina. However, under extreme conditions, these normally comparatively 'benign' lesions can induce ACS by preventing a sufficient increase of coronary blood supply to meet the large increase in myocardial metabolic demand, leading to myocardial injury and necrosis (type 2 myocardial infarction by the Universal Classification system [11]). Such severe physiologic conditions can occur following marked reductions in circulating volume following dehydration or blood loss, attenuated oxygen carriage due to severe anaemia or hypoxaemia, hypotension as may occur in severe sepsis, or increased metabolic load as occurs in thyrotoxicosis. Many of these factors are frequently encountered in critical care situations and result in acute myocardial ischaemia through a demand/perfusion mismatch of the myocardium downstream to the occlusive lesion.

Acute ACS without an elevation in demand however necessitates impairment in supply; typically, this is due to destabilization of a vulnerable plaque.

Thrombotic CAD: the vulnerable plaque

As the natural history of atherosclerosis progresses, there is continued accumulation of inflammatory cellular components that, with release of hydrolytic enzymes and chemoattractants, induce further intimal damage and focal necrosis. This can lead to the

development of a necrotic lipid core of the atherosclerotic plaque [12]. Proliferation of smooth muscle cells and synthesis of fibrous tissue occur as part of the plaque's reorganisation, with the formation of a fibrous cap characteristic of the complicated atherosclerotic lesion [12]. Most cases of ACS occur as a result of disruption of an atherosclerotic lesion that was previously haemodynamically insignificant. This high-risk 'vulnerable plaque' [13] is the ultimate pathophysiologic culmination of decades of progressive atherosclerotic inflammation [14]. These lesions are characterized by a thin fibrous cap susceptible to rupture or erosion, leading to intravascular thrombus formation and potential occlusion [13]. The fibrous cap is not a quiescent structure: it undergoes constant dynamic remodelling, but excessive activation of macrophage-derived collagenase/gelatinase matrix metalloproteinases may lead to dangerous thinning and destabilization in the shoulder region of the fibrous cap, resulting in the culprit lesions of ACS [15].

Once the plaque has ruptured or has undergone significant erosion, a cascade of platelet aggregation, activation of coagulation/fibrin deposition, and vasoconstriction is triggered, leading to intraluminal thrombosis and variable degrees of vascular occlusion. The classification of the resultant ACS—ST-elevation MI, non-ST-elevation MI, or unstable angina—depends upon the severity and duration of obstruction, and the metabolic demand placed upon the jeopardised myocardium. Thereafter, the volume of myocardium affected and the ability of the rest of the heart to compensate following the acute injury dictates the ultimate clinical course of the injury—the larger the volume of necrotic myocardium, the poorer the outcome.

Risk factors for CAD

While shear stress is an important component in the development of the early atherosclerotic plaque, it is neither the sole perturbation nor is it necessarily sufficient in isolation to lead to the development of pathological ACS-inducing atherosclerotic lesions. For the lesion to be initiated and to progress requires a further insult to the vascular lining of the coronary vessel to trigger the prerequisite endothelial dysfunction. This represents the Ross 'response-to-injury' hypothesis of atheroma formation [12]. Endothelial dysfunction [16] is a common denominator of a wide range of cardiovascular risk factors identified in epidemiological studies; the majority have an important genetic aetiological contribution.

Hypercholesterolemia

Almost uniquely among cardiovascular risk factors, hypercholesterolemia is capable of resulting in significant CAD in the absence of other risk factors. Supply of LDL and its oxidative modification in the intima leads to the inflammatory impairment of endothelial function as already described, with significant reduction in nitric oxide bioavailability and impaired vasodilation [17]. The endothelial impairment appears multifactorial—not only does oxidised LDL induce an inflammatory state, but hypercholesterolemia results in increased AT1-receptor density, increasing vasoconstriction and reactive oxygen species (ROS) generation [18]. ROS impairs bioavailability of nitric oxide through reaction into peroxynitrite. Furthermore, hypercholesterolemia increases generation of asymmetric dimethylarginine (ADMA), an endogenous competitive inhibitor of NO synthase [18]. Therefore, hypercholesterolemia leads to an increased availability of LDL cholesterol that is pivotal to the formation of the lipid-rich atheroma, and also attenuates endothelial defences against further lipid and inflammatory cell deposition.

Diabetes

Development of hyperglycaemia and insulin resistance is a well-recognized risk factor in the development of atherosclerosis and endothelial dysfunction. Increasing oxidative stress and reducing nitric oxide bioavailability, hyperglycaemia may also lead to the generation of advanced glycosylation end-products (AGEs)—stable proteins that are, in themselves, capable of generating ROS and altering endothelial function as a direct consequence [19]. Moreover, diabetes and hyperglycaemia also impact adversely upon the renin-angiotensin system and is procoagulant through platelet dysfunction, increased fibrinogen, increased von Willebrand factor and Factor VII, and reduced tissue plasminogen activator levels [20].

Hypertension

As with other cardiovascular risk factors, hypertension is associated with impaired nitric oxide bioavailability and characteristic morphological changes in endothelial cells [17]. The changes associated with impaired vascular relaxation and diminished L-arginine to nitric oxide generation [16] may in part reflect altered renin-angiotensin aldosterone signalling.

Smoking

Smoking is associated with endothelial dysfunction and with decreased vasodilation found in a variety of experimental models. Tobacco smoke contains a various toxins including nicotine—the consequent generation of ROS results in oxidative modifications of lipoproteins resulting in attenuated nitric oxide bioavailability. This provides the most likely mechanism of the endothelial dysfunction [16].

Conclusion

The pathophysiology of acute coronary syndromes is a complex interplay between multiple causes of endothelial dysfunction, the triggering of inflammatory processes that, over many decades of life, leads to the deposition of modified lipids, ingress of inflammatory cells, cellular and collagen organization, and the development of a fibrous cap. These lesions may ultimately evolve into the high risk vulnerable plaque that is susceptible to erosion or rupture. In the event of exposure of the sub-endothelial layers or the atheroma itself, activation of pro-coagulant pathways are capable of causing intraluminal thrombosis and even complete occlusion of an epicardial coronary vessel. This can culminate in significant myocardial necrosis with its attendant mortality and morbidity.

Recognition of the pathophysiology of ACS and atheromatous disease will continue to inform ongoing development of protective strategies in the management of this disease in primary, secondary, and critical care.

CHAPTER 146

Diagnosis and management of non-STEMI coronary syndromes

David Erlinge and Göran Olivecrona

Key points

- The strongest objective signs of non-ST segment elevation myocardial infarction (NSTEMI) are a positive troponin and ST segment depression.
- NSTEMI should be acutely treated with aspirin, an adenosine diphosphate (ADP)-receptor antagonist, and an anticoagulant (fondaparinux or low molecular weight heparins).
- NSTEMI should be investigated with coronary angiography within 72 hours.
- Curative treatment is percutaneous coronary intervention or coronary artery bypass grafting.
- Secondary prevention includes aspirin, statins, beta-blockers, angiotensin-converting enzyme (ACE) inhibitors, ADP receptor antagonists, and lifestyle changes.

Definition of non-STEMI coronary syndromes

Acute coronary syndromes were previously classified as ST segment elevation myocardial infarction (STEMI), non- ST segment elevation myocardial infarction (NSTEMI) or unstable angina. Diagnosis of unstable angina was based on a history describing novel occurrence or worsening of angina, or angina at rest. NSTEMI diagnosis was based on elevation of cardiac markers and typical symptoms. Today, patients with either novel ST-depression or elevated cardiac markers (together with chest pain or chest pain equivalent) are grouped together as non-STE-acute coronary syndromes (NSTE-ACS) [1]. However, the increased sensitivity of the high sensitivity troponin assays reveals that most ACS patients release cardiac markers and are therefore classified as NSTEMI.

Myocardial infarction criteria

In 2007, new criteria were defined to classify myocardial ischaemic injury according to aetiology and, importantly, to exclude non-ischaemic myocardial injury from the entity of myocardial infarction (Table 146.1) [2]. This classification is important for the choice of treatment. Type 1 is the classical myocardial infarction caused by plaque rupture and thrombus formation that threatens to occlude the coronary artery. This should be treated with antithrombotic drugs and revascularization. Type 2 is not caused by thrombus formation and requires other measures, such as vasodilators, blood transfusion, volume expansion or control of tachycardias, such as atrial fibrillation. These definitions are also important for clinical trials. Many previously positive drug studies have reduced the risk of procedure-related infarction related to percutaneous coronary intervention (PCI; type 4a); whether these are as clinically important as type 1 infarcts is questionable [3].

Diagnostics

Most patients with NSTE-ACS present with a history of chest pain that has subsided spontaneously before or soon after arrival at the emergency room, but with positive cardiac makers (usually troponin T or I) indicative of myocardial infarction. While chest pain is a common symptom of patients presenting to emergency departments, in about 70% of cases it is not due to an acute coronary syndrome. Symptoms of myocardial infarction are highly variable. The most typical is central chest pain radiating down the left arm (referred pain). However, pain may also be experienced in the throat or the back. Patients with a longstanding diabetic polyneuropathy often feel no pain at all, and may present with other symptoms, such as reduced fitness, shortness of breath, or non-specific discomfort.

A good history is the cornerstone of all diagnostics and provides important information; however, it has poor sensitivity and specificity for diagnosing acute coronary syndromes. History and physical examination can often identify obvious non-cardiac conditions, such as muscle pain, inflammation of the costal cartilages (Tietze´s syndrome), pleuritis, pericarditis herpes zoster, joint pain, gastrointestinal, or biliary pain. Aortic dissection is a serious differential diagnosis with a high mortality if not diagnosed and treated quickly. This often presents with very sudden onset and intense pain, often radiating to the back. It can present with hypotension, but also initially with hypertension. Lack of ST-segment elevation or ST-segment depression in a patient with severe chest pain mimicking symptoms of acute myocardial infarction should raise the suspicion of aortic dissection. A blood pressure difference between the arms and a newly-identified murmur may indicate aortic dissection, but diagnosis is made formally with acute transoesophageal echocardiography or computed tomography, followed by immediate referral to (cardio)thoracic surgeons.

Pulmonary embolism may produce chest pain often combined with dyspnoea. There may be ST-depression in right ventricular leads (V1–V2) and hypoxaemia. Echocardiography may show elevated pulmonary pressures though computed tomography confirms the diagnosis.

Table 146.1 Clinical classification of different types of myocardial infarction

Type	Features
Type 1	Spontaneous myocardial infarction related to ischaemia due to a primary coronary event, such as plaque erosion and/or rupture, fissuring, or dissection
Type 2	Myocardial infarction secondary to ischaemia due to either increased oxygen demand or decreased supply, e.g. coronary artery spasm, coronary embolism, anaemia, arrhythmias, hypertension, or hypotension
Type 3	Sudden unexpected cardiac death, including cardiac arrest, often with symptoms suggestive of myocardial ischaemia, accompanied by presumably new ST-elevation, or new left bundle branch block, or evidence of fresh thrombus in a coronary artery by angiography and/or at autopsy, but death occurring before blood samples could be obtained, or at a time before the appearance of cardiac biomarkers in the blood
Type 4a	Myocardial infarction associated with PCI
Type 4b	Myocardial infarction associated with stent thrombosis as documented by angiography or at autopsy
Type 5	Myocardial infarction associated with CABG

Electrocardiogram

The strongest objective signs of NSTE-ACS are new ST depression, and elevated cardiac markers, particularly troponin. Chronic ST depression may occur in patients with old infarcts, a hypertrophic ventricle or heart failure, but these are usually known from previous electrocardiogram (ECGs). Digoxin also commonly causes slight ST depression. Novel ST-segment depression is a very serious prognostic sign requiring immediate treatment. Negative T waves are more non-specific, especially among women, but can indicate NSTE-ACS.

Troponin and other biomarkers of myocardial injury

An increased plasma troponin level above the 99th percentile limit is indicative of NSTE-ACS, and requires prompt investigation and treatment. Troponin is heart-specific, but can be elevated in other conditions, such as renal failure, severe sepsis, myocarditis, and pulmonary embolism (Box 146.1). Troponin is usually released when thrombus in the damaged plaque releases micro-emboli, causing micro-infarctions downstream in the coronary artery. Troponin rises after 3–6 hours. If larger amounts are released, it may take several days before levels are normalized, but smaller elevations may normalize rapidly. Creatinine kinase MB isozyme (CKMB), and myoglobin are less specific and sensitive compared with troponin, but can be useful to detect re-infarction when troponin is already elevated, since they return to normal levels more rapidly.

If initial ECG and laboratory tests do not provide the diagnosis in a patient suspected of having ACS, the patient needs continuous ECG and ST-segment monitoring and repeated troponin measurements. Pro-BNP may provide guidance on the patient's mortality risk status and may indicate the presence of heart failure. An exercise test can be performed in some patients, but has low sensitivity and specificity. Nuclear myocardial perfusion with stress-rest imaging gives important information regarding inducible ischaemia. Echocardiography may be useful for diagnosing pericarditis, aortic dissection and larger pulmonary embolism, and for finding areas of regional hypokinesia indicating ischaemic heart disease. Stress echocardiography is diagnostic for ischaemia.

Modern CT angiography with lower radiation and higher image quality is rapidly becoming a diagnostic alternative [4]. However, accuracy is still limited in patients with calcifications and previous stenting, and is currently only recommended for low-to-intermediate risk patients.

Box 146.1 Elevations of troponin not caused by an acute coronary syndrome

- Cardiac contusion, or other trauma including surgery, ablation, pacing, etc.
- Congestive heart failure—acute and chronic.
- Aortic dissection.
- Aortic valve disease.
- Hypertrophic cardiomyopathy.
- Tachy- or bradyarrhythmias, or heart block.
- Apical ballooning syndrome (Takotsubo).
- Rhabdomyolysis with cardiac injury.
- Pulmonary embolism, severe pulmonary hypertension.
- Renal failure.
- Age (>70 years).
- Acute neurological disease, including stroke or subarachnoid haemorrhage.
- Infiltrative diseases, e.g. amyloidosis, haemochromatosis, sarcoidosis, and scleroderma.
- Inflammatory diseases, e.g. myocarditis or myocardial extension of endo- and pericarditis.
- Drug toxicity or toxins.
- Critically-ill patients, especially with respiratory failure or sepsis.
- Burns, especially if affecting >30% of body surface area.
- Extreme exertion.

Risk scores

Structured risk scores enable a more objective quantitative assessment of risk [1]. Commonly used scores to assess ischaemic risk are GRACE [5] and TIMI [6], both of which are useful in guiding clinical decision-making. Several of the treatments administered to reduce ischaemic risk (antiplatelet drugs, anticoagulants, invasive procedures) increase the risk of bleeding complications that, in turn, increases mortality. It is therefore advisable to also use a bleeding risk score (e.g. the CRUSADE risk score [7]) to balance treatment correctly.

Treatment of NSTE-ACS

Patients exhibiting objective signs of NSTE-ACS (especially ST-depression or positive troponin) should immediately receive intensive treatment with continuous ECG monitoring, and be scheduled for coronary angiography as soon as possible. Guidelines recommend a maximum time limit of 72h before angiography [1,8–10], but should be done immediately (<2 hours) if the patient becomes more unstable, with recurrent chest pain or recurrent ST-depression not resolving with nitroglycerin and beta-blockade.

Initial drug treatment should consist of short-acting nitroglycerin, morphine, and beta-blockers to relieve chest pain. Oxygen is often routinely administered, but there is no strong evidence to support its use in patients with arterial saturations >90% [1]. Antithrombotic therapy should be given quickly, aiming at both platelet and coagulation inhibition to prevent thrombus progression that may lead to occlusion of the affected coronary artery, potentially resulting in loss of heart muscle and life-threatening arrhythmias.

Platelets are inhibited by rapidly administered bolus doses of aspirin and an ADP receptor antagonist. Prasugrel and ticagrelor are new, more efficient ADP receptor blockers that are recommended as first choice agents. Clopidogrel should only be used for patients who cannot take ticagrelor or prasugrel [1,10], e.g. those on warfarin or with a very high bleeding risk. Prasugrel is not recommended for patients >75 years, with low body weight (<60 kg) or previous stroke.

The subcutaneous Xa inhibitor fondaparinux is recommended to inhibit the coagulation system as it has the most favourable efficacy-safety profile [1]. Compared with low molecular weight heparins (LMWH), fondaparinux has reduced bleeding complications yet maintains a similar efficacy for cardiac events, with a greater overall reduction in mortality [11]. For patients in urgent need of surgery, LMWH may be preferred because of its shorter half-life. Coronary artery bypass grafting (CABG) within 36 hours from the last fondaparinux dose is associated with an increased bleeding risk [12]. Fondaparinux and LMWH dosages need to be adjusted according to renal function to decrease the risk of bleeding complications.

Reversible GPIIb/IIIa inhibitors (e.g. eptifibatide, tirofiban) provide additional platelet inhibition and may protect against new coronary events. They do cause bleeding complications, and there is no strong evidence to support their clinical value when ADP receptor antagonists are used as baseline treatment [13]. They should not be used routinely pre-angiography, but reserved for high-risk groups, such as patients with recurrent chest pain or ST segment depression despite aspirin, ADP-inhibitors, and anticoagulation.

Angiography and PCI

Patients with NSTE-ACS should normally be investigated by coronary angiography [1], with most of the lesions found being treated immediately by percutaneous coronary intervention (PCI). Drug-eluting stents reduce rates of repeat revascularization, but should be avoided in patients unable to tolerate dual antiplatelet therapy (DAPT) due to an increased risk of bleeding complications, or in those requiring surgery. Warfarin treatment is a relative contraindication for DAPT. If warfarin is deemed necessary, DAPT combined with warfarin should be given for as short a time as possible, usually only 1 month, followed by warfarin and aspirin. After PCI, therapy with ADP receptor antagonists should continue for 12 months and aspirin lifelong. The more potent agents prasugrel and ticagrelor are currently preferred due to better long-term outcomes (reductions in coronary events, stent thrombosis, and mortality) compared with clopidogrel [14,15].

CABG could be favoured over PCI in patients with significant left main stem lesions or in those with advanced multivessel coronary disease, particularly if they are diabetic [1]. Clopidogrel and ticagrelor are discontinued 5 days and prasugrel 7 days pre-CABG to reduce the risk of bleeding complications. After CABG, patients should be treated with aspirin for life, ADP blockers for 12 months, and with statins, ACE inhibitors and beta-blockers for secondary prevention.

Non-invasive medical treatment of NSTEMI is an option, usually in very elderly patients with multiple comorbidities and high bleeding risks. However, such patients have the most to gain from invasive procedures. It is important to ensure that adequate medical therapy is given to patients not undergoing PCI or CABG. ADP blockers are clearly under-utilized for conservatively managed NSTE-ACS. Fondaparinux is also an excellent option for patients with a high risk of bleeding who are treated medically. On discharge, patients should ideally receive ADP-receptor blockers for up to 1 year, aspirin for life, plus statins, beta-blockers, and ACE inhibitors.

Prognosis and follow-up

NSTE-ACS has a risk of recurrent myocardial infarction of 15–20% and a 15% 1-year mortality. Patients with NSTE-ACS are at similar risk as a STEMI patient at 1 year. It is therefore very important to offer optimal secondary prophylaxis with aspirin, statins, beta-blockers, ACE inhibitors, and ADP receptor antagonists, as well as lifestyle changes. Statin treatment should aim for an LDL <1.8 mmol/L (<70 mg/dL), while lifestyle changes should include cessation of smoking, physical exercise five times a week, and diet recommendations.

CHAPTER 147

Diagnosis and management of ST-elevation of myocardial infarction

David Erlinge and Göran Olivecrona

Key points

- STEMI should be diagnosed rapidly, based on the combination of ST-segment elevation and symptoms of acute myocardial infarction.
- The main treatment objective is myocardial tissue reperfusion as quickly as possible.
- The preferred method of reperfusion is primary percutaneous coronary intervention if transport time is below 2 hours, and thrombolysis if longer.
- STEMI patients with acute onset cardiogenic shock should be evaluated by echocardiography to exclude mechanical complications, such as flail mitral insufficiency, ventricular septal defect, or tamponade.
- Secondary prevention includes aspirin, adenosine diphosphate receptor antagonists, statins, beta-blockers, angiotensin-converting enzyme (ACE) inhibitors, and lifestyle changes.

Symptoms and diagnosis, and the importance of rapid reperfusion

ST-elevation myocardial infarction (STEMI) is generally caused by a ruptured plaque that triggers local thrombus formation, which occludes the coronary artery [1]. This mechanism is similar to non-ST elevation myocardial infarction and unstable angina, but differs only in the degree of obliteration of the lumen by the thrombus. When the artery is completely occluded, oxygen and nutrient supply to the myocardium is completely interrupted. Most patients suffering from STEMI have a clear onset of central chest pain; diagnosis is confirmed by regional ST-segment elevations (Fig. 147.1). By definition, 0.1 mV ST elevation must be present in two adjacent distal leads, V1, or V4–V6. The V2–V3 leads require 0.2 mV ST-elevation for men and 0.15 mV for women. There is often reciprocal ST segment depression in opposite ECG areas (Fig. 147.1) [2,3]. However, an isolated ST elevation in aVL may represent a large anterior wall infarction. New elevated T waves often occur before the ST elevation and may be an early sign of an occluded coronary artery. Novel left bundle branch block (LBBB) may represent an anterior STEMI, where septal ischaemia results in the LBBB. This represents a widespread and usually long-standing infarction.

Completely 'silent' heart attacks with no chest pain may occur, especially in diabetics. 'Referred pain' is when patients experience pain in areas other than the heart, most typically radiating down the left arm, but also to the jaw and teeth. Inferior infarctions are often experienced in the back or the epigastrium. They often cause vagal symptoms, bradycardia, and nausea.

Acute malignant ventricular arrhythmias, such as ventricular fibrillation may lead to sudden death if not treated with cardiopulmonary resuscitation (CPR) and defibrillation. Up to 30% of patients with STEMI suffer cardiac arrest and die, many within the first hour. The second danger is loss of heart muscle. The longer the coronary artery is occluded, the larger the infarct size—time is muscle. Large myocardial infarctions frequently lead to severe heart failure and increased mortality.

Diagnosis of STEMI is often relatively straightforward. The challenge lies in reducing time to treatment to re-establish myocardial tissue perfusion promptly. A well-functioning logistical chain of events needs to be established. Patients should recognize the symptoms and call an ambulance immediately. Bystanders should be able to give CPR in case of cardiac arrest and paramedics must be in place quickly to defibrillate, give medication, and transport the patient to a hospital with the capability to perform percutaneous coronary interventions (PCI), ideally within 2 hours from arrival of the ambulance at the scene. If transport time is longer, fibrinolytic therapy should be administered in the ambulance or at the closest hospital as an alternative to PCI for myocardial tissue reperfusion. Prehospital ECGs performed by ambulance crews can be sent by telecommunication for confirmation of a STEMI diagnosis. Patients should then be administered aspirin, ADP receptor blockers, heparin, oxygen, and morphine en route to hospital. On arrival the patient should be fast-tracked directly to the catheterization laboratory for PCI, without stopping at the emergency room. Coronary angiography confirms the diagnosis and usually identifies an occluded, thrombotic artery (Figs 147.2 and 147.3).

Differential diagnosis

As mentioned previously, diagnosis of STEMI is usually based on symptoms and ECG. There is no time to wait for laboratory tests.

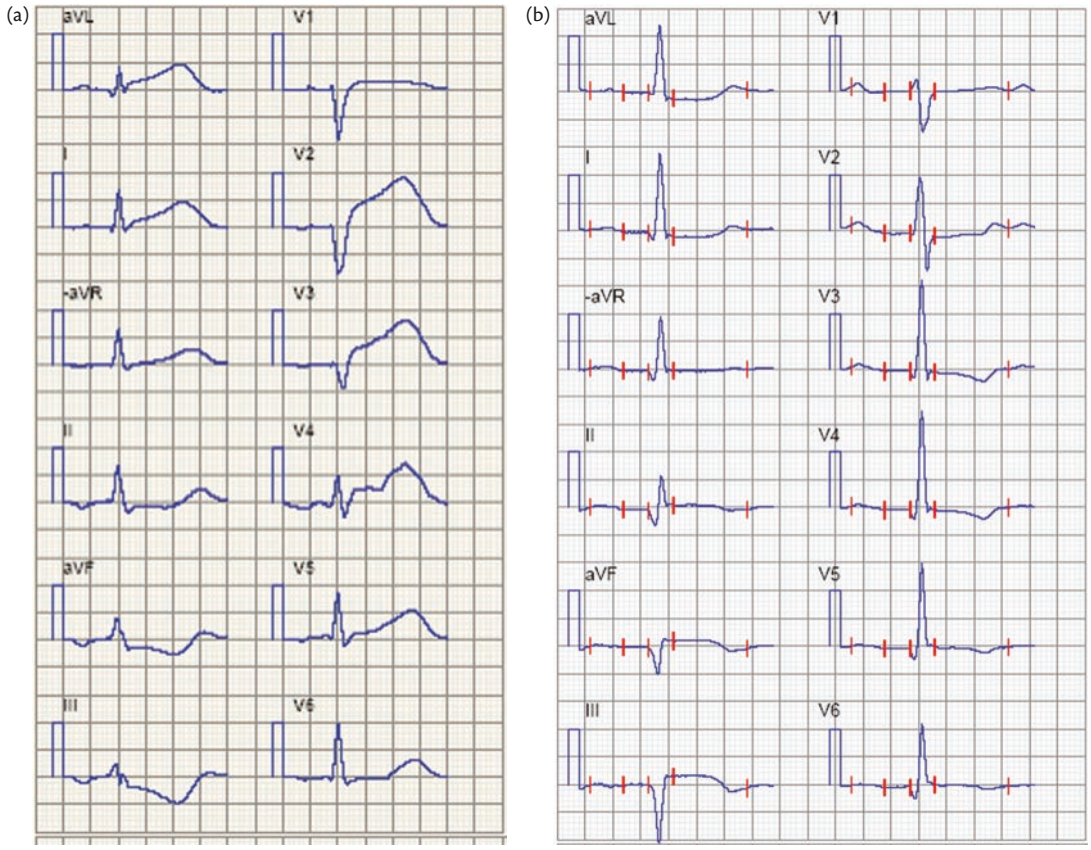

Fig. 147.1 Schematic representation of ST-T changes in acute coronary syndromes. ST segment elevations in anterior and inferior infarction. (a) Anterior STEMI. (b) Inferior STEMI.

However, the diagnosis may be unclear and more tests may have to be performed. It is important to not risk delaying reperfusion of a STEMI so some normal acute angiograms should be accepted.

Myocarditis

Pericarditis or myocarditis may cause a clinical picture similar to STEMI, but chest pain usually presents more gradually and is worsened by deep inspiration [4]. Patients are often young, the pain has a slower onset, and an increase in CRP is often detected. ST-segment elevations are not restricted to any of the coronary artery regions, but are often more general (Fig. 147.4). As a rule, ST-elevations are not as pronounced, usually upward concave, and usually without reciprocal ST depression. If in doubt, cardiac magnetic resonance imaging (MRI) is a valuable tool to diagnose perimyocarditis. Echocardiography may demonstrate pericardial fluid, which strengthens the diagnosis.

Takotsubo cardiomyopathy

This relatively newly-discovered condition mainly affects post-menopausal women [5]. The etiology is probably a stress-induced hyperactivity of sympathetic nerves resulting in catecholaminergic toxicity of the apical portions of the heart. The condition often presents as an anterior STEMI triggered by severe emotional stress. Angiography shows normal epicardial vessels, but left ventricular angiography or echocardiography shows typical ballooning of a severely hypokinetic or akinetic apex. Conventional heart failure treatment usually provides resolution within a few months (Fig. 147.4).

Electrolyte imbalances and Brugada's syndrome

ST elevations are not uncommon during marked electrolyte imbalances, or in Brugada's syndrome [6], a rare hereditary sodium channel defect (Fig. 147.4).

Aortic dissection

Aortic dissection is a serious differential diagnosis with a high mortality if not diagnosed and treated quickly. The history is often of very sudden onset and severe chest pain, often radiating to the back, mimicking a heart attack in symptoms, but without ST elevation. A blood pressure difference between the arms and a newly-identified murmur may indicate aortic dissection. Diagnosis is formally made with acute transoesophageal echocardiography or computed tomography, followed by (cardio)thoracic surgical referral.

Treatment

STEMI patients should be treated acutely with aspirin, ADP receptor antagonists (primarily ticagrelor [7] or prasugrel [8], but clopidogrel in those with a high bleeding risk), nitroglycerin, morphine, and oxygen. Immediate transfer to hospital for diagnostic coronary angiography followed by PCI is called primary PCI. This reduces infarct size, and the risk of intracranial bleeding, re-infarction, stroke, and death compared with thrombolysis.

Primary PCI is the preferred treatment if transport time is within 2 hours [2,9]. Angiography usually shows a coronary artery

occluded or semi-occluded (TIMI1-flow) by a thrombus (Fig. 147.3). Heparin and GpIIb/IIIa inhibitors, or the direct thrombin inhibitor bivalirudin, are administered as adjunctive treatment during PCI. Bivalirudin reduces major bleeding complications, resulting in lower mortality rates up to 3 years later compared to GpIIb/IIIa inhibitors [10]. To re-establish coronary blood flow, the thrombotic occlusion is treated either with thrombectomy, where the thrombus is removed by aspiration, or via balloon angioplasty. In most cases, the artery is then stented (Fig. 147.3). In a few cases when PCI is not technically possible, emergency coronary artery bypass grafting operation (CABG) is a reasonable option. This is undertaken in approximately 1% of STEMI patients.

Primary PCI is clearly indicated up to 12 hours after onset of pain. This time limit is based on thrombolysis trial data [2], however the longer the time delay, the less myocardium can be salvaged. For thrombolysis, the passage of time also makes it more difficult

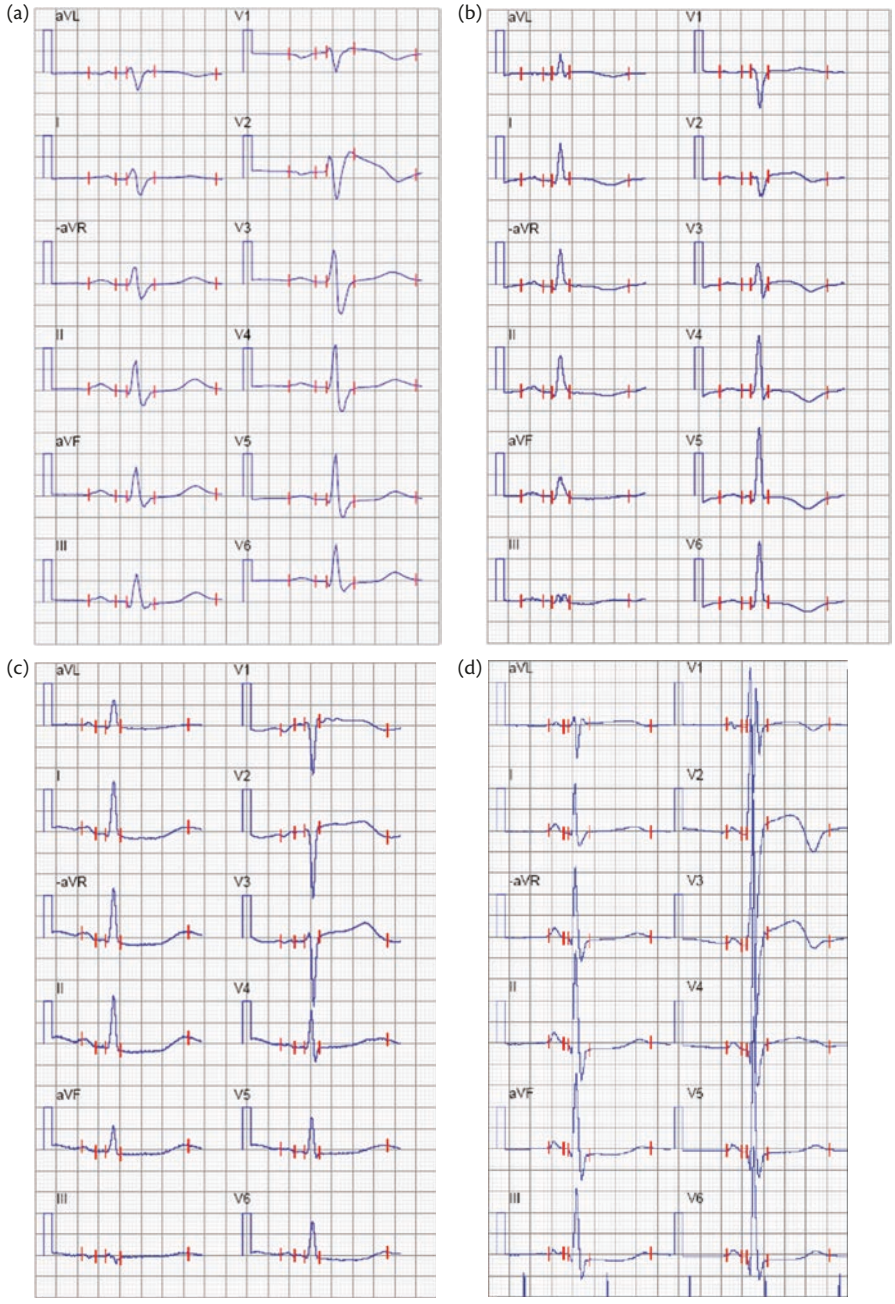

Fig. 147.2 Differential diagnosis of STEMI. (a) Brugada's syndrome involves a sodium channel mutation that confers loss of action potentials selectively in the right ventricular epicardium. (b) Takotsubo-cardiomyopathy in a 78-year-old woman whose husband died the previous day. Upward convex ST-elevation and negative T-waves anteriorly, compared to an older ECG. Maximum troponin T level was 920 ng/l. Echocardiography showed severe apical hypokinesia with hyperkinesia in other areas. (c) Subarachnoid haemorrhage in a 57-year-old woman. Anteroseptal ST elevation and ST-depression laterally, compared with prior ECG. Maximum troponin T level of 440 ng/l. (d) Hypertrophic cardiomyopathy with high R-wave amplitudes and secondary ST-T changes. (e) Perimyocarditis with general concave ST-elevation. (f) Hyperkalaemia with high T-waves.

(e)

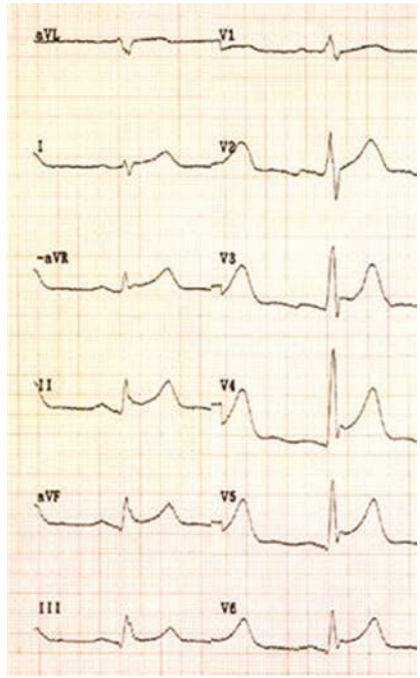

Fig. 147.2 Continued

to dissolve the clot as it becomes increasingly organized. With PCI, clot organization is not an issue; 95% of occlusions can be successfully treated with PCI, even after many hours [11]. After 12 hours, PCI is indicated for patients with persistent or newly recurrent chest pain, or for cardiogenic shock. Late angiography in patients without ongoing chest pain does not necessarily have to be performed out-of-hours. However, estimation of the duration of occlusion of a coronary artery can be difficult in patients that present late. This must be primarily based on symptoms and patient history, which may be uncertain.

Pulmonary oedema is treated with loop diuretics, nitroglycerin, and continuous positive airway pressure (CPAP). Inferior STEMI with right ventricle involvement can present with severe hypotension and bradycardia. This requires plenty of fluid (2–3 L or sometimes more), and is associated with an increased risk of atrioventricular block or bradycardia, which may require atropine or temporary pacing.

Coronary angiography and PCI requires awareness of the risks of contrast-induced nephropathy. To reduce the risk of kidney damage, the amount of contrast should be minimized, and plenty of fluids given before and after the procedure.

When coronary artery reperfusion is established with PCI, the patient may suffer reperfusion injury and arrhythmias such as ventricular fibrillation or tachycardia. More commonly, bradycardia, or asystole occur, the latter especially for inferior STEMI patients. Following reperfusion, the coronary blood flow is assessed, with optimal normal flow termed TIMI-3 flow. A few patients with slightly reduced flow have TIMI-2 flow, while a very small number have little or no flow, despite a fully patent coronary vessel. Reduced coronary flow (<TIMI-3) can be caused by micro-embolization or reperfusion injury leading to microcirculatory swelling and inflammation, resulting in microvascular obstruction. This is a poor prognostic sign. Such patients may develop systemic hypotension, larger infarct sizes, and cardiogenic shock. There is currently no treatment for reperfusion injury, but promising clinical trials with cyclosporin, adenosine, post-conditioning, and hypothermia are ongoing [12].

Thrombolysis

Thrombolysis (most commonly modified variants of tissue plasminogen activator, t-PA) is an alternative treatment for STEMI if initiated within 12 hours from onset of symptoms, and where transfer time to a PCI laboratory exceeds 2 hours. Thrombolysis carries a risk of bleeding, especially intracranial, and only succeeds in reperfusing the occluded artery in 50–60% of cases. Following successful thrombolysis the patient should be transferred within 3–24 hours to the nearest PCI centre for angiography and possible PCI. If thrombolysis does not achieve reperfusion within 90 minutes, the patient may be transferred for rescue PCI.

Post-infarction treatment

Beta-blockers should be used with great caution in the early phase of STEMI in patients with signs of heart failure [13]. They should only be used in patients with clearly elevated blood pressure and

(a) (b)

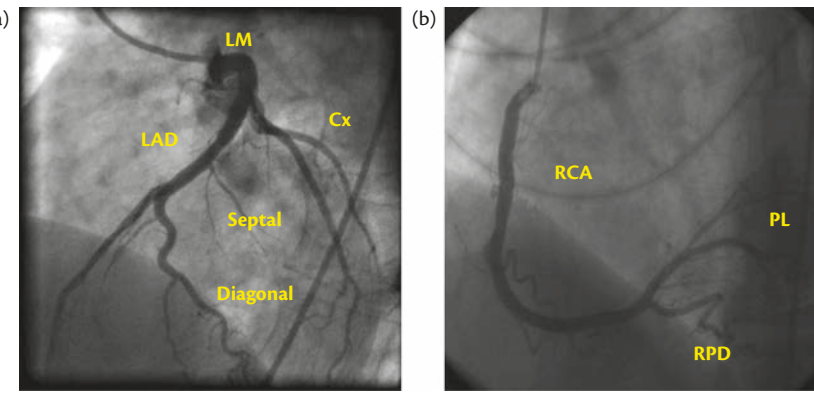

Fig. 147.3 Coronary angiography. The left coronary artery begins with the left main artery (LM) which branches into the left anterior descending (LAD) and circumflex artery (Cx). The LAD branches into diagonal and septal branches and supplies the anterior and apical septal parts of the heart. The Cx supplies the lateral part of the heart. The right coronary artery (RCA) branches into the right posterior descending artery (RPD) and posterolateral (PL) arteries that supply the inferior part of the heart and the basal area of the septum.

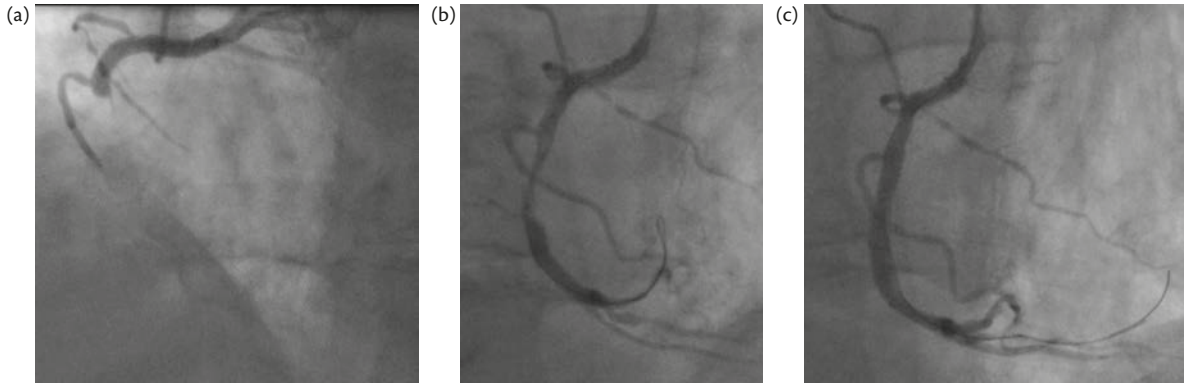

Fig. 147.4 Primary PCI. 61-year-old man with acute inferior STEMI. He was a smoker with three previous PCIs, and a previous anterior STEMI (a). An occlusion in the mid-right coronary artery was recanalized with balloon angioplasty (b), then stented with a bare metal stent (4.0x28 mm) (c).

tachycardia in the early phase. However, following haemodynamic recovery, it is important to start oral beta-blocker therapy, and to continue this post-infarction to reduce the risk of new infarction and death.

Lifelong treatment with aspirin and treatment with ADP receptor antagonists for up to 1 year is recommended. Statin therapy should be initiated quickly and reach the target levels of lowering LDL below 1.8mmol/L (70 mg/dL). Hypertension should be treated to target levels. Approximately 25% of patients with acute coronary syndromes have a history of diabetes, but an additional third have early stage diabetes that can be diagnosed by an oral glucose tolerance test. Precise treatment is essential for prognosis so glucose levels should be carefully monitored and treated with insulin, as indicated. ACE inhibitors should be given to most patients. The routine STEMI patient should thus be discharged with aspirin, ADP receptor antagonists (preferably ticagrelor or prasugrel), statins, beta-blockers, and ACE inhibitors. Diabetic patients should be followed up separately with regard to their diabetes. Equally important is to encourage lifestyle changes, such as smoking cessation, avoiding weight gain and increasing physical activity. A good goal is physical activity for 30 minutes in which patients experience increased heart rate, at least five times a week.

Complications of STEMI

Cardiogenic shock (persistent systolic BP <90 mmHg) is a life-threatening condition. Mortality rates used to be 90%, but primary PCI has reduced this to about 50%. Patients with cardiogenic shock should be primarily treated with PCI, if possible. Echocardiography should be done immediately to rule out possible mechanical complications, e.g. ventricular septal defect (VSD), cardiac tamponade, or flail mitral insufficiency. Other treatments include inotropic drugs (noradrenaline, dobutamine, or levosimendan), intra-aortic balloon pump, and percutaneous left ventricular assist devices.

Papillary muscle rupture leading to acute flail mitral insufficiency manifests a few days following STEMI, usually as cardiogenic shock and pulmonary oedema of sudden onset. Concurrent tachycardia may accentuate the ST elevations incurred from the previously untreated infarction. The flail mitral insufficiency causes an extreme low output syndrome. It is important to recognize this small subgroup of patients as they need continuous pulmonary airway pressure (CPAP) or mechanical ventilation, and immediate referral to cardiac surgery.

Acute VSD is a rupture caused by necrosis of the infarcted zone in the septum resulting in blood from the left ventricle pumping into the right ventricle. It often occurs after a few days to a week and results in rapidly developing hypotension and shock. A systolic murmur can be heard, but the larger the defect, the weaker the murmur. Diagnosis is made with echocardiography and immediate surgery is necessary.

Tamponade in a patient post-STEMI carries a very poor prognosis. Rupture of the free left ventricular wall leads to rapid filling of the pericardium with blood. This compresses the right ventricle and then the left ventricle, leading to hypotension. As a rule, the patient dies quickly, but sometimes the rupture is covered partially by adhesions that allow slower progression. Clinical signs are hypotension and tachycardia. The heart rate can vary with respiration (pulsus paradoxus) and the ECG may show electrical alternans (R-wave amplitude changes). Rapid infusion of fluid is a first treatment, followed by pericardial drainage and immediate transfer to surgery.

Post-myocardial infarction syndrome (Dressler's syndrome) is an inflammatory reaction that may occur usually 1–3 weeks post-STEMI. Fever, raised CRP, and pericardial effusion are seen. Treatment is with corticosteroids or NSAIDs for prolonged periods.

Coronary artery stent thrombosis is a dangerous condition with high mortality. The most common reasons are premature cessation of antiplatelet therapy or an undersized stent. Patients should be treated with PCI and the stent checked with intravascular ultrasound to verify that the struts are well opposed to the vessel wall. Platelet reactivity may be tested in patients with stent thrombosis.

Arrhythmias

Bradycardia and heart block is treated with atropine, isoprenaline (isoproterenol), or temporary transvenous pacing. It is a common complication following inferior infarction. Atrial fibrillation rate control is regulated primarily by beta-blockade and electrical cardioversion within 48 hours. Amiodarone can also be used. Ventricular arrhythmias leading to cardiac arrest are treated with cardiopulmonary resuscitation and defibrillation. Ventricular arrhythmias within 48 hours are considered part of the normal

course of an infarction and reperfusion, but if they occur later, an intracardiac defibrillator should be considered.

Prognosis and follow-up

Patients experiencing STEMI have a worse short-term prognosis than those with NSTE-ACS, but after 1 year, patients with NSTE-ACS fare almost as badly. Both conditions have a 1-year mortality of almost 15%. When comparing STEMI patients with NSTEMI patients with ST-depression, survival rates are similar, in part due to NSTEMI patients being generally older. The co-occurrence of diabetes or renal failure significantly impairs prognosis. It is important to provide the best secondary prevention as possible. This includes aspirin, ADP receptor antagonists, statins, beta-blockers, ACE inhibitors, and lifestyle changes, such as cessation of smoking, physical exercise five times a week, and diet recommendations.

PART 5.4

Aortic dissection

CHAPTER 148

Pathophysiology, diagnosis, and management of aortic dissection

Samuel J. Youssef and John A. Elefteriades

Key points

- Have a high index of suspicion for aortic dissection in patients presenting with chest pain and remember it is 'the great masquerader' that can mimic disease of any organ.
- Aortic dissection kills via: rupture, cardiac tamponade, acute aortic insufficiency, and organ ischaemia.
- Use liberal imaging (usually by CT and echocardiography). Remember the utility of the 'triple rule-out CT' (to rule out dissection, myocardial infarction, pulmonary embolism).
- Upon diagnosis, start 'anti-impulse' treatment (Rx). Do not use unopposed afterload reduction (glyceryl trinitrate, nitroprusside) without concomitant ß-blockade to decrease dp/dt.
- Ascending aortic dissection requires urgent surgery; Descending aortic dissection is treated medically.

Introduction

A patient who presents to the emergency department with acute onset chest pain will more often be correctly diagnosed with an acute myocardial infarction, rather than an acute aortic dissection. However, if present and not accurately diagnosed, an acute aortic dissection will undoubtedly become a lethal event. This combination of characteristics—difficulty in diagnosis and lethality—poses a real challenge to caregivers on the front lines.

Acute aortic dissection has a well-known reputation as 'the great masquerader'. Presenting symptoms and signs may mimic the pathology of any organ system in the body (myocardial infarction, stroke, abdominal catastrophe, spinal cord injury, and limb ischaemia) [1]. By the time the aortic specialist is called, the hard work of sifting out and identifying the patient who is dissecting has already been done. Those of us who care for the thoracic aorta have a great deal of respect for the talented physicians charged with sorting out the aetiology and triaging the care for this critical illness.

Definition

Aortic dissection is a splitting of the aortic wall into inner and outer layers. The split occurs in mid media, at varying depths of penetration into the medial lamellae (Fig. 148.1). The split then propagates for varying distances longitudinally along the aorta. The most important distinction is between **ascending** (Type A) and **descending** (Type B) aortic dissection (Fig. 148.2).

Ascending aortic dissection begins with a tear 1–2 cm above the coronary ostia and propagates longitudinally along the aorta (usually to the aortic bifurcation or beyond). Ascending aortic dissection requires urgent surgery. Descending aortic dissection begins with an intimal tear 1–2 cm beyond the origin of the left subclavian artery and propagates for various distances down the aorta, usually to the aortic bifurcation or beyond. Descending aortic dissection is usually treated medically.

Aside from the distinction of ascending versus descending, it is important to recognize that aortic dissection can take three morphologies: **typical dissection** (with the splitting of two layers as just described), **penetrating ulcer** (in which an ulcer in the aortic wall permits entry of blood into the thickness of the aorta), and **intramural haematoma** (in which a crescentic layer of blood forms in the aortic wall, but without a frank separation of layers with an inner intimal flap) (Figs 148.3 and 148.4) [2]. All three can present with acute symptoms (pain), recently termed as the '**acute aortic syndrome**'.

Pathophysiology

Aortic disease was long thought to be a manifestation of arteriosclerosis. However, it is becoming increasingly clear that, for the ascending aorta especially, the development of aneurysm and dissection are not at all related to arteriosclerosis, or to arteriosclerotic risk factors, but rather are manifestations of inborn, genetically-mediated, connective tissue weakness [3–7].

The pathological sequence that leads to acute aortic dissection is now clarified [3], with its origins in the recognition that aortic aneurysm and dissection run strongly in families [3–7], and that acute physical and emotional stress can trigger aortic dissection [8–10]. We first identified this factor in five healthy young weight lifters treated at our institution within a short time for acute ascending aortic dissection.

Acute aortic dissection can kill a patient quickly in four ways (Fig. 148.5):

- Cardiac tamponade (from intrapericardial rupture of ascending aortic dissection).
- Acute aortic insufficiency (from distortion of the aortic valve).
- Free rupture (usually into the left pleural space).
- Organ ischaemia (any organ can be affected).

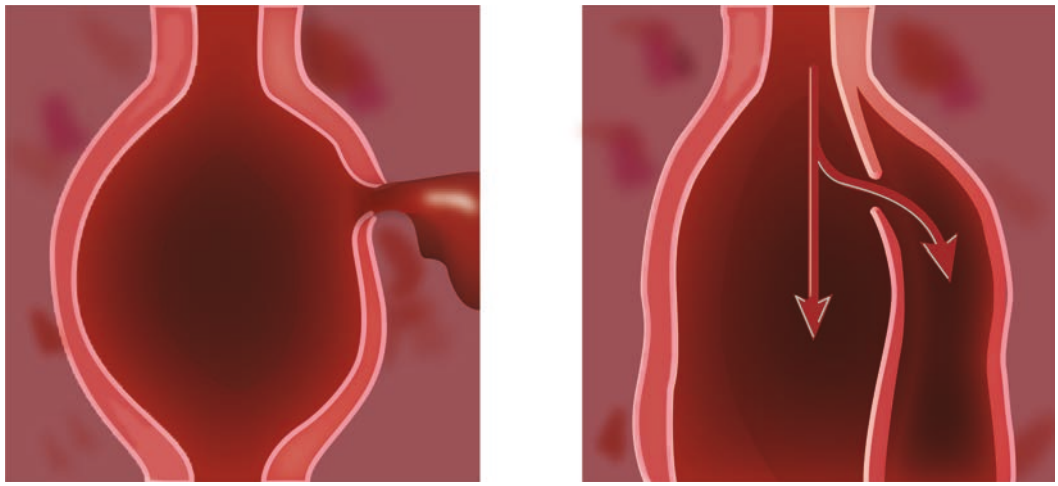

Fig. 148.1 Artist's depiction of aortic dissection. Note the difference between **free rupture**, shown schematically (left), and **aortic dissection** (right). In bottom right, note dissection in mid-media in this pathological specimen. Bottom left shows typical CT scan appearance of aortic dissection. Note flap in ascending and descending aorta.

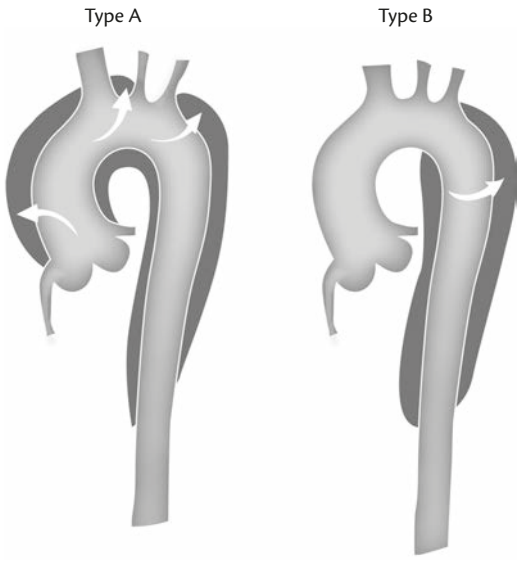

Fig. 148.2 Classification system for aortic dissection: Type A (ascending) and Type B (descending). Treatment is predicated on type (ascending usually requires urgent surgical replacement of the aorta, whereas descending is usually treated medically).

Diagnosis

Diagnosis of aortic dissection is both difficult and of paramount importance for the reasons mentioned in the introductory paragraph. The quintessential symptom is pain with characteristics that vividly reflect the nature of the disorder. The pain is described as the most severe possible (more than a kidney stone and more than childbirth), with a tearing or knife-like quality. With ascending dissection, the pain originates and is maximal under the breastbone. With descending dissection, the pain typically originates between the shoulder blades in the upper thoracic back. The pain may migrate distally as the dissection splits the layers further, travelling toward the abdomen and legs. The pain usually has an abrupt onset and is often preceded by acute physical exertion or an acute emotional event.

History

A family history of aortic aneurysm, aortic valve disease (bicuspid valve is strongly associated with aortic dissection), or premature sudden cardiac death should be sought.

Physical examination

This may be negative, but occasionally, the murmur of aortic insufficiency is heard, reflecting unseating of the aortic valve by an ascending aortic dissection. A pulse may be absent, usually a femoral, or perhaps a brachial or carotid. A difference in blood pressure between the two arms may be a clue that the branch arteries are being compromised. Patients may present in shock, usually reflecting internal bleeding from rupture of the dissection or cardiac tamponade from intrapericardial rupture. In the latter case, jugular venous distention and greyish discoloration of the face may be found.

The patient who presents with sharp, extremely severe, substernal chest pain of sudden onset following strenuous exertion may be easy to recognize as an acute ascending aortic dissection. However, aortic dissection may masquerade as a disease of virtually any organ of the body as any feeding branch of the aorta may be compromised or occluded by the dissection process (Fig. 148.5). Thus, aortic dissection may present as stroke, arm ischaemia, myocardial infarction, or pericarditis, paraplegia from involvement of critical intercostal arteries, an acute abdomen, or as leg ischaemia. Abdominal presentation is especially difficult to recognize. Aortic dissection is often misdiagnosed as anxiety attack, transient ischaemic attack, lumbar disc disease, cholecystitis, or gastroenteritis, among other possible diagnoses [1].

Certain physical stigmata may be part of the overall appearance in patients with connective tissue disease. A tall, thin body

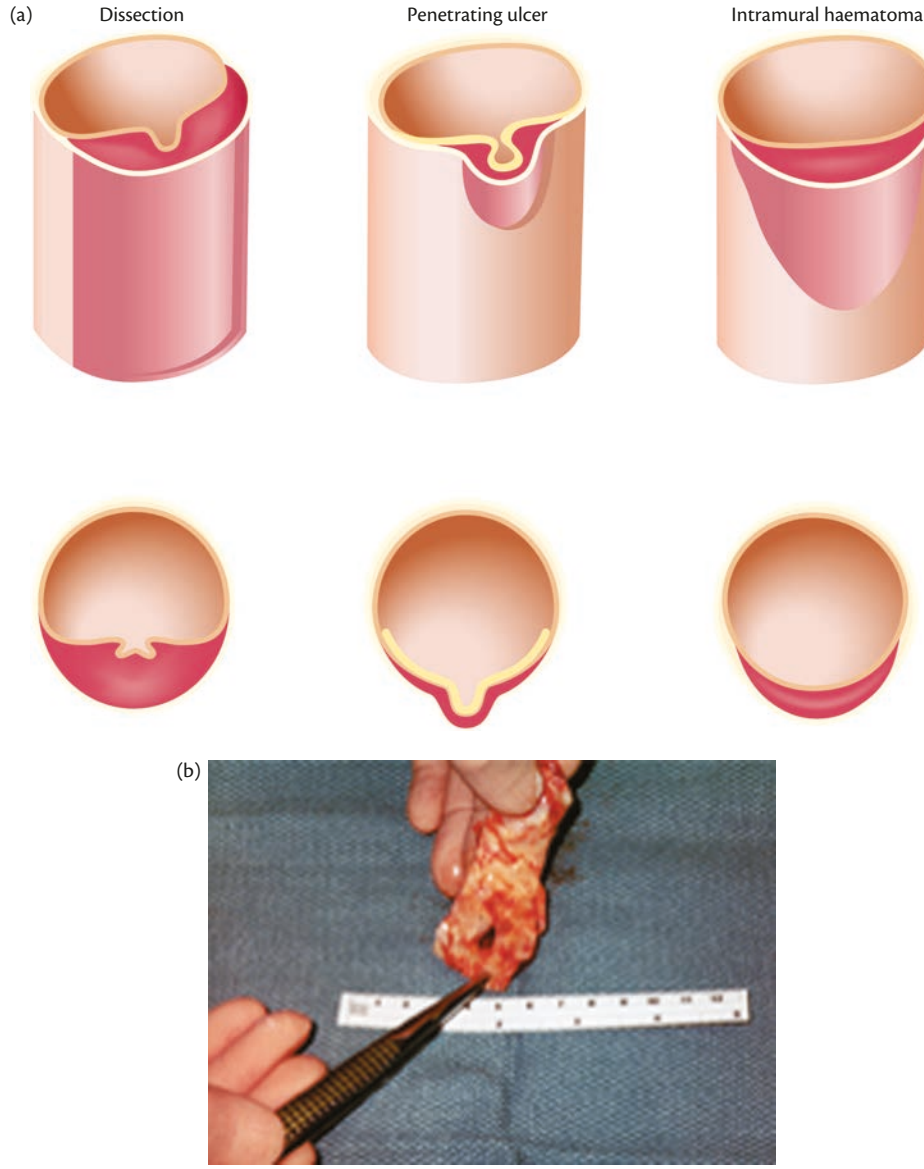

Fig. 148.3 Types of aortic dissection. (a) Typical aortic dissection with a flap traversing the lumen. Penetrating ulcer permits entry of blood into the aortic wall at the base of the ulcer. Intramural haematoma involves a circumferential collection of blood in the aortic wall, but without a frank flap. (b) Penetrating ulcer of the aorta (surgical specimen shown) closely resembles duodenal ulcer in its overall appearance.

build should be a clue, not only for Marfan's disease, but also for non-Marfanoid connective tissue disease. Pectus excavatum or carinatum is another sign of connective tissue disease, as is the 'thumb-palm sign' in which the thumb can stretch all the way beyond the flat palm. A history of 'double-jointedness' is another clue that the connective tissues are lax.

Laboratory tests

A full battery of blood tests is typically done for these patients. The D-dimer test is especially useful [11,12] as this is released very quickly from the breakdown of thrombus that invariably forms in the space between the dissected layers. The test is >99% sensitive at detecting aortic dissection so a negative test essentially excludes acute aortic dissection. It is poorly specific as it is also released in acute myocardial infarction, pulmonary embolism and other conditions. However, its sensitivity makes it of paramount value. Despite concerted efforts, no other predictive (before the fact) or diagnostic (after the fact) blood markers for aortic dissection have come into clinical practice, although promising progress is being made [12].

Imaging studies

The main advice is to **image liberally**. Whenever aortic dissection is in the differential diagnosis—and it should frequently be so—an imaging study should be obtained. Echocardiography, CT, and MRI are all sensitive and specific for aortic dissection. MRI is usually more difficult to obtain and the imaging facilities are often located remote from acute care areas. Transthoracic echocardiography

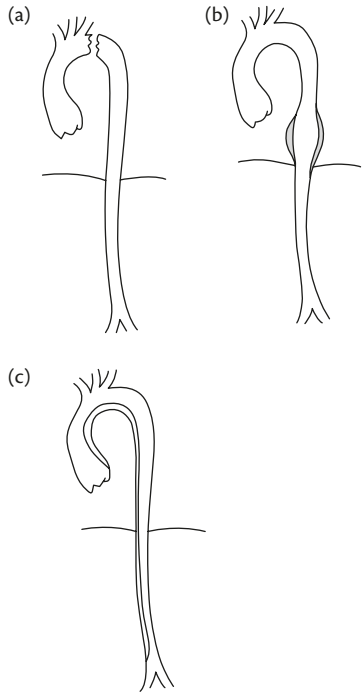

Fig. 148.4 Differentiation of three commonly confused conditions, whose terminology is often inappropriately applied—aortic transection (a), 'degenerative' aortic ulcer (b), and acute aortic dissection (c). See text.

(TTE) is available in essentially every emergency department and is completely benign. It is important to recognize, however, that TTE cannot 'see' more than a few centimetres up the aorta from the aortic valve. CT imaging is also recommended for a complete visualization of the aorta, especially the TTE-inaccessible descending aorta. Transoesophageal echo (TEE) gives even more precise images and can certainly be employed. It is important to avoid the patient's bucking and straining against the TEE probe; we have seen many cases where the stimulus of a TEE probe or an endotracheal tube is just enough to produce rupture of an ascending aortic dissection.

Between TTE and CT scan, aortic dissection will essentially be ruled in or out conclusively. The CT scan will also be of other benefit. The 'triple rule-out CT' [1] recognizes the three chest conditions that may commonly take the life of an acutely-ill patient and all may be ruled in or out by CT scanning. These are aortic dissection, acute pulmonary embolism, which will be seen clearly on contrast CT, and acute myocardial infarction. While the CT will not visualize the myocardial infarct itself, it will show the coronary calcification that leads to the infarction.

A plain chest X-ray can also give important clues about the aorta. The aortic contours can usually be well discerned. The ascending aorta, if enlarged or dissected, will 'peek out' beyond the right mediastinal shadow. The aortic knob, representing the aortic arch will be enlarged if the arch is large or dissected. The paravertebral straight line representing the descending aorta will be enlarged and/or deviated if the descending aorta is enlarged or dissected. Not infrequently, alterations in the aortic silhouette may be the 'smoking gun' left behind by an acute aortic dissection.

Management

The main goal upon presentation is to entertain and confirm the diagnosis of aortic dissection.

The second goal is to begin medical management of the dissection [13,14]. Initial management, regardless of the type of dissection and irrespective of whether or not surgery is pending, entails the so-called 'anti-impulse' therapy. Blood pressure must be lowered to decrease aortic wall tension. This is done by straightforward means, usually with intravenous (iv) glyceryl trinitrate or nitroprusside. However, it is vital to recognize that, without concomitant beta-blocking therapy to decrease the strength of the cardiac impulse, or dp/dt, lowering the blood pressure will actually increase stress on the aortic wall. Thus, along with the afterload-reducing drugs, we administer a β-blocker, usually esmolol intravenously. Labetalol, which has both α- and β-blocking properties and thus offers afterload reduction, is an acceptable alternative to the

two-drug combination. In patients with bronchospasm in whom β-blockers are to be avoided, we often use a calcium channel blocker to decrease dp/dt. Table 148.1 gives a complete roster of therapeutic alternatives for anti-impulse therapy.

In a patient with an acute aortic dissection, we usually aim to drop the systolic blood pressure to about 90 mmHg, at least initially. Mentation and urine output are closely monitored, and if such a low pressure produces mental changes or oliguria, we mildly liberalize our blood pressure (BP) target. Some patients with chronic hypertension and severe vascular disease may not be able to function at low pressures, and there may be no alternative but to permit systolic BPs of 120–130 mmHg.

Pearls and pitfalls

The heavy burden of misdiagnosis comes not necessarily from the mere fact of having a wrong diagnosis, but rather from the sequelae of initiating a treatment plan that can exacerbate another condition. Such is the case in an acute aortic dissection mistaken for an acute coronary event. The mainstay of emergency room treatment in ruling out a coronary syndrome is to anticoagulate, and then rush the patient to the catheterization laboratory. While a heparin bolus or TPA administration will benefit the coronary syndrome, such treatment will let loose the aortic dissection, leading to aortic rupture and sudden death. Hence, no patient with sudden onset chest pain should go to the catheterization laboratory or receive anticoagulation without first having at least a chest X-ray or echo, and a full physical exam including all peripheral pulses. Once a dissection is ruled out, then the emergency room physician can proceed to expedite the 'door-to-balloon' time.

The pearls of diagnosing a dissection reside in careful evaluation of the presenting history and physical exam. A genetic predisposition coupled with an inciting event (emotional or physical stress) may bring a young weight lifter or a post-partum mother into the emergency department with severe tearing chest pain—and an aortic dissection. Also, it is essential to remember the possible masquerade behind any patient presenting with a stroke, unilateral arm weakness, sudden onset abdominal pain, or severe back pain; these deceptive symptoms may have their origin in aortic dissection.

Definitive treatment

Definitive treatment depends on the location of the aortic dissection. Ascending aortic dissections, with a tear just above the coronary arteries, require urgent surgery because of the danger of death from rupture, tamponade, coronary ischaemia, or aortic insufficiency. It has been estimated that these patients die at about 1% per hour, in the absence of surgical treatment. However, if the diagnosis of aortic dissection is made in a delayed fashion, as is often the case, the 'eye of the storm' may have passed, and surgery may be done semi-electively. Specifically, if more than 48–72 hours has passed between the onset of symptoms and correct diagnosis, we usually do not operate in the middle of the night. It is not uncommon for a late diagnosis of this type to be made, usually by accident through an imaging study done for another purpose.

Descending aortic dissections are managed by a 'complication-specific' approach. If there are no complications, they are managed exclusively medically with anti-impulse therapy, transitioned after several days to oral therapy. A repeat CT scan is

Table 148.1 Intravenous agents for treatment of ascending dissection

Name	Category	Loading dose	Maintenance dose	Adverse effects	Caution
Sodium nitroprusside	Vasodilator	0.3–3 mcg/kg/min; max. limit for an adult is 10 mcg/kg/min for 10 min	1–3 mcg/kg/min	Nausea, vomiting, agitation, muscle twitching, sweating, cutis anserina and cyanide toxicity, tachycardia	In patients with hepatic or renal dysfunction
Propranolol	β-blocker	1–3 mg (given at 1 mg intervals over 1 minutes). Can be repeated not less than every 4 hours	1–3 mg every 4 hours	Hypotension, nausea, dizziness, cold extremities, reversible hair loss, bradycardia	In patients with bradycardia or history of CHF and bronchospasm. Max. initial dose should not exceed 0.15 mg/hour
Esmolol	β-blocker	500 mcg/kg bolus	Continuous iv infusion from 50 to 200 mcg/kg/min	Hypotension, nausea, dizziness, bronchospasm, dyspepsia, constipation, increases digoxin level	In patients with CHF or asthma or on concomitant CCB therapy
Labetalol	α- & β-blockers	20 mg over 2 minutes, then 40–80 mg every 10–15 minutes (max. 300)	Continuous iv infusion starting at 2 mg/min and titrate up to 5–10 mg/min	Vomiting, nausea, scalp tingling, burning in throat, dizziness, heart disease, block, orthostatic hypotension	In patients with concomitant CCB therapy
Diltiazem	CCB	0.25 mg/kg iv bolus (up to 25 mg)	5–10 mg/hour by continuous infusion	Heart block, constipation, liver dysfunction	In patients with heart failure, concomitant β–blocker therapy
Enalapril	Vasodilator ACE inhibitor	0.625–1.25 mg bolus	0.625–5 mg every 6 hours	Precipitates fall in BP in high renin states, variable response, renal failure	In patients with high possibility of MI, renal dysfunction
Fenoldopam	Dopamine D1 receptor agonist	0.03–0.1 mcg/kg/min initially	0.1–0.3 mcg/kg/min, max. 1.6 mcg/kg/min	Tachycardia, hypotension, headache, nausea, flushing, hypokalaemia, elevation of IOP	In patients with glaucoma

CCB, calcium channel blocker; ACE, angiotensin-converting enzyme; iv, intravenous; BP, blood pressure; IOP, intraocular pressure; CHF, congestive heart failure; MI, myocardial ischaemia.

performed at 72 hours and then again before hospital discharge, to ensure there is no rapid early progression on medical therapy.

If there are complications of descending aortic dissection, then surgery is required. For rupture, aortic replacement is performed. For organ ischaemia, surgical fenestration is performed, taking the pressure off the true lumen, and permitting resumption of organ flow. For persistent pain or rapid enlargement, surgical replacement is performed.

Interventional therapy, with endovascular stent therapy, is developing a role in the treatment of aortic dissection. Some ruptures and rapid enlargements may be treated by stent. Organ ischaemia may be treated by stenting open the compromised vessel. Fenestration can be done by deliberate endovascular rupture or incision of the offending false membrane. These therapies have produced satisfactory early results. Although often performed with the goal of 'obliterating the false lumen', endovascular therapy of uncomplicated descending aortic dissection is unproven and potentially harmful. Retrograde dissection into the ascending aorta, a very serious complication, is seen in a percentage of patients subjected to routine stent placement for uncomplicated descending aortic dissection.

Conclusion

Aortic dissection is a virulent foe for those on the front lines in the Emergency Department and those doing later battle in the operating room. By following key principles, based on recent data, this shrewd opponent can be combatted. Although still a humbling disease, as for Osler 100 years ago, aortic dissection is slowly yielding to thoughtful, evidence-based diagnosis, and therapy.

PART 5.5

The hypotensive patient

CHAPTER 149

Pathophysiology of shock

Antoine Kimmoun and Bruno Levy

Key points

- Commonly described shock states can be categorized into 'distributive shock' usually characterized by high cardiac output and low peripheral vascular resistance, and 'resistive shock' characterized by low cardiac output and high peripheral vascular resistance.
- Cardiogenic and hypovolaemic shock induce an ischaemia reperfusion syndrome.
- Septic shock and ischaemia reperfusion syndrome share a common pathophysiology.
- Nitric oxide overproduction is the cornerstone of vascular hyporeactivity in shock states.
- Decreased myofilament calcium sensitivity probably plays a major role in cardiac dysfunction in shock states.

Introduction

Shock has been defined as 'a life-threatening, generalized maldistribution of blood flow resulting in failure to deliver and/or utilize adequate amounts of oxygen, leading to tissue dysoxia' [1]. Shock is traditionally categorized into:

- **Cardiogenic shock**: impairment of cardiac reserve.
- **Obstructive shock**: obstruction of normal circulatory flow.
- **Hypovolaemic shock**: fluid losses decreasing ventricular preload.
- **Distributive shock**: vascular hyporesponsiveness resulting in abnormal blood flow distribution.

These initial haemodynamic disorders all lead to tissue hypoperfusion and are often inter-related. Clinically, they share a common presentation—hypotension with a particular pattern for each shock type, tachycardia, oliguria, mottling, pallor, coldness, peripheral cyanosis, altered mental status, and dyspnoea. Lactic acidosis is most often observed during shock states.

Over the last two decades, a new pathophysiological approach has emerged following recognition of the immune-inflammatory response as both cause and consequence of various shock states, and related complications, such as vascular hyporesponsiveness. Thus, pro-inflammatory cytokines play a major role in the initiation of sepsis leading to hypotension, tissue hypoperfusion, and vascular hyporeactivity. Similarly, ischaemia reperfusion injury during cardiogenic or hypovolaemic shock is also associated with massive cytokine release and multi-organ failure.

We will briefly review the different shock states and the common characteristics of vascular and cardiac hyporesponsiveness to catecholamines. Anaphylactic shock is discussed elsewhere.

Shock categories

The commonly described shock states can be categorized into 'distributive shock' (septic, anaphylactic) usually characterized by high cardiac output and low peripheral vascular resistance, and 'resistive shock' (cardiogenic, hypovolaemic, obstructive) characterized by low cardiac output and high peripheral vascular resistance.

Septic shock

This is currently defined by pre-existing sepsis with systolic arterial pressure (SAP) <90 mmHg or mean arterial pressure (MAP) <70 mmHg in the absence of other causes of hypotension and despite adequate fluid resuscitation [2]. The initial reduction in vascular tone with a hyperdynamic cardiac state accounts for the relatively sustained SAP, low diastolic arterial pressure (DAP) and wide pulse pressure (PP) (= SAP – DAP). The decreased vascular resistance to left ventricular ejection allows a maintained/elevated cardiac output despite a frequent myocardial depression. At the tissue level, there is an initial increase in oxygen demand associated with a limited oxygen extraction capacity and microcirculatory flow redistribution. At the cellular level, mitochondria cannot utilize oxygen for oxidative phosphorylation and ATP production [3]. Consequently, SvO_2, a global marker of tissue oxygen balance, is usually normal or elevated in the euvolaemic septic patient.

During any phase of septic shock, although more frequently seen later on, cardiac performance can decrease with depressed systolic function and a low cardiac output. This septic cardiomyopathy is, however, completely reversible with the resolution of shock.

Hypovolaemic shock

This is the commonest shock state and often relates to blood loss from blunt and/or penetrating traumatic injuries, gastrointestinal bleeding, aortic rupture, and post-operative haemorrhage. Severe dehydration (extensive burns, massive emesis, profuse diarrhoea, etc.) is also a frequent cause of hypovolaemic shock.

The reduction in venous return leads to a decreased cardiac output with, early on, preserved vascular tone and reactivity. Thus, a typical haemodynamic pattern is of a low SAP (<90 mmHg) and MAP (<65 mmHg) with a relatively sustained DAP and narrow PP. Sympathetic adrenergic stimulation is preserved, increasing central vascular contraction. However, in some organ beds, blood flow is preserved, while in others there is vasoconstriction and reduced flow.

Two adaptive mechanisms permit an increase in tissue oxygen extraction:

- Redistribution of organ blood flow towards organs with high oxygen extraction (brain, heart), while sacrificing flow to organs with low extraction (e.g. skin, splanchnic area).

- Microcirculatory recruitment within heart and brain.

Hence, mixed venous oxygen saturation is decreased due to increased oxygen extraction, but in the most severe cases, massive release of pro-inflammatory cytokines occurs through prolonged ischaemia and subsequent reperfusion, promoting a sepsis-like syndrome with multiple organ failure.

Cardiogenic and obstructive shock

Here, cardiac failure results from either myocardial pump injury or obstruction of ventricular ejection. Extensive myocardial infarction, myocardial stunning (post-cardiac surgery, post-cardiac arrest, Takotsubo syndrome), myocarditis, severe arrhythmias, and valvular cardiomyopathies are the most common causes of non-obstructive cardiogenic shock.

Massive pulmonary embolism and cardiac tamponade are the two principal aetiologies underlying obstructive shock. In the former, the obstacle is in the right outflow tract leading to specific right ventricular dysfunction with the paradoxical septal motion of acute cor pulmonale. In contrast, cardiac tamponade directly affects filling of the left and right ventricles. It typically presents as a low cardiac index (<2.2 L/min/m^2) with increased left ventricular diastolic pressure and high systemic vascular resistance. As in hypovolaemic shock, sympathetic adrenergic stimulation is preserved, and tissue oxygen extraction increases via the same mechanisms. Thus, the haemodynamic pattern is similar to hypovolaemic shock, and only the clinical context (e.g. history of chest pain, pulmonary oedema symptoms), preload-dependency (or otherwise) for cardiac output, and echocardiography can reliably distinguish between them.

While this haemodynamic classification serves an educational purpose, in reality it often becomes increasingly complex when the consequences of resuscitation including ischaemia reperfusion and bacterial translocation are considered. These may contribute towards vascular hyporesponsiveness that may exacerbate symptoms and worsen prognosis.

Septic shock-induced vasoplegia and ischaemia reperfusion: a common pathophysiology for cardiovascular hyporeactivity

Shock states are associated with a dysregulated inflammatory response due to either the primary insult (sepsis) or secondary to an ischaemia reperfusion syndrome (haemorrhagic or cardiogenic shock). In advanced stages, all shock states evolve to a common haemodynamic pattern usually characterized by both vascular and cardiac dysfunction.

During septic shock, pathogen-associated molecular patterns (PAMPs) such as endotoxins, lipoproteins, and outer membrane proteins are recognized by pattern recognition receptors (e.g. Toll-like receptors [TLRs]) located on immune cell types. This induces signal transduction resulting in increased transcription of nuclear factor-κb (NF-κb) and other factors that, in turn, initiate and amplify the pro-inflammatory response leading to cardiovascular dysfunction.

Ischaemia-reperfusion injury plays a major role in both prolonged, and resuscitated haemorrhagic and cardiogenic shock. TLRs are also involved, responding to endogenous damage-associated molecular patterns (DAMPs) released from reperfusion (e.g. heat shock protein-70, haem, mitochondria).

Irrespective of the initial aetiology, the NF-κb system activates >150 pro-inflammatory genes and receptors (iNOS, COX-2, IL-1, IL-6, TNFα …), thereby explaining the shared pathophysiology of different shock states. The role of counter-inflammatory signalling, including the cholinergic anti-inflammatory pathway, is also being investigated. The balance between pro- and counter-inflammatory mechanisms is increasingly recognized as an important area for focus.

Vascular hyporesponsiveness

While there is currently no clear published definition, we propose that vascular hyporesponsiveness represents an inability to increase blood pressure despite vasopressors in shocked patients. Accordingly, vascular hyporeactivity is the failure of vascular smooth muscle constriction to sustain a sufficient blood pressure. Various mechanisms are involved:

Nitric oxide

Nitric oxide (NO) has many roles, including participation in the regulation of blood flow, coagulation, neural activity, and immune functions. It is produced in picomolar concentrations from L-arginine in endothelial and other cells by cNOS, a constitutive isoform of NO synthase. NO diffuses through the endothelium to the vascular smooth muscle cell (VSMC) cytoplasm, inducing vasorelaxation. However, inflammation during shock leads to expression of the inducible isoform, iNOS, in vessel walls and within the smooth muscle with a 1000-fold increase in NO production.

Vasodilator effects of NO have been widely studied, particularly in septic shock. The pressor response to noradrenaline is significantly affected, but restored by NOS inhibition. As this reversal is endothelium-independent, this strongly implies VSMC NO production by iNOS. This probably explains the profound vasoplegia and limited response to stimuli that normally regulate blood flow and tissue perfusion.

NO overproduction during ischaemia reperfusion injury from cardiogenic or haemorrhagic shock is also largely involved in vascular hyporesponsiveness. In the SHOCK trial of patients with cardiogenic shock, one-fifth exhibited clinical evidence of systemic inflammation [4]. High levels of iNOS and NO have been observed in models of reperfusion following myocardial infarction [5]. Haemorrhagic shock also induces NOS activation with vascular hyporesponsiveness to adrenergic agonists that can be reversed by NOS inhibition [6]. However, blocking NO production can lead to serious negative effects.

Free radicals: peroxynitrite and superoxide

Free radicals, such as superoxide, are highly unstable molecules generated via incomplete reduction of molecular oxygen that have one or more unpaired electrons in their outer orbital. Increased formation of NO and superoxide generates large quantities of peroxynitrite. This reactive nitrogen species may be responsible for much of the biological effect of NO [7]. Overproduction during a state of 'oxidative stress' can induce organ injury and, more specifically, endothelial dysfunction and hypovasoreactivity.

During septic shock, vascular hyporeactivity can be reversed by peroxynitrite inhibition or by genetic suppression of NADPH, which reduces peroxynitrite [7]. Catecholamines can also be auto-oxidized by superoxide. Likewise, peroxynitrite worsened

vascular hyporesponsiveness to catecholamines in cardiogenic shock, while ischaemia reperfusion injury generated excess peroxynitrite in experimental haemorrhagic shock [8].

Prostacyclin and COX-2 pathways

Prostacyclin (PGI2), a lipid mediator belonging to the prostaglandin family, is a main product of arachidonic acid metabolism produced in the endothelium by cyclo-oxygenase (COX) and prostacyclin synthase. PGI2 has potent antithrombotic and vasodilator effects. Vasorelaxant effects on VSMCs are mediated through cAMP after stimulation of inositol phosphate [9]. In sepsis, PGI2 is up-regulated, mainly by COX-2, an inducible isoform of COX. Use of a COX-2 blocker restored blood pressure experimentally [10].

PGI2 is also elevated in experimental resuscitated haemorrhagic shock. Splanchnic blood flow decreased with a compensatory release of PGI2 and an increase in COX expression. High prostacyclin levels have been measured in lung and hepatic injury following ischaemia reperfusion [11].

ATP-sensitive potassium channels

Under normal conditions, channel opening induces K^+ loss from the cell resulting in membrane repolarization. Excessive activation on VSMC membranes leads to hyperpolarization and inhibition of voltage-sensitive calcium channels, inducing cell relaxation, vasodilation, hypotension, and vascular hyporeactivity. Hypoxia, acidosis, hyperlactataemia, NO, and peroxynitrite all activate ATP-sensitive (K_{ATP}) K^+ channels, leading to vasorelaxation.

K_{ATP} channels are implicated in vascular hyporeactivity during septic shock, where they are over-expressed and partially regulated by NO via NF-κB activation [12]. K_{ATP} channel inhibition by glibenclamide (glyburide) can effectively restore systemic haemodynamics and regional perfusion in prolonged haemorrhagic shock. However, this activation may actually protect the myocardium against ischaemia or during reperfusion acidosis [13].

Large conductance calcium-activated potassium channels

Large conductance calcium-activated potassium (BKCa) channels are the most widespread vascular K^+ channel. During depolarization, high levels of intracellular calcium activate BKCa channels, inducing hyperpolarization and contributing to VSMC relaxation. NO, peroxynitrite, and superoxide are involved in BKCa modulation during shock states. Specific inhibition of the BKCa channel however produced variable results [12].

Vascular hyporesponsiveness following resuscitated haemorrhagic shock is also, in part, mediated by BKCa activation. As with K_{ATP} channels, BKCa may have a protective effect on ischaemic myocardium [14].

Critical illness-related corticosteroid insufficiency

Critical illness-related corticosteroid insufficiency (CIRCI) is characterized by adrenal insufficiency, tissue resistance to glucocorticoids and an excessive pro-inflammatory response. Glucocorticoids and mineralocorticoids improve the vasoconstrictor response to catecholamines [15]. However, underlying mechanisms remain complex and probably involve various pathways, e.g. iNOS, COX-2 inhibition, phosphoinositide stimulation, and inhibition of NF-κb. By decreasing NF-κb, corticosteroids decrease NO production via iNOS. Corticosteroids involve both genomic and non-genomic effects after activation of its nuclear receptor [16].

Adrenal insufficiency has not been formally assessed during cardiogenic shock. However, during severe trauma and haemorrhagic shock, limited retrospective studies reported a significantly higher mortality, longer hospital, and intensive care lengths of stay, and fewer ventilator-free days in untreated adrenal-insufficient patients [17].

Modifications of catecholamine signalling

During the early hyperkinetic phase of septic shock, myocardial α_1-adrenoreceptors are externalized to the sarcolemma, but are internalized during the late hypokinetic phase. Peroxynitrite decreases the number of α_{1a}- and α_{1d}-adrenoreceptors without altering their affinities and also inhibits the increase in intracellular calcium normally stimulated by norepinephrine.

Catecholamine signalling has been less studied during haemorrhagic or cardiogenic shock. Prolonged ischaemia can result in a 'no reflow' phenomenon with intense vasoconstriction at the early stage of reperfusion completely impeding blood flow, resulting in vascular damage and catecholamine hyporesponsiveness.

Myocardial dysfunction during shock

Septic shock

Myocardial dysfunction, a frequent (30–70%) complication of septic shock, is characterized by reversible biventricular systolic and diastolic dysfunction. Many factors contribute to cardiac depression at both supracellular and cellular levels, although reduced coronary blood flow is not contributory. The sepsis-related increase in plasma troponin is not related to necrosis, but possibly to transient pro-inflammatory cytokine-related increases in cardiomyocyte membrane permeability [18]. Circulating myocardial depressant factors (e.g. IL-1, IL-6, TNFα) probably explains the myocardial depression observed during initial sepsis. However, cardiac performance remains altered over 7 days, whereas cytokine levels normalize within 48 hours. Therefore, intrinsic impairments of cardiac muscle probably participate in prolonged cardiac impairment:

- Beta-adrenergic receptors and beta-agonist efficacy are decreased during late septic shock in humans [19].
- Decreased cardiomyofilament calcium sensitivity likely plays a major role [20].
- Excess peroxynitrite decreases ventricular contractility by depressing mitochondrial function and by inducing calcium flux abnormalities [7].

Ischaemia reperfusion

Ischaemia reperfusion during cardiogenic or haemorrhagic shock may contribute to transient cardiac dysfunction. During the no-flow phase, prolonged ischaemia leads to a decrease in ATP synthesis, plasma membrane depolarization and activation of voltage-dependent calcium channels. The sarcolemma releases calcium into the cytoplasm, and this is responsible for myocardial cellular damage and contractile dysfunction.

Reperfusion, subsequent to resuscitation, induces major cytotoxicity with the formation of reactive oxygen species, which, in

turn, inactivates cytochromes and damages cellular membranes. Reperfusion is also associated with endothelial damage and an acute pro-oxidant state leading to production of pro-inflammatory cytokines, adhesion molecules and complement activation. These processes extend the myocardial dysfunction.

Conclusion

The classification of shock states is traditionally driven by typical haemodynamic assessment. However, this pragmatic approach remains part of the pathophysiological process. Clinicians must be aware that, in the latter stages, cardiovascular hyporesponsiveness is not only a consequence of shock aetiology, but is also secondary to the shock-induced pro-inflammatory process.

CHAPTER 150

Diagnosis and management of shock in the ICU

Antoinette Spevetz and Joseph E. Parrillo

Key points

- If the underlying process leading to shock is corrected quickly and circulating volume is restored in a timely fashion, the progression of shock can be reversed.
- Despite different causes of shock there is a common pathway that involves similar biochemical and metabolic pathways, such that the cardiovascular system is unable to cope with the insult.
- The body has the capability to autoregulate over a wide range of blood pressures (mean arterial pressure 50–150 mmHg).
- Shock affects multiple organs in the body. These effects may or may not be reversible depending upon the duration of the shock state.
- Shock may not be recognized initially based upon vital signs and common physiological parameters. Lactate production seems to be a better marker for the recognition of shock.

Introduction

The word 'shock' used in everyday conversation usually refers to an emotional reaction to a stressful situation. In medicine 'shock' refers to a disease state that describes the body's response to a stressful situation. It is more specifically defined as inadequate tissue perfusion resulting in cellular injury. For varying reasons, the tissues do not receive enough oxygen and nutrients to function normally. This can ultimately lead to cell death that can progress to organ failure and, finally, death of the individual if left untreated for an extended period of time.

Inadequate organ perfusion and tissue oxygenation must be recognized early on in the patient's course. Delay in diagnosis and management can eventually lead to a point of no return. Vital signs and traditional measures of illness are often not sensitive enough to make an early diagnosis. The presence of acidosis and an elevated serum lactate as a measure of cellular perfusion may be a better marker of serious pathology [1].

The intensivist must be well versed in the management of shock as this is a frequent cause of death. Cardiogenic, hypovolaemic, and septic shock are commonly seen in the ICU, and are associated with other comorbidities, such as infection and multiple organ dysfunction.

The purpose of this chapter is to give an overview of the types of shock, the underlying mechanisms, and a brief discussion regarding management of each type of shock, details of each will be discussed elsewhere in the book. Shock is often the final common pathway through which a patient experiences cardiovascular collapse and subsequent death. The manner in which the patient arrives at this point varies with the disease process. However, the final common pathway focuses on microvascular dysfunction, cellular injury, oxygen supply dependency, and compensatory responses.

Mechanisms of shock: pathogenesis and organ response

While there are different aetiologies of shock, most involve similar biochemical and metabolic pathways. In essence, the cardiovascular system cannot adapt to an insult regardless of the aetiology, such that cardiac output (CO) and blood pressure (BP) are compromised.

BP depends upon CO and systemic vascular resistance (SVR). The brain and heart are able to autoregulate blood flow over a wide range of BPs (mean arterial pressure (MAP) 50–150 mmHg) [2]. Hence, a MAP that falls below this range indicates a severe reduction in CO. Blood flow to organs may be affected by microvascular regulation to maintain blood flow to those organs requiring the highest metabolic activity.

Organ blood flow depends upon the maintenance of BP within defined ranges that vary from organ to organ. Good autoregulation exists between mean pressures of 60–100 mm Hg in the context of normal physiology [3].

Autoregulation of blood flow occurs through two mechanisms. Changes in neurovascular tone are mediated through endothelial stretch receptors, such that as perfusion falls there is an opposing increase in vascular resistance so that overall perfusion is maintained. Additionally, the increased metabolic activity in the tissue causes an increase in CO_2 and H^+, resulting in vasodilatation and increased perfusion.

During periods of shock the autoregulatory response of most vascular beds are overwhelmed. Blood flow to the vital organs of the heart and brain are preserved due to dominant autoregulation of flow. The brain and heart have high metabolic rates, and a low storage of substrate. Neither will tolerate ischaemia for long. Flow to other organs falls secondary to the decrease in CO as organ SVR increases to maintain BP [4]. This adaptation of the body preserves blood flow to vital organs with just a mild drop in CO. If the insult continues, organ failure, and death can ensue. Even with resuscitation the abnormalities of the microvasculature can persist for days.

Shock is also associated with disruption of the endothelial cell barrier integrity, which maintains oncotic pressure within the circulatory space. With this loss, oncotic pressure falls, interstitial oedema develops and circulating volume decreases. Microthrombi may also occur, leading to further endothelial cell injury.

Cellular response

As the interstitial transport of nutrients is impaired, there is a fall in intracellular high energy phosphate (adenosine triphosphate, ATP) stores. This leads to the accumulation of hydrogen ions, lactate, and other by-products of aerobic metabolism. As shock progresses these metabolites reduce vasomotor tone and further hypotension ensues [5].

Cellular ischaemia occurs as a result of supply dependence on oxygen and the imbalance between supply of oxygen and the demands of the tissues. The critical value seems to be 8–10 mL oxygen/min/kg body weight. In the shocked patient there is a pathological oxygen supply dependency.

Inflammatory mediators (including cytokines, platelet-activating factor, leukotrines, prostaglandins, and thromboxanes) lead to inadequate perfusion or can cause direct cell injury to the cells in a number of organs, through causing transmembrane ion gradient dysfunction. Typically, release of inflammatory mediators is beneficial to the host by increasing blood flow to damaged tissues and activating host defences. In sepsis, the response becomes excessive and unregulated. Free radicals develop after ischaemia and reperfusion, which can then inactivate proteins, damage DNA, induce lipid peroxidation, and lead to tissue injury and cell death. Apoptosis can occur as heat shock proteins, interfere with synthetic pathways, and initiate programmed cell death.

Compensatory mechanisms in shock attempt to maintain effective tissue perfusion. This is achieved via stimulation of the sympathetic nervous system, release of hormones such as angiotensin II, norepinephrine, epinephrine, and vasopressin, and by enhancing the unloading of oxygen. This compensation is effective for a period of time, but then becomes overwhelmed by the ongoing shock process with subsequent tissue damage.

Manifestations of shock

Multiple organs can be affected in shock states. This diffuse damage may lead to multiple organ dysfunction.

Central nervous system

Cerebral perfusion is impaired in shock, but flow remains relatively well preserved until the MAP is <50–60 mmHg [6]. The cerebral cortex is the area most sensitive to ischaemia. Prior to this the patient may have an altered level of consciousness ranging from confusion to coma.

Heart

Sympatho-adrenal stimulation causes an increase in heart rate that may lead to supraventricular tachycardia or ventricular ectopy in the setting of ischaemia. Just like the brain, the blood supply to the heart is autoregulated making it resistant to sympathetically-driven vasoconstriction and hypoperfusion injury from shock.

Contractility is increased in most forms of shock. Hypotension is associated with decreased coronary artery perfusion pressure, which may lead to ischaemia in patients with coronary artery disease. Circulating myocardial depressant factors are seen in sepsis, haemorrhagic and cardiogenic shock [7,8].

Respiratory system

Patients may have an increased minute volume, hypocapnia, and a respiratory alkalosis. An increase in the work of breathing, plus respiratory and diaphragmatic muscle impairment from hypoperfusion may lead to respiratory failure. They may also develop an acute respiratory distress syndrome with fibrin-neutrophil aggregates in the pulmonary microvasculature, inflammatory damage to the interstitium and alveoli, and exudation of proteinaceous fluid into the alveolar space. As the work of breathing increases, respiratory muscles may fatigue and result in respiratory failure.

Kidneys

Acute renal failure increases mortality by 35–80% in the setting of shock [9]. Urine output initially decreases, followed by a rise in blood urea nitrogen and creatinine that occurs over the next few days. The kidney is moderately autoregulated maintaining glomerular perfusion by increasing efferent arteriolar tone. Cortical followed by medullary ischaemic injury occurs late in shock.

Gastrointestinal system

The splanchnic circulation is highly sensitive to sympathetic vasoconstriction. Ileus, gastritis, pancreatitis, acalculous cholecystitis, and colonic submucosal haemorrhage can be seen. Ischaemia of the gut can lead to translocation of bacteria from the gut to the circulation [10].

Similarly, the liver may exhibit elevated transaminases and LDH. These usually peak in 1–3 days and then resolve. Synthetic function of prealbumin, albumin, and hepatic coagulation factors are affected and evidence of biliary stasis can be seen.

Haematological

Septic shock causes disseminated intravascular coagulation (DIC) by activation of coagulation and fibrinolysis cascades. Differentiation of DIC from sepsis can be done by measuring the plasma Factor VIII level, which is normal or increased in hepatic dysfunction. Thrombocytopenia, which is often dilutional, is commonly seen following resuscitation [11].

Metabolic

Hyperglycaemia is most commonly seen in shock states resulting from decreased insulin release. Additionally, epinephrine release results in skeletal muscle insulin resistance in order to preserve glucose for the heart and brain. Another common metabolic derangement is increased protein catabolism resulting in a negative nitrogen balance.

Immune system

Immune dysfunctions probably contributes to late mortality of the patient with shock. The mucosal barrier of the colon and gut may be disrupted, leading to translocation of bacteria. There is also inflammation, ischaemia, and free radical injury, as well as dysfunction of the cellular and humoral immune system.

Drugs used in resuscitation may also play a role. For example, dopamine suppresses pituitary production of prolactin, which

then suppresses T cell proliferative responses [12]. This immunological dysfunction may contribute towards the ultimate mortality of patients late in their course from ongoing or new sources of infection.

General approach to treatment

Shock is a life-threatening emergency that must be recognized immediately and aggressive therapy initiated. While early diagnosis of the aetiology of the shock is important, studies often cannot be done immediately due to the patient's severity of illness and the inability to be safely transported.

Shock patients typically present with hypotension, tachycardia, tachypnoea, and oliguria. Extremities are cool and may become mottled. The patient may have an altered mental status. There may be clues to differentiate among the aetiologies of shock. Cardiogenic shock patients have jugular venous distension, S3 and S4 heart sounds, and regurgitation murmurs. With pulmonary embolus, patients have hypoxaemia, dyspnoea and elevated right heart pressures. Cardiac tamponade has pulses paradoxus and distant heart sounds. Septic shock patients have fever, chills, and usually a nidus of infection.

The immediate goals in shock are to restore BP and circulating volume. Goals are to achieve MAP >60 mmHg, CVP >8 mmHg and a cardiac index >2.2L/min/m^2 to maintain oxygen delivery and, hopefully, reverse organ dysfunction.

Types of shock and an approach to management

Hypovolaemic shock

Hypovolaemic shock is characterized by a fall in preload, resulting in decreased filling pressures and a drop in BP. It can be caused by dehydration, haemorrhage, gastrointestinal fluid or urinary losses, or as a result of a decrease in vascular permeability from sepsis. Patients have cool, clammy, mottled skin, tachycardia, hypotension, decreased filling pressures, low urine output, and altered mental status. The severity of hypovolaemic shock depends upon both the amount and severity of the fluid loss. Acute loss of 10% circulating blood volume results in tachycardia and an increase in SVR, but BP is maintained. A loss of 20–25% results in mild hypotension. CO starts to fall and lactate levels start to rise. With a loss of 40% the patient becomes hypotensive with signs of shock indicating tissue hypoperfusion, plus activation of the inflammatory cascade and the risk of widespread cellular damage. Rapid reversal of this process with blood, colloid, or crystalloid is required. The underlying source of the blood or fluid loss must be determined using endoscopy, angiography, CT/MRI, or other means.

Cardiogenic shock

Cardiogenic shock is caused by failure of the heart as a pump and is the most common cause of in-hospital mortality in patients with Q wave myocardial infarction. It can be caused by myocardial, valvular, or other structural abnormalities. There is an increased ventricular preload with increases in ventricular filling pressures and, often, ventricular volume. This results in a fall in BP and cardiac output as a result of the failing pump. Patients have signs of congestive heart failure, an S3 heart sound, elevated neck veins, and peripheral hypoperfusion. Mortality is lower in patients with cardiogenic shock caused by surgically correctable lesions.

In the setting of left ventricular infarction, apart from optimizing fluid loading and administering inotropes, cardiac assist devices, cardiac angiography, and revascularization are options for management. With right-sided infarcts, fluids and inotropes are the mainstay of therapy, and more aggressive haemodynamic monitoring may be necessary to guide therapy. Right ventricular infarction should also be treated with coronary angiography, revacularization, and in certain circumstances, a cardiac assist device. For valvular or mechanical abnormalities, echocardiography, cardiac catheterization, and surgery may be warranted.

Extracardiac obstructive shock

Extracardiac obstructive shock results from obstruction to blood flow in the cardiovascular circuit. Causes include pericardial tamponade, constrictive pericarditis, and pulmonary embolus.

Tamponade and constrictive pericarditis impair diastolic filling of the right ventricle. An increased and equalized right and left ventricular diastolic pressure usually develops. Acute pulmonary embolus results in right heart failure with elevated pulmonary artery and right heart pressures, but with low or normal left heart filling pressures. Other causes of obstructive shock include tension pneumothorax and mediastinal tumours. As with other types of shock, the acuity of the shock impacts on the body's ability to compensate. An acute accumulation of as little as 150 mL of blood in the myocardium can result in immediate tamponade and shock. Conversely, the slow accumulation of 1–2 L of fluid can occur before showing signs of shock.

Management involves rapid diagnosis that can often be made with echocardiography. If pericardial tamponade is diagnosed, percutaneous needle/catheter pericardiocentesis or surgical drainage is needed. In the case of a pulmonary embolus, diagnosis is usually made by CT scanning. Heparinization is initiated and, in the case of profound shock and hypoxaemia, thrombolytic therapy, or catheter or surgical embolectomy should be considered.

Distributive shock

Distributive shock is defined by a loss of peripheral resistance with an overall decrease in SVR. Septic shock is the leading example, but other examples include anaphylaxis, drug overdose, neurogenic insults, and Addisonian crisis. Fluid leaks from the microvasculature leading to inadequate intravascular volume and decreased preload. Volume resuscitation improves the preload. Characteristically, a normal or elevated CO, normal stroke volume, and tachycardia are seen, as well as hypotension. However, myocardial depression is also seen which is characterized by decreased stroke work in response to volume loading, plus a biventricular reduction in ejection fraction, and ventricular dilatation. This ventricular dilatation is probably an attempt to compensate for the depressed ejection fraction and maintain stroke volume.

Treatment involves identification of the source of infection, if possible, with drainage or surgery. Prompt initiation of appropriate antibiotic therapy, fluid resuscitation, and vasopressors (norepinephrine is favoured) or inotropes as needed, should be performed to optimize blood pressure and cardiac index using a sepsis protocol. Most patients with severe sepsis will also require ventilator support for respiratory failure.

Anaphylactic shock

Anaphylactic shock is a type of distributive shock caused by release of mediators from mast cells and basophils. It is an immediate hypersensitivity reaction mediated by interaction between the antibodies on the surface of mast cells and basophils with the appropriate antigen. It can be triggered by insect envenomations, drugs, particularly antibiotics and, less frequently, heterologous serum, blood transfusions, immunoglobulin, and egg-based vaccines. Anaphylactoid reactions result from direct non-immunological release of mediators from mast cells and basophils, and can also lead to shock. They can be caused by ionic contrast media, opiates, protamine, dextran and hydroxyethyl starch, muscle relaxants and anaesthetic agents.

Haemodynamic features of anaphylactic shock are similar to septic shock with hypovolaemia and myocardial depression. In addition to the typical findings of shock, they may have urticaria, angioedema, laryngeal oedema and severe bronchospasm.

Treatment consists of stopping or removing the offending agent, and administration of epinephrine either subcutaneously or via infusion for haemodynamic instability, plus appropriate management of other complications, such as bronchospasm and laryngospasm. Other useful agents are steroids, benadryl, and H_1 and H_2 blockers.

Neurogenic shock

Neurogenic shock involves loss of peripheral vasomotor control secondary to injury or dysfunction of the nervous system. Examples include shock associated with spinal injury, as well as vasovagal syncope and spinal anaesthesia. These are usually self-limited and transient. Therapy includes volume repletion and vasoactive support.

Adrenal crisis

Adrenal crisis is uncommon and difficult to differentiate from other types of shock. It is life-threatening, and requires prompt diagnosis and management. It is caused by a deficiency of mineralocorticoids and glucocorticoids. In the critical care setting, it may arise from bilateral adrenal haemorrhage in conjunction with overwhelming infections, such as meningococcal infections or HIV. It may also be seen with anticoagulation, fungal infections, and malignancy. In the ICU it is not uncommon to see an inadequate adrenal response leading to hypotension.

Symptoms of adrenal insufficiency are non-specific and may include anorexia, nausea, vomiting, diarrhoea, abdominal pain, myalgia, joint pains, headaches, weakness, confusion, and delirium. Fever and hypotension are usually present.

Adrenal crisis is treated by glucocorticoid replacement, and fluid resuscitation as needed. Dexamethasone should be used to avoid interference with the ACTH stimulation test.

Conclusion

Although there are various aetiologies for shock there is a final common pathway. Early and aggressive intervention in the underlying disease state can result in an improved outcome for the patient.

PART 5.6

Cardiac failure

CHAPTER 151

Pathophysiology and causes of cardiac failure

Alexandre Mebazaa and Mervyn Singer

Key points

- Organ congestion upstream of the dysfunctional left and/or right ventricle, with preserved stroke volume, is the most frequent feature of myocardial failure.
- Clinical manifestations do not necessarily correlate with the degree of left ventricular systolic dysfunction (i.e. left ventricular ejection fraction).
- Systolic and/or diastolic dysfunction may be present; systolic dysfunction usually predominates.
- Pulmonary oedema is related to left ventricular diastolic dysfunction.
- Compensatory mechanisms (within the heart and/or periphery) may prove paradoxically disadvantageous on ventricular stroke work and stroke volume.

Pathophysiology

The most frequent scenario of heart failure is organ congestion upstream of the heart with an adequate stroke volume. In acute coronary syndrome, heart failure may be primarily due to an inadequate stroke volume.

Aetiology

Although high-output failure states exist (e.g. sepsis, hyperthyroidism), the usual situation is pump failure leading to congestion upstream the ventricles with or without a low cardiac output [1]. Ischaemic heart disease and long-standing hypertension are the most common causes of myocardial failure, although other aetiologies affecting muscle function (e.g. cardiomyopathy), valvular function (e.g. stenosis, endocarditis), electrical activity (e.g. bradycardia, tachyarrhythmia), or ventricular filling (e.g. pericardial tamponade) should also be considered (see Box 151.1). Atheromatous coronary artery disease leads to either progressive myocardial ischaemia and damage, or alternatively, an abrupt deterioration, such as that seen following plaque and thrombus formation in acute myocardial infarction. A further scenario is acute decompensation where a chronically dysfunctional heart is subjected to an undue degree of stress, for example, following infection or haemorrhage.

The critically-ill patient may be admitted to the ICU with de novo heart failure, or it may develop from a combination of factors including hypoperfusion, sepsis (where myocardial function is often depressed despite a normal or even high cardiac output), arrhythmias, drugs with undesired negative inotropic properties (e.g. most anti-arrhythmics), and metabolic abnormalities such as hypocalcaemia, pericardial effusion, and endocarditis.

Although an intracellular acidosis is negatively inotropic, myocardial dysfunction is often wrongly ascribed to extracellular (arterial) acidosis. Bicarbonate and equimolar saline have been compared in cardiac failure patients and no benefit was found from arterial pH correction. Patients with severe diabetic ketoacidosis rarely show any evidence of co-existing failure.

Another important distinction, albeit clinically difficult to assess, is to distinguish between a 'hibernating' and a 'stunned' myocardium [2]. In the former, myocardial ischaemia is ongoing, whereas in the stunned myocardium, which often follows an ischaemia–reperfusion injury, blood flow is (almost) fully restored. Both retain a myocardial reserve and have reversible contractile dysfunction. However, with hibernation, an increase in contractile function is at the expense of metabolic recovery and treatment should aim to restore flow to the hypoperfused tissue. Myocardial stunning often requires no treatment and usually recovers spontaneously, although if the patient is compromised, inotropic stimulation can be used without inducing further myocardial damage.

Clinical features

The most frequent clinical features of heart failure in the ICU are acute pulmonary oedema and cardiogenic shock.

Pulmonary oedema

Breathlessness and fatigue are very common symptoms in patients with acute heart failure. Acute pulmonary oedema is frequently seen in patients with a history of chronic heart failure (altered left ventricular ejection fraction and dilated left ventricle) or in patients with a sudden elevation of systolic blood pressure (preserved left ventricular ejection fraction and altered left ventricular diastolic dysfunction). In those with a more chronic history of heart failure, dyspnoea is often present for several days prior to presentation and is associated with body weight gain. In cases related to sudden increases in blood pressure, pulmonary oedema is often associated with no increase in body weight.

Cardiogenic pulmonary oedema formation occurs as a consequence of raised pulmonary venous pressures leading to an increase in hydrostatic pressure. Increased pulmonary capillary permeability has been reported after myocardial infarction. Removal of

Box 151.1 Causes of heart failure

Overload

- **Pressure**: e.g. hypertension, aortic stenosis, aortic coarctation.
- **Volume**: e.g. excess intravascular fluid, oligoanuric renal failure, valvular regurgitation (such as endocarditis), congenital left-to-right shunts, high output states (e.g. beriberi, hyperthyroidism).

Abnormal filling

Mitral stenosis, atrial myxoma, restrictive cardiomyopathy, pericardial tamponade, constrictive pericarditis, pulmonary embolus, arrhythmias.

Loss of myocardial contractility

- **Partial**: e.g. coronary artery disease (focal infarction/ischaemia).
- **Generalized**: e.g. widespread atheroma, dilated cardiomyopathy, myocarditis, malnutrition, drugs/poisons, (e.g. β-blockers, alcohol), sepsis, metabolic (e.g. hypocalcaemia).

interstitial oedema is predominantly via the lymphatics. In chronic failure states, lymphatic clearance levels are raised considerably. However, in the acute situation, the lymphatics may take several days to reduce extravascular lung water and improve the radiographic appearance. The presence of pulmonary oedema bears no relationship to intravascular volume and such patients should not be automatically assumed to be fluid overloaded.

Interstitial oedema is erroneously considered to be the predominant reason for dyspnoea in heart failure. Other factors include attempted respiratory compensation for the concurrent metabolic acidosis, respiratory muscle fatigue secondary to hypoperfusion, arterial hypoxaemia arising from a low SvO_2, anxiety, and/or pain, and pulmonary venous engorgement leading to activation of afferent stretch receptors.

Right ventricular failure, which also frequently occurs in chronic heart failure, is another cause of dyspnoea in acute heart failure due to a diminished cardiac output. Right ventricular congestion induces leg oedema, turgescent jugular veins, and hepatomegaly; it also induces alterations in kidney function with or without oliguria.

Cardiogenic shock

In acute myocardial infarction, pump failure may produce symptoms at rest, with evidence of impaired organ perfusion (oliguria, confusion, drowsiness) and/or lung congestion. Cardiogenic shock refers to the situation where oxygen supply by the heart is inadequate to prevent significant tissue hypoxia. This term is usually applied in error to describe a co-existing hypotensive state that need not be present.

Mechanisms of ventricular failure

With decompensated chronic heart failure, systolic and diastolic dysfunction often co-exist, although the systolic component usually predominates (see Fig. 151.1). This relates to impaired ventricular contractility and a defective ability of the myofibrils to shorten

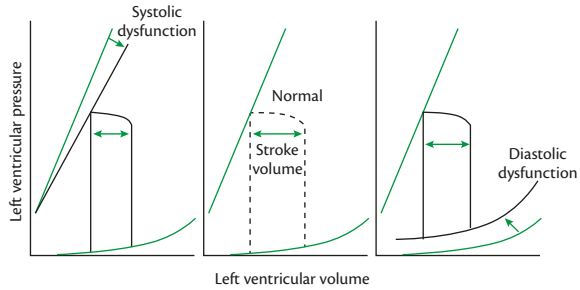

Fig. 151.1 Effects of systolic and diastolic dysfunction on the ventricular pressure–volume curve.

against a load with a consequent decrease in ejection fraction. The ventricle lies on a flatter left ventricular function curve (see Fig. 151.2) and, consequently, the ability to increase stroke volume by an increase in preload is impaired. The ventricle is particularly sensitive to increases in afterload.

In cases of pulmonary oedema associated with sudden elevations in blood pressure, left ventricular diastolic dysfunction predominates despite a relatively normal ejection fraction and ventricular size. The fundamental process underlying this syndrome is a progressive decrease in ventricular compliance, resulting in marked increases in filling pressures at relatively normal end-diastolic volumes (see Fig. 151.1). This abnormal pressure–volume relationship is related to changes in active relaxation during the initial phases of diastole and/or passive compliance during the slow-filling phase. Depending on the ventricle affected, rises in pressure will produce systemic and/or pulmonary venous congestion and interstitial oedema. Compared with systolic dysfunction, there appears to be a lower sensitivity to increases in afterload and compensatory neuroendocrine activation is probably less marked. With decreases in compliance there is a progressively limited ability to respond positively to a fluid challenge (see Fig. 151.3).

Diastolic dysfunction is more common in the elderly (up to 40% of patients). Aetiologies include recurrent ischaemia, hypertrophic cardiomyopathy, hypertension, and aortic stenosis. The response to standard failure therapy is generally worse in patients with predominant diastolic dysfunction.

One or both ventricles may be primarily affected by the underlying disease process. While symptoms and signs of systolic dysfunction are similar for both left and right ventricles, diastolic dysfunction affecting the left heart produces pulmonary oedema

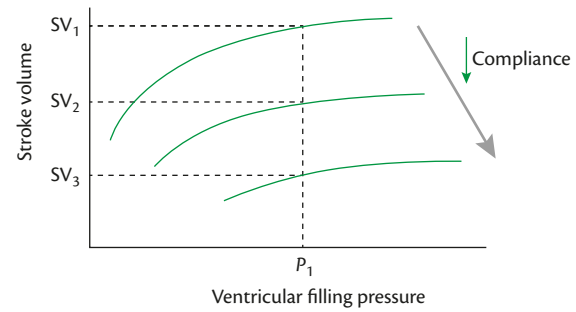

Fig. 151.2 Effect of progressive reductions in ventricular compliance on ventricular function curves. If blood pressure remains constant, a similar end-diastolic pressure will generate progressively lower stroke volumes as compliance decreases.

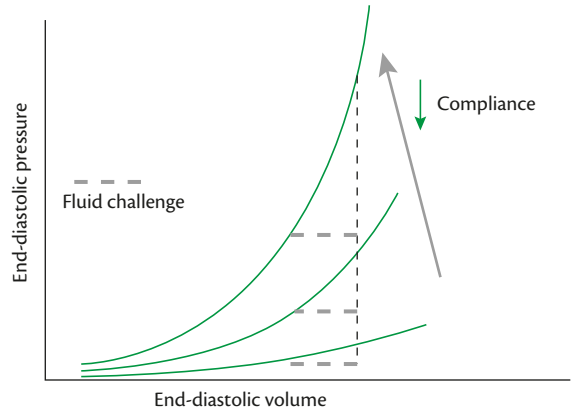

Fig. 151.3 Ventricular end-diastolic pressure–volume relationship. As compliance decreases, an increase in end-diastolic volume by a fluid challenge will generate a much higher increase in end-diastolic pressure. This can lead to venous congestion and oedema.

and, for the right heart, liver and kidney congestion, and dependent peripheral oedema. A diseased ventricle will often impact upon the functioning ventricle (e.g. septal shift, increased pulmonary vascular resistance).

At the cellular level there appear to be abnormalities in cytosolic calcium handling, myofilament sensitivity to calcium, myocyte energetics, and phosphodiesterase and adenyl cyclase production/activity. Other changes include down-regulation of both $ß_1$- and $ß_2$-adrenergic receptors and possible uncoupling of these ß-adrenoreceptors from adenylate cyclase. Alterations in the activity and/or number of myocyte enzymes and transport channels involved in the excitation–contraction coupling mechanism are also implicated in many of the processes described.

Compensatory mechanisms in low cardiac output states

Heart ventriculo-arterial coupling

In low-output failure the cardiac output is often maintained by increases in heart rate, chamber size and muscle mass. Stroke volume usually falls unless severe bradycardia is present. Acute compensation occurs via sympathetic activation of heart rate. However, over days to weeks, progressive ventricular dilatation increases end-diastolic volume, thereby helping to maintain stroke volume in the face of a falling ejection fraction. By the Laplace law, dilatation will increase systolic wall stress; this is partially offset by a remodelling process in which functioning myofibres hypertrophy. The resultant increase in muscular mass permits an increase in cardiac work, although not at the expense of wall stress. Hypertrophy is a slow compensatory process that will nevertheless adversely affect diastolic function, ventricular compliance, and the end-diastolic pressure–volume relationship.

The left ventricle can be considered an elastic chamber that periodically increases its volume elastance V_e to a value equal to the slope of the relationship between end-systolic pressure and end-systolic volume. The arterial load property is measured as arterial elastance E_a, i.e. the slope of the relationship between arterial end-systolic pressure P_{es} and stroke volume. The end-systolic elastance E_{es} varies in response to ventricular contractility, while P_{es} varies inversely with stroke volume SV for a given end-diastolic volume V_{ed}:

$$P_{es} = E_{es}\left(V_{ed} - SV - V_0\right) = E_{es}\left(V_{es} - V_0\right) \qquad \text{[eqn 1]}$$

where V_0 is a constant reference volume.

The ventricle produces maximal external work to the arterial load when the ventricular and arterial elastances are equalized [3]. In normal subjects, the ventricular elastance is nearly twice as large as arterial elastance, thereby affording maximal efficiency. However, in moderate heart failure, the two elastance values are almost identical, thereby maximizing stroke work from a given end-diastolic volume, but at the expense of work efficiency. Finally, in severe failure, ventricular elastance is less than half arterial elastance values, resulting in increased potential energy, and an inability to maintain either stroke work or work efficiency properly.

Peripheral

In response to inadequate stroke volume, neuroendocrine activation leads to vasoconstriction and, in the longer term, salt and water retention. Vasoconstriction is mediated via sympathetic and renin–angiotensin pathways, redistributing blood flow away from cutaneous, splanchnic, and muscular beds to more 'vital' organs, such as brain and heart. Venous tone also increases, enhancing venous return. While vasoconstriction is an appropriate response to haemorrhage and hypovolaemia, it is often deleterious in heart failure as myocardial work and function are adversely affected. The body initially attempts to compensate by raising circulating levels of atrial natriuretic peptide and adrenomedullin that enhance natriuresis and vasodilatation. However, over time, salt and water retention will predominate. This is primarily mediated by increased secretion of aldosterone and, to a lesser extent, antidiuretic hormone.

The negative consequences of these compensatory mechanisms include:

- A progressive decrease in renal blood flow and the potential development of renal dysfunction [4].
- Pulmonary and systemic interstitial oedema which may worsen oxygenation and symptoms.
- A further fall in ventricular compliance and an increase in cardiac work, placing greater strain upon an already damaged heart.

Thus, increased ventricular stiffness will result from pathophysiological processes, occurring either as a direct consequence of heart failure or secondary to the body's compensatory mechanisms. Ischaemia, ventricular hypertrophy, excessive afterload or preload, or an inadequate preload with compensatory vasoconstriction will all contribute, as will misguided treatment regimens, such as excessive diuresis. For the same end-diastolic pressure, a less compliant ventricle on a flatter ventricular function curve will generate a much lower stroke volume (see Fig. 151.2). This underlines the potentially catastrophic consequences of afterload increases, the therapeutic importance of optimizing compliance, and the problems inherent in an over-reliance on pressure measurements (central venous pressure, pulmonary artery wedge pressure) to the exclusion of volume or flow. It further illustrates how a vicious downward spiral is actually facilitated by the body's attempts at correction.

Biomarkers

In patients admitted in the emergency department or in the intensive care unit (ICU) with acute dyspnoea, therapy should be started promptly. Together with the clinical signs, the level of plasma natriuretic peptides discriminate acute heart failure from acute dyspnoea related to other causes. In addition, natriuretic peptides measured at admission allow the prediction of outcome.

Other biomarkers or organ dysfunction should also be measured in case of myocardial failure—troponin (myocardial ischaemia), renal biomarkers, or liver function tests.

CHAPTER 152

Therapeutic strategy in cardiac failure

Alexandre Mebazaa and Mervyn Singer

Key points

- In hospital mortality from acute cardiogenic shock remains in the order of 40–60%.
- Management of pulmonary oedema comprises non-invasive ventilation, large doses of vasodilators and small dose of diuretics.
- The oxygen supply–demand balance should be optimized within both the myocardium and the body as a whole. Therapy should be aimed at both decreasing demand and increasing supply.
- This can be achieved through judicious use of drug, fluid, and mechanical support therapies.
- A considerable improvement in the outcome of cardiogenic shock can be obtained with an aggressive regimen of myocardial revascularization, drug therapy with appropriately targeted monitoring and, if needed, a cardiac assist device or other organ support.

Introduction

The 1-year mortality for patients admitted with dyspnoea related to acute heart failure is approximately 20%. However, acute cardiogenic shock generally carries a hospital mortality in the order of 40–60%, although recent data suggest a considerable improvement with an aggressive regimen of myocardial revascularization and, if needed, early use of a cardiac assist device.

The fundamental therapeutic principles of heart failure management are for acute heart failure mainly with signs of pulmonary congestion, normal or high blood pressure, and no signs of low cardiac output to reduce pulmonary congestion without affecting blood pressure.

Management principles of cardiogenic shock management comprise improvement of forward flow with restoration/maintenance of adequate organ perfusion.

Appropriate management requires sound appreciation of the underlying pathophysiology, awareness of the actions and potential side-effects of each therapeutic intervention, and a level of monitoring and investigation sophisticated enough to assess disease severity and the effectiveness (or otherwise) of any treatment being given [1]. Where possible, consideration of previous comorbid factors and chronic symptomatology should guide how aggressive intervention should be. However, these must be based on documented fact, rather than hearsay or supposition. The patient should always be given the benefit of the doubt.

Principles of management

Acute pulmonary oedema

The aim is to improve left ventricular diastolic dysfunction and should focus on reducing left ventricular afterload. Reducing blood pressure will reduce myocardial oxygen consumption and favour (in the case of coronary disease) a mismatch between oxygen delivery and consumption in the endocardial portion of the myocardium. Heart rate should be maintained as low as possible.

Low cardiac output

The aim is to maintain an adequate oxygen supply–demand balance within both the myocardium and the body as a whole. A decrease in cardiac output relative to the body's oxygen requirements is manifest as symptoms of poor forward flow, for example weakness, fatigue, oligoanuria, confusion, drowsiness, and tachypnoea secondary to metabolic acidosis. Thus, therapy should be aimed at both increasing supply and decreasing demand (see Box 152.1).

Reducing demand

Reducing both myocardial and total body oxygen requirements is beneficial to the failing heart by lowering the cardiac work demanded of an already compromised and dysfunctional myocardium. This can be achieved pharmacologically by optimizing pre- and afterload, and thus ventricular compliance. Such measures include appropriately monitored fluid challenges, vasodilators, and, in the relatively unusual situation of intravascular volume overload, diuretics. Mechanical support devices are also effective; these include early mechanical ventilation, which rests the heart by reducing pre- and afterload, maintaining normoxaemia, and removing the work of breathing; 30–40% of cardiac output may be required purely to support the work of breathing in a dyspnoeic subject. Respiratory muscle fatigue leading to hypercapnia is a prelude to cardiorespiratory collapse.

Total body oxygen consumption can be reduced further by alleviation of pain or anxiety. This is achieved by psychological support in addition to adequate analgesia (usually opiates that also have intrinsic vasodilating and anxiolytic properties).

Increasing supply

Apart from reducing cardiac work, optimizing pre- and afterload also enhances forward flow. Additional augmentation can be achieved by inotropic agents, although usually at the expense of

Box 152.1 Achieving an adequate oxygen supply–demand balance

Decreasing the demand

- Sedation, pain relief.
  - **Mechanical ventilation**: permits heavier sedation and removes the work of breathing.
- Reduction in pyrexia (e.g. by antipyretics, tepid sponging).

Increasing the supply

- **Oxygen**: FiO_2 0.6–1.0 to maintain (near) complete arterial oxygen saturation.
- **Blood transfusion**: the optimal figure is still contentious. A haemoglobin level of 10–12 g/dL is a reasonable compromise between oxygen carriage and microcirculatory flow.
- **Optimization of pre- and afterload**:
  - *If fluid overloaded (rare)*—venodilatation + diuretics to optimal stroke volume.
  - *If hypovolaemic*—fluid challenge to optimal stroke volume.
  - *If vasoconstriction persists* (SVR > 1400 dyn s/cm^5)—arterial dilatation through a combination of dilator + fluid may be necessary.
- **Inotrope administration**: inotropes increase cardiac work and place additional stress on an already diseased heart, so should ideally be used after pre-/afterload optimization when an inadequate organ perfusion and/or blood pressure remains.
- **Mechanical ventilation + PEEP**: positive-pressure ventilation + additional PEEP will often augment cardiac output in heart failure states by preload and left ventricular afterload reduction.
- **Intra-aortic balloon counterpulsation**:
  - Improves forward flow, augments coronary perfusion, and reduces afterload.
  - Its outcome benefits are still debatable.
- **Correction of any anatomical abnormalities**: e.g. valve replacement, pericardiocentesis.
- **Other cardiac assist devices**: no large randomized trials have been performed. There are suggestions of benefit in case series of patients with reversible causes of myocardial dysfunction, e.g. viral myocarditis, or as a bridge to surgery (including transplantation).

increased cardiac work. Mechanical supports such as intra-aortic balloon counterpulsation and ventricular assist devices can also increase output [2].

Achieving adequate perfusion pressure

Despite improving flow, organ function may still remain compromised by an inadequate perfusion pressure. Inotropes, intra-aortic balloon counterpulsation, and for high-output states, vasopressors may be used alone or in combination to elevate perfusion pressure. The ideal perfusion pressure varies between individuals. In general, patients who were not previously hypertensive can often cope with mean systemic blood pressures in the range 60–70 mmHg (or lower), while long-term hypertensives often require higher mean pressures (e.g. 70–80 mmHg). The drawbacks of an excessive blood pressure are an increase in cardiac work and a decreased output.

Relief of symptoms

Tachypnoea results from pain, anxiety, metabolic acidosis, hypoxaemia, and engorgement of the pulmonary vasculature. Management should aim at providing analgesia and anxiolysis, improving organ perfusion, and reducing pulmonary venous pressures, with supplemental high-flow oxygen administration. This strategy will often improve symptoms dramatically. Non-invasive ventilatory support, for example, continuous positive airways pressure (CPAP), may also be useful. Pain relief is provided by adequate analgesia and improved coronary perfusion. Symptoms of poor forward flow (e.g. confusion, oliguria, fatigue, respiratory failure) are relieved by improving organ perfusion.

Investigation and monitoring

While 'first-aid' therapeutic measures are being implemented, continuous ECG and pulse oximetry monitoring, and frequent sphygmomanometric blood pressure measurements should be commenced.

Early and prompt invasive monitoring of cardiovascular function should be instituted, not only in the severely-ill patient, but also in those patients who are either deteriorating or responding poorly to initial therapy. This usually consists of arterial cannulation for continuous measurement of systemic blood pressure and intermittent blood gas analysis, bladder catheterization for hourly measurement of urine output (mostly for cases of low cardiac output), and in the more severe cases, more sophisticated haemodynamic monitoring including, e.g. stroke volume, intracardiac pressures, and mixed venous oxygen saturation, with calculation of systemic and pulmonary vascular resistances.

Urgent investigations include the following: 12-lead (and sometimes right-sided) electrocardiography to diagnose any rhythm disturbances, evidence of infarction (new or old), or ongoing ischaemia (ST-segment depression, T-wave inversion). Cardiac enzymes to indicate recent infarction and, perhaps, prompt urgent thrombolysis with or without angioplasty or surgical revascularization.

Echocardiography should be performed for any patients admitted with myocardial dysfunction and haemodynamic instability. It will detect structural defects including heart chamber and wall dimension abnormalities (including the presence of right heart failure that may be very difficult to detect based on clinical signs alone), valvular disorders, septal defects, pericardial effusion, and segmental wall motion irregularities.

Chest radiography ± computed tomography (CT) scans should seek abnormalities suggestive of specific disorders, such as pneumothorax, aortic aneurysm, and pulmonary embolus.

Markers of severity

A greater degree of heart failure is suggested by progressive dyspnoea, obtundation, hypotension, oliguria, and cyanosis. Biochemical markers of severity include a metabolic acidosis with

associated hyperlactataemia. A low stroke volume and mixed venous oxygen saturation below 60% are additional indicators of poor cardiac performance and inability to meet tissue oxygen demands. Pulmonary artery wedge pressures and central venous pressures are not necessarily elevated.

Treatment

Heart failure should be treated swiftly. The presence of any marker of severity as outlined previously should prompt a more aggressive and interventionist approach to both monitoring and therapy. Aetiology can usually be ascertained rapidly from history, examination, and investigations including electrocardiography, chest radiography, echocardiography, CT scanning, and biochemistry (cardiac enzymes, troponin, B-type natriuretic peptide). Specific diagnoses warrant specific treatments, for example, angioplasty or thrombolysis for myocardial infarction (unless contraindicated), anti-arrhythmics or cardioversion for any compromising arrhythmia, pericardiocentesis for tamponade, and valve replacement for significant valvular stenosis.

Pulmonary oedema

In the prehospital, emergency department or intensive care unit (ICU) setting, oxygen therapy and non-invasive ventilation should be rapidly commenced. Vasodilators (nitrates IV) ± diuretics (<1 mg/kg intravenous furosemide) should also be started promptly [3].

Vasodilatation is desirable and can be rapidly achieved by four sublingual puffs of glyceryl trinitrate (nitroglycerin) spray, resulting in prompt symptomatic relief. This can be then followed by an intravenous nitrate infusion titrated to optimal effect. A patient presenting with low-output failure and hypotension may be unable to tolerate nitrates unless hypovolaemia has been corrected and obstruction to flow (e.g. pericardial tamponade) excluded. Myocardial function will remain compromised until an adequate perfusion pressure and flow are achieved. This may necessitate the 'blind' use of an inotrope, such as adrenaline (epinephrine), until more sophisticated monitoring can be introduced.

The patient's condition (dyspnoea, respiratory rate, blood pressure, heart rate, urine output) should be monitored closely (at least every 30 minutes) until stabilized.

Directed therapy

This requires instrumentation for monitoring as described previously. Suggested targets, many of which indicate adequate organ perfusion, are given in Box 152.2. No target figures are given for cardiac output, oxygen delivery, or oxygen consumption, as individual variations in the oxygen supply–demand balance are such that, while some patients may remain undertreated, many others will have their myocardium needlessly driven.

Box 152.2 Therapeutic endpoints

- Adequate blood pressure to support adequate organ perfusion.
- Optimization of pre- and afterload to maximize stroke volume.
- Mixed venous oxygen saturation >60%.
- Urine output >0.5 mL/kg/hour.
- Removal of any metabolic acidosis secondary to lactic acid production.
- Removal of any evidence of persisting ischaemia (seen on ECG).

Pharmacological support

The choice of therapeutic agent is dictated by therapeutic benefit, familiarity, and desired pharmacological action. If a drug proves unpredictably detrimental, it should either be substituted by another agent that achieves the required effect, or any hitherto unrecognized problem should be dealt with appropriately. Dobutamine or levosimendan may be used as an illustrative agent for both circumstances—in some patients it may induce excessive vasodilatation and hypotension, and require substitution with epinephrine, whereas generation of tachycardia or tachyarrhythmias implies possible concurrent hypovolaemia requiring volume administration. Familiarity with the drugs being used, and awareness of both their actions and potential side-effects are crucial.

- Oxygen should be administered to ensure an arterial oxygen saturation of 95–98%.
- Pain secondary to ongoing myocardial ischaemia is best treated by nitrates, although opiates are useful for their additional anxiolytic and vasodilating properties.
- Vasodilator agents, such as glyceryl trinitrate, hydralazine, and sodium nitroprusside all have effects on both pre-d and afterload. Significant falls in blood pressure with small doses of the aforementioned imply either hypovolaemia or flow obstruction. Nitrate tolerance develops after 24 hours, with increasing doses required to maintain effect. Cyanide accumulation may develop after 24 hours with sodium nitroprusside usage. It is our preference to commence angiotensin-converting enzyme inhibitors such as captopril at this time, provided that blood pressure and lack of contraindications permit, in rapidly escalating dosage, while slowly weaning the original vasodilator.
- Judicious fluid challenges are often appropriate as the heart failure patient may arrive at the ICU in a hypovolaemic state. The end point is no rise in stroke volume to a 100–200-mL fluid challenge. In the absence of flow monitoring, a rise in central venous or wedge pressure ≥3 mmHg following a fluid challenge is suggestive of an adequately filled intravascular compartment.
- Loop diuretics are often inappropriate and detrimental in the first instance for the reasons described earlier (i.e. causation or exacerbation of prior hypovolaemia). However, they may be indicated in fluid-overload situations, when the patient is on chronic diuretic therapy, and when symptoms or oliguria persist after adequate loading with fluid and angiotensin-converting enzyme inhibitors.
- Inotropes are indicated where low pressure and/or low output result in inadequate organ function. Inotropes with associated vasodilator activity, including dobutamine or levosimendan, may all usefully improve output, although they can occasionally produce excessive falls in blood pressure.
- Pressors are rarely indicated, although noradrenaline (norepinephrine) is occasionally needed to generate a blood pressure sufficient to perfuse the organ; it should only be used in case of low blood pressure.

Mechanical support

For the reasons described in the previous list, positive-pressure ventilation with or without positive end-expiratory pressure (PEEP), CPAP, and venticular assist devices may be useful adjuncts to treatment. In particular, mechanical ventilation is a much underestimated support mode. A large study in cardiogenic shock complicating acute myocardial infarction however failed to show any outcome benefit.

CHAPTER 153

Intra-aortic balloon counterpulsation in the ICU

Alain Combes and Nicolas Bréchot

Key points

- A recent large randomized study showed that intra-aortic balloon pump (IABP) did not impact upon the outcome for patients with cardiogenic shock complicating acute myocardial infarction.
- The IABP has been downgraded from a Class I to a Class III recommendation in this setting and IIb in case of mechanical complication following myocardial infarction.
- Current data do not support the use of prophylactic IABP during percutaneous intervention (PCI) in ST-elevation myocardial infarction (STEMI) without shock, or for high-risk coronary procedures (class III recommendation).
- Latest data do not suggest a benefit for pre-operative IABP insertion in patients with poor LV function undergoing CABG.
- IABP should not be used in other forms of shock.

Introduction

The intra-aortic balloon pump (IABP) is a mechanical device consisting of a cylindrical polyethylene balloon that sits approximately 2 cm from the left subclavian artery [1]. A computer-controlled console linked to either an electrocardiogram or a pressure transducer inflates the balloon with helium during diastole (counterpulsation). The balloon actively deflates in systole. The resulting effects are an increase in coronary artery blood flow and cardiac output, and reduced left ventricular afterload. These actions combine to decrease myocardial oxygen demand and increase myocardial oxygen supply [2]. Contraindications include severe aortic valve insufficiency, aortic dissection, and severe aorto-iliac artery disease. Major complications include bleeding at the insertion site and retroperitoneal haemorrhage, critical ischaemia of the catheterized leg, catheter infection, and stroke [3–6]. The IABP usually remains in situ from 48 to 72 hours. Weaning from IABP is not well defined. The most common approach is to reduce cycling of inflation to 1:2 or 1:4 for 15 minutes to several hours before device removal [3,7,8].

Results in humans

Cardiogenic shock in the setting of acute myocardial ischaemia

Based on cohort studies and registries [5,9–11], both European and American cardiology society guidelines strongly recommended (level I recommendation) IABP insertion for cardiogenic shock in the setting of acute myocardial ischaemia [12]. However, evidence supporting these recommendations has recently been challenged. In a meta-analysis of cohort studies of STEMI patients with cardiogenic shock, IABP benefit was restricted to patients who had received thrombolysis, while PCI-treated patients had a significantly higher mortality [13]. A meta-analysis of three small randomized studies [5] also produced disappointing results. Despite some improvements in haemodynamic parameters, IABP had no impact on mortality after cardiogenic shock, and was even associated with higher rates of ischaemic and bleeding complications. Lastly, the large (600-patients), randomized IABP-SHOCK II trial [14] recently showed that use of IABP did not significantly reduce 30-day mortality in patients with cardiogenic shock complicating acute myocardial infarction for whom an early revascularization strategy was planned (relative risk with IABP, 0.96; 95% CI, 0.79–1.17; $p = 0.69$). There were no significant differences in time to haemodynamic stabilization, length of stay in intensive care, serum lactate levels, dose and duration of catecholamine therapy, renal function, and rates of major bleeding, peripheral ischaemic complications, sepsis, and stroke. Therefore, given the concordance of data from meta-analyses and the IABP-SHOCK II trial, the routine use of IABP in patients with acute myocardial infarction complicated by cardiogenic shock received only a class III recommendation in the latest international guidelines for the care of cardiogenic shock and IIb in case of mechanical complication [15].

Myocardial infarction without shock and high-risk percutaneous coronary intervention

IABP has been proposed to prevent haemodynamic compromise in high-risk PCI and STEMI without cardiogenic shock. However, several small randomized studies found no benefit in this patient population [13]. These results were confirmed in the large CRISP-AMI multicentre trial that randomized 337 anterior STEMI patients without cardiogenic shock to undergo IABP prior to PCI versus PCI alone [3]. Mortality and infarct size estimated by MRI were identical in both groups. Similarly, prophylactic IABP before high-risk PCI in patients with severe left ventricular dysfunction (LVEF <30%) and extensive coronary artery disease, did not decrease the rate of the composite primary endpoint of death, myocardial infarction, stroke and revascularization rate, or 6-month mortality [4]. Furthermore, IABP was associated with more bleeding events and complications at the vascular access site [4]. Thus,

current data do not support the use of prophylactic IABP during PCI in STEMI without shock, or during high-risk coronary procedures (class III recommendation) [12].

Pre-operative IABP in patients undergoing coronary artery bypass grafting

Pre-operative IABP is considered to be the gold standard therapy for CABG surgery in high-risk patients (LVEF<40%, three-vessel artery disease or left main artery stenosis, redo-CABG, or unstable angina) [16]. In a meta-analysis of five single-centre randomized studies, mortality was reduced from 23 to 4% in the pre-operative IABP group (OR 0.18, 95% CI 0.08–0.49, $p < 0.0001$), and the incidence of a low post-operative cardiac output from 59 to 21% (OR 0.14, 95% CI 0.08–0.25, $p < 0.0001$) [17]. However, generalizability of the results of this meta-analysis is limited, as it included studies with limited number of patients, conducted by the same investigator, and in which observed mortality was unexpectedly high in control groups. In another randomized study of 221 high-risk patients undergoing off-pump CABG, pre-operative IABP was also associated with a reduction in mortality rate from 3.8 to 2.6% ($p < 0.05$) low cardiac output syndrome (10.4 versus 18.9%, $p < 0.05$), malignant arrhythmias and acute renal failure [18]. Conversely, in a randomized trial suppressed in 110 high-risk patients undergoing CABG, pre-incision implantation of IABP provided no advantage in term of mortality or severe morbidity [19]. Thus, the body of evidence available to date in favour of pre-operative IABP in patients undergoing CABG appears limited, and implanting an IABP in this setting remains highly controversial.

IABP as an adjunct to non-pulsatile cardiopulmonary bypass and cardiac assistance

Pulsatile flow has been suggested to confer haemodynamic advantages in experimental studies of cardiopulmonary bypass by reducing systemic vasoconstriction and improving systemic perfusion. Two small, randomized single-centre studies suggested that IABP could improve post-operative haemodynamics and organ perfusion in high-risk cardiac surgery patients [18,20]. Using IABP in conjunction with peripheral veno-arterial extracorporeal membrane oxygenation moreover decreases pulmonary capillary wedge pressure, and may help to prevent pulmonary oedema in patients with laminar blood flow (personal data not shown).

IABP during other forms of shock

Several animal studies suggested a potential role for IABP in cardiogenic shock due to right ventricular failure or myocardial dysfunction associated with septic shock. However, evidence to date is too limited to recommend its insertion in these situations.

Conclusion

IABP insertion is now only a class III recommendation in patients with cardiogenic shock complicating acute myocardial ischaemia [15]. Indeed, very recently, the large randomized IABP-SHOCK II trial [14] showed that IABP did not significantly reduce 30-day mortality in patients with cardiogenic shock complicating acute myocardial infarction for whom an early revascularization strategy was planned. The utility of IABP in high-risk patients undergoing CABG surgery is also questioned. Therapeutic strategies for cardiogenic shock patients are evolving rapidly. IABP may no longer be recommended in the near future and research on other mechanical devices should be encouraged to reduce the unacceptably high (40%) mortality rate still observed in patients who develop cardiogenic shock.

CHAPTER 154

Ventricular assist devices in the ICU

Alain Combes

Key points

- Extracorporeal membrane oxygenation (ECMO) is the first-line therapy in the setting of acute cardiogenic shock refractory to conventional treatments.
- The INTERMACS severity classification is used to assess the degree of clinical severity of patients with NYHA class IV symptoms, and helps to define the appropriate timing for ventricular assist device (VAD) insertion.
- VAD indications are as a bridge to recovery, or as a bridge to transplantation and destination therapy.
- Miniaturized axial and centrifugal fully implantable left ventricular assist devices have gradually replaced first-generation intracorporeal pulsatile ventricles.
- The SynCardia® CardioWest® Total Artificial is a biventricular, pneumatic, pulsatile pump that totally replaces the native ventricles, solving the problems of persistent ventricular arrhythmias, right ventricular failure or severe valvular heart disease.

Introduction

Despite major advances in pharmacological therapies for heart failure with left ventricular pump dysfunction, the number of hospitalizations for decompensated heart failure is increasing, with most patients ultimately dying of disease complications. Heart transplantation remains the only treatment providing substantial individual benefit for patients with advanced disease. However, fewer than 3000 organ donors are available worldwide per year, limiting its overall impact. Therefore, alternative approaches such as mechanical circulatory support have been the subject of intense research over recent decades [1–6].

The development of mechanical circulatory devices parallels that of cardiac surgery and cardiac transplantation. The first clinical implantation of a pneumatically-driven ventricular assist device (VAD) was performed by De Bakey in 1966. Since then, collaborative efforts between scientists, engineers and clinicians have resulted in major improvements in the design, biocompatibility, and performance of these machines. Better patient selection and management have also improved outcomes. Traditional indications or strategies for mechanical circulatory support included bridge to bridge, in which a first device is used as a bridge to another long-term machine, bridge to recovery of heart function, bridge to transplantation, and destination therapy. However, current practice and the development of economically affordable short-term devices have resulted in updated indications for mechanical circulatory assistance for both short- and long-term support.

Short-term indications for mechanical support

Rescuing the 'crash and burn' patient, and bridging others to recovery

Short-term mechanical circulatory support devices are indicated in patients with medical conditions (acute myocardial infarction, myocarditis, intoxication with cardiotoxic drugs, end-stage dilated cardiomyopathy), post-cardiotomy or post-transplantation acute cardiogenic shock. Most of these 'crash and burn' patients receive a device as salvage therapy after having already developed signs of multiple organ failure. In these situations, mechanical assistance is used as a bridge to decision-making or to 'whatever seems reasonable' if the patient survives the first days to reach the 'decision-making' point. In patients with potentially reversible cardiac failure (e.g. myocarditis, myocardial stunning post-myocardial infarction), a short-term device may also be used as a bridge to recovery [1].

Devices inserted in such situations are catheter- or cannula-based pumps. The Impella CardioSystem® AG is a catheter-based axial flow pump with a propeller at the catheter tip, which is positioned retrogradely across the aortic valve into the LV. The TandemHeart® is a percutaneous ventricular assist device consisting of an extracorporeal centrifugal continuous flow pump that sucks blood from the left atrium via a cannula introduced trans-septally through the femoral vein. Blood is then pumped back to the femoral artery at flow rates of up to 3.5 L/min. The Levitronix CentriMag® is a continuous-flow, centrifugal-type rotary blood pump placed outside the body (extracorporeally). The pump can rotate at speeds of 1500–5500 rpm and can provide flow rates of up to 9.9 L/min. However, in recent years extracorporeal membrane oxygenation (ECMO) or extracorporeal life support (ECLS) has become the first-line therapy in the setting of acute cardiogenic shock. This is due to its easy insertion, even at the bedside, the higher flow rates provided, and its association with less organ failure after implantation compared with biventricular assist devices.

ECMO as first-line support for refractory cardiogenic shock

The ECMO extracorporeal system (Fig. 154.1) consists of venous and arterial cannulae, polyvinyl chloride tubing, a membrane

(a) Translations of labels:

(b)

Fig. 154.1 (a) and (b) Femoral cannulation for veno-arterial ECMO. An additional perfusion catheter is sometimes inserted distally into the femoral artery to reduce the risk of limb ischaemia. Part of image 154.1(b) has been deliberately blurred.

oxygenator and a centrifugal pump. It provides both respiratory and cardiac support [1]. Using the peripheral veno-arterial configuration, where femoral vein and artery are cannulated percutaneously, the circuit is perfectly suited for emergency situations. It can be inserted in less than 30 minutes, under local anaesthesia, can supply blood flow up to 8 L/min, and is either more efficient and durable or less costly than other first-line devices.

Several considerations must be taken into account before instituting ECMO. First, the device should be inserted before the patient has developed multiple organ failure or myocardial failure has led to refractory cardiac arrest, since these conditions are associated with significantly worse outcomes. Secondly, highly unstable patients may benefit from urgent on-site ECMO initiation by a rapid resuscitation team able to operate a portable and quick-to-prime ECMO circuit before transportation to the ECMO referral centre. Thirdly, cardiac failure and other organ injuries should be deemed reversible and the patient's underlying condition should not contraindicate a bridge to a more permanent device or to transplantation. Fourthly, management of patients on ECMO for refractory cardiogenic shock is complex and should be conducted in experienced centres.

ECMO can also be configured using central cannulation where the right atrium, ascending aorta and, sometimes, the left atrium or LV are directly cannulated. This is the first-line configuration used for post-cardiotomy or post-transplantation cardiogenic shock, or if peripheral ECMO has failed to deliver adequate flows or is complicated by severe pulmonary oedema.

In most patients the duration of ECMO support is approximately 1 week. However, ECMO can be maintained for weeks, especially if the central configuration is used. ECMO weaning is considered when there has been a partial or full cardiac recovery, or maintained as a bridge to transplantation or VAD implantation because

of insufficient LV functional recovery. ECMO can also be simply withdrawn in cases of therapeutic futility (severe brain lesions, end-stage multiple organ failure, or absence of myocardial recovery in the context of a definitive contraindication to transplantation or VAD implantation).

Long-term indications for mechanical support

Patient selection and indications

In the large Interagency Registry for Mechanically Assisted Circulatory Support (INTERMACS) registry, indications for VAD implantation at the time of surgery were bridge to transplantation (80%), bridge to recovery (5%), and destination therapy (15%) [3]. Before surgery, patients should undergo a thorough clinical and psychosocial evaluation, specifically assessing the severity of cardiac failure, co-existing life-limiting, or psychiatric illnesses, and the risks associated with surgery. The INTERMACS severity classification (Table 154.1) is commonly used to classify the different degrees of clinical severity of patients with New York Heart Association class IV symptoms, and helps to define the appropriate timing for device insertion [3]. The two most common indications for LVAD placement are cardiogenic shock (INTERMACS level 1, or 'crash and burn') and worsening of symptoms in inotrope-dependent patients (INTERMACS level 2 or 'sliding on inotropes'), which accounts for 80% of all implantations. However, as previously stressed, the most severe patients (INTERMACS level 1, 'crash and burn' or those at INTERMACS 'level 0' 'cardiac arrest, dying, or severe multi-organ failure (MOF)) may benefit from insertion of a first-line device such as ECMO, and later be bridged to a long-term cardiac assist machine after clinical and haemodynamic stabilization. For INTERMACS class 2 patients, an increase in inotrope dose, use of vasopressors, or signs of end-stage organ failure should indicate urgent device placement. Stable, but truly inotrope-dependent patients (INTERMACS level 3) are those who might derive the greatest benefit from heart transplantation or VAD insertion. At this stage of the disease, VAD insertion may be elective, especially for patients expected to have a long waiting time on the transplantation list (large body size, anti-HLA antibodies, or O blood group). VAD implantation in INTERMACS class 4–6 patients is still controversial and depends on the evolution of the disease, and its impact on the patient's functional status and quality of life. Newest generation devices, which are better tolerated and have fewer complications, may significantly increase the number of patients implanted at that stage. Furthermore, since LV function recovery has been demonstrated after prolonged VAD support in a limited series of patients, earlier implantation may become more frequent. Finally, LVAD implantation as destination therapy in non-transplant candidates should be discussed only in selected groups of haemodynamically stable patients, taking into account complication rates and the high costs still associated with these procedures.

Device selection

Selecting the appropriate device depends on many considerations, including body size, the anticipated duration of support, the need for associated right-sided ventricular support, the experience of the medical-surgical team, and total cost. Devices can be categorized as extracorporeal or intracorporeal. The Abiomed® BVS 5000 and the Thoratec® VAD are pneumatic pulsatile extracorporeal pumps that can achieve flow rates up to 6 L/min and can be used for uni- or bi-ventricular support. The main advantages of these systems are their versatility for mono- or bi-ventricular assistance, and their ability to be used in small patients. They have been extensively used worldwide as a bridge to recovery after cardiotomy, for medical cardiogenic shock, or as a bridge to transplantation. However, they limit autonomy and the four large percutaneous blood lines constitute an infection risk. In the first decade of the twenty-first century,

Table 154.1 Interagency Registry for Mechanically Assisted Circulatory Support level of limitation at time of implant

Profile	Description	Time frame for intervention
1	'*Crash and burn*': patient with life-threatening hypotension despite rapidly escalating inotropic support, critical organ hypoperfusion with increasing lactate levels, and/or systemic acidosis.	Needed within hours
2	'*Sliding on inotropes*': patient with declining function despite intravenous inotropic support may be manifest by worsening renal function, nutritional depletion, and inability to restore volume balance.	Needed within few days
3	'*Stable but inotropes dependent*': patient with stable BP, organ function, nutrition, and symptoms on intravenous inotropic support, but demonstrating repeated failure to wean due to recurrent symptomatic hypotension or renal dysfunction.	Elective over a few weeks
4	'*Frequent flyer*': patient can be stabilized with near-normal volume status, but experiences frequent relapses into fluid retention, generally with high diuretic doses. Symptoms are recurrent, rather than refractory. More intensive management strategies should be considered, which in some cases, reveal poor compliance.	Elective over weeks to months as long as treatment of episodes restores stable baseline, including nutrition
5	'*Housebound*': patient is living predominantly within the house, performing activities of daily living and walking from room to room with some difficulty. Patient is comfortable at rest without congestive symptoms, but may have underlying refractory elevated volume status, often with renal dysfunction.	Variable, depends upon nutrition, organ function, and activity
6	'*Walking wounded*': patient without evidence of fluid overload is comfortable at rest, and with activities of daily living and minor activities outside the home, but fatigues after the first few minutes of any meaningful activity.	Variable, depends upon nutrition, organ function, and activity
7	'*Limited activity*': advanced NYHA III patients without recent unstable fluid balance, living comfortably with meaningful activity limited to mild exertion.	Transplantation or circulatory support not currently indicated

miniaturized axial (Jarvik 2000®, Thoratec HeartMate® II) and centrifugal (DuraHeart®, Ventrassist®, and HeartWare®) pumps have gradually replaced first-generation intracorporeal pulsatile devices (e.g. HeartMate® XVE and Novacor®). These non-pulsatile devices deliver up to 10 L/min and their small size facilitates placement and explantation. They also have extended durability because of simpler mechanics, fewer moving parts and points of friction, and they operate more quietly than larger pulsatile pumps (Fig. 154.2). Successful implantation of either first or newest generation left ventricular assist devices depends on preserved right ventricular function, which should be carefully evaluated beforehand.

Two orthotopic artificial hearts have also been developed. These have unique advantages over other machines as they solve problems of persistent ventricular arrhythmias, RV failure, or severe heart valve disease. The AbioCor® Artificial Heart is still under clinical evaluation and only a few patients have received this device as a bridge to transplantation. The SynCardia® Temporary CardioWest® Total Artificial (formerly Jarvik® 7) was recently approved by the FDA as a bridge to transplantation. This biventricular, pneumatic, pulsatile pump totally replaces the native ventricles. Over 1000 implantations have been performed worldwide over the last three decades and the recent development of a smaller driving console may allow greater patient mobility and, eventually, discharge from hospital. Recent data from the large INTERMACS registry indicate that 75% of devices implanted are LVAD, 20% biventricular assist device (BiVAD), and <10% total artificial hearts [3].

Outcomes

In the INTERMACS registry, 6-month and 1-year survival after VAD implantation were 73 and 62%, respectively. One year post-implantation 35% had been transplanted, 35% were alive with the device in place, and <5% had been explanted because of LV functional recovery [3]. Overall survival was worse for older patients, those in INTERMACS class 1 status, patients with ascites and higher bilirubin, and those who received a BiVAD or a total artificial heart because of more advanced disease or complicated conditions, such as RV failure. However, 1-year survival was >70% for patients who received a machine in INTERMACS stages 2–7. Device-related complications were frequent, with <50% of patients being free of infection after 1 year.

A few landmark trials of patients implanted with a VAD have been published in the last decade. The REMATCH trial randomized 129 patients with end-stage heart failure who were ineligible for cardiac transplantation to receive a LVAD (HeartMate® XVE) or optimal medical management [4]. Survival analysis showed a 48% reduction in the risk of death from any cause in the LVAD group with 1-year survival being 52 and 25% in the device and medical therapy groups, respectively ($p = 0.002$). This demonstrates for the first time that 'destination therapy' strategy with an LVAD is an acceptable alternative strategy in selected patients who are not candidates for cardiac transplantation. A non-randomized prospective study showed that the Syncardia CardioWest® total artificial heart could rescue transplant-eligible patients at risk of imminent death from irreversible biventricular cardiac failure [2]. The rate of survival to transplantation was 79% for CardioWest patients versus 35% in historical control patients who met the same entry criteria, but did not receive an artificial heart. Overall, the 1-year survival rate among patients who received the artificial heart was 70%, compared with 31% in controls ($p < 0.001$). One- and five-year survival rates after transplantation among patients who had received a total artificial heart as a bridge to transplantation were 86 and 64%, respectively. These are close to those observed after elective heart transplantation. Finally, a randomized trial compared outcomes of patients with advanced heart failure who were ineligible for transplantation and who received a continuous-flow device (HeartMate® II) or the first-generation electric pulsatile-flow device (HeartMate® XVE) as destination therapy [5]. At 2 years, survival free from disabling stroke or re-operation to repair/replace the device was 46% of patients with continuous-flow devices, but only 11% with pulsatile-flow devices ($p < 0.001$). Patients with continuous-flow devices had superior actuarial 2-year survival rates (58 versus 24%, $p = 0.008$). Adverse events and device replacement were also less frequent in patients with the continuous-flow device. Finally, the small, intrapericardially positioned, continuous-flow, HeartWare® centrifugal pump was recently shown to be non-inferior to other latest generation implanted LVADs, improving functional capacity and quality of life, and having a favourable adverse event profile [6].

Conclusion

Mechanical circulatory assistance is now a frequent therapeutic option for patients with advanced heart failure. Indications for device implantation have changed significantly in the last decade. For patients with acute cardiogenic shock and impaired organ function, short-term assistance using ECMO is now the leading therapeutic option and enables a 'bridge to decision-making', i.e. withdrawal of the device after myocardial recovery or after recognition of therapeutic futility, or as a bridge to transplantation or long-term mechanical support. For INTERMACS classes 2–6 patients, implantation of a long-term VAD should be considered before progression to multiple organ failure. Most patients receive a VAD as a bridge to transplantation in this setting. However, implantations as bridge-to-recovery and, more recently, as a permanent heart function support or 'destination therapy' are increasing, mostly because of major technological and engineering advances making newer devices more reliable, less invasive, and associated with fewer complications than first-generation machines.

PART 5.7

Tachyarrhythmias

CHAPTER 155

Causes and diagnosis of tachyarrhythmias

Allan J. Walkey and David D. McManus

Key points

- Tachyarrhythmias occur in approximately 12% of critically-ill patients.
- Adenosine administration or vagal manoeuvres during continuous ECG monitoring can assist in ascertaining the specific diagnosis for undetermined supraventricular tachycardia.
- After acute stabilization of the patient, the underlying arrhythmia trigger should be identified and addressed.
- Atrial fibrillation during severe sepsis is associated with increased risk for in-hospital mortality and stroke.
- *Torsades de pointes* is often the result of QT-interval-prolonging medications administered during critical illness.

Introduction

Sustained tachyarrhythmias are common in patients with critical illness, occurring in approximately 12% of patients admitted to general medical/surgical ICUs [1]. The occurrence of new tachyarrhythmia (i.e. heart rate greater than 100 beats/min) during critical illness is associated with increased mortality, morbidity, length of stay, and cost [1–6]. This chapter reviews the causes and diagnostic approach to supraventricular and ventricular tach*y*arrhythmias in the critically-ill patient. We exclude sinus tachycardia, which is generally an adaptive response that increases cardiac output to match increased metabolic (e.g. fever), haemodynamic (e.g. hypovolaemia), or catecholamine (e.g. pain/anxiety) stressors of critical illness. Instead, tachyarrhythmias are maladaptive responses to a wide range of insults. Tachyarrhythmias may result in acute decompensation of the critically-ill patient, usually due to decreased cardiac output from supraphysiological heart rates. After acute stabilization of patients, health care providers should evaluate and address potentially reversible triggers of new tachyarrhythmia in the critically ill (Table 155.1).

Supraventricular tachyarrhythmias

Supraventricular tachyarrhythmias (SVTs) include atrial fibrillation (AF), atrial flutter, atrial tachycardia, atrioventricular nodal tachycardia (AVNRT) or atrioventricular re-entry tachycardia (AVRT), and multifocal atrial tachycardia (MAT). SVTs most commonly present as a narrow QRS complex (QRS <120 ms) tachycardia, although they may have wide QRS rhythms in the setting of aberrant conduction. Mechanisms of SVT involve enhanced automaticity, triggered activity, or re-entry. Management of SVT involves correct diagnosis of the arrhythmia, elucidation of the electrophysiological mechanisms underlying the arrhythmia, and targeted treatment.

Diagnosis of supraventricular tachycardia

Proper diagnosis requires electrocardiographic (ECG) analysis. Use of adenosine (6 mg intravenous (iv) bolus, followed by 12 mg iv bolus if the first dose is ineffective in producing AV block) or vagal manoeuvres (e.g. carotid massage in patients without atherosclerosis, Valsalva) can temporarily block or slow atrioventricular nodal conduction to assess the underlying atrial activity. In atrioventricular node-dependent arrhythmias, adenosine or vagal manoeuvers may also terminate the arrhythmia. Since atrioventricular block can promote antegrade conduction of AF down an accessory pathway, adenosine is contraindicated in patients with a Wolff-Parkinson White pattern on the ECG; adenosine is also contraindicated in patients with bronchospasm.

Atrial fibrillation

AF (Fig. 155.1) is the most common arrhythmia in critical illness. Classically, AF presents paroxysmally as an 'irregularly irregular'

Table 155.1 Potentially reversible causes of new-onset tachyarrhythmias in the critically ill

Cause	Example
Electrolyte disturbances	Hyper or hypo: -kalaemia, -magnesaemia, -calcaemia, -natremia; hypoxaemia
Beta$_1$-agonist medications	Dobutamine > epinephrine > dopamine > norepinephrine
Acute atrial or ventricular stretch	Acute pulmonary embolism, volume overload, or cardiomyopathy
Systemic inflammatory response syndrome	Sepsis
Cardiac injury	Myocardial ischaemia/infarction, central venous catheter irritation
Intrathoracic pressure swings	Ventilator dyssynchrony, airway obstruction [12]
Overdose/ingestion	Digoxin

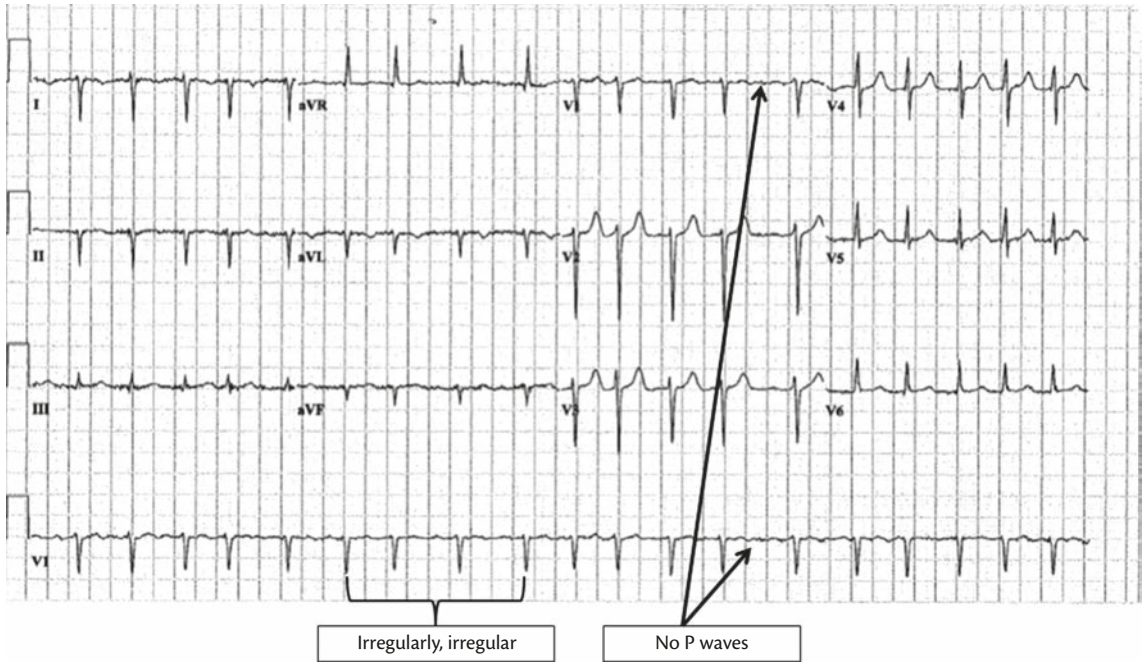

Fig. 155.1 Electrocardiogram demonstrating atrial fibrillation. Note narrow QRS complex, irregularly irregular rhythm, and absence of P waves.

narrow QRS complex tachycardia without discernible P waves. New-onset AF occurs in approximately 4% of the critically ill and 6–40% of patients with severe sepsis or septic shock [1–6]. In patients with sepsis, demographic factors (increasing age, male sex, and white race), comorbid conditions (a history of heart failure or obesity), and acute factors (number of acute organ failures, use of mechanical ventilation, vasopressors, pulmonary artery catheter) are associated with its development [1,2]. Multiple characteristics of critical illness are known triggers (Table 155.1) and represent potential therapeutic targets.

As is true of AF occurring in the community setting, AF complicating severe sepsis is also associated with an increased risk for death and ischemic stroke [2]. More than 50% of patients with new-onset AF during severe sepsis do not survive their hospitalization and 3% experience new, in-hospital stroke. The risk of ischaemic stroke in patients with new-onset AF during severe sepsis is approximately 0.2% per day, which is greater than stroke risks reported with AF in the community. Additionally, the increased risk of stroke with new-onset AF during severe sepsis may extend beyond hospital discharge. Traditional stroke risk scores (e.g. $CHADS_2$) excluded patients with critical illness and are of unknown predictive value in the critically ill. Thus, little evidence currently exists to guide the risk/benefit analysis of whether to initiate anticoagulants in patients with new-onset AF during critical illness.

Atrial flutter

Typical counter-clockwise atrial flutter is a macro-re-entrant tachyarrhythmia characterized by rapid atrial activity ('sawtooth' flutter waves, approximately 300 beats/min) that conducts to the ventricle to produce heart rates most commonly of ~150 beats/min. Atrial flutter is less common than atrial fibrillation, occurring in 1–2% of critically-ill patients. It is currently unknown whether risk factors or outcomes for atrial flutter during critical illness differ from those of atrial fibrillation.

Multifocal atrial tachycardia

This results from multiple ectopic sites of triggered atrial activity. MAT is diagnosed through identification of at least three different P wave morphologies. It is precipitated by acute illness, often in patients with chronic pulmonary disease. However, with the declining use of theophylline, MAT has become rare (<1% of hospitalized patients) [7,8]. Like AF, development of MAT in hospitalized patients is associated with poor outcomes [9].

Atrioventricular re-entry tachycardia and atrioventricular nodal re-entry tachycardia

Although common in the community setting, AVRT and AVNRT are rare in the general medical/surgical ICU, occurring in <1% of patients. Orthodromic AVRT and AVNRT are atrioventricular nodal-dependent arrhythmias that involve antegrade conduction down the AV node and retrograde conduction up an accessory or AV nodal pathway, respectively. Examination of the ECG R wave to P-wave interval (RP) can help differentiate between typical short-RP arrhythmias (RP interval < P-wave to R-wave interval, e.g. typical slow/fast AVNRT, Fig. 155.2) and AVRT (long RP) with a slowly conducting accessory pathway. Like most arrhythmias, AVRT and AVNRT may be exacerbated by electrolyte disturbances and high catecholamine states.

Atrial tachycardia

Atrial tachycardia (AT) is the result of a focus of atrial electrical activity ectopic to the sinoatrial node. It may be generated though micro-re-entry, enhanced automaticity, or triggered foci. AT is

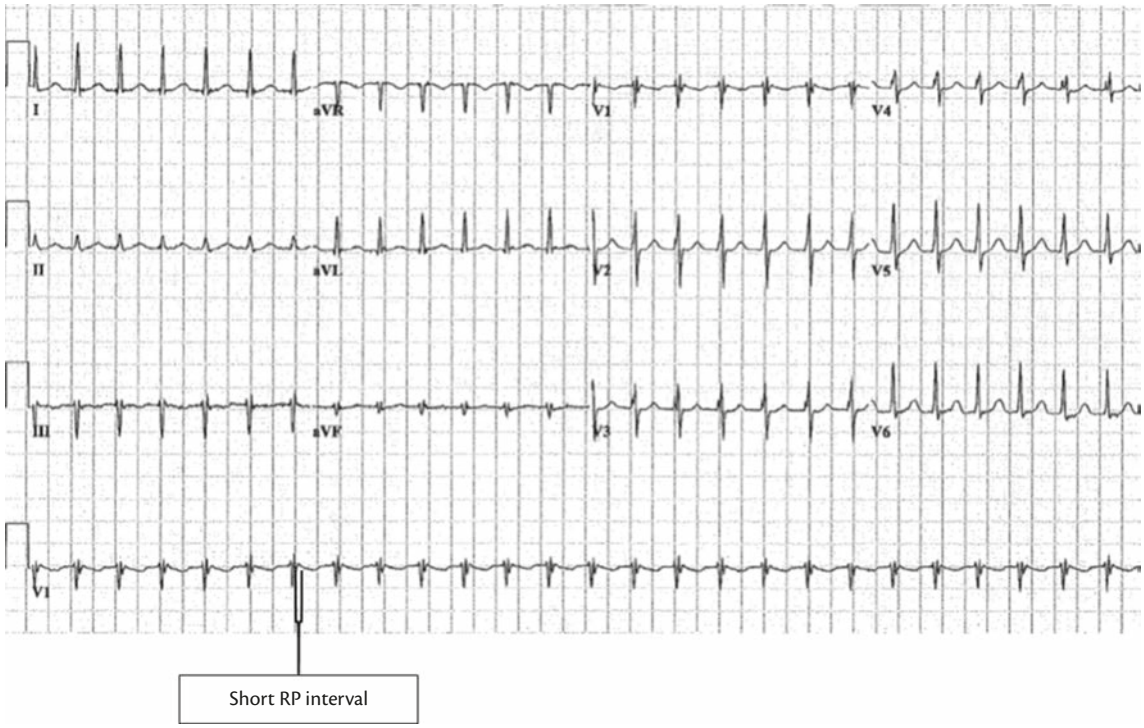

Fig. 155.2 Electrocardiogram demonstrating short RP interval supraventricular tachycardia. This patient reverted to normal sinus rhythm after intravenous administration of adenosine 6 mg.

generally paroxysmal, and diagnosed through identification of P wave morphology that differs from the patient's baseline sinus node conduction. Similar to other supraventricular tachyarrhythmias, initial evaluation consists of identification and reversal of the underlying trigger (Table 155.1).

Ventricular arrhythmias

Ventricular arrhythmias that develop secondary to pre-existing critical illness are associated with poor prognosis; in one study, only 27% of general intensive care unit (ICU) patients who developed ventricular arrhythmia survived the hospitalization [1]. Whereas SVT is associated with a small increase in hospital mortality that may or may not be directly attributed to the arrhythmia, ventricular arrhythmias are often the proximate cause of death [1]. Thus, rapid assessment of haemodynamic status, rhythm ascertainment, and institution of acute cardiac life support treatment are imperative.

Ventricular tachycardia (VT) is a wide complex tachyarrhythmia that can complicate critical illness, occurring in approximately 2% of general ICU patients. Monomorphic VT is generally a result of re-entry around fibrotic ventricular myocardium. Due to important prognostic and treatment considerations, monomorphic VT should be discriminated from SVT with aberrant conduction or antidromic AVRT. Discrimination of VT from aberrant SVT includes assessment of the pre-test probability of VT (known cardiomyopathy or prior myocardial infarction) versus SVT (known history of SVT, known bundle branch block of similar morphology to observed QRS, pre-existing accessory pathway). Identification of supraventricular–ventricular fusion beats and atrioventricular dissociation are specific, but insensitive for the identification of VT. Classic right bundle branch block (Lead I: broad S wave; Lead V1: rSR') or left bundle branch block patterns (Lead I: QS; Lead V1: un-notched RS) are unlikely to be seen in VT. Although not validated in critically-ill patients, Brugada's algorithm (Table 155.2) can be used to discriminate aberrant SVT from VT with high sensitivity (99%) and specificity (97%) [10]. However, if questions remain regarding a wide complex tachycardia, assume VT.

Polymorphic VT in the critically-ill patient is often associated with active myocardial ischaemia or acute myocardial injury, is rarely tolerated, and generally requires DC cardioversion. Torsades de pointes ('turning around a point', Tdp) is a type of polymorphic VT occurring in the setting of a prolonged QT interval and characterized by a varying QRS amplitude along an isoelectric line. In the ICU, Tdp is frequently associated with QT-prolonging medications, many of which are frequently administered to critically-ill patients.

Table 155.2 Brugada algorithm for diagnosis of monomorphic ventricular tachycardia (VT) [10]. Presence of any criterion indicates diagnosis of ventricular tachycardia

Brugada criterion	Sensitivity for VT	Specificity for VT
1. No RS in precordial leads	21%	100%
2. R to S interval >100 ms in any precordial lead	21%	100%
3. A–V dissociation	82%	98%
4. No classic RBBB or LBBB pattern	98%	97%

RBBB, right bundle branch block; LBBB, left bundle branch block; A–V, atrio-ventricular.

Reproduced from Brugada P et al., 'A new approach to the differential diagnosis of a regular tachycardia with a wide QRS complex', *Circulation*, **83**, pp. 1649–59, copyright 1991, with permission from American Heart Association and Wolters Kluwer Health.

Table 155.3 Medications with high-risk of QT prolongation commonly used in the critically ill

Class	Examples
Anti-psychotics/anti-emetics	Haloperidol, chlorpromazine, droperidol, domperidone
Anti-arrhythmic	Amiodarone, disopyramide, dofetilide, flecainide, ibutilide, procainamide, quinidine, sotalol
Antibiotics	Macrolides (e.g. erythromycin, azithromycin), fluoroquinolones (e.g. moxifloxacin), pentamidine
Anti-malarials	Chloroquine
Methadone derivatives	Methadone
Anti-depressants	Citalopram

Screening for prolonged QT interval prior to administration of QT-prolonging medications listed in Table 155.3 and avoidance of high-risk medications in patients with prolonged QTc intervals (> 500ms) is recommended; risk of Tdp is increased 2–3-fold for patients with QTc >500 ms [11].

CHAPTER 156

Therapeutic strategy in tachyarrhythmias

Allan J. Walkey and Jared Magnani

Key points

- Critically-ill patients with acute tachyarrhythmia require immediate assessment of clinical stability, cardiac substrate, and precipitating factors.
- Tachyarrhythmias that cause severe haemodynamic instability require emergent direct current cardioversion.
- Effects of direct current cardioversion during critical illness are often transient, unless the underlying arrhythmia precipitant is eliminated and longer-acting rate- or rhythm-controlling medications are instituted.
- Atrial fibrillation often responds favourably to a rate-control strategy and treatment of the underlying precipitants.
- Assessment of the QT interval in patients with polymorphic ventricular tachycardia is important in determining the underlying etiology and treatment strategy.

General approach

The therapeutic strategy for tachyarrhythmias in critical illness depends upon the following patient assessments:

- **Haemodynamic status**: evidence of clinical instability associated with the arrhythmia requires urgent treatment.
- **The specific tachyarrhythmia and its precipitating factors**: successful arrhythmia treatment depends on elimination of precipitants, as well as institution of appropriate medications.

Clinical instability

Narrow complex or monomorphic wide complex tachycardias that cause acute clinical instability warrant emergent synchronized direct current cardioversion (DCCV), under conscious sedation whenever possible. Advanced cardiac life support principles and algorithms are required for patients who develop cardiac arrest or who become acutely unstable due to the arrhythmia. The acute decline in cardiac output induced by tachyarrhythmia may manifest as mental status change, shock, heart failure, or cardiac ischaemia. More subtle signs of low cardiac output—renal dysfunction, slow capillary refill, or lactic acidosis—also indicate urgency for arrhythmia treatment.

Narrow complex tachycardia

Critically-ill patients frequently experience narrow complex, supraventricular tachyarrhythmias (SVT). In critically-ill—but haemodynamically stable—patients, assessment of a continuous 12-lead ECG rhythm strip with simultaneous vagal stimulation or adenosine administration helps to discriminate between the narrow complex tachyarrhythmias. In all new-onset arrhythmias, care should be taken to address the underlying trigger in addition to instituting medications to treat the clinically significant arrhythmia.

Atrial fibrillation and atrial flutter

Clinically significant atrial fibrillation (AF) or atrial flutter (AFL) may be treated with either a heart rate-lowering (rate-control) or a rhythm conversion strategy (rhythm-control). Rate-control improves ventricular filling time, thereby increasing cardiac output. Rhythm-control may restore atrial systole, further enhancing cardiac output. AF is the most commonly encountered clinical arrhythmia and may be secondary to underlying cardiac disease, sympathetic stress, or an inflammatory state. Addressing the underlying critical illness and clinical stabilization are foremost goals for management.

With the exception of unstable patients requiring emergent DCCV, guidelines do not favour rate- or rhythm-control in the critically ill [1]. One trial comparing a rate-control approach (diltiazem, 25 mg bolus followed by 20 mg/hour infusion) to a rhythm-control approach (amiodarone, 300 mg bolus followed by 45 mg/hour infusion) in 60 critically-ill patients with SVT did not find a difference in conversion to sinus rhythm between the two groups [2]. However, heart rate was better controlled with diltiazem.

Atrial fibrillation and atrial flutter: rate control

Atrioventricular (AV) nodal-slowing agents are often used as initial therapy for AF or AFL with a rapid ventricular response (generally heart rates >150 beat/min) without immediately life-threatening clinical instability. However, little evidence guides the selection between various AV node-slowing agents. Intravenous non-dihydropyridine calcium channel (CCB) antagonists (e.g. verapamil, diltiazem) and intravenous β_1-selective (BB) antagonists (e.g. metoprolol, esmolol) are commonly used for AF/AFL heart

rate control in the critically ill. A randomized trial showed similar heart rate improvement between esmolol and diltiazem in patients with acute AF [3], although conversion to sinus rhythm occurred more frequently in patients given esmolol.

The major side effect of BB and CCB in the critically ill is hypotension. The cardiac glycoside digoxin is frequently chosen for rate control during critical illness because of its lower risk for precipitating hypotension or decreasing inotropy. However, digoxin alone does not achieve comparable heart rate control to BB or CCB therapy during acute AF [4]. The high sympathetic state of critical illness renders the vagomimetic actions of digoxin less effective. Digoxin may improve heart rate control when added to sub-optimal or hypotension-inducing BB or CCB therapy [5], or in patients who may not tolerate reduced inotropy (level I) [1], however toxicity is of concern in patients with acute renal failure.

Magnesium sulphate competes with calcium to prolong the action potential duration and may be an effective rate-control adjunct to CCB, BB, or digoxin therapy [6], but may be ineffective as a single agent [7].

In patients who develop hypotension after administration of BB or CCB therapy for AF/AFL, the addition of the selective α_1-adrenoreceptor agonist phenylephrine may improve blood pressure and suppress AF [8]. However, reflex vagal stimulation from phenylephrine also has potential to act as an AF trigger; the net effect of phenylephrine on outcomes in critically-ill patients with AF is unknown.

AF and AFL: rhythm control

Non-emergent rhythm-control therapy in AF/AFL is often instituted when attempts at rate-control have failed or produced complications. The most basic rhythm-control strategy is synchronized DCCV. However, in critically-ill patients with ongoing AF precipitants, AF is likely to recur after DCCV. A single ICU observational study found that 70% of patients with AF required at least three DCCV attempts to achieve successful cardioversion; only 16% of patients remained in sinus rhythm 24 hours after DCCV [9].

Due to high rates of reversion to AF/AFL after DCCV, longer-acting anti-arrhythmic therapy may be preferable to DCCV in critically-ill patients treated with a rhythm-control strategy. Amiodarone is commonly used for rhythm-control in the critically ill. Amiodarone's mild potency β_1- blocking activity may also effectively reduce heart rate in the absence of successful cardioversion. The efficacy of amiodarone in AF/AFL of critical illness was studied in approximately 100 patients, with 50–80% success rates for cardioversion within 12 hours after the first dose [10]. No studies have been placebo-controlled and, notably, amiodarone was not superior to magnesium sulphate (which achieved 72% successful 12-hour cardioversion rates) [11]. Side effects of amiodarone include hypotension (though less common than CCB or BB) and QT-prolongation; in addition, amiodarone may rarely induce fatal pulmonary toxicity in the critically ill.

Other anti-arrhythmics, such as procainamide, ibutilide, and flecainide may be efficacious for AF, but are limited by significant side effects and understudied in critical illness. For example, procainamide frequently causes hypotension (10% incidence), ibutilide is associated with significant ventricular arrhythmias from QT prolongation (~8% incidence) [12], while flecainide is associated with increased mortality in patients with acute cardiac ischaemia [13]. These therapies require electrophysiological consultation. Pulmonary vein isolation (i.e. ablation) is contraindicated during critical illness.

AF and AFL: anticoagulation

In addition to haemodynamic collapse, cardio-embolic stroke is a feared complication of AF/AFL. The risk of stroke is increased in patients with new-onset AF during severe sepsis [14]. New strokes occur in approximately 3% of patients with new-onset AF during severe sepsis, as compared with only 0.5% of patients without new-onset AF during severe sepsis. Stroke risk prediction scores developed in populations that excluded the critically ill (e.g. $CHADS_2$) are likely to be inapplicable to the ICU setting. An increased risk for post-cardioversion cardio-embolic stroke due to atrial stunning can occur after electrical, pharmacologic, or spontaneous [15] cardioversion. The American College of Chest Physicians Guidelines recommend institution of anticoagulation in all patients with AF undergoing cardioversion (electrical or pharmacological) for 4 weeks after cardioversion [AF lasting >48 hours, level IB; AF <48 hours, level IIC] [16]. Estimates of severe bleeding risk from anticoagulation during critical illness are currently unavailable and risk/benefit ratio for anticoagulation of AF during critical illness is not clear.

Atrial tachycardia and multifocal atrial tachycardia

The principles of treating atrial tachycardia (AT) and multifocal atrial tachycardia (MAT) are similar to that of AF—address underlying arrhythmia triggers, assess the clinical significance of the arrhythmia, and achieve adequate rate control in cases of clinically significant tachycardia. Common triggers include acute exacerbations of chronic obstructive pulmonary disease (COPD), heart failure, hypoxia, theophylline, hypokalaemia, and hypomagnesaemia. Correction of underlying factors is generally associated with resolution. If additional treatment is warranted, CCB and BB are treatments of choice to reduce atrial ectopy and slow AV nodal conduction. BB may be more effective than CCB, one small trial of 13 patients demonstrated that 89% of patients had improved heart rate or rhythm conversion after metoprolol as compared with 44% of patients given verapamil [17]. Cardioselective BB do not appear to induce bronchospasm in patients with COPD during MAT. DCCV is ineffective for MAT.

Other SVTs

Atrioventricular nodal re-entrant tachycardia (AVNRT) is rare in the critically ill. Its treatment is focused on interfering with the AV node micro-re-entry circuit. Vagal manoeuvres, adenosine, or AV nodal slowing agents all can be used to slow AV node conduction and treat AVNRT [18].

In contrast to AVNRT, AV nodal slowing agents are contraindicated in macro-re-entry atrioventricular tachycardia (AVRT) in which an accessory bypass tract may bypass the AV node to rapidly conduct atrial fibrillation or flutter waves. A pre-excitation (delta) wave preceding the QRS complex on a baseline EKG provides evidence of an accessory pathway. DCCV is the treatment of choice in unstable AVRT. Class IA (e.g. flecainide), IC (e.g. procainamide), and Class III (e.g. amiodarone) anti-arrhythmic agents

may be used to slow the accessory pathway and resolve AVRT [18]. Electrophysiology consultation is recommended for consideration of radiofrequency ablation of the accessory pathway following clinical stabilization.

Ventricular tachycardia

DCCV is used to treat unstable patients with wide complex tachycardia (level IC) [19]. Stable patients with wide complex tachycardia determined to be ventricular tachycardia should be assessed for arrhythmia morphology (monomorphic, polymorphic, torsades de pointes) and the presence of any underlying cardiomyopathy or myocardial ischaemia. Wide complex tachycardia is presumed ventricular tachycardia (VT) if the diagnosis is unclear. Electrophysiology consultation is indicated in patients with recurrent VT.

Monomorphic VT

Guidelines recommend intravenous procainamide as the most effective first line agent for stable monomorphic VT (level IIa) [19]. In patients who do not tolerate hypotension associated with procainamide, intravenous amiodarone is recommended as a second line agent (level IIa). Lidocaine may be effective when other agents are unavailable (level IIb). BB therapy may reduce the frequency of recurrent monomorphic VT.

Polymorphic VT

Polymorphic VT without evidence of a long QT interval is often precipitated by cardiac ischaemia, is rarely haemodynamically tolerated, and generally requires unsynchronized cardioversion. Intravenous BB therapy (level IB) is associated with decreased mortality in myocardial ischaemia-induced recurrent polymorphic VT. Amiodarone (level IC) may also be effective in terminating recurrent ischaemia-associated polymorphic VT. Patients with ischaemia-associated VT should be considered for a coronary revascularization procedure [19].

Polymorphic VT associated with long QT can be managed acutely by unsynchronized cardioversion and/or intravenous magnesium sulphate (level IIa). QT-interval prolongation is common in critical illness. After acute stabilization, polymorphic VT requires withdrawal of QT-prolonging medications (level IA), correction of potassium to 4.5–5 mmol/L (level IIb), and consideration of overdrive pacing (level IA) or isoproterenol therapy (IIa) [19].

PART 5.8

Bradyarrhythmias

CHAPTER 157

Causes, diagnosis, and therapeutic strategy in bradyarrhythmias

Harminder S. Gill and Jaswinder S. Gill

Key points

- Bradycardias are common in the critical care setting.
- Early identification and intervention is important.
- Diagnosis of the arrhythmia is generally made from the electrocardiogram.
- Treat the arrhythmia with drugs, including atropine and sympathomimetics.
- Have a low threshold for using temporary (with or without permanent) pacing.

Introduction

Bradycardia is defined as a heart rate <60 beats/min, and can be either physiological or pathological. Bradycardias are common in critically-ill patients and occur in about 10% of patients admitted to an intensive care unit (ICU). Here, a number of different factors may underlie the abnormal rhythm. As with any dysrhythmia, it is crucial to identify the abnormal rhythm correctly, to then allow prompt institution of appropriate management [1].

Types

Bradyarrhythmias occur at three levels within the conduction system:

- Sino-atrial node.
- Atrioventricular node.
- Bundle branches.

Causes

Patients in the critical care setting are often seriously ill with multisystem disorders and receive multiple therapies that can influence the conduction system. Causes can be classified as shown in Box 157.1 [2,3].

Diagnosis

History

Bradycardias are sometimes identified in asymptomatic patients who present for other reasons, but the arrhythmia may require management. Other patients present with dizziness, syncope, or seizures. In the critical care setting, a patient may present with a sudden drop in blood pressure, impairment of conscious level or haemodynamic collapse which, in some cases, may require immediate resuscitation. Many patients will be continually monitored and this will draw immediate attention to rate abnormalities.

Clinical examination

Palpating the pulse reveals bradycardia. Features of a low cardiac output state (peripheral shutdown, sluggish capillary refill) should always have bradycardia considered as an underlying cause.

Box 157.1 Types of bradycardia

Physiological

Highly trained-athletes have low resting heart rates (often in the range classified as bradycardia).

Pathological

- **General systemic:**
  - Hypothermia.
  - Hypothyroidism.
  - Pain.
  - Vagal responses.
  - *Raised intracranial pressure*: stroke, haemorrhage, encephalopathy.
  - Cholestatic jaundice.
  - Operations.
  - Sepsis.
  - Diabetes.
  - Intubation.
- **Cardiovascular:**
  - Degenerative conduction disease.
  - Ischaemic heart disease.

- Valvular heart disease.
- Cardiomyopathy.
- Congenital heart disease.
- Infiltrative disease.
- Myocardial disease.

◆ **Medications:**

- β-blockers.
- Anti-arrhythmic drugs.
- Digoxin.
- Amiodarone.
- Calcium antagonists.
- Tricyclics.
- Neuroleptics.
- Dementia medications.
- Toxins.

Investigations

The most critical diagnostic investigation is the electrocardiogram (ECG). The presence of the P wave and its relationship to the QRS complex are critically important features. ICU patients frequently have one- or three-lead monitoring as routine, although a formal 12-lead is preferable and may help elucidate the cause. In most cases, Holter and loop recorders are not required, since patients are already undergoing intensive monitoring.

Types of bradycardia

Sinus node disease

This is common and can affect any age group, but is particularly prevalent in the elderly. The sinus node receives rich innervations from the cardiac sympathetic and parasympathetic nerves, and is therefore very sensitive to vagal influences and drugs.

Sinus bradycardia

Accounts for around 30% of all bradyarrhythmias and is manifest by a heart rate <60 beats/min which is inappropriate to the clinical state of the patient [4]. The heart rate frequently fails to respond appropriately to exercise or activity (see Fig. 157.1).

Diagnosis

P-wave slowing but each P wave is followed by a QRS complex.

Sinus arrest

This occurs when the SA node transiently fails to exhibit normal automaticity. The ECG demonstrates a pause without P waves and the length of the pause is not a multiple of the preceding P–P interval. Pauses of 2–3 seconds' duration are seen in 11% of healthy asymptomatic individuals, whereas pauses >3 seconds during waking hours are usually due to sinus node dysfunction. These may lead to life-threatening asystole and therefore require treatment with either drugs and/or pacing (see Figs 157.2 and 157.3).

Sinus exit block

The SA node fires, but the impulse is delayed or fails to propagate beyond the sinus node, resulting in failure of atrial depolarization. The ECG shows a pause without P waves. Type I second degree SA exit block demonstrates progressive P–P interval shortening before the pause (duration is less than two P–P cycles). In Type II second-degree sino-atrial exit block, the pause duration is theoretically an exact multiple of the previous P–P interval as the SA node continues to fire at its own intrinsic rate. Pauses with this condition are generally short and do not require treatment.

Diagnosis

P-wave absence occurs with no QRS, unless the patient has a junctional escape rhythm

AV-nodal conduction disease

It is important to distinguish between block within the AV node and block within or below the His bundle (infranodal AV block), as both prognosis and appropriate treatment depend on this distinction. A surface ECG can assist in making this differentiation. Prolongation of the P–R interval before block (Wenckebach pattern) is strongly suggestive of AV nodal block, whereas sudden block without prolongation of the P–R interval is very suggestive of infranodal block. The escape rate in the setting of complete AV block is higher (40–60 beats/min) in AV nodal block, as the escape pacemaker is usually in the His/proximal Purkinje system. Infranodal block results in a less reliable, more distal (often ventricular) escape rhythm (heart rate <40 beats/min). The width of the QRS complex is also helpful: the QRS duration in AV nodal block is generally relatively narrow (<120 milliseconds), whereas the QRS duration in infranodal block is relatively wide.

1st-degree AV block

Commonly seen where each atrial impulse is successfully conducted to the ventricle but with a delay (see Fig. 157.4).This is of little importance as it does not affect cardiac physiology and generally does not require treatment. However, this is liable to progress to higher degrees of heart block and should alert the physician.

Fig. 157.1 Sinus bradycardia. Rate is below 60 beats/min, but each P wave is followed by a QRS complex.

Fig. 157.2 Sinus arrest. Sudden bradycardia is followed by absence of P wave activity.

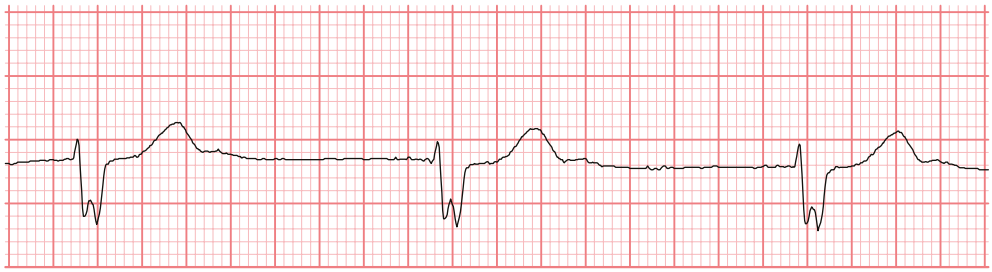

Fig. 157.3 Sinus arrest—with infra-Hissian escape rhythm.

Fig. 157.4 First degree heart block. The PR interval is prolonged, but each P wave is followed by a QRS.

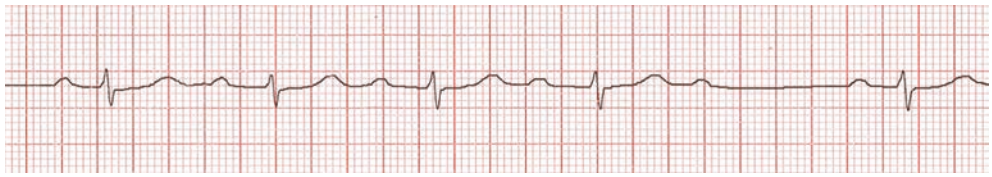

Fig. 157.5 Mobitz type 1 block. The PR interval demonstrates progressive prolongation until one fails to conduct.

Diagnosis

Each P wave is followed by a QRS, but with prolongation in the P–R interval >200 milliseconds

When the QRS complex is narrow, the level of conduction delay is within the AV node in >90% of cases. First-degree AV block with a bundle branch block/wide QRS may represent infranodal conduction delay in up to 45% of patients.

Second-degree AV block–Mobitz type

In this condition, some atrial impulses fail to reach the ventricle. The surface ECG demonstrates some P waves that are not followed by a QRS complex.

Mobitz type 1 (Wenkebach block)

Most commonly associated with AV nodal conduction system disease (see Fig. 157.5). The P–R interval shows progressive prolongation with shortening of the R–R interval until a P wave fails to conduct to the ventricle, and then the cycle starts again. This type of block is usually not of importance and is unlikely to be harmful unless the degree of block progresses. Wenckebach block is almost always a result of block in the AV node, particularly when associated with a narrow QRS complex. The pause during this cycle is short. This block does not generally require pacing, but may herald of higher degrees of block.

Diagnosis

PR-interval shows progressive prolongation until a P wave fails to conduct to the ventricle.

Mobitz type 2 block

The P wave fails to conduct to the ventricle and the previous QRS does not show any evidence of PR prolongation (see Fig. 157.6). The underlying QRS may be narrow or broad. This type of block can commonly occur nocturnally or in patients with high vagal tone, e.g. very fit individuals. Block during the day indicates more extensive conduction disease and usually merits pacing due to the unpredictable nature and duration of pauses.

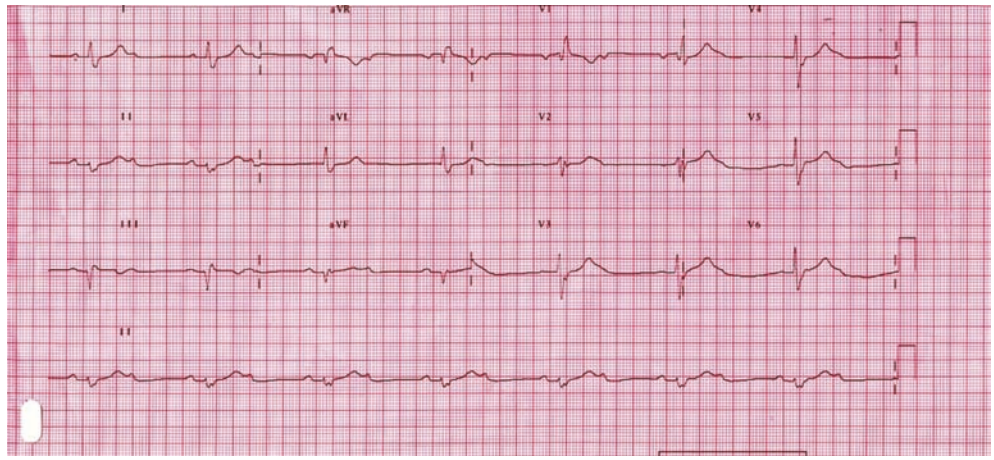

Fig. 157.6 Mobitz type 2 block with 2-to-1 conduction from the atrium to the ventricle. The P wave is dropped without any PR prolongation on the previous complex. The QRS is broad, suggesting infra-Hissian conduction system disease.

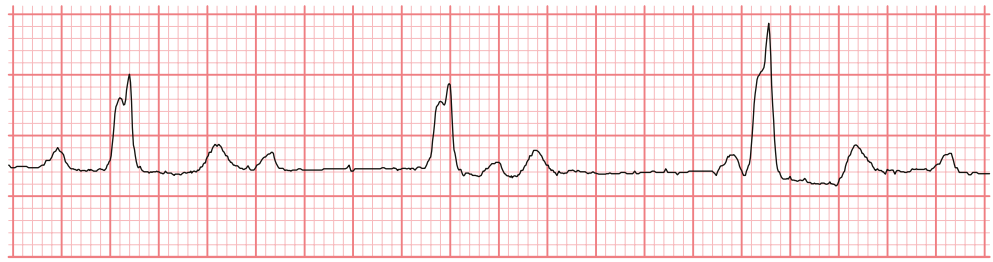

Fig. 157.7 Complete heart block with an infra-Hissian escape rhythm. The P waves have no relationship to the QRS complexes.

Diagnosis

P wave fails to conduct to the ventricle and the previous conducted P-QRS does not show any evidence of PR prolongation.

3rd-degree (complete) heart block

Here, the atria and ventricles function independently (see Fig. 157.7). The P wave has no relation to the QRS, which can be narrow or broad, and the level of block can be either in the AV node or infranodal. Acquired causes (which predominate in the ICU care setting) are often infranodal and potentially life-threatening. A common exception is after acute inferior myocardial infarction where the block is generally nodal and frequently reversible. Digitalis toxicity is a common cause of reversible AV block.

Prognostically, patients with a narrow QRS fare better than those with more extensive disease who demonstrate broad QRS complexes. Although some patients with complete heart block and narrow QRS can be left unpaced (e.g. congenital complete heart block), those with a broad QRS nearly always need pacing.

Diagnosis

The P wave has no relationship with the QRS.

Infra-Hisian conduction block

Right-bundle branch block

This can commonly be found in individuals where the heart is structurally normal. This usually does not need intervention.

Left bundle branch blocks

Left anterior fascicular block, left posterior fasicular block, and complete left bundle branch block are much more likely to be associated with underlying cardiac disease, are frequently progressive and may require pacemaker insertion.

These blocks are important when associated with sinus and AV nodal abnormalities, since they suggest more extensive disease of the conduction system that may fail suddenly.

Management

Identification of the type of bradycardia is of critical importance to the management. Particular interventions are likely to precipitate bradycardia in the critical care setting [5]. These include intubation, endotracheal suction, and sometimes bladder catheterization. In patients who demonstrate this tendency, the prior administration of glycopyrroniumbromide (0.1 mg IV) or 600 μg atropine before the intervention may avoid the bradycardia. Rarely patients may have several seconds of asystole in association with the intervention and this is not responsive to anti-cholinergics. In these cases insertion of a temporary pacing electrode prior to the intervention may be required.

In the acute setting where the patient suddenly becomes bradycardic or asystolic acute resuscitation may be required. A precordial thump may occasionally reverse asystole and start the heart beating again. If this does not occur, cardiorespiratory resuscitation may be required and should be maintained until pacing can be initiated.

Pacing should also be initiated in patients who do not respond to atropine (or second-line drugs). Pacing is also recommended for severely symptomatic patients, especially when the block is at or below the His-Purkinje level (i.e. type II second-degree or third-degree AV block).

Drugs

Atropine

The first-line drug for acute symptomatic bradycardia with an initial dose of 0.5 mg intravenous (iv) every 3–5 minutes to a maximum total dose of 3 mg. Atropine reverses cholinergic-mediated decreases in heart rate, symptomatic sinus bradycardia, symptomatic high-degree AV block and any type of AV block at the nodal level. The increased heart rate caused by atropine in acute coronary ischaemia or myocardial infarction may worsen the ischemia or increase the zone of infarction so this drug must be used cautiously. Avoid relying on atropine in type II second-degree or third-degree AV block or in patients with third-degree AV block with a new wide-QRS complex. These patients require immediate pacing.

Alternative drugs

May be considered with bradycardias that are unresponsive to atropine, while awaiting the availability of a pacemaker:

- **Adrenaline**: infusion at 2–10 μg/min and titrate to patient response. Provide intravascular volume and support as needed.
- **Dopamine**: infusion (at rates of 2–10 μg/kg/min) can be added to epinephrine, or administered alone.
- **Isoprenaline**: infuse at 2–10 μg/min and titrate against heart rate response. This drug is more likely to raise the blood pressure, but patients can often be maintained for several hours before pacing is initiated.
- **Glucagon**: one case series documented improvement in heart rates with iv glucagon (3 mg initially, followed by infusion at 3 mg/hour if necessary) when given to patients with drug-induced bradycardia not responding to atropine.

Pacing

Several modalities of pacing are available including external, oesophageal, and transvenous [6–8].

External pacing

Transcutaneous external pacemakers have a special pulse duration, surface electrodes, and a current generator:

- **Pulse duration**: long electrical pulse duration are used (40 milliseconds pulses for Zoll or 20 milliseconds pulses for all others).
- **Electrodes**: large surface electrodes (80–100 cm^2) are used since pain is directly related to the amount of current delivered and inversely related to the skin surface area over which it is delivered. Thus, pain is minimized by using electrodes with large surface areas.
- **Current**: the average current necessary for external pacing ranges from 50 to 100 milliamperes (mA). This delivers approximately 0.1 Joules (J), below the 1–2 J required to cause an uncomfortable tingling sensation in the skin. Transcutaneous external pacemaker discomfort at these low levels of current delivery is due to the force of skeletal muscle contraction, rather than the electric current. More than 90% of patients tolerate pacing for ≥15 minutes with modern devices capable of delivering up to 140–200 mA.
- Before beginning transcutaneous external pacing, the patient should be informed of the reason for pacing, the discomfort that may be experienced, and the option of providing analgesia or sedation, if possible.
- **Pad application**: pacemaker pads are applied over the cardiac apex and just medial to the left scapula. Excessive body hair should be shaved to ensure good contact.
- **Pacemaker operation**: heart rate should be set to 80 beats/min and the current initially set to 0 milliamperes (mA). The pacemaker unit is turned on, and the current increased in 10 mA increments until capture is achieved. Capture should be confirmed by palpable carotid pulses, and ECG evidence on monitoring.
- **Synchronous/asynchronous modes**: in the asynchronous (fixed-rate) mode, the electrical stimulus is delivered at preset intervals, independent of intrinsic cardiac activity. Synchronous pacing is a demand mode in which the pacer fires only when no complex is sensed for a predetermined amount of time. Generally, pacing should be started in synchronous mode.
- **Minimizing discomfort**: sedation with a short-acting agent, such as midazolam or an opiate, should be considered.
- **Complications**: pain, coughing, and hiccoughs may result from stimulation of the diaphragm and thoracic muscles. Skin burns have been reported with prolonged use.

Oesophageal pacing

A specialized pacing electrode can be placed via the oesophagus and manipulated to 30–40 cm from the teeth. At this level, the left atrium is in close proximity and pacing can give atrial capture reliably using a special stimulator, which has long amplitude pulses with high amplitude. Ventricular stimulation is less reliable because of the greater distance of the oesophagus from the ventricle; this technique should not be used for atrioventricular block. Leads inserted via the nostril (similar to nasogastric tubes) can be maintained for several days. Complications include oesophageal discomfort (rarely, burns with high outputs) and phrenic nerve stimulation.

Temporary intracardiac pacing

A pacing electrode is inserted through an introducer sheath sited in the subclavian or internal jugular vein (rarely, femoral) and then fluroscopically-guided to the right ventricular apex.

In the emergency situation a flotation electrode can be used. This is a Swan–Ganz type of balloon catheter with pacing electrodes. It is floated from the entry site into the heart with the electrocardiogram being recorded. When a ventricular trace is obtained, pacing is commenced, the balloon deflated and the lead secured. Pacing thresholds of <1 mV with a pulse duration of 0.5 milliseconds are satisfactory. Leads can also be placed in the atrium; specialized leads with screw-in tips are available designed for atrial pacing. Placement of leads in the atrium and ventricle allow co-ordinated atrioventricular pacing. These leads do not cause discomfort and pacing can be maintained for several days.

Complications are generally related to access (pneumothorax, haematoma, air embolism), myocardial perforation leading to tamponade, ventricular arrhythmias, and infection.

Permanent pacemaker insertion

A permanent pacing system can be acutely implanted for the treatment of sudden onset bradycardia without a reversible cause and at the discretion of the managing physician. The techniques of implantation are beyond the scope of this chapter

A summary algorithm for bradycardia management can be accessed for free on the American Heart Association website (www.heart.org/).

PART 5.9

Valvular problems

CHAPTER 158

Causes and diagnosis of valvular problems

Jason F. Deen and Karen K. Stout

Key points

- Significant aortic stenosis may present with angina pectoris, dyspnoea, or syncope.
- Acute aortic regurgitation usually arises as a consequence of infective endocarditis and, if severe, will most commonly result in cardiogenic shock and hypotension.
- Mitral stenosis is usually chronic in nature, but may manifest for the first time clinically with other forms of haemodynamic stress, such as pregnancy, amenia, fever, or atrial arrhythmia.
- Mitral regurgitation should be categorized to primary versus secondary causes to inform appropriate therapeutic options.
- Transthoracic echocardiography remains with imaging modality of choice for primary valve assessment.

Aortic stenosis

Aetiology and pathophysiology

Aortic stenosis (AS) is the most prevalent form of valvular heart disease and its prevalence increases with older age. Common aetiologies include calcific stenosis, congenital AS, including stenosis of a bicuspid aortic valve, and rheumatic heart disease. The pathophysiological endpoint is left ventricular outflow tract obstruction, with salient clinical manifestations of angina pectoris, syncope, and symptoms related to left ventricular failure (including dyspnoea, activity intolerance, pulmonary oedema, and orthopnoea) [1].

Calcific AS remains the most common cause in industrialized countries; approximately 25% of US adults have aortic sclerosis (early valve cusp calcification without significant outflow tract obstruction), while 2% have overt calcific AS (an advanced stage associated with a decreased functional valve orifice leading to left ventricular outflow tract obstruction) [2]. It is a manifestation of an ongoing systemic disease process of vascular osteoblastic activity, which begins within the valve tissue, and shares the histological features of atherosclerosis with inflammation and calcification. Risk factors for calcific AS are similar to atherosclerotic disease and include older age, male sex, tobacco use, hypertension, diabetes mellitus, and hyperlipidaemia. Just as with vascular calcification, hyperlipidaemia, in particular, has been identified as an inciting factor in cell signalling related to valvular calcification. Additionally, untoward genetics seem to play a role in developing the calcific phenotype [3,4].

Congenital AS represents a wide range of clinical manifestations with severe forms presenting in infancy. Bicuspid aortic valve is the most common form of congenital heart disease seen in adults, occurring in approximately 2% of the population, exhibiting a male predominance. Abnormal valve leaflet structure leads to more rapid progression to calcific AS as compared with tri-leaflet valves in the presence of traditional cardiovascular risk factors [5]. Furthermore, there are associations with aortic root and ascending aorta dilatation, which may predispose to aortic dissection that are independent of valve stenosis severity.

Although rare in industrialized countries, rheumatic heart disease may lead to AS. Isolated AS is uncommon, and is usually accompanied by mitral valve disease, as well as aortic regurgitation. Rheumatic aortic disease is distinguished from calcific aortic disease by the presence of commissural fusion.

AS leads to left ventricular outflow tract obstruction and produces an increased pressure load on the left ventricle. There is compensatory hypertrophy of the left ventricle, which may be explained by the law of Laplace, which states that wall stress of the ventricle is directly proportional to the pressure load, though inversely proportional to the wall thickness. As the ventricle becomes more hypertrophied, it is able to ameliorate the pressure load on the ventricle itself. This creates a physiological latency defined by increasing obstruction counteracted by increasing hypertrophy that, in turn preserves cardiac output. Unfortunately, the left ventricular hypertrophy is maladaptive, leading to diastolic dysfunction and impaired coronary flow reserve. Myocardial ischaemia occurs secondary to increased myocardial oxygen demand in the presence of decreased myocardial oxygen delivery and, if left untreated, leads to systolic dysfunction and eventual dilation [2]. The onset of the hallmark symptoms of severe AS—angina pectoris, syncope and heart failure—signifies an increased mortality risk [1].

Diagnosis

The characteristic murmur of AS is a systolic ejection murmur heard at the base of the heart in the right second intercostal space. It is usually harsh in quality with radiation to the carotid arteries. As the stenosis worsens, the peak of the crescendo-decrescendo murmur moves towards the second heart sound corresponding with a slowed, delayed carotid artery upstroke (*pulsus parvus et tardus*). The intensity of the murmur may decrease, while radiation may be extended toward the apex where a high-pitched vibratory murmur, akin to a paediatric Still's murmur, may be heard (Gallavardin

phenomenon). The A2 component of the second heart sound softens, leading to a single S2 and an S4 that may be auscultated. Palpation may reveal a thrill at the sternal notch and a displaced left ventricular apical impulse.

Electrocardiograms are usually non-diagnostic, but may show signs of left ventricular hypertrophy with ST and T wave abnormalities indicative of LV strain, as well as left atrial enlargement.

Chest radiography is usually normal with AS, but may show calcification of the aortic valve. Patients with bicuspid aortic valves may exhibit dilation of the ascending aorta. As AS progresses and left ventricular failure ensues, the cardiac silhouette enlarges and pulmonary oedema may be evident.

Transthoracic echocardiography remains the imaging modality of choice to assess AS. Information obtained includes valve structure, annular size, aortic valve area, transvalvular peak jet velocity, left ventricular systolic function, and the extent of left ventricular hypertrophy. Transvalvular gradients can be estimated using the velocity of flow through the valve orifice via the modified Bernoulli equation. More advanced diagnostics may be obtained to estimate valvular load, systemic arterial compliance, and overall left ventricular haemodynamic load. Exercise stress echocardiography is a useful adjunct to unmask findings that may be absent at rest [6].

Computed tomography angiography (CTA) provides anatomic detail of the aortic valve, left ventricle, and ascending aorta, which may be useful when the CTA is obtained as a method of studying the coronary arteries. The high radiation load, as well as the lack of flow-related parameters, makes CTA a poor choice for primary valve assessment [7].

Cardiovascular magnetic resonance imaging has become a useful adjunct to echocardiography in assessing aortic valve disease, particularly when information regarding the left ventricle, such as ventricular volumes and mass, is sought. Abnormalities in the left ventricular myocardium may be observed through the use of late-gadolinium techniques [8].

Aortic regurgitation

Aetiology and pathophysiology

Acute aortic regurgitation (AR) is differentiated from chronic AR as the former often results in unexpected haemodynamic compromise necessitating intensive care management. Infective endocarditis causes most acute AR, although it is less commonly caused by type A aortic dissection (usually in the setting of connective tissue disorders, bicuspid aortic valve, or atherosclerotic disease), blunt chest trauma, or a ruptured aortic valve leaflet fenestration. After aortic valve replacement, prosthetic valve regurgitation may occur after tearing or thrombosis of a valve leaflet. Perivalvular leaks may occur due to infection of the valve annulus after valve replacement [9].

Acute AR leads to a marked rise in left ventricular end-diastolic pressure due to the regurgitant volume. This pressure may be transmitted to the left atrium and pulmonary vascular bed leading to pulmonary oedema. The left ventricle is non-compliant and fails to dilate in response to its volume load. Cardiac output is therefore impaired due to a decreased stoke volume, while the pulse pressure narrows. Myocardial ischaemia may result due to decreased diastolic coronary pressure in the setting of high myocardial oxygen demand brought on by tachycardia and elevated end-diastolic pressure.

Diagnosis

The soft early diastolic murmur of acute AR is differentiated from chronic AR, which is a decrescendo murmur that is longer in duration and of higher pitch. Non-coaptation (non-apposition) of the aortic valve leaflets may lead to a soft A2 component of the second heart sound. Haemodynamically, patients with acute severe AR are usually tachycardiac and hypotensive. Tachypnoea and increased work of breathing accompanied by crackles on pulmonary auscultation are ominous signs. Differential pulses may be observed with AR due to aortic dissection.

Electrocardiography in acute AR usually shows sinus tachycardia, although non-specific ST segment and T wave changes indicative of left ventricular strain may be present. Ischaemic ST segment and T wave changes may be seen in primary ischaemia leading to AR, as well as haemodynamic coronary insufficiency.

Chest radiography usually shows pulmonary oedema without cardiomegaly unless the AR is chronic and associated with a dilated left ventricle. The mediastinum may be widened with aortic dissection.

If acute AR is suspected, urgent transthoracic echocardiography is indicated. TTE with provide information regarding valve anatomy, left ventricular size and function, as well as the anatomy of the proximal aorta. Severity of insufficiency may be delineated with colour flow Doppler examination of the regurgitant jet, as well as the distal aorta. TTE may determine aetiology, e.g. a valve vegetation consistent with endocarditis, a dilated aortic root or a bicuspid aortic valve. Transoesophageal echocardiography may be indicated with a non-diagnostic TTE study [10].

Computed tomography gives similar anatomic details regarding the aortic valve and root as echocardiography, although the lack of haemodynamic assessment capabilities and the radiation burden make it a poor choice for primary valve assessment. [7]. If aortic dissection is suspected, CT angiography is the diagnostic modality of choice.

While cardiac magnetic resonance imaging provides information regarding aortic regurgitant fraction, left ventricular size and function, as well as aortic root anatomy, this modality is more suited for comprehensive assessment of chronic AR, rather than acute AR [8].

Mitral stenosis

Aetiology and pathophysiology

Although measures are now well established to diagnose and treat *Streptococcal* pharyngitis and have reduced the incidence of mitral stenosis (MS), rheumatic disease, albeit rare, remains the leading cause of MS in industrialized countries. The rheumatic heart disease burden in developing countries remains a significant source of mortality and morbidity. Less common causes of MS include calcification of the mitral valve annulus associated with atherosclerosis, past infective endocarditis, underlying congenital abnormalities, underlying rheumatological or renal disease. Rheumatic heart disease causes inflammation of the mitral valve leaflets and supporting structures, and leads to thickening and scarring of the valve leaflets and chordea tendinae with valve leaflet fusion. Although the mitral valve is primarily affected, dysfunction of all other valves may be seen [11].

With progressive MS, a pressure gradient forms between the left atrium and left ventricle, leading to left atrial hypertension. The

increase in left atrial pressure causes an increased pressure load on the right ventricle. With severe MS, pulmonary hypertension occurs and may manifest as right ventricular failure with dyspnoea and exercise intolerance. MS is a slowly progressive disease with symptoms of activity intolerance, dyspnoea on exertion, paroxysmal nocturnal dyspnoea and orthopnoea occurring during a prolonged latent period. Atrial arrhythmias may be the initial presenting symptom, while others may become symptomatic after a period of haemodynamic stress, such as with fever, anaemia, hypovolaemia or pregnancy [12].

Diagnosis

Patients with severe MS often present with signs of heart failure, including pulmonary crackles, jugular venous distention, hepatomegaly, and lower extremity oedema. Cardiac examination reveals an accentuated first heart sound with an opening snap followed by a low-frequency diastolic rumble. In advanced disease, the first heart sound may become softer as the valve leaflets become more dysfunctional. There may be a right ventricular lift with underlying pulmonary hypertension. The timing of the second heart sound in relation to the opening snap may be a clue towards gauging severity of disease, with decreasing S2 to OS intervals indicating increasing left atrial pressure and worsening disease.

Electrocardiography may show left atrial enlargement with right ventricular hypertrophy seen in advanced disease. Underlying atrial fibrillation may be diagnosed if present.

Chest radiography may exhibit left atrial enlargement with enlargement of the main pulmonary arteries. Right ventricular enlargement is seen with advanced disease. Left atrial hypertension may be manifest as pulmonary oedema or effusions.

Transthoracic echocardiography (TTE) is the diagnostic modality of choice, providing information regarding valve leaflet anatomy that may differentiate between aetiologies of MS and amenability to percutaneous treatment. The mitral valve area can be calculated, which grades the severity of disease. Doppler examination provides the mitral transvalvular pressure gradient that estimates the pressure difference between left atrium and left ventricle. Left atrial dilation can be detected while right ventricular systolic pressure can be estimated with an adequate tricuspid regurgitation jet. Lastly, information regarding size and function of the left and right ventricles can be obtained [13].

CTA provides similar anatomic detail with regard to valve leaflet anatomy and chamber sizes. However, the lack of haemodynamic assessment capabilities and the radiation burden make it a poor choice for primary valve assessment [7].

Cardiac magnetic resonance imaging provides much of the same information as echocardiography including anatomic detail and some haemodynamic parameters. It may be a useful adjunct to echo to better visualize restricted mitral valve leaflets [8].

Mitral regurgitation

Aetiology and pathophysiology

Acute, as opposed to chronic, magnetic resonance (MR) may lead to haemodynamic compromise and pulmonary oedema necessitating ICU management. Acute MR is either due to 'primary' or 'secondary' causes. This useful classification guides initial treatment as the former are best treated surgically, while the latter may be amenable to early medical treatment. 'Primary' MR results from disruption of the mitral valve apparatus, either at the leaflet or supporting structures. Endocarditis or decelerating trauma may cause perforation or rupture of a valve leaflet, respectively. Underlying myxomatous disease may lead to chordal rupture. Papillary muscle rupture can occur with myocardial infarction. 'Secondary' MR is more often chronic than acute, and results from abnormalities of the left ventricle. Cardiomyopathy results in displacement of the papillary muscles and ischaemia may result in dyskinesis of the ventricular wall, both of which may prevent proper mitral valve closure. Occasionally, acute 'functional' MR may arise with myocardial infarction or acute heart failure exacerbations, such as rapidly progressing myocarditis or post-partum cardiomyopathy [9].

Acute MR results in a rapid increase in the volume load of the left atrium. The left atrial hypertension frequently leads to pulmonary oedema, although patients with a more compliant left atrium, such as those with chronic MR, may be more tolerant of the volume load. Left ventricular systolic function may be preserved or augmented due to an increase in preload conditions, although patients with underlying systolic dysfunction may be profoundly symptomatic.

Diagnosis

Acute MR causes a soft, early S1-coincident murmur as opposed to the holosystolic murmur heard in chronic MR due to the early equalization of left atrial and ventricular pressures. The patient is usually tachycardic. The first heart sound may be of decreased intensity. Pulmonary examination may reveal tachypnoea with crackles on pulmonary examination.

Electrocardiography may show sinus tachycardia with non-specific ST segment and T wave changes. Left atrial enlargement may be present. Ischaemic ST segment and T wave changes may be present if myocardial ischaemia is the aetiology of, or if the ischaemia is caused by, MR. Underlying atrial fibrillation may be diagnosed.

Chest radiography usually shows a normal cardiac silhouette with pulmonary oedema in acute MR. Left atrial and left ventricular enlargement is seen in chronic MR. If the regurgitant jet is directed toward a particular pulmonary vein, the oedema primarily will be seen in the draining lung segment, which may mimic a lobar pneumonia [14].

Transthoracic echocardiography provides the diagnosis of MR and can quantify its severity. Left ventricular size and function may be assessed as well. The presence of severe MR without compensatory left ventricular enlargement raises the suspicion of an acute process. The mechanism of regurgitation may be assessed, particularly with regard to an organic (i.e. due to a ruptured chordae or perforated leaflet) versus a functional cause (i.e. with underlying myocardial dysfunction). Right ventricular pressures may be estimated if an appropriate tricuspid regurgitant jet is present [15].

CTA is a poor choice to evaluate causes of acute MR, as aetiologies, such as ruptured chordae may be difficult to see. As with other forms of valve disease, the lack of haemodynamic data and the large radiation load make CTA a poor choice of primary assessment of MR [7].

Cardiac magnetic resonance imaging quantifies regurgitant and ventricular volumes, as well as ventricular function and may hint at an aetiology of mitral valve regurgitation. While not particularly suited for primary assessment of acute MR, it remains a useful adjunct to echocardiography in terms of assessment of chronic MR [8].

Prosthetic valve dysfunction

Surgical therapy is the primary treatment modality for severe heart valve lesions, and its superiority over medical treatment in haemodynamically important lesions is well documented. Prosthetic valve replacement is the most prevalent of surgical procedures to address heart valve problems, although the long-term survival after valve replacement is truncated, with a poorer prognosis for mitral valve replacement as compared with aortic valve replacement [16]. Prosthetic valves are either mechanical or bioprosthetic with patient age, anticoagulation issues, pre-operative condition, re-operation concerns, and patient preference informing the decision regarding the type of implant. The durability of mechanical valves with the need for life-long anticoagulation is contrasted with a bioprosthetic valve's exceedingly low risk of thromboembolic events in the setting of a shortened duration before valve deterioration. All prosthetic valves are at risk for structural valve deterioration, the time course of which is related to age at valve replacement surgery, with younger patients experiencing a shorter valve lifespan. Acute prosthetic valve dysfunction may lead to haemodynamic compromise necessitating ICU management. Notable aetiologies of acute prosthetic valve dysfunction include valve thrombosis, prosthetic valve endocarditis and perivalvular regurgitation [17]. Patients with prosthetic valves presenting to the ICU with haemodynamic abnormalities warrant transthoracic or transoesophageal echocardiography to assess prosthetic valve function.

CHAPTER 159

Therapeutic strategy in valvular problems

Jason F. Deen and Karen K. Stout

Key points

- Medical management of aortic stenosis may be guided via the use of invasive haemodynamic monitoring, such as a Swan–Ganz catheter.
- Patients with severe symptomatic aortic stenosis with decreased left ventricular function may benefit from transcatheter aortic valve replacement if surgical aortic valve replacement is too high risk.
- Acute aortic regurgitation often leads to haemodynamic compromise and may be treated with afterload reduction along with inotropic support.
- Ideally, mitral stenosis is treated with percutaneous balloon valvuloplasty if the mitral valve anatomy is favourable.
- Chronic mitral regurgitation may be managed surgically or medically, depending on the aetiology of the valve incompetence, while acute severe mitral regurgitation most often requires surgery.

Aortic stenosis

For patients with severe aortic stenosis, surgical aortic valve replacement remains the definitive treatment. For those presenting with profound heart failure symptoms or cardiogenic shock, surgery remains the definitive treatment, but diuresis can be carefully performed. Close attention must be paid to the patient's volume status, as decreases in left ventricular preload may result in decreased cardiac output. Afterload reduction can be carefully pursued in select patients, but afterload reduction in patients with limited ability to augment stroke volume can precipitate haemodynamic collapse. Therefore, caution should be undertaken in medically managing what is inherently a mechanical abnormality of fixed, high afterload. Medical management, therefore, may be best guided via invasive hemodynamic monitoring [1]. Management of patients with low-flow/low-gradient aortic stenosis is complex. Those with diminished left ventricular systolic function due to increased afterload usually experience an improvement in left ventricular systolic function following surgery, while patients with decreased left ventricular systolic function due to fibrosis from myocardial ischaemia or cardiomyopathy are less like to benefit. Determining contractile reserve is useful here, and is defined as an increase in stroke volume >20% with inotrope (dobutamine) infusion [2]. Aortic valve replacement should be considered in low-flow/low-gradient aortic stenosis, particularly those with intact contractile reserve.

Aortic valve replacement should be offered to symptomatic patients with severe aortic stenosis in the absence of surgical contraindications. Patients with severe aortic stenosis, with or without symptoms, who are scheduled for coronary artery bypass grafting, should have an aortic valve replacement (AVR) at the time of surgery. Post-operative mortality for aortic valve replacement is approximately 4%, although the risk increases to 6.8% if the aortic valve replacement is combined with coronary artery bypass grafting [3]. Older age at time of surgery is not a contraindication, as surgical outcomes are similar between patients less than and greater than 80 years [4]. Surgical risk may be calculated through online tools from the Society of Thoracic Surgeons or the EuroSCORE. Symptomatic patients deemed inoperable or those patients with severely diminished left ventricular systolic function may benefit from transcatheter aortic valve replacement (TAVR) [5,6]. Aortic balloon valvuloplasty may be performed in haemodynamically unstable patients as a bridge to aortic valve replacement or TAVR, and is considered palliative when both surgery and TAVR are contraindicated [7].

Indications for surgical therapy

Severe aortic stenosis (AS) is defined by an aortic valve area <1.0 cm^2, mean transvalvular gradient >40 mmHg and peak jet velocity >4.0 m/sec. Patients with severe AS and symptoms related to aortic stenosis should undergo aortic valve replacement, either primarily or at the time of coronary artery bypass grafting. Asymptomatic patients with severe AS and decreased left ventricular systolic function (ejection fraction (EF) <50%), symptoms of AS on exercise testing, or who are undergoing coronary artery bypass grafting should undergo aortic valve replacement [7].

Aortic regurgitation

Acute aortic regurgitation (AR) is treated surgically with either valve replacement or valve repair. Pre-operative medical management is often necessary in haemodynamically unstable patients. Afterload reduction with vasodilators, such as nitroprusside, together with inotropic agents, may improve cardiac output. Associated ascending aortic dissection (type A) necessitates aortic root repair, although it may also require an additional aortic valve procedure to ensure competency if the aortic valve is congenitally abnormal or otherwise aneurysmal [8]. Surgery for chronic severe AR is

indicated when symptomatic or in the asymptomatic patient with diminished left ventricular systolic function (EF <50%). Severe AR should be addressed surgically with concomitant coronary artery bypass grafting or surgery on the ascending aorta irrespective of the absence of symptoms. Surgery should be considered in those patients with severe AR and normal left ventricular systolic function if the left ventricle is dilated (end-diastolic dimension >70 mm or end-systolic dimension >50 mm) [7].

Mitral stenosis

Severe symptomatic mitral stenosis (MS) is definitively treated by relieving the mechanical obstruction to flow into the left ventricle. This may be accomplished via balloon mitral valvuloplasty, surgical commissurotomy, or mitral valve replacement. Medical management may be necessary to treat associated pulmonary hypertension, pulmonary oedema, or atrial fibrillation. Atrial fibrillation with a rapid ventricular response unresponsive to medical therapies for rate control may be treated with direct cardioversion [9]. Factors that may exacerbate the symptoms of MS, such as volume overloading and anaemia should be corrected. Medical management, with diuresis and rate control to optimize diastolic filling, can significantly improve symptomatology.

Severe MS is defined as a mitral valve area <1.0 cm^2 with a transvalvular gradient >10 mmHg. Patients with symptomatic MS or a mitral valve area ≤1.5 cm^2 meet criteria for intervention. With favourable valve anatomy, percutaneous balloon mitral valvuloplasty is the treatment of choice as the mortality risk is less compared with open surgery. This is especially true if there are contraindications to surgery. A successful result, as defined by a valve area >1.5 cm^2 without significant mitral insufficiency, is achieved in the majority of cases. If there is a contraindication to balloon mitral valvuloplasty, including mitral valve area >1.5 cm^2, the presence of significant mitral regurgitation, left atrial thrombus, non-favourable valve anatomy or the presence of concomitant aortic valve disease, surgery is indicated [7]. Mitral valve replacement is performed more often than open commissurotomy with an operative mortality risk of 3–8% and correlates with the presence of pulmonary hypertension, underlying function status, age, and the presence of coronary artery disease [9].

Mitral regurgitation

Classification of acute mitral regurgitation (MR) etiology into subgroups of primary versus secondary informs therapeutic options. Primary MR, which results from disruption of the mitral valve apparatus either at the leaflet or supporting structure level, is treated surgically. Secondary MR is due to abnormalities in the left ventricle and is initially treated medically, with a default to surgery if medical options directed at the underlying pathophysiology fail. Patients with acute MR due to obstructive coronary artery disease and subsequent ischaemic cardiomyopathy require revascularization. In both organic and functional types of severe MR, initial medical stabilization plays a major role in an ICU setting. This may be accomplished by reducing afterload with vasodilatory agents (i.e. nitroprusside) along with inotropes, if cardiac output is compromised, and diuretics if pulmonary oedema is present. Intra-aortic balloon pumps may be used to acutely lower left ventricular afterload and are particularly useful in acute secondary mitral regurgitation due to myocardial ischaemia or cardiomyopathy [8].

When mitral valve surgery is undertaken, mitral valve repair, as opposed to valve replacement, results in lower short- and long-term mortality, while better preserving left ventricular function, but there is a higher incidence of recurrent regurgitation [7,10]. Factors favouring mitral valve replacement include underlying calcification of the valve leaflets and endocarditis, and mitral regurgitation. Surgery for secondary MR is riskier than surgery for primary MR and is associated with impaired survival, particularly in the setting of decreased left ventricular function [10]. For those patients in poor clinical condition who may have relative contraindications to surgery, including those with left ventricular dysfunction, percutaneous mitral valve repair is feasible, and is associated with a high rate of success and improvement in post-procedural left ventricular function [11]. Data, especially long-term, remain incomplete and the role of percutaneous intervention remains unclear.

PART 5.10

Endocarditis

CHAPTER 160

Pathophysiology and causes of endocarditis

Franck Thuny and Didier Raoult

Key points

- Endocarditis is a fatal disease if not promptly diagnosed and treated.
- The pathophysiology is complex, and is based on a local prothrombogenic state of the endocardium and the capacity of some pathogens to adhere, colonize, and invade this altered endocardium.
- *Staphylococcus aureus* is the commonest cause of infective endocarditis.
- Blood cultures and echocardiography are the cornerstones of diagnosis, but can be negative in >10% of cases.
- Other microbiological, immunological, and imaging testing should be considered in difficult diagnostic situations.

Introduction

Endocarditis is defined as an inflammation of the endocardial surface of the heart. This may include heart valves, mural endocardium or the endocardium that covers implanted material, such as prosthetic valves, pacemaker/defibrillator leads, and catheters. Infective and non-infective-related causes must be distinguished (Box 160.1). In most cases, the inflammation is related to a bacterial or fungal infection with oral streptococci, group D streptococci, staphylococci and enterococci accounting for 85% of episodes. Infective endocarditis (IE) is a serious disease with an incidence ranging from 30 to 100 episodes/million patient-years [1]. From various portals of entry (e.g. oral, digestive, cutaneous) and a subsequent bacteraemia, pathogens can adhere and colonize intracardiac foreign material or adhere to previously damaged endocardium, due to numerous complex processes based on a unique host–pathogen interaction. Rarely, endocarditis can be related to non-infective causes, such as immunological or neoplastic.

Mortality is high, with more than one-third dying within a year of diagnosis from complications such as acute heart failure or emboli [2]. This disease still remains a diagnostic challenge, with many cases being identified and subsequently treated too late. Diagnosis of IE usually relies on the association between an infectious syndrome and recent endocardial involvement. Blood cultures and echocardiography are the main diagnostic procedures, but are negative in almost 30% of cases, requiring the use of more sophisticated techniques, including serological and molecular tests. Computed tomography, magnetic resonance imaging (MRI), and positron emission tomography are promising imaging modalities.

Improved understanding of its pathophysiology and the development of relevant diagnostic strategies enables accelerated identification and treatment, and thus an improved prognosis [3].

Aetiology

IE results in a complex pathogenesis involving many host-pathogen interactions. Oral streptococci, group D streptococci (e.g. *Streptococcus gallolyticus*), staphylococci, and enterococci are involved in 85% of episodes [1], with staphylococci accounting for 30% [1,4]. Oral streptococci are the major IE pathogens in the general population, while *Staphylococcus aureus* and coagulase-negative staphylococci are more often found in intravenous drug users, and in those with prosthetic valve or health care-related IE [4,5]. *Streptococcus gallolyticus* and enterococci are increasingly prevalent in the elderly, and often associated with colon tumours [6]. In 15% of cases no aetiology is found by blood culture [7]. Although often related to previous antibiotic therapy (commonly with streptococcal IE), a substantial number result from intracellular bacteria, fungi or other fastidious organisms (Box 160.1) [8].

Endocarditis can result from non-infective pathological conditions such as autoimmune disease and neoplasia (marantic endocarditis) [8,9]. Libman–Sacks endocarditis is the commonest cardiac manifestation of systemic lupus erythematosus, and is associated with primary or secondary antiphospholipid syndrome. Antiphospholipid antibodies, especially the IgG anticardiolipin and lupus anticoagulant, are involved in the pathogenesis of the disease by favouring formation of non-bacterial thrombotic vegetations [10]. Endocarditis has been described in other autoimmune conditions, such as rheumatoid arthritis. Immunological inflammation can be observed during rheumatic fever, where damage to endocardium, myocardium, and pericardium results from antibody cross-reactivity following *Streptococcus pyogenes* infection. Thrombotic sterile vegetations can be observed in the context of neoplasia (especially lung and pancreas) due to hypercoagulable states and, sometimes, with antiphospholipid antibodies. Loeffler's endocarditis is a form of restrictive cardiomyopathy with eosinophilic proliferation in endocardial and myocardial tissue. Finally, foreign material rejection or allergic phenomena may be a cause of non-infective porcine bioprosthetic valve endocarditis [9].

Box 160.1 Causes of endocarditis

Infective causes

'Standard' bacteria

- Oral (viridans) streptococci.
- *Streptococcus gallolyticus* (and other group D streptococci).
- *Streptococcus pneumonia.*
- *Streptococcus pyogenes.*
- Enterococci.
- *Staphylococcus aureus.*
- Coagulase negative staphylococci.
- Enterobacteriaceae.

Fastidious bacteria

- HACEK group.
- *Coxiella burnetii.*
- *Bartonella* spp.
- *Propionibacterium acnes.*
- *Tropheryma whipplei.*
- *Abiotrophia* ssp.
- *Mycoplasma* spp.
- *Legionella* spp.
- *Corynebacterium diphteriae.*
- *Listeria monocytogenes.*
- *Chlamydia* spp.
- *Finegoldia magna.*
- *Candida* spp.
- *Aspergillus* spp.

Virus (controversial)

Enterovirus.

Non-infective causes

- Acute rheumatic fever.
- Libman-Sacks endocarditis (antiphospholipid syndrome):
  - With systemic lupus.
  - With systemic lupus.
  - Without systemic lupus.
- Rheumatoid arthritis.
- Marantic endocarditis (neoplasia).
- Loeffler endocarditis.

HACEK, *Haemophilus* spp., *Actinobacillus* spp., *Cardiobacterium* spp., *Eikenella* spp., *Kingella* spp.

Pathophysiology

IE usually occurs on an endocardium with pre-existing lesions, or on intracardiac foreign material [2]. From various portals of entry (e.g. oral, digestive, cutaneous) and a subsequent bacteraemia, pathogens can adhere and colonize previously damaged endocardium due to numerous complex processes based on an unique host-pathogen interaction [11]. Severe life-threatening complications such as acute heart failure or embolic events can then occur (Fig. 160.1).

Underlying host lesions

The endocardium is normally resistant to infection. However, degenerative processes (fibrosis, calcifications), turbulent blood flow created by valvular or congenital heart diseases, and mechanical lesions secondary to material implantation can provoke endocardial damage. This results in exposure of the extracellular matrix, apoptosis, production of tissue factor, and then thrombus formation (non-bacterial vegetations). The presence of underlying endocardial damage may induce exposure of altered phospholipids (cardiolipin) on the outer membrane of endothelial cells, resulting in antiphospholipid antibody production by immune cells. Antiphospholipid antibodies may be involved in thrombus formation, even in the absence of autoimmune disease [12]. The formation of such non-bacterial thrombotic endocarditis may be a key event facilitating pathogen adherence and infection.

Alternatively, an endocardium free of previous lesions can form an adhesive surface to circulating virulent pathogens, such as *S. aureus*, due to expression of integrins by endothelial cells [13].

The role of bacteraemia

This has been studied in animals with catheter-induced, non-bacterial thrombotic endocarditis. Both the magnitude of bacteraemia and the pathogen's ability to attach to damaged valves are important. Bacteraemia occurs with invasive procedures, but also from routine daily activities, such as chewing, flossing, and tooth brushing. Accumulating numbers of circulating bacteria are greater after these activities than after an invasive puncture procedure. Such spontaneous low-grade, short duration, but repeated, bacteraemia may explain why most cases of IE are not preceded by invasive procedures. This questions the efficacy of single-dose antibiotic prophylaxis.

The host–pathogen interaction

During bacteraemia, some pathogens can adhere to components of the non-bacterial thrombotic vegetation or the inflamed endocardium. Fibrinogen, fibronectin or platelet proteins are recognized by adhesins located on the pathogen surface [5]. The predominance of Gram-positive pathogens can be explained by these organisms being the most equipped with these adhesins, collectively referred to as microbial surface component reacting with adhesive matrix molecules [5]. After adhesion, subsequent colonization and invasion of the endocardium maintain both inflammatory and coagulation processes, resulting in a vicious circle with the formation of infective vegetations in which the pathogens persist, multiply, and escape from the host defence systems. Consequently, the vegetations grow, a neo-angiogenesis process occurs and the valve tissue is destroyed, resulting ultimately in embolic events, abscess formation, and valve dysfunction [11]. An excessive host response

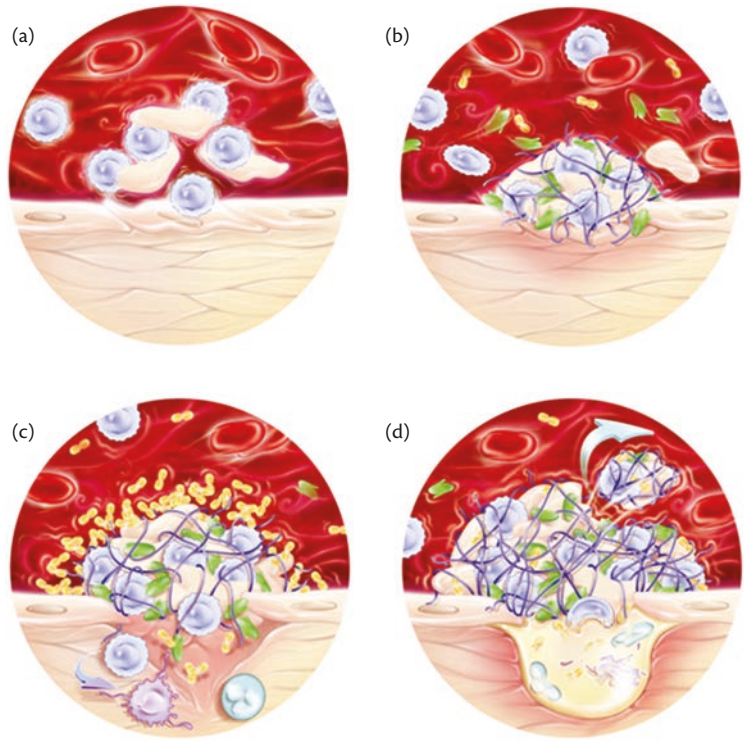

Fig. 160.1 Illustration of the infective endocarditis (IE) pathophysiology. The natural history of IE may be deconstructed into successive steps including cell apoptosis that may be promoted by blood turbulence in the vicinity of the valve lesion. (a) Procoagulant activity that results in fibrin and platelet deposition. (b) Bacterial colonization and chemoattraction of neutrophils increasing vegetation size. (c) Tissue remodelling and neoangiogenesis leading to the functional destruction of the valve (d). At this stage, the situation is irreversible and cardiac surgery is necessary.

may also be responsible for aggravation of lesions by secondary autoimmune effects, such as immune complex glomerulonephritis and vasculitis, but also an increasing risk of embolic events due to hypersecretion and activation of matrix metalloproteinases [14] and increased production of antiphospholipid antibodies (Fig. 160.1) [12].

Diagnosis

Evolution of diagnostic strategies

In cases carrying a high suspicion of IE, appropriate antibiotics must be started as soon as possible as delay has a negative effect on outcome. Efforts should be made to rapidly identify both patients with a likely diagnosis of IE and the causative pathogen to ensure that appropriate antibiotic therapy begins promptly.

Diagnosis usually relies on the association between an infectious syndrome and recent endocardial involvement. This is the cornerstone of the various classifications and scores, such as the Duke University criteria, proposed to facilitate the difficult diagnosis of this disease. In 2002, these criteria were further modified to include *Coxiella burnetii* serology as a new major criterion (Box 160.2) [15]. However, sensitivity is limited, especially at an early stage of the disease, in cases of negative blood culture and in the presence of prosthetic valve or pacemaker/defibrillator leads. New diagnostic strategies are emerging to improve pathogen identification when blood cultures are negative, and to demonstrate endocardial involvement when echocardiography is negative or doubtful. Polymerase chain reaction (PCR) techniques, immunohistochemistry, systematic serologies, antiphospholipid antibodies, MRI, and positron emission tomography-computed tomography (PET-CT) scans are promising tools that could be integrated into future diagnostic classifications (Fig. 160.2), as proposed by Raoult et al. for *Coxiella burnetii* endocarditis (Box 160.3) [16].

Clinical presentation

Although fever in a patient with a cardiac predisposition (heart valve disease, intracardiac materials, congenital heart disease) is the most frequent circumstance leading to diagnosis (almost 50% of cases [2]), clinical histories are highly variable (Box 160.4). Therefore, a high index of suspicion and low threshold for investigation are essential. Blood cultures and echocardiography still remain the cornerstones for diagnosis [6].

Microbiological investigations

The challenges are to rapidly identify the causative pathogen and the rare cases of non-infective endocarditis. In IE, blood cultures are negative in 2.5–31% of cases [7,8]. This often poses diagnostic and therapeutic issues. While culture-negative endocarditis is often related to previous antibiotic therapy, many result from infection with obligate intracellular bacteria, fungi, and fastidious pathogens whose isolation requires specialized culture techniques [8]. Appropriate antibiotic treatment is often delayed in such cases, potentially affecting outcomes.

To resolve these issues, some authors propose standardization of the timing and type of laboratory tests. This improves yields by systematically screening for all potential causes of IE [7]. The 'diagnostic

Box 160.2 Definition of infective endocarditis according to the proposed modified Duke criteria

Definite infective endocarditis

Pathological criteria

- **Micro-organisms**: demonstrated by culture or histological examination of a vegetation, a vegetation that has embolized, or an intracardiac abscess specimen.

  Or

- **Pathological lesions**: vegetation or intracardiac abscess confirmed by histological examination showing active endocarditis.

Clinical criteria

- Two major criteria; or
- One major criterion and three minor criteria; or
- Five minor criteria.

Possible infective endocarditis

- One major criterion and one minor criterion.
  Or
- Three minor criteria.

Rejected

- Firm alternate diagnosis explaining evidence of infective endocarditis.
- Resolution of infective endocarditis syndrome with antibiotic therapy for <4 days.
- No pathological evidence of infective endocarditis at surgery or autopsy, with antibiotic therapy for ≤4 days.
- Does not meet criteria for possible infective endocarditis, as above.

Major criteria

Blood culture positive for IE

- **Typical micro-organisms consistent with IE from two separate blood cultures**: (Viridans streptococci, *Streptococcus bovis,* HACEK group, *Staphylococcus aureus*; or community-acquired enterococci, in the absence of a primary focus; or micro-organisms consistent with IE from persistently positive blood cultures, defined as follows: at least two positive cultures of blood samples drawn >12 hours apart; or all of three or a majority of ≥4 separate cultures of blood (with first and last sample drawn at least 1 hour apart).
- Single positive blood culture for *Coxiella burnetii* or antiphase I IgG antibody titre >1:800.

Evidence of endocardial involvement

- Echocardiogram positive for IE defined as follows:
  - Oscillating intracardiac mass on valve or supporting structures, in the path of regurgitant jets, or on implanted material in the absence of an alternative anatomic explanation; or
  - Abscess; or
  - New partial dehiscence of prosthetic valve or new valvular regurgitation (worsening or changing of pre-existing murmur not sufficient).

Minor criteria

- Predisposition, predisposing heart condition or injection drug use.
- Fever, temperature >38°C.
- Vascular phenomena, major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial haemorrhage, conjunctival haemorrhages, and Janeway's lesions.
- **Immunological phenomena**: glomerulonephritis, Osler's nodes, Roth's spots, and rheumatoid factor.
- **Microbiological evidence**: positive blood culture, but does not meet a major criterion as noted above or serological evidence of active infection with organism consistent with IE.

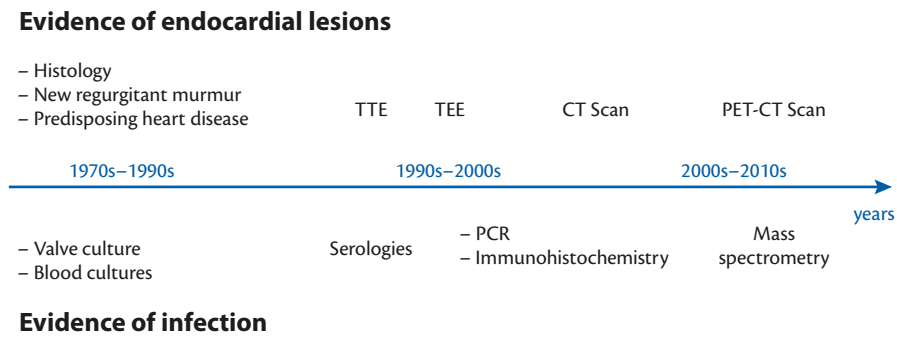

Fig. 160.2 Evolution of diagnostic methods to diagnose infective endocarditis.
TTE, transthoracic echocardiography; TEE, trans-oesophageal echocardiography; CT, computed tomography; PET, positron emission tomography.

kit', composed of three units, can be performed within 2 hours for every patient with suspected IE. The first, performed immediately, includes a set of two blood culture bottles, for aerobic and anaerobic cultures, and a tube to collect a serum sample for detection of rheumatoid factor and estimation of specific antibodies directed against *Coxiella burnetii, Legionella pneumophila, Bartonella, Brucella, Mycoplasma*, and *Aspergillus* spp. The second and third units each contain a set of two blood culture bottles to be used 2 hours after the first. The results of these diagnostic tests can be obtained soon after admission, thus shortening the time to institution of a specific therapy. Using this approach, clinicians would not have to defer serological testing until blood cultures are shown to be negative.

Box 160.3 Definition of Q fever endocarditis, adapted from Raoult D. Chronic Q fever: expert opinion versus literature analysis and consensus

Definite criterion

Positive culture, PCR, or immunochemistry of a cardiac valve.

Major criteria

- Microbiology: positive culture or PCR of the blood or an emboli or serology with IgGI antibodies ≥6400.
- Evidence of endocardial involvement:
  - *Echocardiogram positive for IE*: oscillating intra-cardiac mass on valve or supporting structures, in the path of regurgitant jets, or on implanted material in the absence of an alternative anatomic explanation; or abscess; or new partial dehiscence of prosthetic valve; or new valvular regurgitation (worsening or changing of pre-existing murmur not sufficient).
  - PET-scan showing a specific valve fixation and mycotic aneurism.

Minor criteria

- Predisposing heart condition (know or found on echography).
- Fever, temperature > 38°.
- Vascular phenomena, major arterial emboli, septic pulmonary infarcts, mycotic aneurysm (see PET-scan), intracranial haemorrhage, conjunctival haemorrhages, and Janeway's lesions.
- **Immunological phenomena**: glomerulonephritis, Osler's nodes, Roth's spots, or rheumatoid factor.
- **Serological evidence**: IgGI antibodies ≥800 <6400.

Diagnosis definite

- 1A criterion.
- 2B criteria.
- 1B criterion, and 3C criteria (including one microbiology evidence, and cardiac predisposition).

Diagnosis possible

- 1B criterion, 2C criteria (including 1 microbiology evidence, and cardiac predisposition).
- 3C criteria (including positive serology, and cardiac predisposition).

Box 160.4 Clinical presentation of IE

IE must be suspected in the following situations

- New regurgitant heart murmur.
- Embolic events of unknown origin.
- Sepsis of unknown origin (especially if associated with IE causative organism).
- **Fever**: the most frequent sign of IE. Should be suspected if fever is associated with:
  - Intracardiac prosthetic material (e.g. prosthetic valve, pacemaker, implantable defibrillator, surgical baffle/conduit.
  - Previous history of IE.
  - Previous valvular or congenital heart disease.
  - Other predisposition for IE (e.g. immunocompromised state, IVDA).
  - Predisposition and recent intervention with associated bacteraemia.
  - Evidence of congestive heart failure.
  - New conduction disturbance.
  - Positive blood cultures with typical IE causative organism or positive serology for chronic Q fever.
  - **Vascular or immunological phenomena**: embolic event, Roth spots, splinter haemorrhages, Janeway lesions, Osler's nodes.
  - Focal or non-specific neurological symptoms and signs.
  - Evidence of pulmonary embolism/infiltration (right-sided IE).
  - Peripheral abscesses (renal, splenic, cerebral vertebral) of unknown cause.

Reproduced from Habib G et al., 'Guidelines on the prevention, diagnosis, and treatment of infective endocarditis (new version 2009): the Task Force on the Prevention, Diagnosis, and Treatment of Infective Endocarditis of the European Society of Cardiology (ESC)', *European Heart Journal*, 2009, 30, 19, pp. 2369–2413, by permission of Oxford University Press © European Society of Cardiology, HYPERLINK "http://www.escardio.org/guidelines" www.escardio.org/guidelines.

Causative pathogens can also be identified by other means, such as cultures from valve tissue. However, pathogen detection often poses a challenge for pathologists. It can be done by non-specific histochemical stains or immunohistochemical analyses. As specific antibodies are often not available, another method termed auto-immunohistochemistry, which uses the patient's own serum, has been described for detection of micro-organisms in valve specimens.

The rapid and reliable detection of pathogens by PCR has been validated in valve tissue from patients undergoing surgery for IE. Molecular pathogen detection in blood using pathogen-specific or broad-range PCR assays for bacteria and fungi is also promising. However, cautious interpretation is crucial, because of the risk of interfering contamination (false positives). The clinical context must also be considered. These advanced methods can be integrated into a standardized multimodal strategy that allows better identification of the causes of blood-culture-negative endocarditis (Fig. 160.3) [8].

Imaging investigations

Echocardiography

Echocardiography can accurately detect endocardial involvement in IE, and must be done rapidly and repeated weekly as soon as the condition is suspected. Transthoracic echocardiography (TTE) should be used initially as a normal scan in low-risk patients provides a rapid, non-invasive confirmation that the diagnosis is unlikely. TTE is superior to transoesophageal echocardiography (TEE) for detecting anterior cardiac abscesses and for haemodynamic assessment of valvular dysfunction. Because of its higher sensitivity and specificity, TEE is recommended in cases of:

- A negative TTE associated with high clinical suspicion.
- Poor TTE quality.
- The presence of prosthetic valves or intracardiac device.
- A positive TTE [6].

The identification of vegetations, abscess, valvular perforation, or new prosthetic-valve dehiscence will confirm the diagnosis in most, though not all, cases. Diagnosis may be particularly challenging in patients with intracardiac devices, a valvular prosthesis, pre-existing severe lesions, or very small or no vegetations. An erroneous diagnosis of IE may occur in several situations; for example, differentiating between vegetations and thrombi, prolapsed cusp, cardiac tumours (myxoma or fibroelastoma), myxomatous changes, Lambl's excrescences, or strands. Innovations in imaging techniques are emerging to resolve these issues, e.g. multislice CT, PET, molecular imaging and MRI [3].

Other imaging modalities

Other imaging modalities can assist in difficult diagnosis or in therapeutic decision-making.

Computed tomography (CT) scan offers rapid imaging of the heart and other organs, thus identifying both cardiac lesions and any extracardiac complications that may modify the therapeutic strategy such as emboli, infectious aneurysms, haemorrhage and septic metastases. Moreover, it provides an anatomical assessment of the coronary bed, which is important in preoperative evaluation. CT appears useful in cases of inconclusive echocardiographic studies, especially perivalvular (abscess and pseudoaneurysms) involvement [17]. Contrast products should be used cautiously in patients with renal failure or haemodynamic instability because of the risk of worsening renal impairment in combination with antibiotic nephrotoxicity. Specific recommendations are needed to clearly define appropriate situations where contrast should be used.

Although multiple case reports demonstrate how MRI can identify valvular and perivalvular damage, the identification of silent cerebral complications appears to be its main utility. Systematic MRI detected subclinical cerebrovascular complications in about 50% of patients, and this may modify disease management [18].

Preliminary results have shown much promise for PET-CT scans in the setting of pacemaker/defibrillator leads and prosthetic valve IE [19]. This imaging modality enables measurement of metabolic activity within an organ obtained from the emission of positrons following disintegration of the injected radioactive product. It can identify inflammatory and infectious processes as the inflammatory cells have significant fluorodeoxyglucose (FDG) uptake.

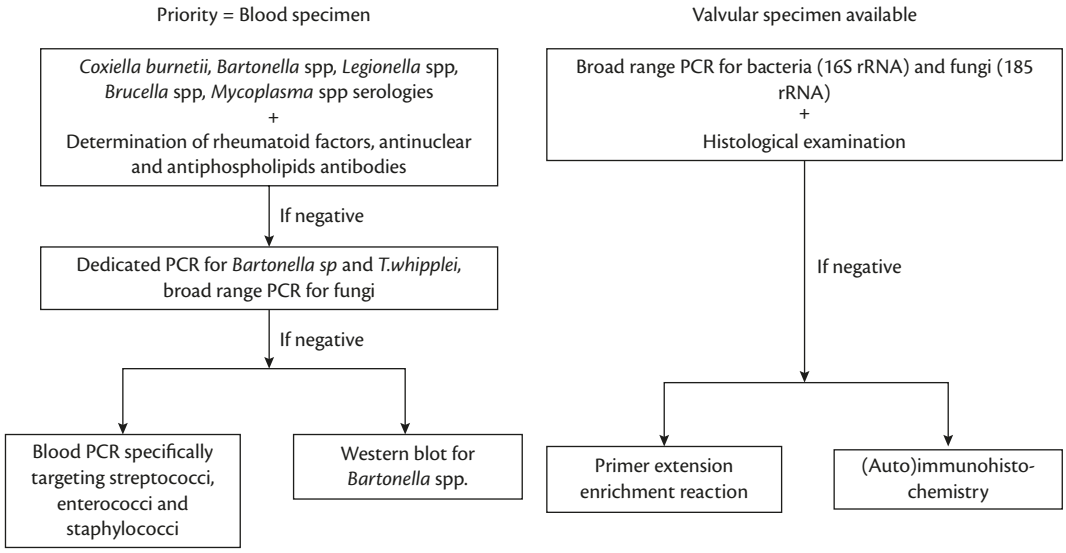

Fig. 160.3 Diagnostic tests applied to clinical specimens for identification of the causative agents of blood culture–negative endocarditis.
Adapted from Fournier PE et al., 'Comprehensive diagnostic strategy for blood culture-negative endocarditis: a prospective study of 819 new cases', Clinical Infectious Diseases, 2010, 51, 2, pp. 131–408, by permission of Oxford University Press and Infectious Diseases Society of America.

Fluorine-18 fluorodeoxyglucose (18F-FDG) PET-CT may detect periprosthetic valve abscesses when initial TTE and TEE studies are normal or of doubtful significance (Fig. 160.4). A recent study showed that the implementation of a positive PET-CT as a major criterion in the modified Duke classification significantly increases its sensitivity in cases of suspicion of prosthetic valve IE [20]. Moreover, it may reveal the source of infection, e.g. a neoplasm such as bowel cancer. At present, 18F-FDG PET-CT is being evaluated for its ability to detect peripheral emboli and to diagnose implantable electronic device infections.

Gallium-67, indium-111 or technecium-99m-HMPAO labelled-leucocyte scintigraphy is another option for imaging

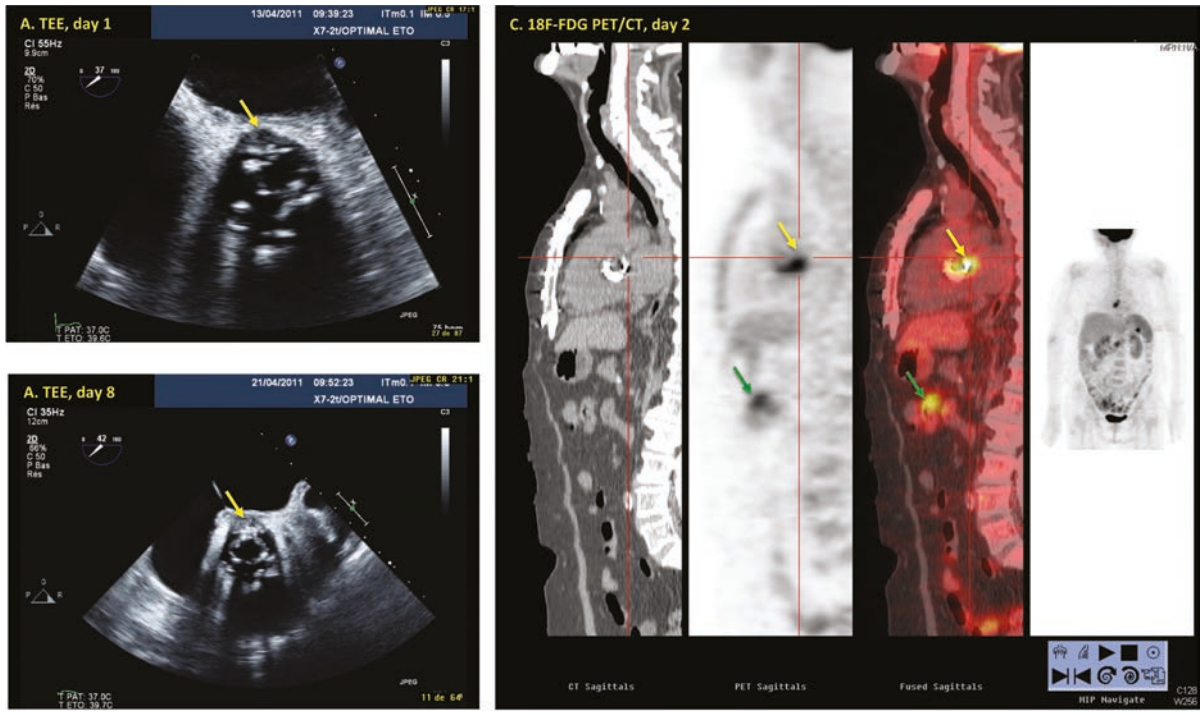

Fig. 160.4 Results of echocardiographic studies and 18F-FDG PET-CT in a case of suspicion of aortic bioprosthetic valve infective endocarditis. The first TEE (a) showed a small doubtful thickening around the aortic bioprosthetic annulus (yellow arrow) in a patient with fever and negative blood cultures. The second TEE (b), performed 8 days after, showed the development of a periprosthetic abscess (yellow arrow). The 18F-FDG PET-CT performed the day after the first TEE showed a hyperfixation around the aortic prosthesis (c, yellow arrow). The patient underwent urgent valve surgery, which confirmed the abscess. Of note, colonic hyperfixation was shown by18F-FDG PET-CT (green arrow), which reveals a polyp at subsequent colonoscopy.

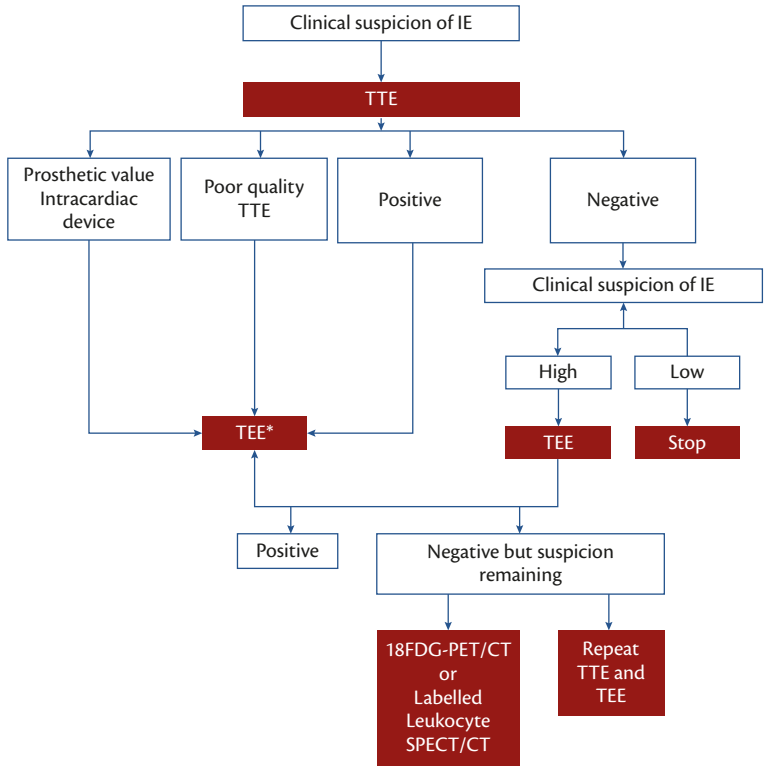

Fig. 160.5 Indications for cardiac imaging in suspected infective endocarditis.
*TEE is not mandatory in isolated right-sided native valve IE with good quality TTE examination and unequivocal echocardiographic findings.
IE, infective endocarditis; TEE, transoesophageal echocardiography; TTE, transthoracic echocardiography.

infection, both with or without incorporation with CT images. Unlike ^{18}F-FDG PET/CT this method is more specific for infection, but is more time-consuming (24 hours). Indications for cardiac imaging are summarized in Fig. 160.5.

CHAPTER 161

Prevention and treatment of endocarditis

Dominique Grisoli and Didier Raoult

Key points

- Data supporting antibiotic prophylaxis for infective endocarditis (IE) are poor and benefits are hypothetical. Nevertheless, in order to avoid medico-legal issues, physicians should follow recommendations provided by learned societies from their countries.
- General preventive measures are crucial. Invasive procedures, especially intravenous catheterization, should be restricted to the minimum in patients with predisposing cardiac conditions.
- IE is one of the deadliest infectious diseases, and its treatment must be undertaken in reference centres in a standardized and multidisciplinary manner.
- IE has become a 'surgical disease' so dedicated surgeons should be involved in therapeutic discussions from the very beginning. When indicated, surgery has to be performed without delay. Most deaths from IE result from complications that constitute definite surgical indications.
- Patients with severe symptoms or perivalvular damages are at risk of sudden death and should be monitored in critical care, while awaiting surgery.

Introduction

Initially always lethal, the prognosis of infective endocarditis (IE) has been revolutionized by antibacterial therapy and valve surgery. Nevertheless, it remains one of the deadliest infectious diseases, with ≥30% of patients dying within a year of diagnosis [1]. Its incidence has also remained stable at 25–50 cases per million per year [2].

IE results predominantly from a combination of bacteraemia and a predisposing cardiac condition including endocardial lesions and/or intracardiac foreign material. While antibiotic prophylaxis is recommended by various learned societies to cover health care procedures with the potential of causing bacteraemia in at-risk patients, there is no evidence to support this strategy. Even though the benefits are hypothetical, national guidelines should still be followed to avoid medico-legal issues. General preventive measures, such as education of clinicians and at-risk patients appear to be more crucial. Invasive procedures, especially intravenous (iv) catheterization, should be kept to the minimum possible.

The severity of IE mandates a multidisciplinary and standardized approach to treatment, with involvement of dedicated surgeons within specialist centres. Standardized antibiotic protocols have produced dramatic reductions in hospital and 1-year mortality in reference centres. Most deaths now result from complications that constitute definite surgical indications, so optimization of surgical management and avoidance of delay will clearly improve prognosis. This disease has now entered an 'early surgery' era, with a more aggressive surgical approach showing promising results [3].

Conditions such as septic shock, sudden death, and vancomycin-resistant staphylococcal endocarditis still constitute therapeutic and research challenges, and justify an important role for specialist centres.

Prevention

Existing evidence

Prophylaxis aims at preventing bacteria from growing on endocardial lesions in patients with known predisposing cardiac conditions. It is based on screening and treatment of potential entry sites for organisms, and on antibiotic prophylaxis given before health care procedures that carry various rates of induced bacteraemia.

Surprisingly, no strong evidence supports the use of antibiotic prophylaxis. Recommendations are mainly based on experimental studies using transient high-grade bacteraemia to reproduce the potential effects of a dental procedure [4]. However, everyday actions, such as chewing or tooth brushing may also cause low-grade bacteraemia [5], while cumulative everyday bacteraemia over 1 year was estimated at 6 million times higher than bacteraemia following dental extraction. As underlined by a recent Cochrane review of antibiotic prophylaxis against IE in dentistry [6], only a few case-control studies exist, of which only one could be included in their review, with no significant protective effect being shown.

Furthermore, in large observational studies, only a minority of IE cases was secondary to medical procedures [7]. It is unlikely that new data will be provided in the near future. Indeed, because of the low incidence of this disease, a randomized controlled trial would need a huge number of patients, and would probably cause legal and ethical issues. Despite low reported rates of hypersensitivity and anaphylaxis, any benefit from antibiotic prophylaxis must also be balanced against potential adverse effects. Of note, the extensive use of antibiotics is responsible for the development of resistant bacteria, although the impact of single doses is uncertain.

Table 161.1 Classification of PCC according to the risk of developing infective endocarditis

High risk PCC	Class[a]	Level[b]
Valvular prostheses (mechanical, bioprosthese, homograft)	IIa	C
History of infective endocarditis	IIa	C
Surgically constructed pulmonary-systemic shunts	IIa	C
Non-operated cyanotic congenital heart disease	IIa	C
Cardiac transplantation recipients who develop cardiac valvulopathy*		
Moderate/lower risk PCC		
Acquired valvular dysfunction	III	C
Mitral valve prolapse with regurgitation and/or thickened leaflets	III	C
Other congenital cardiac disease (except ostium secondum ASD)	III	C
Hypertrophic cardiomyopathy	III	C
Bicuspid aortic valve†	III	C

PCC, predisposing cardiac condition; ASD, atrial septal defect.

Data from Gould FK et al., 'Guidelines for the prevention of endocarditis: report of the Working Party of the British Society for Antimicrobial Chemotherapy', *Journal of Antimicrobial Chemotherapy*, 2006, 57, pp. 1035–1042; and Wilson W et al., 'Prevention of infective endocarditis: guidelines from the American Heart Association: a guideline from the American Heart Association Rheumatic Fever, Endocarditis, and Kawasaki Disease Committee, Council on Cardiovascular Disease in the Young, and the Council on Clinical Cardiology, Council on Cardiovascular Surgery and Anesthesia, and the Quality of Care and Outcomes Research Interdisciplinary Working Group', *Circulation*, 2007, 116, pp. 1736–1754.

Recommendations

Antibiotic prophylaxis has been recommended since 1955. Recurrent updates have since been published by numerous national and international societies. Over the last decade, and influenced by extensive literature reviews that highlight the lack of evidence supporting antibiotic prophylaxis for IE [6], there has been a noticeable change, with a major trend to restricting use to highest-risk patients and procedures. This began with the 2002 French recommendations [8], and climaxed with the 2008 National Institute for Health and Clinical Excellence (NICE) guidance, where no prophylaxis was recommended [9]. Although the same trend can generally be noted elsewhere, considerable variation still exists.

The classification of predisposing cardiac conditions according to the risk of developing IE is detailed in Table 161.1, while Tables 161.2 and 161.3 provide indications for prophylaxis in the setting of dental and non-dental procedures according to recent guidelines [8–12]. Recommendations concerning choices of drugs, doses, and routes of administration for dental and non-dental procedures are summarized in Tables 161.4, 161.5, 161.6, and 161.7.

Our recommendations

Despite the absence of evidence supporting the use of prophylaxis for IE in at-risk patients, malpractice claims are not uncommon, especially in the United States, from patients who developed endocarditis after dental care for which they did not receive prophylaxis. In one study reviewing 319 legal cases from various countries, 83 (26%) were successful in legally associating a dental procedure to the onset of IE [13]. However, the most recent guidelines are highly disparate between the different learned societies (see Tables 161.8 and 161.9 for guidance in interpreting these guidelines). Therefore, following national guidelines where practiced is advised, mainly to avoid medico-legal issues.

While data supporting current recommendations are poor, and the benefits of prophylaxis hypothetical, the education of at-risk patients is crucial. General preventive measures must be highlighted. Early identification and treatment of potential sources of endocarditis are mandatory. Patients with predisposing cardiac conditions should be urged to consult their physicians about fever or other lasting symptoms. Physicians should also be aware of the importance of blood cultures before any antibiotic prescription in this setting. Because of the suspected major role of everyday bacteraemia in IE [5], the need for good oral hygiene and frequent dental assessments are critical. Finally, the absolute necessity to limit

Table 161.2 Indications for endocarditis prophylaxis in the setting of dental procedures

	Dental procedures	**Predisposing cardiac condition**

invasive procedures should also be highlighted. Indeed, the use of iv catheters should be dramatically restricted in both frequency and duration in patients with intracardiac devices to reduce the risk of nosocomial bacteraemia and, therefore, health care-induced IE. To sum up, '*primum non nocere*'.

Treatment

In our tertiary care centre, diagnostic strategy was standardized in 1994, and therapeutic protocols in 2002, using a very limited number of antimicrobial agents. The implementation of this standardized therapeutic protocol has been associated with a reduction in hospital mortality from 12.7% to 4.4%, and overall 1-year mortality from 18.5% to 8.2% [14].

Antibiotics

For suspected or confirmed IE, empiric antibiotic therapy should be promptly initiated after microbiological sampling. This should be subsequently modified according to laboratory results. Early antibiotic therapy dramatically reduces morbidity and mortality [15]. In our tertiary care centre, this is started within 2 hours of admission in patients with a high suspicion of IE. We use a standardized diagnostic kit that limits the number of blood cultures taken over 2 hours and enables, through serological testing, identification of the major organisms responsible for blood culture-negative endocarditis (BCNE). Unlike prophylaxis, guidelines for antimicrobial therapy are consensual between societies [12, 16] and supported by a strong evidence base.

General principles of antibiotics in IE

The recommended duration of antibiotic therapy begins on the first day of effective treatment, i.e. the first day on which blood cultures are negative. For BCNE, counting of days should begin on the first day of clinical efficacy with no pyrexia. For prosthetic valve endocarditis (PVE), the antibiotic duration should be longer (at least 6 weeks) than for native valve endocarditis (NVE). When NVE requires prosthetic valve replacement, the post-operative antibiotic regimen should be as for NVE [12]. Post-operatively, if the valve cultures are positive, a full course of antibiotic therapy should be restarted.

Table 161.8 Classes of recommendations

Class of recommendation	Definition
Class I	Evidence and/or general agreement that a given treatment or procedure is beneficial, useful, effective
Class II	Conflicting evidence and/or a divergence of opinion about the usefulness/efficacy of the given treatment or procedure
Class IIa	Weight of evidence/opinion is in favour of usefulness/efficacy
Class IIb	Usefulness/efficacy is less well established by evidence/opinion
Class III	Evidence or general agreement that the given treatment or procedure is not useful/effective, and in some cases may be harmful

Adapted with kind permission from Agency for Healthcare Research and Quality (previously Agency for Health Care Policy and Research), AHCPR Clinical Practice Guidelines, '1. Acute Pain Management' (Feb. 1992) and '9. Management of Cancer Pain' (March 1994), available from http://www.ahrq.gov/professionals/clinicians-providers/guidelines-recommendations/archive.html (select "Clinical Guides").

Table 161.9 Levels of evidence

Level of Evidence A	Data derived from multiple randomized clinical trials or meta-analyses
Level of Evidence B	Data derived from a single randomized clinical trial or large non-randomized studies
Level of Evidence C	Consensus of opinion of the experts and/or small studies, retrospective studies, registries

Adapted with kind permission from Agency for Healthcare Research and Quality (previously Agency for Health Care Policy and Research), AHCPR Clinical Practice Guidelines, '1. Acute Pain Management' (Feb. 1992) and '9. Management of Cancer Pain' (March 1994), available from http://www.ahrq.gov/professionals/clinicians-providers/guidelines-recommendations/archive.html (select "Clinical Guides").

Empirical antibiotic therapy

Our empirical antibiotic protocol (Table 161.10) combines amoxicillin with gentamicin for community-acquired IE. For nosocomial IE (cardiac surgery or pacemaker within the last 12 months, and right-sided IE), a combination of vancomycin with gentamicin and rifampicin is used [14].

Antibiotic regimens when a micro-organism has been identified

- **Common organisms:** for the most common organisms (*Streptococcus*, *Staphylococcus*, and *Enterococcus* spp.), Table 161.11 details our adaptations of the antibiotic regimens advised by the latest recommendations [12].
- **Rare organisms:**
  - *Non-HACEK Gram-negative bacterial IE*—rare and severe, this requires involvement of a specialized infectious disease team. Early surgery is often required and the antibiotic treatment includes long-term (≥6 weeks) combinations of β-lactams and aminoglycosides, sometimes with additional quinolones or cotrimoxazole.
  - *Fungal IE*—carrying high rates of mortality (>50%), this pathology predominantly affects prosthetic valves, and/or occurs in immunocompromised patients or iv drug abusers. Fungi, mainly *Candida* and *Aspergillus* spp., are the most frequent pathogens involved in post-operative BCNE. Treatment includes valve replacement and amphotericin B with or without azoles. Long-term oral treatment with azoles is often required, sometimes for life.
  - *Fastidious micro-organisms IE*—Table 161.12 summarizes proposed regimens for fastidious micro-organisms [12]. However, no strong evidence base supports these therapeutic strategies.

BCNE

Representing 2.5–31% of all cases of endocarditis, these are both diagnostically and therapeutically challenging, and should be managed by infectious disease specialists. Although often related to previous antibiotic therapy, or to issues in sampling and diagnosis, an important proportion of BCNE is attributable to fastidious pathogens, obligate intracellular bacteria, and fungi.

When the causal micro-organism has been identified, antibiotic therapy is rarely a concern. Indeed, relapses are very rare unless an indicated surgical treatment could not be performed. A 7-year relapse rate ≤5% was reported in a series including BCNE patients [17].

Antibiotic resistance issues concern very few patients with IE. The emergence of meticillin-resistant *Staphylococci* has not resulted in a higher mortality from *S. aureus* IE because of the introduction of vancomycin in 1958. Surprisingly, half a century later, this drug is still the antibiotic of choice in this setting [12,16], although some vancomycin-resistant strains have been recently identified.

Surgery

Indications

Since the first reported success in 1965, the role of surgery in active IE has gradually expanded, especially over the last decade. The latest guidelines recommend surgical treatment for complicated left-sided endocarditis [12,16]. Indications for surgical management of IE are

Table 161.10 Empirical antibiotic regimens before micro-organism identification

Medical history	Drugs (no β-lactam intolerance)	Drugs (β-lactam intolerance)	Duration (weeks)
Native valve	Amoxicillin[a]	Vancomycin[c]	4–6
	+ Gentamicin[b]	+ Gentamicin[b]	4–6
Prosthetic valve > 1 year	Amoxicillin[a]	Vancomycin[c]	6
	+ Gentamicin[b]	+ Gentamicin[b]	6
Prosthetic valve < 1 year	Vancomycin[c]		6
	+ Gentamicin[b]		2
	+ Rifampicin[d]		6
Early PVE after cardiac surgery	Vancomycin[c]		6
	+ Gentamicin[b]		2
	+ Amphoteracin B		4–6

[a] 100–200 mg/kg/day iv in 4–6 doses. [b] 3 mg/kg/day iv or im in one dose, renal function and serum gentamicin concentrations should be monitored once a week, pre-dose (trough) concentrations should be <1 mg/L and post-dose (1 hour after injection) serum concentrations should be around 10–12 mg/L. [c] 30 mg/kg/day iv in two doses, serum vancomycin concentrations should achieve 25–30 mg/L at predose levels. [d] 1200 mg/day iv or po in two doses.

PVE, prosthetic valve endocarditis.

Table 161.11 Antibiotic regimens after micro-organism identification

Micro-organisms	Drugs (no β-lactam intolerance)	Drugs (β-lactam intolerance)	Duration (weeks)
Streptococcus spp.	Amoxicillin[a]	Vancomycin[c]	4–6
HACEK-related species	+ Gentamicin[b]	+ Gentamicin[b]	2
Enterococcus spp.	Amoxicillin[a]	Vancomycin[c]	6
	+ Gentamicin[b]	+ Gentamicin[b]	6
Staphylococcus species (methicillin-susceptible)	Oxacillin[d]	Vancomycin[c]	4–6
	+ Gentamicin[b]	+ Gentamicin[b]	5 days*
	+ Rifampicin if PVE[e]	+ Rifampicin if PVE[e]	4–6
Staphylococcus spp. (methicillin-resistant)	Vancomycin[c]		4–6
	+ Gentamicin[b]		5 days*
	+ Rifampicin if PVE[e]		4–6
Coxiella burnetii	Doxycycline[f]		18 months†
	+ Hydroxychloroquine[g]		18 months†

[a] 100–200 mg/kg/day iv in 4–6 doses. [b] 3 mg/kg/day iv or im in one dose, to be monitored as in Table 161.10. [c] 30 mg/kg/day iv in two doses, to be monitored as in Table 161.10. [d] 12 g/day iv in 4–6 doses. [e] 1200 mg/day iv or po in two doses. [f] 200 mg/24 hours po. [g] 200–600 mg/24 hours po.

*2 weeks if PVE. †24 months if PVE.

PVE, prosthetic valve endocarditis.

detailed in Table 161.13 [12]. Whereas American and European guidelines are consensual in situations of congestive heart failure or uncontrolled infection, they still remain controversial regarding embolic risk, with European guidelines being more surgically aggressive [12,16].

These guidelines are, however, largely based on observational studies or expert opinion. We recently published a systematic review showing a significant inverse correlation between rates of early surgery and in-hospital mortality [2]. Moreover, a recent randomized controlled trial, comparing early surgery and conventional treatment in patients with IE and large vegetations (>10 mm), showed significant reductions in death and embolic events in the early surgery group [3]. Therefore, management of complicated IE has clearly entered the era of early surgery.

Principles of surgery

The main objectives are eradication of all infected tissue for infection control and reconstruction of cardiac morphology.

The type of prosthesis (mechanical or bioprosthetic) used to replace the infected valve has no prognostic impact. However, whenever possible, valvular repair techniques offer better outcomes than prosthetic valve replacement, especially for the mitral valve, with a lower risk of relapse [18].

Valvular and perivalvular damages can be extreme in IE, and surgical management often requires particular surgical techniques

Table 161.12 Antibiotic regimens for fastidious organisms

Micro-organisms	Antibiotic therapy	Treatment duration/outcome
Brucella spp.	Doxycycline (200 mg/24 hours) po + Cotrimoxazole (960 mg/12 hours) po + Rifampicin (300–600 mg/24 hours) po	◆ 3 months *Success*: antibody titre < 1:60
Coxiella burnetii (agent of Q fever)	Doxycycline (200 mg/24 hours) + Hydroxychloroquine (200–600 mg/24 hours) po	18 months for NVE 24 months for PVE *Success at 1 year*: 4-times decrease of phase I IgG and IgA + disappearance of phase II IgM
Bartonella spp.	Ceftriaxone (2 g/24 hours) iv or Doxycycline (200 mg/24 hours) po + Gentamicin (3 mg/24 hours) or Netilmicin iv	6 weeks 3 weeks *Success*: >90%
Legionella spp.	Erythromycin (3 g/24 hours) iv for 2 weeks then po for 4 weeks + Rifampicin (300–1200 mg/24 hours) or Ciprofloxacin po	6 weeks 6 weeks (optimal treatment unknown)
Mycoplasma	Newer fluoroquinolones	> 6 months (optimal treatment unknown)
Tropheryma whipplei	Ceftriaxone iv 2 weeks, then Trimethoprim-sulphamethoxazole 1 year	Long-term treatment Optimal treatment unknown

Table 161.13 Indications for surgical management of infective endocarditis

Indication	Timing[a]	Class	Level of evidence
Heart failure			
Aortic or mitral severe acute regurgitation, obstruction, or fistula with refractory pulmonary oedema or cardiogenic shock	Emergent	I	B
Aortic or mitral severe acute regurgitation or obstruction with persisting heart failure or echo signs of poor tolerance	Urgent	I	B
Aortic or mitral severe regurgitation or severe prosthetic dehiscence with no heart failure	Elective	IIa	B
Right heart failure due to severe tricuspid regurgitation with poor response to diuretics	Urgent/elective	IIa	C
Uncontrolled infection			
Locally: abscess, false aneurysm, fistula, enlarging vegetation	Urgent	I	B
Persisting fever and positive blood cultures >7–10 days	Urgent	I	B
Fungi or multiresistant organisms	Urgent/elective	I	B
PVE[b] due to staphylococci or Gram-negative bacteria	Urgent/elective	IIa	C
Prevention of embolism			
Aortic/mitral large vegetations (>10 mm) following embolic(s) event(s) despite appropriate antibiotic therapy	Urgent	I	B
Aortic/mitral large vegetations (>10 mm) and other predictors of complicated course	Urgent	I	C
Aortic/mitral isolated very large vegetations (>15 mm)[c]	Urgent	IIb	C
Persistent tricuspid valve vegetations >20 mm after recurrent pulmonary emboli	Urgent/elective	IIa	C

[a] Emergent surgery = within 24 hours. Urgent surgery, within a few days. Elective surgery, after at least 1 or 2 weeks of antibiotic therapy.

[b] PVE, prosthetic valve endocarditis.

[c] Surgery might be preferred if valve repair is feasible.

Adapted from Habib G et al., 'Guidelines on the prevention, diagnosis, and treatment of infective endocarditis (new version 2009): the Task Force on the Prevention, Diagnosis, and Treatment of Infective Endocarditis of the European Society of Cardiology (ESC)', *European Heart Journal*, 2009, **30**(19), pp. 2369–413, by permission of Oxford University Press © European Society of Cardiology, www.escardio.org/guidelines.

and skills. Thus, severe cases should be referred to specialized departments (1).

Therapeutic challenges

IE still carries high mortality rates, namely ≥20% at 1 year [2]. Most deaths relate to complications that constitute definite surgical indications [12], e.g. heart failure, embolic events, and uncontrolled infection [2]. Thus, optimization of surgical approach in such patients constitutes the clearest opportunity to reduce mortality rates [2,3]. However, several other conditions still remain matters of concern, especially septic shock, sudden death, and vancomycin-resistant staphylococcal IE.

Septic shock

Septic shock has been constantly associated with a poor prognosis for IE. We found 15 of 37 in-hospital deaths were secondary to multi-organ failure/septic shock [1]. Predictors include diabetes mellitus, *Staphylococcus aureus* infection, acute renal failure, supraventricular tachycardia, vegetation size >15 mm and signs of persistent infection [19]. Mechanisms leading from local infection to multi-organ failure and shock are not clearly understood. Indeed, the amount of blood-circulating bacteria has not been correlated with the risk of developing septic shock. Therefore, bacterial toxins and host inflammatory mediators are likely to play a major role in the occurrence of this disastrous situation. In this setting, we are currently evaluating the benefit of combining clindamycin and vancomycin.

Sudden death

We found sudden death (SD) occurred in 2.7% of patients at 6 months during or after conservative management, most dying during the first hospitalization. Identified risk factors were diabetes, signs of heart failure at admission, and a high comorbidity index [20]. These findings underline the importance of performing surgery without delay even if heart failure symptoms have responded well to medical treatment, considering the risk of sudden worsening. Indeed, in our series, 4 of 10 patients who experienced sudden death were awaiting surgery [20]. ICU monitoring is obviously mandatory for patients with severe symptoms or perivalvular damage.

Vancomycin-resistant staphylococci

Vancomycin-resistant staphylococci have recently emerged, with the occurrence of persistent bacteraemia despite appropriate antibiotic regimens. Strains with various degrees of vancomycin resistance have been isolated. New drugs have been proposed (e.g. teicoplanin, linezolid, daptomycin), but strong evidence of efficacy are still missing. We are currently evaluating the combination of cotrimoxazole with clindamycin in this challenging situation. The involvement of a dedicated infectious diseases team in such cases is mandatory.

Conclusion

IE remains one of the deadliest infectious diseases. Management must be undertaken in a standardized manner to shorten delays in diagnosis, risk stratification, and treatment. The rapid performance of surgery, when indicated, appears to be key in reducing mortality. This global approach is only possible in multidisciplinary reference centres that include an experienced surgical team.

PART 5.11

Severe hypertension

CHAPTER 162

Pathophysiology and causes of severe hypertension

Jerrold H. Levy and David Faraoni

Key points

- Endothelial and vascular circulatory interactions are critical parts of normal vascular control of blood pressure.
- The pathophysiology of hypertension is complex and depends on patient-related factors, genetics, and multiple factors that interact at cellular and organ levels.
- Of these factors, vascular endothelial and circulatory dysfunction with loss of endothelial-derived relaxing factors, such as nitric oxide and prostacyclin, are critical lesions.
- In certain patients, other factors may contribute to hypertension, including the renin-angiotensin system, mediators, but also hyperdynamic hypertension in young critically-ill patients.
- Despite the complex pathophysiological responses, therapy should be multimodal and often requires targeting of several different receptors or mediators to control hypertension that may often be resistant to therapy in critically-ill patients.

Introduction

Hypertension affects multiple groups of patients characterized by different clinical presentations and a spectrum of potential causes. The pathophysiology is complex and multifactorial. Although most patients are labelled 'essential hypertension', multiple mechanisms are involved in blood pressure regulation. Factors that influence blood pressure homeostasis include endothelial function, the renin-angiotensin system, and the sympathetic nervous system. In elderly patients, hypertension is common as the vascular system and arterial stiffness also contribute. Other important factors include inflammatory processes as part of systemic diseases, including atherosclerosis that may contribute to renal and vascular injury. Hypertension is also associated with metabolic disturbances including dyslipidaemia that manifests in obese patients who also have insulin resistance. These different pathways all represent potential targets for treatment, but also increase the challenge of multimodal pathophysiology.

The normal vascular endothelium regulates vascular tone and structure, and is critical to maintain vascular patency by its anticoagulant properties. Vascular tone is maintained by the release of both vasodilator and constrictor mediators. Vasodilation is a critical aspect of endothelial function; an essential endothelial-derived relaxing factor is nitric oxide [1]. Other endothelium-derived or modulated vasodilators include prostacyclin and bradykinin. Endothelial and inflammatory dysfunction may also contribute to vascular dysfunction, and act synergistically, increasing atherosclerosis and further endothelial dysfunction. Oxidative stress, defined as a substantial increase in the level of reactive oxygen species (ROS), also contributes to hypertensive pathophysiology and cellular injury. Free radicals may also reduce nitric oxide availability. Because of the multiple factors involved, this review discusses different mechanisms as part of the multiple pathophysiological causes of hypertension, especially in the critically ill.

Understanding the risk

The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC-7) classified blood pressure as normal, prehypertension, and stages 1 and 2 hypertension [2]. Prehypertension (formally known as 'high normal' BP) is also associated with increased cardiovascular morbidity and mortality, as well as subclinical atherosclerosis and target-organ damage. The recently published executive summary of the JNC-8 guidelines [3] did not alter these definitions, but defined thresholds for pharmacological treatment and updated some treatment goals for specific populations based on new evidence review. Moreover, some patients will be admitted to intensive care units (ICUs) with hypertensive crises that require a specific understanding of the underlying mechanisms to guide therapeutic approaches.

Blood pressure determinants as causes of hypertension

Blood pressure is the product of cardiac output and systemic vascular resistance. Hypertensive patients may have a normal cardiac output, but increased peripheral vascular resistance due to multiple aetiologies. Systemic vascular resistance is determined by small arterioles that play a critical role in vascular tone and its regulation, and may be sensitive to multiple mediators that are part of normal physiological and pathophysiological responses. The role of L-type calcium channels in vascular smooth muscle cells is important for regulation of vascular tone by modifying intracellular calcium concentrations. Ongoing sympathetic activation may produce prolonged smooth muscle constriction inducing structural changes with thickening of the arteriolar vessel walls. This is possibly mediated by angiotensin leading to an irreversible rise in peripheral

resistance. Acutely, however, in the ICU setting, patients suffering major injury may be hyperdynamic with increased cardiac output due to sympathetic hyperactivity. The increased sympathetic tone may also increase systemic arteriolar resistance further contributing to hypertension. The renin-angiotensin system may contribute in part to this sympathetic hyperactivity.

Renin-angiotensin system

The renin-angiotensin system is an important mechanism for regulating blood pressure. Renin is stored in the juxtaglomerular apparatus of the kidney. It is secreted to convert angiotensinogen to angiotensin I following decreased glomerular perfusion, or in response to sympathetic nervous system stimulation. In turn, angiotensin I is rapidly converted to angiotensin II by a lung endothelial kininase (angiotensin-converting enzyme (ACE)). Angiotensin II is a potent vasoconstrictor that contributes to hypertension, but also stimulates aldosterone release from the zona glomerulosa of the adrenal gland. Aldosterone is an important autocoid that causes sodium and water retention, further increasing hypertension. Of note, the renin-angiotensin system is a critical target for multiple pharmacological agents used to treat hypertension and heart failure, including ACE inhibitors, angiotensin II, and aldosterone antagonists. By inhibiting kininase, ACE inhibitors also increase generation of bradykinin from high molecular weight kininogen, which is also responsible for secondary angioedema and cough. Despite the critical role of the renin-angiotensin system in blood pressure regulation, many hypertensive patients have low levels of renin and angiotensin II.

Autonomic nervous system

Sympathetic activation leads to release of norepinephrine, and stimulates both α_1 and β_1 receptors. Stimulation of α_1 receptors activates membrane phospholipase-C which, in turn hydrolyses phosphatidylinositol-4,5-diphosphate and leads to the generation of two second messengers—diacylglycerol and inositol triphosphate. Both these second messengers increase cytosolic Ca^{2+} by different mechanisms, including facilitating release of calcium from the sarcoplasmic reticulum, and potentially increasing calcium sensitivity of the contractile proteins in vascular smooth muscle. As a consequence, stimulation of the sympathetic nervous system can cause arteriolar constriction. Activation of β_1 receptors increases heart rate and contractility, thereby increasing cardiac output. Activation of the autonomic nervous system is thus important in maintaining normal blood pressure. However, following stress and other mechanisms of activation, it may also produce hypertension.

Patients who increase their cardiac output following exercise have a normal compensatory drop in vascular resistance due to endothelial activation associated with increased flow, especially in patients with normal vascular endothelial function. Endothelial activation causes release of NO and prostaglandins that stimulate vascular smooth muscles to relax, and hence cause vasodilation. Elderly patients with vascular and circulatory dysfunction may not drop their blood pressure in response to exercise. Overall, blood pressure changes and the potential to develop hypertension, especially in a critically-ill patient, is determined by complex interactions among many of the factors described including the autonomic nervous system, renin-angiotensin system, circulating intravascular volume, endothelial function, and multiple mediators, which may or may not be released.

Endothelial function

The endothelium is a monolayer of cells that lines the vasculature, and is strategically placed to oversee and regulate critical homeostatic and haemostatic functions. The endothelium directly interfaces with blood flow and responds by releasing or modifying a multitude of factors that regulate vasomotor function, haemostasis, and inflammatory processes. Following increased flow, the related shear stress releases vasodilatory mediators (nitric oxide (NO) and prostacyclin) producing both vascular relaxation and vasodilation, but also inhibits platelet and inflammatory cell activation. For normal endothelial function, critical processes include the important antiproliferative and antithrombotic molecules, NO, and prostacyclin [4]. Nitric oxide is a vasodilator agent that inhibits platelet aggregation, monocyte adhesion to endothelial cells, and abnormal smooth muscle cell proliferation. Thus, NO has a critical role as an important 'anti-atherogenic' moiety [4].

Endothelial dysfunction is often defined as the inability of the endothelium to release NO (and, by implication, to protect against atherogenesis). The critical role of endothelium-dependent and also smooth muscle-dependent vasomotor properties of the vasculature in hypertension highlights another important concept in cardiovascular pathophysiology. Vascular and circulatory functions may play a very important role in determining cardiovascular risk [4]. Vessel function (particularly the propensity for vessels to constrict, rather than dilate during conditions of physical and/or mental stress) appears to confer important risk in the pathophysiology of acute vascular events [5]. Consistent with this suggested importance of vascular function in risk determination, many studies have now been published correlating endothelial function measurements with prospectively determined risk of cardiovascular events during follow-up [6].

Most studies examining in vivo endothelial function have measured endothelium-dependent dilatation, in large part because techniques have been developed to assess this particular aspect of endothelial physiology. However, the endothelium has a multiplicity of functions beyond regulation of vessel tone, as previously noted. Thus, articles reporting 'endothelial function' and 'dysfunction' on the basis of the measurement of endothelium-dependent dilatation give insights into only one aspect of endothelial physiology, albeit an important one. To date, little work has evaluated whether the various endothelial functions correlate with each other in disease states (for example, how impaired endothelium-dependent dilatation, regulation of endothelial cell adhesion molecule expression, and release of key haemostatic regulatory molecules relate to one another).

Vasoactive substances

Many vasoactive mediators alter both intravascular volume regulation and vascular tone as part of normal blood pressure maintenance, but their role in essential hypertension is not well known. Rare events such as a pheochromocytoma, a catecholamine-secreting tumour derived from chromaffin cells, causes excessive catecholamine secretion, and may generate life-threatening hypertensive crises and/or cardiac arrhythmias.

The endothelium also produces vasoconstrictor substances such as endothelin, which is perhaps the most potent endogenous

vasoconstrictor, and angiotensin II [1]. Angiotensin II is a potent vasoconstrictor, but also stimulates endothelin production. Endothelin and angiotensin II promote proliferation of smooth muscle cells and thereby contribute to the formation of plaque. Activated macrophages and vascular smooth muscle cells, characteristic cellular components of atherosclerotic plaque, produce large amounts of endothelin that also activates local renin-angiotensin systems [1].

Atrial natriuretic peptide (ANP) is a hormone secreted from the heart atria in response to increased blood volume. ANP increases sodium and water excretion from the kidney as a sort of natural diuretic. A defect in this system may cause fluid retention and hypertension. Sodium transport across vascular smooth muscle cell walls is also thought to influence blood pressure via its interrelation with calcium transport.

Diabetes and hypertension

Several risk factors are associated with hypertension, including obesity, glucose intolerance, diabetes mellitus, and hyperlipidaemia as part of a final common pathway to cause raised blood pressure and vascular damage. Some non-obese hypertensive patients can display insulin resistance. Vascular endothelial and circulatory dysfunctions are major mechanisms involved in the association between hypertension and diabetes, while the two conditions are linked with cardiovascular disease, stroke, and progression of renal disease. Of note, JNC 7 and 8 recommendations are consistent with guidelines from the American Diabetes Association that recommends rigorous blood pressure control to reduce the progression of diabetic nephropathy to end-stage renal disease.

Genetic factors

Recent findings suggest that the onset of prehypertension may be, at least in part, genetically determined [7]. Genetic abnormalities associated with hypertension include rare syndromes, such as mineralocorticoid-remediable aldosteronism, mineralocorticoid excess, and pseudohypoaldosteronism. Other genetic mutations may contribute to hypertension in the general population. Genetic association studies have identified polymorphisms in specific genes, such as those encoding for angiotensinogen and adrenergic receptors. Again, these are rare events in the general population and beyond the scope of this review.

Pregnancy and hypertension

Approximately 10% of all pregnancies are complicated by hypertension, with eclampsia and pre-eclampsia accounting for approximately half. The clinical manifestations of preeclampsia are hypertension and proteinuria with or without co-existing systemic abnormalities. Eclampsia is a life-threatening condition, similar to hypertensive emergencies. Overall, pre-eclampsia is characterized by endothelial dysfunction, and may be a contributor to future cardiovascular diseases. Underlying mechanisms include endothelial and circulatory dysfunction that occur in a complex milieu of other influencing factors, such as maternal immunological intolerance, placental issues, genetics, environmental factors, and vascular and inflammatory changes similar those that produce atherosclerotic vascular disease.

Hypercoagulability

Hypertensive patients have multiple vascular abnormalities that include endothelial dysfunction, atheromatous injury and/or plaque formation, and vessel wall abnormalities that may also occur as part of the ageing process. Endothelial function is critical for inhibiting thrombosis, promoting anticoagulation, and fibrinolysis. In hypertensive patients, especially in hypertensive emergencies, endothelial dysfunction further contributes to arterial wall injury. The endothelium is critical in maintaining vascular patency by providing a multitude of anticoagulant, antiplatelet, and fibrinolytic properties. Endothelium-derived relaxing factors including NO and prostacyclin also inhibit platelet aggregation. The endothelium also catalyses the formation of bradykinin that further stimulates release of NO, prostacyclin, and tissue plasminogen activator (t-PA), modulating a critical role in fibrinolysis [1].

Hypertension and hypertensive crisis may further damage the endothelium and increase endothelial permeability, platelet aggregation, leukocyte adhesion, and cytokine generation [1]. Thrombomodulin, another important vascular endothelial receptor, binds to thrombin to scavenge this important procoagulant mediator. As part of this thrombin–thrombomodulin complex activation, the endothelium is further activated releasing NO, prostacyclin, tPA and activated protein C that, along with its cofactor protein S, degrades FVa and FVIIIa, blocking amplification of the coagulation system and thus limiting further thrombin formation [1]. In summary, hypertension promotes hypercoagulability by causing further injury to vascular endothelial function.

Identifiable causes of hypertension

Despite the complex pathophysiology of hypertension, some identifiable aetiologies or associated syndromes commonly present in an ICU setting (Box 162.1). Some are reversible, such as fluid overload associated with renal failure, while others may require targeted therapy of the underlying disease. Regardless of cause, management of blood pressure, especially in patients who are symptomatic (as in hypertensive crises) is critical. Other important causes of hypertensive crises are listed in Box 162.2.

Box 162.1 Identifiable causes of hypertension

- Chronic kidney disease.
- Coarctation of the aorta.
- Cushing's syndrome.
- Drug-induced.
- Obstructive uropathy.
- Pheochromocytoma.
- Primary aldosteronism/mineralocorticoid excess.
- Renovascular hypertension.
- Sleep apnoea.
- Thyroid or parathyroid disease.

Box 162.2 Causes of hypertensive emergencies

- Acute renal failure/injury.
- Antihypertensive withdrawal.
- Autonomic hyperreactivity.
- Cushing's syndrome.
- Drug interactions with monoamine-oxidase inhibitors (tyramine), amphetamines.
- **Drugs**: cocaine, sympathomimetics.
- Eclampsia.
- Guillain-Barré syndrome.
- Head injury, intracranial hypertension.
- Pheochromocytoma.
- Pregnancy.
- Renal artery stenosis.
- Renovascular disease.
- Vasculitis.

Resistant hypertension

In an ICU setting, despite therapy, resistant hypertension can occur even in patients who do not present with hypertensive crises. Resistant hypertension may reflect the severity of vascular and endothelial dysfunction, and may be analogous to patients with pulmonary hypertension who progress to end-stage disease with increased cardiovascular morbidity and mortality. Multiple factors may contribute to resistant hypertension, including increased sympathetic activity, insulin resistance, endothelial dysfunction, chemoreceptors, and baroreceptor dysregulation [8]. Managing patients with resistant hypertension, especially with hypertensive crises, may require targeting of multiple receptors including L-type calcium channels with dihydropyridine calcium channel blockers, β and α-adrenergic receptors with dual sympathetic blocking agents such as labetalol, and central-acting sympatholytic agents like clonidine, an α_2 adrenergic agonist that inhibits synaptic release of neurotransmitters.

CHAPTER 163

Management of severe hypertension in the ICU

Jerrold H. Levy

Key points

- Hypertensive emergencies are characterized by acute end-organ dysfunction and require immediate intervention to reduce the blood pressure (BP) and include acute cardiopulmonary/neurological dysfunction.
- The degree of BP reduction depends on the clinical situation, as acute reduction of BP may also cause acute organ dysfunction.
- Acute changes in BP require acute interventions, while chronic hypertension should usually be treated with oral therapy.
- Intravenous dihydropyridine agents provide reliable and predictable acute BP management, and have increasingly replaced nitroprusside as a parenteral agent for hypertensive emergencies.
- Patients who are hypertensive and tachycardic may benefit from agents such as labetalol that have beta- and alpha-adrenergic blocking effects.

Clinical evaluation

The clinical evaluation of a hypertensive patient requires determining whether acute organ dysfunction is present in order to confirm a hypertensive emergency. As in any emergency, immediate therapy is necessary, while additional information including history, physical examination, and laboratory information can be obtained after therapy is initiated. According to the most recent guidelines of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 8), patients with a hypertensive emergency should be admitted to an ICU for continuous monitoring of BP and treatment with an appropriate agent [1].

Goal of therapy in hypertensive emergencies

The initial goal of therapy is to reduce mean arterial BP by no more than 15% ((diastolic 110 mmHg) within minutes to 1 hour). Complications may result from aggressive reduction, especially with overshoot hypotension due to dysfunctional cerebral autoregulation. The use of rapid-acting and titratable agents is critical. Once the BP is stable, it should then be reduced to 160/100–110 mmHg within the next 2–6 hours. Significant drops in BP should be avoided to prevent cerebral, renal, and/or coronary ischaemia. Furthermore, special considerations should be taken when treating specific causes of acute hypertension, such as aortic dissection, acute cerebral haemorrhage, sympathetic crisis, and post-operative hypertension. For example, in aortic dissection, rapid titration and BP control are essential in order to stabilize patients for surgery [2,3].

Hypertensive urgencies

Hypertensive urgencies are common presentations, and may present with exceedingly high blood pressures, but without symptomatic manifestations. Therapy often involves (re-)starting oral medications. When treating hypertension in this setting, avoiding overshoot is critical, with the goal of reducing, but not necessarily normalizing BP.

Uncomplicated severe hypertension

Patients often present with asymptomatic hypertension that may be related to acute conditions, such as pain due to injury (e.g. bone fracture), anxiety, withdrawal symptoms, or, in young patients, hyperdynamic physiological responses following injury. This is commonplace in the ICU; patients following major surgical procedures may be hypertensive during weaning from mechanical ventilation, or in the initial post-operative period. In these circumstances, it is critical to treat any pain and/or underlying disorder. Again, in these circumstances, avoiding overshoot hypotension with multimodal therapy is important.

Pharmacological principles of therapy

Pharmacological therapy is used to treat hypertensive crises, urgencies, and chronic hypertension and includes:

- α1-adrenergic receptor blockade, ganglionic blockade and calcium channel blockade.
- Stimulation of central α2-adrenergic receptors, dopamine1-adrenergic receptors, or vascular guanylate cyclase and adenylate cyclase.
- Inhibition of phosphodiesterase enzymes.
- Inhibition of angiotensin-converting enzymes
- β-blockade [4].

Decreasing sympathetic tone decreases blood pressure by decreasing myocardial contractility and heart rate, thus altering cardiac output. It is an important therapeutic approach in the hyperdynamic

patient with hypertension and tachycardia. As a spectrum of different drugs can produce vasodilation and/or treat hypertension, the various potential pharmacological approaches to vasodilation will be described in the following section (see Table 163.1).

Mechanisms of vasodilation

Vascular tone is regulated by the flux of calcium in and out of vascular smooth muscle. Hence, calcium channel blockade produces vasodilation by decreasing calcium entry. Increasing cyclic nucleotides -adenosine-3',5'-monophosphate (cyclic AMP) or guanine-3',5'-monophosphate (cyclic GMP)—in vascular smooth muscle facilitates calcium uptake by intracellular storage sites, thus decreasing the calcium available for contraction. The net effect of increasing calcium uptake is to produce vascular smooth muscle relaxation and, hence, vasodilation. Prostaglandins stimulate vascular adenylate cyclase to increase cyclic AMP and produce pulmonary and systemic vasodilation. Phosphodiesterase inhibitors block the breakdown of cyclic nucleotides and can also produce vasodilation.

Nitrovasodilators: glyceryl trinitrate and nitroprusside

Nitrates and sodium nitroprusside generate nitric oxide (NO) which, in turn, activates guanylyl cyclase to generate cyclic GMP that ultimately produces vascular relaxation [5]. Any nitrovasodilator must be converted to NO, where nitrogen is in a +2 oxidation state. For nitroprusside, this is easily accomplished as the nitrogen is in a +3 oxidation state, with the NO molecule bound to the charged iron molecule in an unstable manner. Thus, nitroprusside readily donates its NO moiety. However, for glyceryl trinitrate, nitrogen exists in a +5 oxidation state. This must undergo several metabolic transformations before conversion to an active molecule. The reason that glyceryl trinitrate does not produce coronary steal compared with nitroprusside is that the small intracoronary resistance vessels lack the metabolic transformation pathway required to convert glyceryl trinitrate into NO. Importantly, nitroprusside and glyceryl trinitrate both produce venodilation and this contributes significantly to the labile haemodynamic state, especially in hypertensive patients. Tremendous fluctuations in blood pressure may be seen when sodium nitroprusside is started for the treatment of hypertension in the immediate post-operative period. In the hypertensive patient, intravenous (iv) volume administration is often employed to allow nitroprusside to be safely infused due to the relative intravascular hypovolaemia. Nitroprusside is 44% cyanide by weight so cyanide toxicity can occur, producing coronary vasodilation and coronary steal [5].

Intravenous dihydropyridine calcium channel blockers

These agents are increasingly used in critically-ill patients for their specific arterial vasodilating effect. They differ from antiarrhythmic agents such as diltiazem that will also produce AV nodal blockade.

Table 163.1 Currently available IV antihypertensive agents

Agent	Onset/duration	Elimination half-life	Adverse events	Cautions/concerns
Enalaprilat	<15 min/12–24 hours	11 hours	Precipitous fall in BP in high-renin states, headache, cough, renal failure, hyperkalaemia, angioedema	Avoid in acute MI, long duration of action
Esmolol	1–2 min/10–30 min	2–9 min	Heart block, hypotension, nausea, bronchospasm, overt heart failure, cardiogenic shock	Reduces cardiac output, which may impair organ perfusion
Fenoldopam	5–15 min/ 30 min–4 hours	5 min	Tachycardia, headache, nausea, dizziness, flushing, hypotension, increased intra-ocular pressure	Caution with glaucoma
Hydralazine	10–20 min/1–4 hours	1 hour	Marked hypotension, tachycardia, flushing	Avoid in aortic dissection, MI, severe renal disease. Prolonged and unpredictable effects. Difficult to titrate
Labetalol	<5 min/3–6 hours	5.5 hours	Bradycardia (heart block), overt heart failure, cardiogenic shock, oedema, nausea, vomiting	Avoid in acute heart failure. Severe bradycardia. Heart block, asthma
Nicardipine	5–10 min/ 15 min–4 h	44.8 min	Tachycardia, headache, nausea, flushing, thrombophlebitis, hypotension, vomiting	Avoid in acute heart failure; caution with coronary ischemia; long duration of action
Glyceryl trinitrate	2–5 min/ 5–10 min	1-4 min	Flushing, headache, vomiting, hypotension, methaemoglobinaemia, decreased arterial resistance, reflex tachycardia	Reduction in preload and cardiac output undesirable in patients with compromised renal and cerebral perfusion
Sodium nitroprusside	Immediate/2–3 min	2–3 min	Nausea, muscle twitching, sweating, thiocyanate and cyanide intoxication, hypotension	Increases intracranial pressure. May reduce coronary perfusion pressure (coronary 'steal'). Cyanide toxicity
Clevidipine	2–4 min 5–15 min	1 min	Headache, nausea, vomiting	Lipid suspension, no preservative. Avoid with soy allergy, defective lipid metabolism

BP, blood pressure; MI, myocardial infarction.

Dihydropyridine calcium channel blockers (DHP CCBs) available for parenteral administration in the USA and some other countries include nicardipine and clevidipine [6]. DHP CCBs produce vasodilation by high affinity binding to L-type calcium channels, decreasing calcium entry into vascular smooth muscle. DHP CCBs are arterial-specific agents that primarily affect resistance arteries, resulting in a more or less generalized vasodilatation in the renal, cerebral, and coronary vascular beds. They have minimal direct negative effects on cardiac contractility or conduction, and usually do not result in reflex tachycardia during prolonged antihypertensive treatment. Calcium channel blockers (CCBs) have minimal effects on venous smooth muscle, probably due to the relatively low density of L-type calcium channels present in the vascular capacitance bed, and do not affect cardiac filling pressure and preload. As a result, cardiac output often increases when a CCB is administered to treat hypertension.

DHP CCBs are direct arterial vasodilators. Nifedipine was the first such agent, followed by second generation water-soluble agents that are also available in iv form including isradipine and nicardipine, and the third generation, ultrashort-acting agent clevidipine. Nicardipine produces arterial vasodilation without any effects on the vascular capacitance bed, no effects on atrioventricular nodal conduction, and no depression of ventricular function (i.e. contractility). DHP CCBs have significant vasodilatory properties and preferentially dilate coronary, cerebral, and skeletal muscle vasculature, without impairment of atrioventricular conduction or myocardial contractility.

Dopaminergic receptor agonists (fenoldopam)

Fenoldopam is a selective agonist to peripheral dopaminergic DA_1-receptors, producing vasodilatation, increasing renal perfusion, and enhancing natriuresis. Fenoldopam has a short duration of action with an elimination half-life of <10 minutes. In doses of 0.1–1.5 mcg/kg/min, fenoldopam reduced both systolic and diastolic BP, but also increased heart rate. There were no significant differences in plasma levels of adrenaline, noradrenaline, or dopamine in the fenoldopam patients. Because of a unique mechanism of action, fenoldopam may have advantages in selected subsets of patients.

Pharmacokinetic principles of vasoactive therapy in the ICU

Pharmacokinetic considerations are important for dosing vasoactive drugs in the ICU. Drugs often reach a therapeutic level after approximately three half-lives from initiating an infusion. For short-acting drugs like nitroprusside or glyceryl trinitrate whose half-lives are only several minutes, stable plasma concentrations are achieved soon (<10 minutes) after beginning a constant-rate infusion. Based on this short half-life, the drug can be efficiently titrated by just changing the infusion rate. Dosing strategies for other agents may be less straightforward. Many drugs behave pharmacokinetically as if the body consists of two or three compartments. With iv use, the drug is administered into a central compartment, from which it is either eliminated by metabolic processes, or distributed into one or two peripheral compartments. The central compartment can be identified with blood volume and organs that rapidly equilibrate with the circulation. In general, the effect of the drug is proportional to its concentration in the central compartment. The peripheral compartments can be identified with less rapidly equilibrating tissues. In most cases, the elimination process is slow in comparison to the rate at which the drug distributes from the central into the peripheral compartments. Thus, to establish effective plasma levels of the drug, one must initially give enough to compensate for the loss of drug from the central compartment by both distribution and elimination. As the peripheral compartments 'fill up' with drug, the rate of drug administration can be decreased to the point of simply matching the rate at which the drug is eliminated by metabolism. Practically, this usually means that the drug is administered by continuous infusion with the rate decreasing in stepwise fashion. However, in some circumstances, where a rapid therapeutic effect is needed, the drug should be administered as an initial loading bolus dose with concomitant institution of a continuous steady-state infusion. Esmolol and nicardipine are example of these types of drugs.

Nicardipine, a dihydropyridine derivative calcium channel blocker, has several important pharmacodynamic properties, including its arteriolar selectivity and lack of effects on the vascular capacitance bed. However, its pharmacokinetic profile, based on preliminary data, indicates that effective administration will require variable rate infusions, decreasing in stepwise fashion [7]. In a comparison with sodium nitroprusside in the treatment of perioperative hypertension, the effectiveness of dosing nicardipine in this manner has been demonstrated, with control of hypertension achieved in 14 minutes. If even more rapid control is essential, a dosing strategy consisting of a loading bolus or rapid infusion dose with constant rate infusion may be more efficient [8].

Transitioning/weaning from intravenous to oral therapy for hypertension

Patients should be rapidly transitioned to oral from iv therapy as soon as possible due to cost and ability to transfer to a general ward. This can often occur by restarting preoperative antihypertensive agents, or starting new oral agents. Patients receiving iv DHP CCBs can be readily transitioned to oral agents, such as amlodipine, nicardipine, or nifedipine. Furthermore, if patients were receiving higher doses of DHP CCBs to control BP, then iv β-blockers (e.g. metoprolol or labetalol) are often administered if the patient is tachycardic in order to control heart rate. In post-operative hypertension, patients often have transient and self-limiting hypertension that only may require therapy until extubation. Steps should be taken to identify barriers to transitioning patients to oral therapy. For patients requiring extended anti-hypertensive therapy beyond the immediate post-operative period, β-blocking agents are often ineffective monotherapy. Patients who require continuous infusions of iv DHP CCBs will likely require combination oral therapy utilizing medications with different mechanisms of action. Finally, patients with renal failure and fluid overload, may sometimes have their hypertensive emergency completely treated by appropriate dialysis and fluid removal.

JNC-8 guidelines and what's new

The new guidelines [1] have modified goals for chronic BP management; in hypertensive persons ≥60 years the BP should be targeted <150/90 mmHg, while in those aged 30–59 years a diastolic goal <90 mmHg should be sought. The Panel felt there was

insufficient evidence in hypertensive persons <60 years to recommend a systolic goal, or a diastolic goal in those <30 years so, based on expert opinion, they recommended a BP target <140/90 mmHg for these groups. The same thresholds and goals as for hypertensive patients <60 years were also recommended for diabetics and those with non-diabetic chronic kidney disease. They suggested drug treatment should be initiated with an angiotensin-converting enzyme inhibitor, angiotensin receptor blocker, CCB, or thiazide diuretic in non-black hypertensives, including diabetics. In black hypertensives (including diabetics), a calcium channel blocker or thiazide-type diuretic was recommended as initial therapy. Importantly, the Panel stressed that their recommendations are not a substitute for clinical judgment. Decisions about care should be carefully considered, and take into account both clinical characteristics and circumstances of the individual patient.

PART 5.12

Severe capillary leak

CHAPTER 164

Pathophysiology of severe capillary leak

Anatole Harrois and Jacques Duranteau

Key points

- Severe capillary leak plays an important role in the pathogenesis of sepsis, acute lung injury, and shock syndromes.
- Tissue oedema can impair tissue oxygenation and likely contributes to organ dysfunction.
- Microvascular permeability is mainly regulated by four components—the glycocalyx, endothelial cell–cell junctions (adherens junctions and tight junctions), transcellular transport across the endothelium (caveolae and vesiculo-vacuolar organelles) and endothelial–associated cells.
- Inflammatory mediators such as cytokines, endotoxin, microbial compounds, angiogenic (e.g. vascular endothelial growth factor) and pro-coagulant (e.g. thrombin) factors increase microvascular permeability by weakening endothelial junctions.
- An understanding of the pathogenesis of microvascular permeability may lead to new therapies targeting the microvascular barrier in sepsis and acute lung injury.

Introduction

Severe capillary leak is an important factor in the pathogenesis of many inflammatory syndromes, including sepsis and acute respiratory distress syndrome (ARDS). Microvascular leak is caused by an increase in endothelial permeability. The microvascular barrier consists of an endothelial cell monolayer comprised of endothelial cells, associated endothelial cell–cell junctions, and extracellular components, and the glycocalyx. The microvascular barrier functions as an interface between circulating blood and surrounding tissues by controlling the exchange of fluid, metabolic compounds and cells from the circulation into the tissues. Inflammatory mediators such as cytokines, endotoxin, microbial compounds, reactive oxygen species, angiogenic (e.g. vascular endothelial growth factor (VEGF)) or pro-coagulant (e.g. thrombin) factors increase vascular permeability by destabilizing endothelial junctions. This then results in tissue oedema with potential harmful effects on tissue oxygenation, probably contributing to organ dysfunction. Tissue oedema could impair tissue oxygenation by increasing the distance required for the diffusion of oxygen to the cells and by decreasing microvascular perfusion due to increases in interstitial pressure.

Microvascular permeability

Microvascular permeability differs between organs. Microvascular barrier can be physiologically leaky with a high permeability for macromolecules, as in endocrine glands, or for fluid, as in the kidney and liver. In contrast, the microvascular barrier can be highly selective with a low permeability and high transendothelial resistance as observed in the blood brain barrier [1].

Microvascular permeability is mainly regulated by four components (Fig. 164.1):

- The glycocalyx.
- Endothelial cell–cell junctions (adherens junctions and tight junctions), i.e. paracellular permeability.
- Transcellular transport across the endothelium (caveolae and vesiculo-vacuolar organelles, VVOs), i.e. transcellular permeability.
- Endothelial–associated cells associated with capillaries in the 'vascular unit' e.g. pericytes, alveolar epithelial cells, smooth muscle cells and macrophages [2–4].

Appropriate regulation of these components maintains a low and selective permeability to fluid and solutes under normal physiological conditions. The strength of the endothelial barrier results from a balance between stabilizing and destabilizing signals, allowing the vascular system to adapt to physiological needs.

The glycocalyx

The glycocalyx is a thin gel-like layer of glycoproteins and polysaccharides that covers the luminal surface of the microvascular endothelium with an estimated thickness ranging from 150–500 nm [5,6]. The glycocalyx serves as a vascular permeability barrier, a mechanotransducer of flow-induced shear stress to endothelial cells, and a regulator of leukocyte-endothelial interactions.

The major components of the glycocalyx are proteoglycans (transmembrane syndecans, membrane-bound glypicans, and matrix-localized perlecans) and glycosaminoglycans (GAGs). Glycosaminoglycans are linked to endothelial membrane-bound proteoglycans, which link the glycocalyx to the actin cytoskeleton. The majority of GAG sidechains are heparin sulphate, chondroitin/dermatan sulphate, and hyaluronic acid or hyaluronan. These constituents form a negatively-charged network that can rebuff blood cells and select plasma components according to their electrostatic

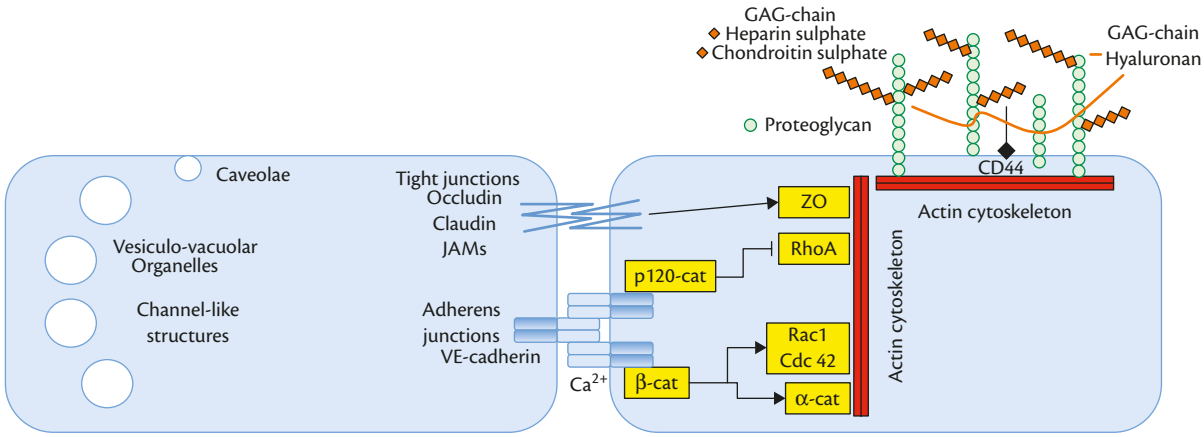

Fig. 164.1 Schematic representation of the components involved in the regulation of microvascular permeability.
Cat, catenin; ZO, zona occludens proteins; GAG, glycosaminoglycan.

charge. The glycocalyx is a dynamic structure that is highly dependent upon the local micro-environment (local ionic strength) and pH. Endothelial cells also regulate the biosynthesis of new glycosaminoglycans to allow adaptations to changes in the local environment, such as shear stress and local pH. The structure of the glycocalyx has an underlying three-dimensional fibrous meshwork with a characteristic spacing of 20 nm in all directions [7]. Such spacing can act as a molecular filter for plasma proteins, and control filtration, both when the endothelium is continuous and when it is fenestrated.

Paracellular permeability

The endothelial junctions consist of adherens, tight, and gap junctions. Adherens junctions (AJs) are found in all microvascular beds, whereas tight junctions (TJs) are mainly expressed in the blood–brain barrier and the blood retinal barrier. Gap junctions form channels between adjacent endothelial cells, and allow diffusion of water, ions, and other small molecules with transmission of signals within the contiguous monolayer of cells.

AJs are mainly made by calcium-dependent vascular endothelial cadherin proteins (VE-cadherin). VE-cadherin forms interactions between adjacent endothelial cells by their extracellular domains in a calcium-dependent manner. The intracellular domain of VE-cadherin is connected to the actin cytoskeleton via a family of catenins (α-, β-, γ-, and p120-catenins) [1]. VE-cadherins not only serve as a structural linkage between endothelial cells, but are also involved in intracellular signalling and in the control of cell–cell communications. The stability of VE-cadherin complexes is regulated by phosphorylation, which induces its internalization and disrupts barrier integrity, thus resulting in vascular permeability. VE-cadherins play a key role in the communication between adherens and tight junctions, as well as supporting and stabilizing the tight junctions. For example, VE-cadherin can transmit shear stress signals to tight junction occludin through engagement of Tiam1/Rac1, thereby leading to barrier stabilization [8].

Catenins play a critical role in stabilizing the VE-cadherin–catenin–cytoskeleton system that is undergoing constant remodelling. The cytoplasmic domain of VE-cadherin interacts with β-, γ-, and p120-catenins through its cytoplasmic domain. The α-/β-catenin interaction induces cell–cell adhesion through an interaction with actin and formation of cortical actin bundles. In addition, β-catenin and γ-catenin (plakoglobin) prevent VE-cadherin proteolysis. Finally, β-catenin and 120-catenin modulate the actin cytoskeleton by way of RhoGTPase activation (p190RhoGAP, Rac1, Cdc42, RhoA).

Tight junctions are composed of three types of transmembrane proteins—occludin, claudin and junctional adhesion molecules (JAM) [9]. These proteins are connected to the actin cytoskeleton via zona occludens proteins (ZO-1, ZO-2) and α-catenin. Similar to adherens junctions, phosphorylation of both tight junction proteins and their intracellular partners regulate endothelial cell–cell junctions and vascular permeability.

It is essential to understand that adherens and tight junctions not only have a function of linking endothelial cells, but serve also as signalling molecules through their interaction with the actin cytoskeleton for the regulation of cell polarity, cellular movement, and fluid sensing. Another major point is the fact that endothelial-associated cells, which form with capillaries the 'vascular unit', contribute to stabilization of the endothelial barrier. For example, pericytes and alveolar epithelial cells (alveolar-capillary membrane) can markedly attenuate microvascular hyperpermeability by controlling pro-permeability signals [10].

Transcellular permeability

This mechanism involves vesicle-mediated endocytosis at the endothelial luminal membrane, followed by transcytosis across the cell, and exocytosis at the basolateral membrane. Transcellular permeability is an energy-dependent process involving caveolae and clusters of interconnected VVOs that form channel-like structures of diameter = 80–200 nm. Caveolae are 60–80 nm diameter pits that are seen in the endothelium membrane, and as free vesicles within the cytoplasm.

Formation of caveolae at the membrane of the endothelium implies inclusion of caveolin-1 (Cav-1), a structural protein of caveolae, into membrane lipid microdomains enriched with cholesterol and sphingolipids. There are two caveolin isoforms in endothelial cells, caveolin-1 and 2, but only Cav-1 exclusively regulates caveolae formation and transcytosis. Caveolae are involved in several functions including endocytosis, transcytosis, potocytosis, lipid regulation, calcium signalling, and in diverse signalling pathways.

Caveolae may mediate transcellular transport of molecules such as albumin, iron-transferrin, insulin, low-density lipoproteins, and chemokines. The transport of albumin by caveolae is crucial for regulation of transendothelial oncotic pressure and is crucial for fluid balance across the endothelium.

VVOs consist of clusters of 1–2 μm vesicles or vacuoles. Unlike caveolae, VVOs are sessile structures that can assemble into transcellular membranous channels. These channels open into the luminal, abluminal, or lateral endothelial cell surfaces. The channel-forming VVOs provide a transcellular permeability pathway to macromolecules. Further data are needed to clarify their function in the control of microvascular permeability.

Capillary leak during sepsis and the acute respiratory distress syndrome

As illustrated in Fig. 164.2, during sepsis or ARDS, increased microvascular leak occurs due to loss of intercellular junctional integrity, remodelling of the cellular cytoskeleton, or endothelial apoptosis or damage. Inflammatory mediators such as cytokines, endotoxin, microbial compounds, angiogenic (e.g. VEGF) and pro-coagulant (e.g. thrombin) factors increase microvascular permeability by weakening endothelial junctions. The most common effects reported with these mediators are alterations of the glycocalyx, endothelial junctions (especially phosphorylation of constituents of AJs with VE-cadherin internalization), and activation of actomyosin contractility causing interendothelial gaps (Fig. 164.2).

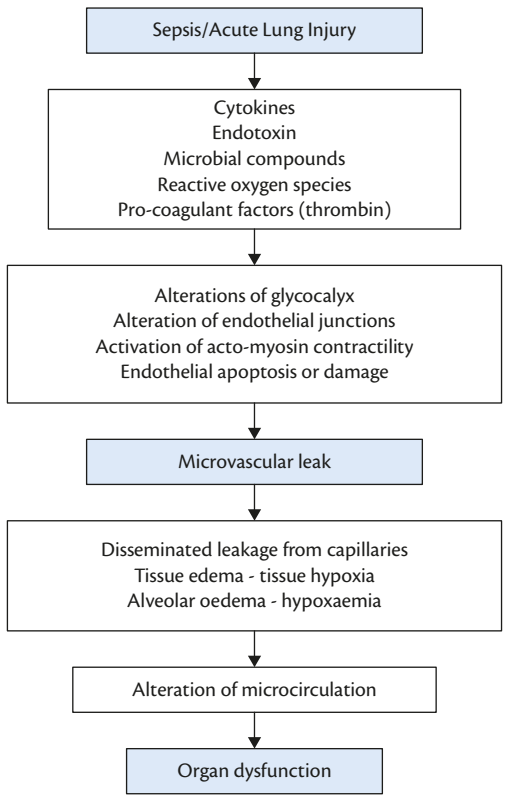

Fig. 164.2 Schematic representation of causes and consequences of microvascular leak in sepsis and ARDS.

These processes facilitate the migration of immune cells, antibody, and other substances to sites of microbial invasion. However, excessive release of inflammatory mediators into the circulation could paradoxically injure organs by triggering a disseminated leakage from capillaries, inducing uncontrolled fluid extravasation and tissue oedema. Accumulation of interstitial fluid is detrimental to tissue oxygenation and organ function as oedema increases the diffusion distance for oxygen and nutrients, and compresses capillaries by increasing the interstitial pressure in organs with non-expendable interstitial volumes (kidney, brain, muscle). In addition, oedema in the lungs leads to alveolar flooding and hypoxaemia. Microvascular leak is a major cause underlying the generalized alteration of the microcirculation induced by sepsis. For example, peritonitis induces not only intestinal capillary leak, but also alterations within the microvascular pulmonary microcirculation with increases in the number of stationary leukocytes and protein leak into the pulmonary alveoli [11].

The loss of endothelial barrier function and the resultant capillary leak appears to be a key factor underlying multiple organ dysfunction (MOD). This has been demonstrated in several models of sepsis using different strategies to prevent capillary leak [12–15]. Xu et al. [13] used transgenic mice that selectively overexpress the NF-κB inhibitor I-κBα on endothelium. They reported that this selective prevention of endothelial activation and capillary leak could avoid the resultant sepsis-induced MOD. London et al. [14] found that reduction of capillary leak by a recombinant Slit2N fragment improved survival in animal models of endotoxin, polymicrobial sepsis, and H5N1 influenza. They identified the Slit-induced signalling pathway as a modulator of vascular stability that can strengthen endothelial cell–cell interactions through inhibition of VEGF in a process dependent on the endothelial-specific receptor Robo4.

As previously mentioned, sepsis induces an alteration of the glycocalyx. In humans, endotoxin administration led to alterations of the endothelial glycocalyx illustrated by a profound reduction in microvascular glycocalyx thickness (polarization spectroscopy imaging of sublingual microcirculation) with a significant rise in circulating hyaluronan levels [16]. This abnormality has been confirmed in septic patients with high levels of glycocalyx markers (syndecan-1, heparan sulphate) correlating with disease severity and mortality [17–19].

Conclusion

Capillary leak contributes to organ dysfunction in sepsis and ARDS. An understanding of the pathogenesis of microvascular permeability may lead to new therapies targeting the microvascular barrier in sepsis and ARDS.

CHAPTER 165

Management of acute non-cardiogenic pulmonary oedema

Sébastien Tanaka and Jacques Duranteau

Key points

- Severe capillary leak is an important factor in the pathogenesis of organ dysfunction following inflammatory syndromes such as sepsis-induced acute lung injury (ALI) and acute respiratory distress syndrome (ARDS).
- The Surviving Sepsis Campaign recommends a conservative, rather than liberal fluid strategy for patients with established sepsis-induced ARDS who do not have evidence of tissue hypoperfusion.
- There is no evidence to recommend the use of diuretics to prevent tissue oedema.
- Several therapeutic options that restore microvascular permeability have been investigated in preclinical sepsis models.
- The challenge is now to proceed into carefully designed clinical trials.

Introduction

Microvascular leak caused by an increase in endothelial permeability plays an important role in the pathogenesis of many inflammatory syndromes, such as sepsis, acute lung injury (ALI) and acute respiratory distress syndrome (ARDS). The resulting tissue oedema impairs tissue oxygenation, thereby contributing to organ dysfunction. It would thus appear rational to prevent, ameliorate, or reverse excessive capillary leak. Several interventions in current practice are designed to maintain intravascular colloid osmotic pressure, reduce capillary leak, or reduce extravascular water. The evidence base underlying these will be reviewed. In addition, there are novel targeted strategies specifically designed to reduce capillary leak with encouraging preclinical data. The challenge is now to prove the clinical effectiveness of these strategies with carefully designed clinical trials.

Current therapeutic options

Fluid management

Fluid resuscitation is one of the first line treatments in septic patient management. However, the risk of excessive fluid administration is now well demonstrated. This risk is particularly apparent in patients with ARDS where a positive fluid balance was associated with worse outcomes and was an independent indicator of mortality [1]. Thus, the challenge for the physician is to find a good balance between intravascular volume restoration and tissue oxygenation, without inducing fluid overload and worsening lung injury. However, the strict application of a fluid-restrictive strategy is not always possible because of haemodynamic instability. Only a few prospective studies have evaluated the effects of a conservative fluid strategy, reporting that a fluid restriction strategy can improve oxygenation and increase the number of ventilator-free days [2,3]. Fluid restriction was variably associated with diuretic treatment and vasopressor use, but the study design did not allow an assessment of their impact on mortality. The Surviving Sepsis Campaign recommends a conservative, rather than liberal fluid strategy for patients with established sepsis-induced ARDS who do not have evidence of tissue hypoperfusion [4]. Thus, it is crucial to titrate fluid resuscitation to prevent or minimize extravascular lung water. Assessment of pulmonary permeability by transpulmonary thermodilution with monitoring of extravascular lung water (EVLW) could be an interesting tool to manage fluid resuscitation in ARDS.

The choice of fluid to minimize capillary leak remains a matter of significant controversy. It would make sense to increase plasma oncotic pressure to limit the formation of oedema, particularly for septic patients in whom haemodilution and catabolism would reduce plasma protein levels. Experimental studies have demonstrated a beneficial effect of albumin on pulmonary inflammation with a decrease in capillary permeability [5]. In ARDS patients, a moderate improvement of oxygenation was observed when albumin was combined with diuretics compared with diuretic treatment alone [6]. However, no differences in mortality or the numbers of days spent on mechanical ventilation, in intensive care unit (ICU) or in hospital, were observed in the SAFE study comparing albumin 4% and crystalloid administration [7].

Diuretics

Given that relatively few studies have focused on the use of diuretics in ALI/ARDS, there is no evidence to recommend their use to prevent tissue oedema. In a canine oleic acid model of ARDS, furosemide improved the PaO_2/FiO_2 ratio, reduced lung injury, and the level of PEEP [8]. Septic patients with ARDS treated with furosemide alone developed more vascular dysfunction than those

treated with both furosemide and albumin [6]. Patients with ALI randomized to receive a conservative fluid strategy, in which an improvement of lung function was observed, received more diuretics than the liberal fluid strategy group [3]. In the same cohort of patients, diuretic therapy given post-acute kidney injury was associated with an increase in 60-day patient survival [9].

Vasopressin

Low-dose vasopressin (AVP) was recently proposed as a pharmacological approach to decrease capillary leak in ALI. The rationale is that excessive nitric oxide (NO) production accounts for the increased vascular leakage and that vasopressin can limit this excessive NO production. In an established ovine model of ALI, low-dose AVP infusion could attenuate pulmonary dysfunction, shunt fraction, nitrosamine stress, and oedema formation [10]. However, clinical studies are needed to confirm benefit.

Novel therapeutic options

A variety of other therapeutic options to restore microvascular permeability have been investigated in pre-clinical sepsis models. However, the challenge is now to prove their effectiveness in patients with ALI/ARDS and sepsis in carefully designed clinical trials.

Sphingosine-1-phosphate and S1P agonists

Sphingosine-1-phosphate (S1P) is formed in intracellular compartment by phosphorylation of sphingosine and acts on five specific G protein-coupled receptors (S1P receptors S1PR1-5). S1PR1 activation enhances cadherin expression, stabilizes the endothelial cytoskeleton, and counteracts VEGF-induced VE-cadherin internalization and thrombin-activated PAR-1 signalling. Clinical studies suggest that low plasma S1P levels may have an impact on vascular leakage and mortality in malaria and sepsis [11,12]. In endotoxin-induced acute lung injury models, leak and lung injury could be decreased by treatment with FTY720 (an S1P analogue) or S1P. S1PR3 was recently shown to promote lipopolysaccharide (LPS)-induced vascular leakage, while elevated plasma concentrations were associated with an increased mortality in patients with sepsis or ALI [13]. S1PR3 could thus also be a potential therapeutic target.

Angiopoietin (Angpt)-tie pathway

Angiopoietin-1 (Angpt-1) and Angpt-2 are ligands for the endothelial-specific receptor tyrosine kinase Tie2. Angpt-1 is secreted by peri-endothelial cells and promotes vascular endothelial cell survival and endothelial cell adhesion, while inhibiting endothelial permeability in response to VEGF or thrombin. Angpt-2 is synthesized in endothelium and is the natural antagonist of Angpt-1. Angpt-2, by interfering with Angpt-1, leads to endothelial barrier destabilization, endothelial cell activation, and vascular inflammation. In sepsis and ARDS, the Angpt-1/Tie2 axis is suppressed with a concomitant increase in circulating Angpt-2 [14]. Circulating Angpt-2 is associated with pulmonary permeability oedema, and the occurrence and severity of ARDS [15]. A greater reduction in plasma Angpt-2 levels over time has been reported when a conservative fluid strategy was applied to ARDS patients compared to a liberal strategy [15]. Induction of Angpt-2 precedes adverse outcomes, while circulating Angpt-2 levels or a high Angpt-2/Angpt-1 ratio could predict the development of sepsis and shock [16]. Preclinical studies have demonstrated benefits through modulating the Angpt–Tie-2 axis using recombinant Angpt-1, the Angpt-1 agonist (vasculotide), or antibodies specific for Angpt-2 [16]. Furthermore, genetic variants in the Angpt-2 gene are associated with an increased risk of ARDS [16]. Modulation of the Angpt–Tie-2 axis appears to be a particularly strong concept for future clinical trials.

Vascular endothelial growth factor

Vascular endothelial growth factor (VEGF) has been proposed to be a pivotal factor underlying sepsis-related microvascular leak. Numerous reports also suggest a pathological role in ARDS. Through binding with endothelial VEGF receptors (VEGFR1–3), VEGF can increase microvascular permeability by several mechanisms, including VE-cadherin internalization via the VEGFR2-Src-VE-cadherin signaling pathway and cytoskeletal rearrangement. Anti-VEGF therapies may limit sepsis-related microvascular leak. However, the function of VEGF is highly complex, with both protective and pathological effects, so a VEGF-targeted therapeutic agent remains controversial. A neutralizing anti-VEGF antibody (bevacizumab) is at present under consideration for patients in septic shock.

Atrial natriuretic peptide

In a murine model, atrial natriuretic peptide (ANP) significantly decreased endotoxin-induced lung vascular leak through effects on PAK1 (p21-activated kinase)-dependent signalling, leading to EC barrier enhancement [17]. PAK1 is a cytoskeletal Rac effector involved in cortical actin rearrangement and regulation of actin polymerization. The authors also reported that ANP knockout mice developed more severe endotoxin-induced lung injury [17]. In ARDS patients, an infusion of ANP given over 1 hour did not improve pulmonary gas exchange [18]. However, a longer infusion (24 hours) improved the PaO_2/FiO_2 ratio and thoracic compliance with a decrease in pulmonary shunt. The potential clinical role for ANP in ARDS merits further investigation.

Slit2N-robo4 pathway

London et al. identified the Slit-induced signaling pathway as a modulator of vascular stability that can strengthen adherens junctions through an increased expression of VE-cadherin and an inhibition of VEGF-induced vascular hyperpermeability [19]. This was demonstrated in animal models of endotoxin-induced acute lung injury, caecal ligation and puncture, and H5N1 influenza. The Slit2N-Robo4 pathway could also repress enodotoxin-induced endothelial inflammation by inhibiting the Pyk2–NF-kB pathway. Therefore, modulation of the Slit2N- Robo4 pathway may represent another promising therapeutic option to restore microvascular permeability and prevent sepsis-induced organ injury.

Fibrinopeptide $B\beta_{15–42}$

Fibrinopeptide $B\beta_{15-42}$ is released from fibrin following thrombin-induced fibrin formation. This peptide, also called FX06, can be used as an index of fibrinolytic activity. FX06 reduced capillary leakage in three models of capillary leak (Dengue shock, endotoxin shock, endotoxin pneumonitis) [20]. Its protective effect appears related to its binding to VE-cadherin, stabilization of inter-endothelial junctions, and anti-inflammatory effects.

Conclusion

Capillary leak contributes to organ dysfunction in sepsis and ARDS. A number of interventions in current practice are designed to

maintain intravascular colloid osmotic pressure, reduce capillary leak, or reduce extravascular water. A conservative, rather than liberal fluid strategy is recommended. Preclinical studies suggest that preventing microvascular leak may represent a viable therapeutic strategy to decrease organ dysfunction. Therapeutic agents that stabilize the glycocalyx might also prevent inflammation-induced organ failure. The challenge is now to proceed into carefully designed clinical trials.

PART 5.13

Pericardial tamponade

CHAPTER 166

Pathophysiology and causes of pericardial tamponade

John R. Schairer and Steven J. Keteyian

Key points

- Cardiac tamponade is a shock state resulting from the accumulation of blood or fluid in the pericardial space, which limits ventricular filling resulting in a decreased stroke volume and cardiac output.
- Cardiac tamponade is a continuum and not an all-or-nothing diagnosis.
- A rapidly accumulating pericardial effusion can become haemodynamically significant with smaller volumes versus a pericardial effusion that occurs gradually over time.
- Echocardiography is the cornerstone of the work-up of pericardial effusion, providing diagnostic, prognostic, and therapeutic information. Computed tomography and magnetic resonance imaging can also be helpful.
- Comorbid conditions that may affect the pathophysiology of cardiac tamponade and, secondarily, the signs of cardiac tamponade need to be considered when entertaining a diagnosis of cardiac tamponade.

Introduction

Pericardial disease leading to pericardial effusion (PEF) is a common condition encountered by the clinician in day-to-day practice. The most common causes are viral infections, metastatic cancer, renal disease, and bleeding disorders, such as aortic dissection and trauma. If the effusion becomes large enough it can cause haemodynamic compromise or shock, resulting in the clinical condition of cardiac tamponade. Importantly, tamponade is not an all-or-nothing diagnosis, but instead should be viewed along a continuum of progressively worsening haemodynamics.

Epidemiology and aetiology of pericardial effusion

Inflammation of the pericardium or pericarditis is reported in 5% of patients admitted to the emergency department for work-up of chest pain, and in 1% of autopsy studies [1]. The most common cause of pericarditis (80–90%), and thus PEF, is viral infection [2]. Factors associated with increased risk for recurrent pericarditis, tamponade, or pericardial constriction are female gender, fever >38°C, subacute onset (symptoms developing over a period of several days to weeks), large effusion or tamponade, and use of non-steroidal anti-inflammatory agents [3]. Conditions associated with a high incidence of progression to tamponade are neoplasm with metastasis to the pericardium, renal disease, and disorders giving rise to bleeding into the pericardial space, such as aortic dissection and penetrating wounds. Up to one-third of patients with an asymptomatic large PEF eventually developed tamponade [4,5]. Echocardiography, computed tomography, and magnetic resonance imaging (MRI) provide important information in the diagnostic work-up and management of PEF. However, PEF as reported by computed tomography tends to be larger than reported by echocardiography. Echocardiography is considered the more accurate measurement.

Pathophysiology

Intrapericardial and intrathoracic pressures are normally equal and vary with respiration. With inspiration, intrathoracic pressure decreases causing an increased flow into the right side of the heart and a decrease in flow from pulmonary veins into the left side. During expiration the process is reversed. As a result of these respiratory fluctuations in flow, chamber size, intracardiac pressures, vascular pressures, and stroke volume also fluctuate.

The pericardium is composed of parietal and visceral layers. The visceral layer, when inflamed, forms an increased amount of PEF. In situations of gradual accumulation of PEF, such as in malignancy and chronic kidney disease, the pericardium has time to stretch and the effusion can become as large as 2 L without causing haemodynamic compromise. When PEF accumulates rapidly, e.g. with chamber perforation or aortic dissection, the pericardium does not have time to stretch and a PEF as small as 150 mL can lead to tamponade.

As the size of the PEF increases, pressure in the pericardial space also increases. The haemodynamic consequence is a limitation in cardiac filling, similar to diastolic dysfunction. In tamponade, the ventricles no longer fill against the diastolic pressures of the individual chamber, but rather against the common pressure of the intrapericardial space. When the limits of pericardial stretch are reached, the total intrapericardial volume becomes fixed. Any additional increase in PEF results in either a decrease in heart size or if one chamber increases in size during the respiratory cycle, the other chamber must decrease. The normal reciprocal changes in flow and chamber size during respiration become exaggerated; this is referred to as ventricular interdependence. As the right ventricle is a thin-walled structure, it is more susceptible to changes in pressure and volume than the left ventricle. Ventricular interdependence is

the explanation for exaggerated respiratory variation in flows across the four cardiac valves, and the exaggerated respiratory variation in systolic BP known as pulsus paradoxus.

Reddy et al. [6,7] described the haemodynamics of PEF and tamponade. They measured intracardiac, intrapericardial, and arterial pressures, and cardiac output in patients with tamponade before, during, and after pericardiocentesis. Baseline haemodynamics revealed equalization of right atrial (RA), intrapericardial, pulmonary capillary, and left atrial pressures at 16 mmHg or higher. They divided the haemodynamics of an enlarging pericardial effusion into three phases of increasing haemodynamic compromise, beginning with little compromise (Phase 1) and culminating in tamponade with cardiogenic shock (Phase 3; Fig. 166.1). As the abnormal haemodynamics evolve over three phases, tamponade should not be considered as an all-or-nothing diagnosis, but rather a continuum.

Clinical findings in PEF and CT

Phase 1: the early phase of fluid accumulation

The increased fluid within the pericardial space causes a gradual increase in intrapericardial pressure, resulting in an increase in both right ventricle (RV) and left ventricle (LV) filling pressures. At the end of Phase 1, RV filling pressure and intrapericardial pressure are equal at approximately 10 mmHg, there is a small decrease in cardiac output, and arterial pressure decreases slightly during inspiration, although values are still within the normal range. LV filling pressure is still slightly higher than pericardial pressure. The main finding of Phase 1 is an enlarged cardiac silhouette on imaging studies.

Phase 2: pre-tamponade

Here, intrapericardial, right and left atrial pressures continue to increase. The rising intrapericardial pressure causes cardiac chambers to decrease in size and, secondarily, cardiac output to decrease, but there are no signs of shock. Many of the echocardiographic and clinical signs of tamponade may become apparent, although classically they are found in Phase 3. There is a further decrease in arterial pressure during inspiration, approaching the 10 mmHg value that is consistent with pulsus paradoxus. Recognizing Phase 2 is important as it enables prediction of impending tamponade and intervention before the patient goes into shock.

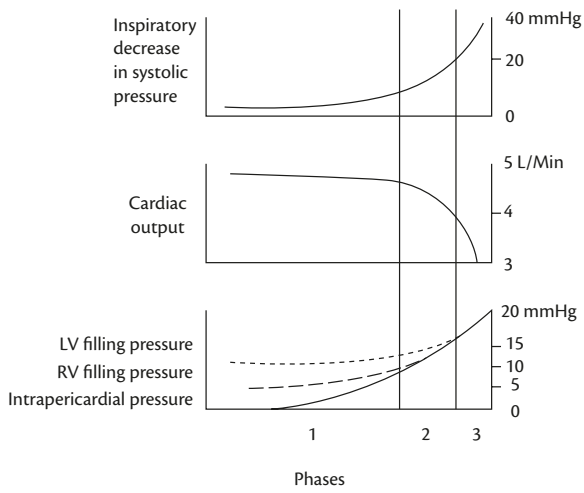

Fig. 166.1 Pathophysiology of cardiac tamponade. Phase 1: Intrapericardial pressure < RA pressure < LV filling pressure. Phase 2: begins with equalization of pericardial and RA pressures. Phase 3: begins with equalization of intrapericardial, RA, and LV filling pressures.

RA, right atrium; LV, left ventricle.

Phase 3: cardiac tamponade

Intrapericardial, right and left atrial pressures equalize at ≥16 mmHg. Increases in intrapericardial pressures >16 mmHg cause a further drop in cardiac output. The inspiratory fall in arterial pressure is now ≥10 mmHg, cardiac chamber size is decreased and circulatory collapse occurs; cardiogenic shock or tamponade ensues. The signs of tamponade are usually present during this phase. Pulsus paradoxus is the *sine qua non* of Phase 3 with an inspiratory drop of systolic pressure >10 mmHg. Although pulsus paradoxus was originally thought to occur only if there was equalization of pressures (i.e. Phase 3), a few patients demonstrate this finding during Phase 2. Finally, it is important to recognize that pulsus paradoxsus may not always be present in tamponade and can also be seen in other disease processes (Box 166.1).

Echocardiography and Doppler in PEF and CT

Echocardiographic evaluation of PEF

Echocardiography is the diagnostic cornerstone of PEF and its complication, tamponade. A major role of echocardiography is

Box 166.1 Comorbid conditions affecting pulsus paradoxus

Conditions in which pulsus paradoxus may be present without tamponade

- Obesity.
- Asthma/chronic obstructive pulmonary disease.
- RV infarction.
- Pulmonary embolism.
- Effusive-constrictive tamponade.
- Heart failure.
- Constriction (rare).

Conditions in which pulsus paradoxus may be absent with tamponade

- Atrial septal defect.
- RV hypertrophy without pulmonary hypertension.
- Shock and severe tamponade.
- Increased LV filling pressures and diastolic stiffness.
- Local pericardial adhesions.
- Positive pressure ventilation.
- Aortic regurgitation.

Reproduced from Schairer JR et al., 'A systematic approach to evaluation of pericardial effusion and cardiac tamponade', *Cardiology in Review*, **19**(5), pp. 233–8, copyright 2011, with permission from Wolters Kluwer Health.

Table 166.1 Estimation of RA pressure using IVC

Inferior vena cava diameter	Decrease in diameter with respiration or 'sniff' test	RA pressure (mean) mmHg
Normal (≤2.1cm)	>50%	0–5 [3]
Normal (≤2.1cm)	<50%	5–10 [9]
Dilated (>2.1cm)	>50%	5–10 (8)
Dilated (>2.1cm)	<50%	>15

determining the presence, size, and location of the PEF. PEF size is designated 'physiological' (25–50 mL) if there is no separation of epicardium and pericardium during end-diastole, 'small' (<100 mL) if the echocardiographic-free space is ≤10 mm, 'moderate' (100–500 mL) if the echocardiographic-free space is between 10–20 mm, and 'large' (>500 mL) if the echocardiographic-free space is ≥20 mm. Measurements should be performed at end-diastole. The distribution of the PEF can be either circumferential or loculated.

The first haemodynamic change to occur with an enlarging PEF is an increase in RA pressure manifested clinically as jugular venous distention, or echocardiographically as inferior vena cava (IVC) dilatation. As RA pressure increases, IVC size increases and its response to respiration decreases until, at an RA pressure of ≥15 mmHg, the IVC is dilated and does not change size with respiration; this is termed IVC plethora (Table 166.1). The sensitivity of IVC plethora for tamponade is 97%, while the specificity is somewhat lower at 66%. Without IVC plethora, tamponade is unlikely.

Doppler evaluation in CT

Appleton et al. [8] described changes in E-wave velocity with respiration across the mitral and tricuspid valves comparing normal subjects, patients with large PEF, and those with tamponade. The normal respiratory variation across the mitral and tricuspid valves is ≤15 and ≤25%, respectively. In general, variations in E-wave velocities during respiration across the mitral and tricuspid valves that are greater than 25 and 50%, respectively, indicate tamponade.

When evaluating respiratory changes in PEF and suspected tamponade, other disease states demonstrating an increase in respiratory flow variation across the valves should also be considered, e.g. chronic obstructive lung disease, pericardial constriction, severe tricuspid regurgitation and RV dysfunction.

Echocardiographic evaluation of tamponade

Because of the increased pressure in the pericardial space in tamponade, there is a reduced size of the RV chamber, RV collapse during diastole, or RA inversion during systole. RV collapse occurs during diastole because pericardial pressure exceeds RV early diastolic pressure (Fig 166.2).

RV chamber size in tamponade achieves its smallest dimension after the onset of the E-wave of the mitral valve and after closure of

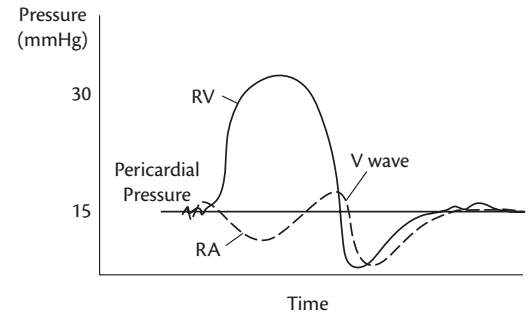

Fig 166.2 Pathophysiology of right ventricular (RV) and right atrial (RA) collapse. Pericardial pressure exceeds RA and RV pressure causing collapse. The y-descent of the v-wave also becomes less prominent.
Reproduced from Schairer JR et al., 'A systematic approach to evaluation of pericardial effusion and cardiac tamponade', *Cardiology in Review*, **19**(5), pp. 233–8, copyright 2011, with permission from Wolters Kluwer Health.

the aortic valve (i.e. during diastole), when the RV should be dilating [9]. RV diastolic collapse involves the free wall of the RV outflow tract (Fig. 166.3). RV collapse is present in patients who did not have clinical tamponade but did have moderate-to-large PEF. This suggests that RV collapse may be a very early sign of tamponade. In all cases the abnormal motion reverts back to normal after drainage of the PEF. Because of the RV collapse in early diastole, passive RV filling becomes less important; filling now depends almost exclusively on atrial contraction. RV collapse was associated with an approximate 20% decrease in cardiac output [10].

Increased pericardial pressure also causes RA collapse or inversion (Fig. 166.2) [11]. The percentage of the cardiac cycle that RA inversion occupies is termed the RA inversion time index. An index ≥0.34 yielded 94% sensitivity, 100% specificity, predictive value of 100%, and accuracy of 97%. The index is believed to be the most sensitive finding for tamponade. The absence of sinus rhythm does not preclude the use of RA collapse to make the diagnosis of tamponade. Increased intrapericardial pressure also explains the loss of the y-decent of the V-wave in the jugular pulse, while the x-descent of the A-wave of the RA waveform is preserved (Fig. 166.2).

False-negative and false-positive findings occur for both RA and RV collapse. False negatives occur in patients with elevated right heart pressures or RV hypertrophy, both of which counter the increased pericardial pressures. One cause of diastolic collapse unrelated to CT is a large pleural effusion.

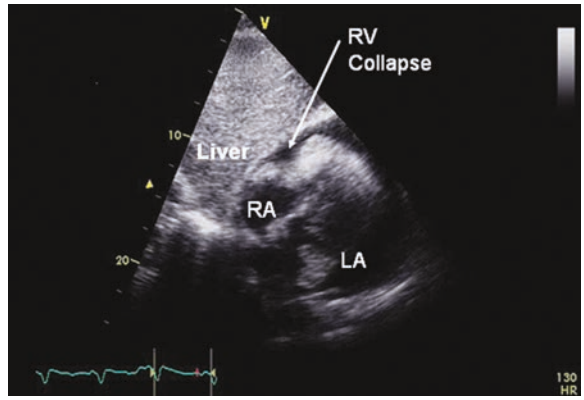

Fig. 166.3 2D-echo demonstrating RV collapse.

Diagnosis of tamponade: detection before haemodynamic embarrassment

Findings can begin during Phase 2 when pericardial pressure is increased, but there is no haemodynamic collapse. Some patients with a large PEF may have variations in flow velocity across the AV valves that exceed normal values, but are not large enough to meet the criteria for tamponade [8]. With pericardiocentesis, these flow velocities return to normal, suggesting a pretamponade state. Just as tamponade is not an all-or-nothing pathological process, the echocardiographic signs should not be viewed as present or absent, but rather as part of a continuum the clinician follows over the course of the disorder. In a haemodynamically stable patient, the development of an 8 mmHg pulsus paradoxus or a respiratory variation across the mitral valve of only 20% may signal impending tamponade, allowing intervention before the patient goes into shock.

Tamponade in the absence of supportive symptoms

If a large PEF or tamponade is suspected, the patient should be initially evaluated for comorbid conditions that may cause false-positive or false-negative findings. A frequently encountered clinical scenario of altered physiology obscuring signs of tamponade is mechanical ventilation. Instead of being negative, intrathoracic pressure during inspiration is now positive, and even more positive than during expiration. Doppler recordings of flow across the tricuspid valve are now greater in expiration, while flow across the mitral valve is greater with inspiration; both are attenuated throughout the respiratory cycle. Also, if the patient is ventilated because of lung disease, they may have pulmonary hypertension and may not demonstrate RA or RV collapse even in the presence of tamponade. The IVC may be dilated due to pulmonary hypertension, RV failure, or tamponade. Other conditions affects signs of tamponade include hypertensive heart disease, volume status, loculated effusions, atrial septal defects, and aortic insufficiency.

Conclusion

PEF and tamponade are not uncommon in patients with both acute and chronic illnesses. Echocardiography is an important tool for identifying the presence of PEF and its haemodynamic consequences. Cardiac tamponade is a continuum and not an all-or-nothing diagnosis. Its diagnosis should be made with the full understanding of the cause of the pericardial disease, and any comorbid conditions that may affect interpretation of the signs.

CHAPTER 167

Management of pericardial tamponade

Santanu Biswas and John J. Frank

Key points

- Haemodynamically unstable cardiac tamponade is a medical emergency, and definitive therapy is usually fluid removal. However, in a select group of clinically stable patients, treatment of the underlying cause may resolve the effusion.
- Assessing the underlying aetiology is important in selecting the proper management strategy, such as for aortic dissection or trauma where surgical management is favoured.
- Aggressive fluid resuscitation is the standard of care for haemodynamic support. The role of other vasoactive agents remains controversial, but inotropes appear to have a theoretical benefit.
- Both pericardiocentesis and surgical approaches are well-established techniques. In most cases, pericardiocentesis remains a first-line procedure due to its safety, speed, and wide availability.
- Whenever possible, pericardiocentesis should be performed with imaging guidance. Exceptions to the case include immediate life-threatening situations.

Introduction

The definitive treatment for cardiac tamponade is fluid removal. However, timing requires a clinical assessment of a patient's stability, rather than the use of any specific finding on echocardiography. If the patient is stable, a case may be made for careful haemodynamic monitoring and serial echocardiography [1]. However, in the unstable patient, urgent aspiration of the pericardial fluid is recommended. Once the decision has been made, the many management aspects to consider include treatment of the underlying cause, the method of haemodynamic support, the actual strategy for fluid removal, and finally, post-procedural care.

Treatment of the underlying cause

Table 167.1 lists various causes of pericardial effusions. While pericarditis is the most common cause for pericardial disease [2], the commonest causes of an effusion leading to clinical tamponade, and its subsequent fluid removal are malignancy and procedure-related perforations [3]. In such cases, pericardiocentesis or surgical fluid removal may be the treatment of choice. In other cases, patients with subclinical tamponade may be managed by addressing the underlying cause, which may subsequently resolve the effusion and avoid the need for an invasive procedure. For example, a large effusion resulting from uraemia usually responds well to dialysis [2]. Such a strategy may be especially attractive in the setting of relative contraindications to pericardiocentesis (e.g. anticoagulation has not been withdrawn). In addition, addressing the causative aetiology usually limits recurrence of effusion.

Supportive measures

Once the decision has been made to pursue drainage, there is often a delay resulting from mobilization of the necessary personnel and equipment. During this time, measures should be taken to support tissue perfusion. The most widely-accepted management strategy is aggressive fluid resuscitation. The usual rationale is that fluids expand intravascular volume, helping to maintain venous pressure above pericardial pressure and thereby continuing to promote circulation [4]. Fluid resuscitation may be beneficial only up to a point, after which, fluids may actually aggravate tamponade [5]. This seemingly counter-intuitive effect is thought to be due to the rapid increase in left ventricular (LV) diastolic pressure against a pericardial sac that is already constrained by the effusion. The increased LV diastolic pressure is transmitted to the pericardium that, in turn, further increases pericardial pressure and then causes RV collapse earlier than would be otherwise observed.

In addition to fluids, various vasopressors, vasodilators, and inotropes may have some theoretical benefit. Human studies are sparse, but animal studies suggest a role for inotropes such as dobutamine and isoprenaline [6,7], as these were shown to preserve cardiac output while counteracting the increased systemic vascular resistance that occurs in tamponade. Studies examining hydralazine and nitroprusside report mixed results [6,8].

If circulatory collapse does occur, then immediate blind pericardiocentesis should be performed as there is no effective medical therapy. Supportive measures, such as chest compressions [9] and mechanical ventilation do little to maintain circulation, and may even be harmful, especially with positive pressure ventilation [10].

In summary, fluid resuscitation remains the standard of care for haemodynamic support in tamponade, but the primary benefit appears to be in hypovolaemic states. Regarding inotropes, the clinical relevance of these agents in humans remains unclear [9].

Table 167.1 Causes of pericardial effusions

Category	Examples
Pericarditis	Viral, bacterial, tuberculosis, autoimmune, idiopathic, post-operative, post-radiation
Trauma	Penetrating injury, blunt trauma, post-surgical
Malignancy	Primary malignancies, metastases to the pericardium, local invasive
Sodium and water retention	Congestive heart failure, nephrotic syndrome, hepatic cirrhosis
Other	Chylopericardium, myxoedema
Idiopathic	

Management strategies

Drainage techniques may be broadly grouped into percutaneous or surgical with many variations in each category (see Table 167.2). Aspects to consider in deciding the proper fluid removal strategy include attention to the suspected aetiology, relative contraindications, and the likelihood of recurrence. For example, in chest trauma either from blunt injury or a penetrating wound, an open surgical approach is recommended given the high likelihood of other unpredictable and potentially catastrophic injuries [11]. Surgery is also favoured over pericardiocentesis in tamponade occurring in the setting of a proximal aortic dissection. Here, the stiff pericardial sac is thought to limit additional blood loss. In such cases, pericardiocentesis may destabilize these patients [12].

Table 167.2 Procedures to remove pericardial effusions

	Comments
Percutaneous	
Blind pericardiocentesis	Should be done only in an emergency
Echocardiography-guided pericardiocentesis	May be done at bedside. Needle entry site can be adjusted to the location of maximal fluid location
Fluoroscopy-guided pericardiocentesis	Needs a room with fluoroscopy capabilities and associated personnel
Pericardiocentesis with intrapericardial sclerosis	Reserved for recurrent malignant effusions
Pericardiocentesis with balloon pericardiotomy	Requires fluoroscopic guidance.
Surgical	
Subxiphoid pericardial window	May be performed with local or general anaesthesia. Decreases effusion recurrence compared with pericardiocentesis, but long-term mortality data are unavailable
Video-assisted thoracoscopic pericardiectomy	Requires general anaesthesia. Usually reserved for effusive-constrictive disease
Pericardioperitoneal shunt	May be performed with local or general anaesthesia
Pericardiectomy	Requires general anaesthesia. Relatively high morbidity procedure

In most other instances, pericardiocentesis is an acceptable first-line strategy given its speed, ease of use, and relative safety. Pericardiocentesis may be performed blind without imaging guidance, however complication rates (5–35%) may be unacceptably high [13]. As a result, either ultrasound or fluoroscopic guidance is recommended. Pericardiocentesis with fluoroscopy usually requires access to a room with fluoroscopic capabilities, haemodynamic monitoring, and support personnel to operate the equipment and monitor the patient. On the other hand, echocardiography-guided pericardiocentesis may be performed at the bedside if needed.

The most common approach for pericardial access is subxiphoid, especially if the procedure is being performed either blindly or with fluoroscopic guidance. With echocardiography, the access site is adapted to the location of the pericardial effusion. The optimum needle entry site is chosen to maximize distance between the myocardium and pericardium and maximize the distance between the needle entry site and other vital organs, such as liver and lungs. Alternative entry sites are often used, as demonstrated in a 20-year case series of echocardiographically-guided pericardiocentesis where the chest wall was favoured over the subxiphoid region in 79% of cases [3].

Pericardiocentesis has been shown to be very safe, with echocardiographic- and fluoroscopically-guided case series reporting total complication rates of 4.7% [3] and 3.7% [14], respectively. The incidence of cardiac perforation was equally low at less than 1%.

Effusion recurrence is a concern; Rafique et al. [15] reported a recurrence rate of 52%. However, recurrence was significantly decreased (12%) when a catheter was left in the pericardial space until drainage decreased to <100 mL over a 24-hour period. The probability of fluid re-accumulation is heavily influenced by the underlying cause. For example, a malignant effusion has a higher likelihood of recurrence whereas an effusion related to inadvertent cardiac perforation in a catheter-based procedure is expected to be self-limiting.

Pericardial sclerosis can be used, especially in malignant effusions, to decrease effusion recurrence. Sclerosing agents (e.g. tetracycline, doxycycline, bleomycin, cisplatin, thioTEPA) scar the pericardium and prevent the visceral pericardium from secreting additional fluid. Success rates are greatly affected by the nature of the malignancy; however, given the generally poor prognosis of this population, long-term data are usually unavailable. Nevertheless, a retrospective review comparing pericardial sclerosis versus surgical pericardial window reported similar recurrence rates (13 and 14%, respectively) [16].

Another modification to the traditional pericardiocentesis is balloon pericardiotomy with the pericardium being accessed from the subxiphoid region. Initially, pericardiocentesis is performed in the usual fashion, but the initial catheter is then exchanged over a guide wire for a balloon-tipped catheter filled with iodinated contrast. The catheter is advanced, under fluoroscopic guidance, until it straddles the pericardial sac. Once proper positioning is confirmed, the balloon is inflated to create the window. While the procedural success and freedom from short-term recurrence is high, long-term success rates cannot be evaluated given the overall poor prognosis due to the underlying disease [17].

Various surgical techniques are described for the management of pericardial effusions; creation of a pericardial window through a subxiphoid incision is the commonest method used. This procedure is relatively quick, safe, and can even be performed under local anaesthesia [18]. Regarding overall efficacy, a study comparing populations receiving a subxiphoid pericardial window

versus pericardiocentesis showed decreased effusion recurrence (4.6 versus 16.5%, respectively); however, the no survival benefit was shown, likely due to the poor prognosis of the underlying cause [19].

Other relatively minor surgical options include video-assisted thorascopic pericardectomy and the creation of a pericardioperitoneal shunt. Video-assisted thorascopic pericardiectomy is usually used in the setting of effusive-constrictive disease. The use of a video camera allows good visualization of the pericardium and safe pericardial resection; however, the procedure does require use of general anaesthesia. The pericardio-peritoneal shunt is a recently described procedure that may be performed under general or local anaesthesia. The procedure appears to be safe and effective, but larger case series or comparative studies are lacking.

The most aggressive surgical method is pericardiectomy, which is usually reserved for refractory constrictive pericarditis. Various approaches may be used including subxiphoid, left anterior thoracotomy, median sternotomy, and bilateral anterior thoracotomy. The subxiphoid approach carries with it the lowest risk of complications, but also suffers from a higher probability of recurrence. The other approaches have higher morbidity rates, but permit a wider area of pericardial resection, which directly affects effusion recurrence [20].

Post-procedure care

After the initial procedure has been completed, the patient should be transferred to a unit not only experienced with recognizing cardiac tamponade, but also experienced in managing drain catheters. If a catheter is left in the pericardium, there is no official guideline as to how long it should remain, although some experts suggest that the catheter may be removed once the quantity of fluid drained is <50 mL in a 24-hour period [9]. Given the high likelihood of recurrence and the emergent nature of cardiac tamponade, the unit personnel should not only be familiar with catheter maintenance protocols, but also have ready access to pericardiocentesis equipment should the need arise to perform a repeat procedure. In addition, the unit should continue to observe for complications that either were not immediately apparent during the procedure or were the result of the procedure itself. Examples include inadvertent arterial puncture and purulent pericarditis. Finally, it should be emphasized that overall mortality is primarily influenced by the underlying disease and treatment should be guided accordingly once a cause has been established.

Conclusion

As cardiac tamponade is a medical emergency, prompt recognition is the key to successful management. Aggressive fluid resuscitation remains the clinical standard for medical treatment, although fluid removal is the ultimate goal. However, there are important differences among the approaches for fluid removal, pericardiocentesis with either echocardiographic or fluoroscopic guidance should be used as the initial procedure for the majority of cases. Finally, it should be emphasized that overall mortality is primarily influenced by the underlying disease; treatment should be guided accordingly once a cause has been established.

PART 5.14

Pulmonary hypertension

CHAPTER 168

Pathophysiology and causes of pulmonary hypertension

Laura Price and S. John Wort

Key points

- Pulmonary hypertension (PH) in the critically ill may reflect an acute cause and/or an exacerbation of pre-existing PH, and is probably under-diagnosed.
- The presence of right ventricular (RV) dysfunction and failure is universally an adverse prognostic feature. In cases of severe, PH, associated 'PH crises' and severe RV failure may progress rapidly to cardiovascular collapse. This is especially the case in RV 'afterload mismatch', when a normal RV is exposed to a sudden increase in afterload, such as following a massive pulmonary embolism (PE) or after heart transplantation.
- Acute *de novo* causes of PH include those relating to acute lung injury, sepsis, and acute PE. Post-operative PH is not an infrequent problem and has many contributing factors. The most prevalent cause of PH on ICU is likely to relate to left-sided heart disease with raised filling pressures ('group 2' PH), which may often co-exist with other causes.
- Patients with pre-existing pulmonary arterial hypertension may require intensive care unit (ICU) management to manage severe RV failure (due to disease progression, intercurrent illness, or post-operatively). This is a very high-risk patient group with an ICU mortality of up to 50%.
- Several general physiological challenges in the critical care environment are recognized to increase pulmonary vascular resistance and/or worsen RV function, including the effects of positive-pressure ventilation, hypoxaemia, and acidosis. In patients with PH, these should, if possible, be minimized.

Introduction

Pulmonary hypertension (PH) occurs frequently in critically-ill patients as part of several ICU syndromes, and, less commonly, as a primary cause for ICU admission. The presence of PH, especially when associated with right ventricular (RV) failure, is associated with high mortality. PH in the intensive care unit (ICU) may be due to acute or acute-on-chronic causes. RV failure is the mode of death in patients with pre-existing 'chronic' pulmonary arterial hypertension (PAH). This chapter outlines the definitions, epidemiology and pathophysiology of acute and acute-on-chronic PH, and resulting RV failure, in the critically ill.

Definitions

Pulmonary hypertension is defined as a mean pulmonary arterial pressure (mPAP) ≥25 mmHg when measured at right-heart catheterization. Precapillary or PAH is defined when the pulmonary capillary or artery wedge pressure (PAWP), is ≤15 mmHg [1]. This is normally, though not always, associated with a low cardiac output and hence a high pulmonary vascular resistance (PVR), calculated according to the equation (mPAP – PAWP)/cardiac output. When PAWP exceeds 15 mmHg, pulmonary venous hypertension is present, although this is usually due to left heart disease. Importantly, however, these definitions were created for patients with chronic PH and may not be representative of patients with acute rises in PVR or acute RV dysfunction.

Acute right ventricular failure

The healthy pulmonary circulation is a 'high-flow–low-pressure system' able to tolerate large increases in blood flow without increasing pulmonary artery pressures. This occurs by recruitment and dilatation of pulmonary vessels through the actions of chemical stimuli (e.g. hypoxaemia), humoral, or neuronal transmitters (e.g. catecholamines, nitric oxide and prostaglandins) on muscular pulmonary vessels. In health, PVR thereby falls as blood flow rises.

In the setting of a pathologically raised PVR, increased RV wall tension increases end-diastolic volume and may overwhelm the RV, leading to ventricular dysfunction and failure. In acute PH, for example, in acute pulmonary embolism, where the thin-walled RV is 'naïve' to a high afterload, this may occur at relatively modest elevations in PVR [2]. Conversely, with an RV exposed to long-standing PH, the more gradual elevation in afterload allows the ventricle to adapt through hypertrophy, allowing stroke volume to be maintained. In either setting, a rapid decline in biventricular function may occur due to right-left ventricular interactions and the phenomenon of ventricular interdependence [3], reducing cardiac output and oxygen delivery. Mechanisms include:

- RV dysfunction reducing pulmonary blood flow and thus LV preload.
- Displacement of the intraventricular septum by the dilated RV impinging on LV filling.
- As LV filling may depend on atrial contraction, atrial fibrillation (if present) and vasodilating therapies will be tolerated very poorly.

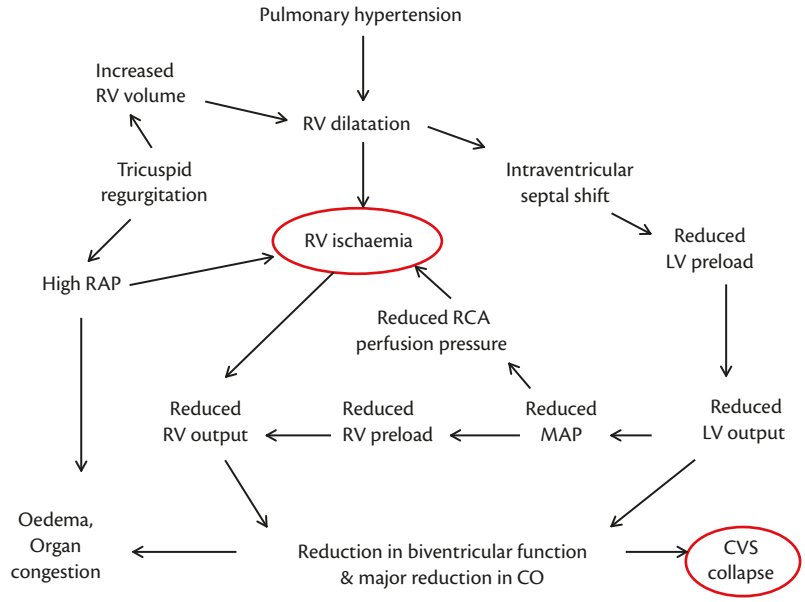

Fig. 168.1 Factors contributing to the onset of right ventricular failure in the setting of pulmonary hypertension.
PVR, pulmonary vascular resistance; CO, cardiac output; RAP, right atrial pressure; MAP, mean arterial pressure; RV, right ventricle; LV, left ventricle; RCA, right coronary artery; CVS, cardiovascular system.

The resulting systemic hypotension reduces the pressure gradient between the aorta and RV required for right coronary artery perfusion, thus precipitating RV ischaemia. In the setting of high PVR, right coronary perfusion is restricted to systole (rather than during the whole cardiac cycle) [4], maintaining aortic root pressure above RV pressure is paramount to avoid a downward spiral of RV failure (Fig. 168.1).

Clinically, acute or acute-on-chronic RV failure is characterized by a reduction in cardiac output and an elevation in RV filling pressure. However, no universal definition exists for this syndrome. In patients with (usually pre-existing) severe PH, 'PH crises' may occur, as defined by acute rises in PVR, such that systemic and pulmonary pressures equalize, with the risk of RV ischaemia and rapid cardiovascular collapse. RV failure may also present with elevated venous filling pressures with signs including raised jugular venous pressure (with 'CV waves' due to tricuspid regurgitation), limb oedema, pulsatile hepatomegaly, renal, and gut dysfunction.

RV failure causes morbidity and mortality with PH due to any cause. Although more commonly occurring in response to an elevated PVR, RV failure can also occur in conditions associated with decreased contractility, such as sepsis, myocarditis, or RV infarction.

Causes and epidemiology of PH in ICU

The most recent classification of PH (Box 168.1) is useful when considering patients with PH in the ICU due to pre-existing causes. It does not specifically encompass causes of PH relating to critical illness, nor contributions reflecting changes in acute physiology. As such, an ICU patient presenting with PH may broadly be classified into acute, pre-existing 'chronic' causes (or both), as well as ICU-related and iatrogenic causes (Box 168.1).

The relative prevalence of PH subtypes in the ICU setting is unknown. In general, pulmonary hypertension in ICU patients is most probably that related to group 2 (associated with left ventricular failure due to an increase in left atrial pressure) and group 3 (chronic hypoxaemic/hypercapnic lung disease such as chronic obstructive pulmonary disease) causes. Group 1 patients are less common, but still important causes of acute-on-chronic PH, where RV dysfunction is likely to be severe at presentation. Important acute causes of PH in the ICU setting include massive pulmonary embolism, acute lung injury, and following cardiothoracic surgery, which do not fit neatly into any of the classifications shown in Box 168.1.

Acute pulmonary hypertension in ICU

PH is a feature of several acute illnesses. As described in Chapter 169, 'Diagnosis of Management of Pulmonary Hypertension', the clinical signs of PH and RV dysfunction/failure are often non-specific, and the effects of ICU syndromes, and their treatment on the pulmonary circulation and the RV should be remembered. The most common important syndromes and factors contributing to PH are outlined.

Pulmonary embolism

Although unusual primary causes of ICU admission, massive and sub-massive PE are important causes of acute RV failure. Further to mechanical obstruction of the pulmonary circulation, hypoxaemia, and local vasoconstrictor release (e.g. serotonin) contribute to acute PH and acute RV dysfunction. In previously healthy patients, the degree of pulmonary obstruction correlates with haemodynamic severity:

- 5–15% angiographic obstruction causes systemic arterial hypoxaemia.
- 25% obstruction causes PH.
- 35% obstruction or mPAP >30 mmHg elevates right atrial pressure.
- A measurable haemodynamic disturbance occurs with 50% obstruction (the latter two also causing an increased central venous pressure) [2].

Registry data demonstrate a clear mortality increase in patients with haemodynamic instability due to acute PE [5].

Acute lung injury

RV dysfunction related to PH is seen in 12.5 (7–25)% of patients with acute lung injury (ALI) [6], although it was previously more common [7]. PH may also be present in non-pulmonary sepsis. One reason for the reduced frequency of PH is the introduction of lung-protective ventilation strategies [8]. However, even in the 'modern era', the presence of PH remains clinically important, with increased indexed PVR and transpulmonary gradient (mPAP – pulmonary arterial wedge pressure (PAWP), risk factors for mortality [9].

There are multiple contributing causes for PH (Fig. 168.1), which vary both anatomically and longitudinally throughout the illness. Early on, endothelial dysfunction causes release of inflammatory mediators and an imbalanced production of vasoconstrictors (e.g. endothelin-1) over vasodilator substances (e.g. nitric oxide), levels of which relate to PH severity [10]. Early studies demonstrate obstruction of the pulmonary microcirculation (Fig. 168.3), which has more recently been associated clinically with increased ventilation-perfusion mismatch, and strongly associated with increased early mortality [11].

Following activation of the pulmonary microvascular endothelium, which initiates inflammation and intravascular coagulation, intravascular microthrombi, fibrin, and intravascular sequestration of cells contribute to the observed pulmonary capillary occlusion. Clots can also form in larger vessels. Vascular tone is increased in muscular pulmonary arterioles and veins due to hypoxic pulmonary vasoconstriction (HPV) in an attempt to maintain ventilation/perfusion matching. An imbalance of vasoactive mediators also contributes, as does reduced lung volume, oedema, positive end-expiratory pressure (PEEP), and atelectasis by causing extrinsic vessel compression. From 14 days onwards, pulmonary vascular remodelling occurs, with neomuscularization of previously non-muscularized arterioles. Post-capillary PH may result from any cause of raised left atrial pressure. Some or all of these factors may contribute to the increase in PVR seen in acute respiratory distress syndrome (ARDS; see Fig. 168.2).

Pulmonary hypertension following cardiothoracic surgery

Post-operative PH may occur following certain cardiothoracic procedures and is associated with a high mortality. It is well recognized to follow corrective congenital cardiac surgery, valve replacement

Box 168.1 Updated clinical classification of pulmonary hypertension

Pulmonary arterial hypertension

- Idiopathic PAH.
- **Heritable PAH**:
  - BMPR2.
  - ALK-1, ENG, SMAD9, CAV1, KCNK3.
  - Unknown.
- Drug and toxin induced.
- **Associated with**:
  - Connective tissue disease.
  - HIV infection.
  - Portal hypertension.
  - Congenital heart diseases.
  - Schistosomiasis.

Pulmonary veno-occlusive disease and/or pulmonary capillary haemangiomatosis

Persistent pulmonary hypertension of the newborn

Pulmonary hypertension due to left heart disease

- Left ventricular systolic dysfunction.
- Left ventricular diastolic dysfunction.
- Valvular disease.
- Congenital/acquired left heart inflow/outflow tract obstruction and congenital cardiomyopathies.

Pulmonary hypertension due to lung diseases and/or hypoxia

- Chronic obstructive pulmonary disease.
- Interstitial lung disease.
- Other pulmonary diseases with mixed restrictive and obstructive pattern.
- Sleep-disordered breathing.
- Alveolar hypoventilation disorders.
- Chronic exposure to high altitude.
- Developmental lung diseases.

Chronic thromboembolic pulmonary hypertension

Pulmonary hypertension with unclear multifactorial mechanisms

- **Haematological disorders**: chronic haemolytic anaemia, myeloproliferative disorders, splenectomy.
- **Systemic disorders**: sarcoidosis, pulmonary histiocytosis, lymphangioleiomyomatosis.
- **Metabolic disorders**: glycogen storage disease, Gaucher disease, thyroid disorders.
- **Others**: tumoural obstruction, fibrosing mediastinitis, chronic renal failure, segmental PH

surgery (mitral more than aortic), cardiac transplantation surgery, and left ventricular assist device insertion. Predisposing factors include pre-existing PH, endothelial dysfunction related to cardiopulmonary bypass, positive-pressure, and single-lung ventilation, and the effects of certain drugs that increase PVR or depress myocardial function.

Effects of ventilatory strategies on the pulmonary circulation

Of several ICU factors recognized to increase PVR in ventilated patients, those potentially increasing PVR and reducing pulmonary blood flow include hypoxaemia, hypercapnia, and compression of the pulmonary circulation at extremes of lung volumes [12]. This latter phenomenon is for example seen after Fontan procedures where institution of positive pressure ventilation markedly increases intrathoracic pressure, impedes passive lung perfusion, and reduces cardiac output [13]. In ALI, high plateau pressures and high levels of PEEP increase PVR, and worsen cardiac output. While reduced with lower tidal volume ventilation, this must be balanced against the effects of resulting hypercapnia, which itself also increases PVR [14].

Chronic pulmonary hypertension

Chronic, or 'group 1', PAH is a rare, but devastating condition (Table 168.1) comprising idiopathic PAH (previously called primary PH

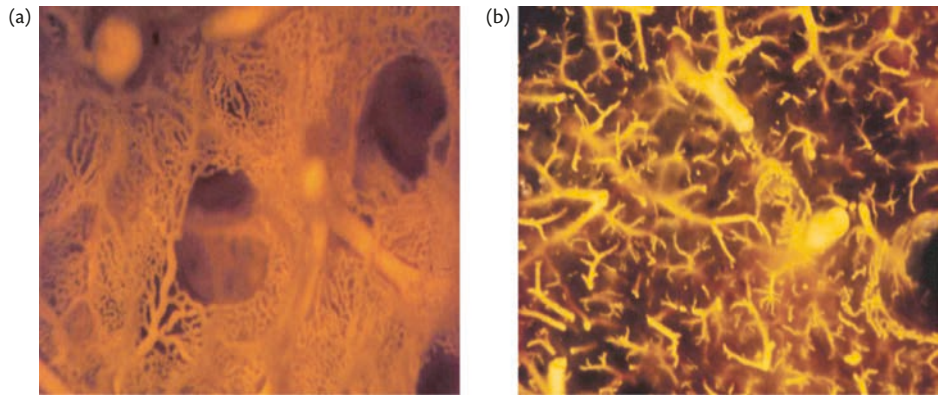

Fig. 168.3 Decreased vascular density in acute respiratory distress syndrome. Stereoscopic perfusion of pulmonary circulation with silicon polymers in post-mortem lung specimens from a patient who died 14 days following the onset of ARDS. (a) Normal human lung capillaries. (b) Lung capillaries day 14 ARDS.

Table 168.1 Causes of pulmonary hypertension in ICU patients

Acute *de novo* PH in ICU	Acute-on-chronic PH in ICU	ICU-related/iatrogenic
Acute pulmonary embolism Acute lung injury, sepsis **Acute post-capillary (group 2) PH**: ◆ Pulmonary venous hypertension due to LV dysfunction/failure with left atrial hypertension. ◆ Acute MI, congestive cardiac failure, diastolic dysfunction, severe valvular heart disease (MR, MS). Acute exacerbation of hypoxic +/– hypercapnic lung disease (with acute group 3 PH; e.g. asthma, COPD, IPF)	**Pulmonary arterial hypertension (group 1)**: ◆ Acute PAH exacerbation (due to hypoxia, sepsis/ALI, PE, peri-operative, pregnancy-related, etc.). ◆ Disease progression (no obvious precipitant). **Post-capillary (group 2) PH**: any acute-on-chronic cause PH due to other causes of pre-existing PH (groups 3–5) with an acute exacerbation	**Acute increase in PVR**: ◆ Hypoxaemia, acidosis, hypercapnia, pain (sympathetic stimulation), laryngoscopy. ◆ Drug-related increases in PVR (e.g. high-dose vasopressors; protamine). ◆ High Pplat or PEEP during IPPV causing small pulmonary vessel compression in high 'West zones' (also follows oedema). ◆ Endothelial dysfunction related to cardiopulmonary bypass

PAH pulmonary arterial hypertension; PH pulmonary hypertension; PVR pulmonary vascular resistance; Pplat plateau pressure; PEEP positive end-expiratory pressure; IPPV intermittent positive-pressure ventilation; COPD chronic obstructive pulmonary disease; IPF interstitial pulmonary fibrosis; MI myocardial infarction; MR mitral regurgitation; MS mitral stenosis; PE pulmonary embolism; LV left ventricular; ALI, acute lung injury.

(PPH)) or PAH due to several associated conditions, e.g. heritable PAH, PAH associated with HIV infection, congenital heart disease, connective tissue diseases and exposure to notable drugs and toxins [15]. Pulmonary veno-occlusive disease is a subgroup with occlusive lesions in small post-capillary pulmonary veins, where lung transplant is the only realistic treatment option. Before the modern treatment era, PAH therapy was usually symptomatic and life expectancy was short. Recent treatment advances have occurred in the last decade however the outlook remains poor with 3-year survival under 60% [16].

'Non-PAH' causes include PH secondary to left-sided heart disease ('group 2') and chronic respiratory disease ('group 3'). Chronic thromboembolic PH ('group 4' PH), is important to diagnose as treatment options differ significantly from other causes of PH, with pulmonary endarterectomy being a realistic cure for patients with surgically accessible disease.

Of all types of chronic PH, PAH is the best characterized. PAH pathophysiology and common acute syndromes will be briefly described.

Pathophysiology of PAH

Pulmonary vascular remodelling defines the characteristic proliferative lesions that occur in PAH in small- and medium-sized muscular pulmonary arteries. This is a maladaptive response where vessel walls thicken in response to a sustained rise in intravascular pressure. The findings originally described in patients with congenital heart diseases including early 'reversible' lesions, were medial hypertrophy, arteriolar neomuscularization, intimal proliferation and fibrosis. 'Irreversible' later lesions included fibrinoid necrosis and, in some cases, plexiform lesions (Fig. 168.4) [17]. These lesions occlude and obliterate the pulmonary circulation, reducing the capacity and thus compliance of the pulmonary vascular bed. Pulmonary endothelial dysfunction is an important initiating feature that increases vasoconstricting, pro-proliferative mediators (e.g. endothelin-1 (ET-1), serotonin and thromboxane A_2), and reduces levels of vasodilating, anti-proliferative mediators (e.g. nitric oxide (NO), prostaglandin I_2, (PGI2, prostacyclin)). Further to the resulting vasoconstriction, the prominent effect of treatments targeting endothelial dysfunction is that of

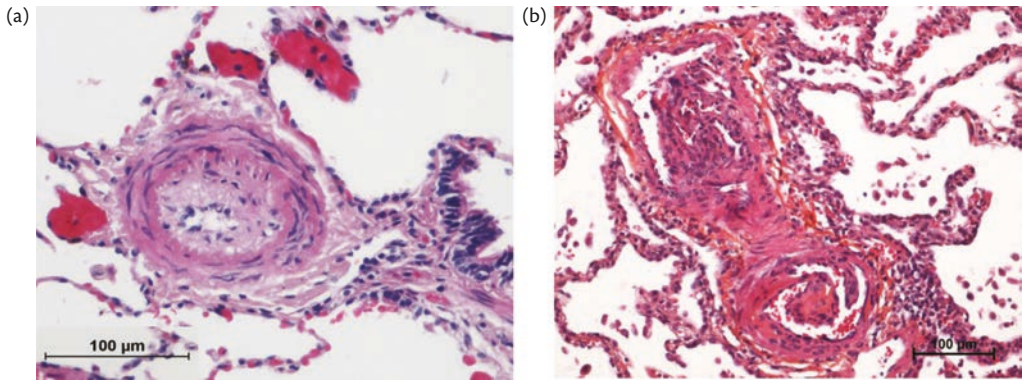

Fig. 168.4 Pulmonary vascular remodelling in PAH. Haematoxylin-eosin stained paraffin-embedded lung sections from a patient with idiopathic PAH following lung transplantation showing a patent remodelled pulmonary artery (a) and an obliterative plexiform lesion (b).
Courtesy of Dr Peter Dorfmuller, Hôpital Marie Lannelongue, University of South Paris, France.

structural vessel changes. The resulting excessive vascular cell growth has even been likened to a cancer-like phenotype, and the influence of growth factors and inflammation is important. A positive family history is found in up to 10% of patients with idiopathic PAH, with mutations seen in the 'pulmonary hypertension gene', bone morphogenetic protein receptor (BMPR) type II, which controls transforming growth factor (TGF) beta signaling. Reduced BMPR-II signalling is also a feature of diverse forms of PAH without mutations, resulting in the inability to dampen the growth of vascular cells.

Acute PAH exacerbations

Fortunately, ICU admission of patients with previously undiagnosed PAH in severe RV failure is increasingly rare. Patients with known PAH may present with a 'PH exacerbation' in severe RV failure due to either a known cause (e.g. infection, atrial dysrhythmias), or in the final stages of their disease with no further medical treatment options. Deterioration can be very rapid. ICU mortality relating to RV failure is up to 50% and almost invariably fatal if the patient is intubated. Predictors of ICU mortality include low systemic blood pressure on ICU admission, elevated serum brain natriuretric peptide and C-reactive protein, low serum sodium, and renal dysfunction [18]. An important multicentre study of cardiopulmonary resuscitation in these patients showed that, although attempts were mostly unsuccessful, resuscitation was most likely if the precipitant for deterioration was known [19].

Particularly high-risk scenarios for these patients include pregnancy and the perioperative setting. Maternal mortality exceeds 25%, even in recent series [20], which relates to the inability of the 'fixed' pulmonary circulation to cope with the cardiovascular demands related to pregnancy. The risk of RV failure increases as blood volume increases from 20 to 24 weeks, and during the peripartum period. Anaesthesia and surgery precipitate PH crises, RV failure, and high mortality in patients with severe PH, especially in those undergoing emergency surgery. Furthermore, bronchoscopy is a high-risk procedure with an increased risk of biopsy-related bleeding.

Conclusion

PH in ICU patients may reflect worsening of pre-existing PH and/or an acute *de novo* cause. PH is probably under-diagnosed in ICU patients. Multiple factors relating to acute derangements in physiology during critical illness contribute, including iatrogenic factors such as the effects of positive pressure ventilation. The adverse effect of increased afterload on RV function is associated with worse outcomes. The resulting acute RV failure may be difficult to monitor and very challenging to manage.

CHAPTER 169

Diagnosis and management of pulmonary hypertension

Philip Marino and Laura Price

Key points

- The diagnosis of PH is suggested by echocardiography, ideally with invasive haemodynamic assessment to confirm the anatomical level (pre-/post-capillary), which determines accurate diagnosis of PH and thus influences management.
- The principles of managing right ventricular (RV) failure in a patient with PH include augmentation of RV function and maintenance of aortic root pressure (avoiding RV ischaemia), avoidance of arrhythmias, and reduction in pulmonary afterload.
- Systemic vasoactive agents and pulmonary vasodilators play an important role. The characteristics of individual agents must be considered and monitored carefully.
- Patients with pulmonary arterial hypertension, pulmonary embolism, or chronic thromboembolic PH should be anticoagulated. Those with haemodynamically unstable PE may require thrombolysis.
- Surgical options exist for patients with PH and RV failure including the use of atrial septostomy, pulmonary embolectomy, and pulmonary endartectomy for those with proximal chronic thromboembolic PH. Support of RV function is advancing through the use of extracorporeal circulatory circulations, increasingly used as a bridge to transplantation in patients with PH.

Introduction

Pulmonary hypertension (PH) is most likely to be detected when severe and associated with right ventricular (RV) dysfunction, and is probably under-diagnosed in the ICU setting. Although several advances have been made in outpatient management, no randomized, controlled trials have included ICU patients. Treatments are based on experimental studies or case reports/series and management can be challenging.

Diagnosis

The presence of PH and/or RV dysfunction may be suggested by clinical examination, although many of the signs will often be non-specific in ICU patients. An electrocardiogram may show enlargement of proximal pulmonary arteries (with peripheral pruning in most patients), and new-onset right heart strain. Chest radiography is often normal but may show right heart chamber enlargement. On computed tomography (CT), an enlarged central pulmonary artery diameter (exceeding that of the thoracic aorta) is usually seen (Fig. 169.1), although this sign is less reliable in lung disease. In ARDS, the presence of microvascular occlusion may be suggested by an elevation in pulmonary dead space fraction, if this is measured at the bedside. Detection of PH and RV dysfunction however rely mainly on a high index of suspicion and a combination of biomarkers,

Table 169.1 Diagnosis of PH + RV dysfunction

Formal definition of PH at right heart catheterization*	Indicators of PH on echocardiography	Indicators of RV failure
mPAP ≥25 mmHg PAWP ≤15 mmHg (i.e. group 1, 3, 4 and 5 PH)	TR velocity >3.4 ms. Short PAT (<80 ms). Right heart dilatation and/or dysfunction RV/LV basal diameter ratio > 1 Flattening of interventricular septum Right atrial area (end-systole) >18cm^2	Low cardiac output (cardiac index <2.5 L/min/m^2). Rising RV filling pressure (RAP >8 mmHg)

*PH is defined at right-heart catheterization, where resting mPAP >25 mmHg. Echocardiographically, PH is suggested by an estimated RV systolic pressure (RVSP) >40 mmHg (severe if >50 mmHg), (note systolic PAP is age dependent, rising with 1mmHg per decade), and a shortened acceleration time across the pulmonary valve (PAT) due to the presence of high pulmonary vascular resistance (PVR). PH severity may depend on chronicity: the magnitude of the PAP generated increases with time because the RV hypertrophies and can generate high pressures. Conversely, in severe end-stage PH, the failing RV may be unable to develop an incremental increase in PA pressure.

PH, pulmonary hypertension; RHC, right-heart catheterization; mPAP, mean pulmonary arterial pressure; PAWP, pulmonary arterial wedge pressure; RVSP, right ventricular systolic pressure; TR, tricuspid regurgitation; RV, right ventricular; RAP, right atrial pressure.

imaging techniques, and haemodynamic assessment, including early bedside echocardiography.

Biomarkers

B-type natriuretic peptide and troponins suggest ventricular strain with or without ischaemia in the setting of PH, although these markers are non-specific. Tests reflecting global oxygen delivery (e.g. mixed venous oxygen saturation, lactate) are useful in unstable patients. Of note, hyponatremia (due to renin-angiotensin axis activation and vasopressin release) is strongly associated with RV failure and poor survival in pulmonary arterial hypertension (PAH) [1].

Invasive haemodynamic assessment and monitoring

PH is classically diagnosed by right-heart catheterization (Table 169.1). This differentiates patients with PAH, i.e. with normal (non-elevated) ventricular end-diastolic pressures, from those with pulmonary venous hypertension (pulmonary artery wedge pressure (PAWP) >15 mmHg) due to left atrial hypertension. The distinction is important as those with PAWP exceeding 15mmHg are by definition group 2 patients, where pulmonary vasodilator therapies may precipitate pulmonary oedema as these agents increase pulmonary blood flow against a relatively fixed outlet. Measurements are classically taken at end-expiration and depend on the patient being euvolaemic, although the mean PAWP value is also used. In the stable setting, a fluid challenge can be used to unmask occult left-sided heart disease (usually heart failure with preserved ejection fraction (HFpEF), i.e. LV diastolic dysfunction), where rises in PAWP >15 mmHg are precipitated by a bolus of 250–500ml normal saline.

No formal guidelines exist regarding haemodynamic monitoring of PH patients with RV failure in the ICU setting. Although recent studies have cast doubt on the use of the pulmonary artery catheter (PAC) in other types of shock, it can provide crucial pulmonary haemodynamic measurements in PH and RV failure. The onset of RV failure is suggested by a rising right atrial pressure and falling systemic mean arterial pressure. With PAC data, a rise in pulmonary vascular resistance (PVR; a composite of pulmonary pressure and cardiac output) would pre-empt this late sign. However, there are potential limitations and complications associated with PAC, including difficulties with severe tricuspid regurgitation affecting thermodilution measurements; and complications including infection, clots, arrhythmias and pulmonary artery rupture. PAC should not be used in patients with significant intra-cardiac shunts or recent tricuspid valve surgery. Other cardiac output (CO) monitors may be useful, although have not been validated against invasive haemodynamic indices in these patients and have the same issues regarding inaccuracy with tricuspid regurgitation.

Echocardiography

Echocardiography is an important diagnostic modality in the assessment of PH in the ICU patient. Transthoracic echo (TTE) estimates pulmonary artery systolic pressure (sPAP) and provides information about aetiology (e.g. LV dysfunction, shunts, pulmonary embolus and right atrial thrombi). Estimation of sPAP is based on calculating the peak velocity of the tricuspid regurgitant jet by the simplified Bernoulli equation (peak pressure gradient of tricuspid regurgitation = 4× tricuspid regurgitation velocity). This value is added to the estimated right atrial pressure (RAP) to calculate right ventricular systolic pressure (RVSP), remembering that normal values for sPAP increase with age, sex, and body mass index [2]. RV function is assessed by several methods including descent of the RV base toward the apex (tricuspid annular plane systolic excursion, TAPSE) or RV fractional shortening. Echocardiographic signs of RV failure include RV dilatation with interventricular septal flattening, with resulting paradoxical septal movement causing LV compression due to ventricular interdependence (Fig. 169.2), RV hypokinesia, a dilated inferior vena cava (IVC) and pericardial effusion. TTE images may be suboptimal in ICU patients due to difficult positioning, other monitoring devices and/or ventilatory support. An alternative is transoesophageal echocardiography (TEE). Although often more accurate, current TEE techniques remain relatively invasive, and have limited repeatability.

Computed tomography

Pulmonary emboli should be excluded in any patient with acute PH and RV failure. Large proximal emboli may be identified using CT in the segmental and subsegmental arteries (up to the 4th division), with positive and negative predictive values >90% compared with conventional pulmonary angiography.

Management of ph in the icu patient

Compared with outpatient management, relatively few studies guide PH management in the ICU setting. Management principles include the prevention of RV failure through the use of optimum ventilatory and fluid balance strategies, prompt treatment of

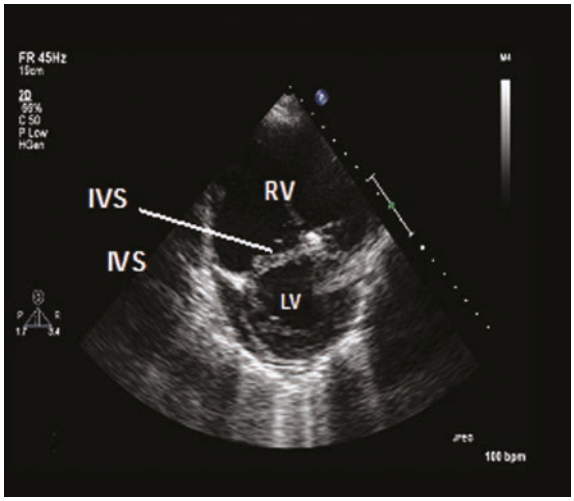

Fig. 169.2 Short-axis view of a transthoracic echocardiogram in a patient with acute pulmonary hypertension having acute dilatation of the right ventricle (RV) compressing the interventricular septum (IVS) and left ventricle (LV).
Courtesy of Dr Susanna Price, Royal Brompton Hospital, London, UK.

arrhythmias, reduced RV afterload and maintenance of an adequate systemic blood pressure (Fig. 169.3). It is important to note that many of these ICU interventions may adversely affect RV function.

Non-pharmacological therapies

Oxygen

In chronic PAH, maintaining arterial saturations >90% is advocated [3]. However, effects of oxygenation on pulmonary haemodynamics have not been formally assessed in ICU patients, where oxygenation is influenced both by the pre-existing baseline and the clinical situation (e.g. ARDS). It should be noted that in acute settings, hypoxia increases pulmonary pressures up to 30%—due to hypoxic pulmonary vasoconstriction—in those with and without underlying PH. This is reversible with resolution of, for example, an acute exacerbation of COPD.

Mechanical ventilation

Through inducing an increase in airway plateau pressure (Pplat), positive pressure ventilation can impair RV function. Positive end-expiratory pressure (PEEP) can also increase RV afterload, while diminishing venous return and preload. In the setting of ARDS with PH and RV failure, the most appropriate ventilation strategy is to keep Pplat and PEEP as low as possible to minimize any adverse effects, while achieving adequate oxygenation and avoiding excessive hypercapnia.

Fluid balance management

Diuretics

Patients with acute or acute-on-chronic RV dysfunction should not be given excessive fluid challenges in the face of hypotension. Decompensated RV failure in severe PAH is characterized by marked fluid retention; diuretics can reduce RV preload and restore ventricular length onto the optimal part of the Starling curve. Reduced RV dilatation in turn prevents LV compression, allowing increased diastolic and coronary artery filling, leading to improved myocardial perfusion, LV–RV synchrony and cardiac output. Although no studies have demonstrated that a strategy of preventing RV over-distension reduces mortality, its use remains a cornerstone of management. If diuretics are unsuccessful, haemofiltration may be needed.

Renal replacement therapy

Acute kidney injury (AKI) can arise in up to 20% of ICU patients. Renal replacement therapy (RRT) augments RV function through rapid fluid removal, as well as correcting acidaemia. However, little evidence is available to support this in terms of restoration of inotropic responsiveness.

Pulmonary vasodilators

Most pulmonary vasodilating agents when administered orally or intravenously, may cause systemic hypotension. This may be avoided with inhaled administration. It is of utmost importance in a patient with known PAH on oral PH therapies not to stop PH therapies in the face of systemic hypotension, as sudden withdrawal of these agents may precipitate sudden worsening of PH. An overview of pulmonary vasodilators is given, with suggestions for use in the ICU setting, as well as chronic use.

Inhaled nitric oxide (iNO)

Nitric oxide (NO) stimulates cyclic guanosine-3',5'-monophosphate (cGMP), which relaxes pulmonary vascular smooth muscle. When delivered to accessible lung units, inhaled NO (iNO) improves ventilation–perfusion mismatch, while lowering PH and RV afterload, with minimal effects on the systemic circulation. This has been demonstrated in patients with ARDS [4], as well as in pulmonary hypertension. iNO is administered to mechanically-ventilated patients via a specifically designed system to ensure adequate delivery and monitoring of concentrations. The gas may also be given by facemask, but drug delivery and monitoring can be difficult. NO is initially administered at 1 part per million (ppm) and increased gradually up to 20 ppm according to clinical response and tolerability. Prolonged administration may be associated with adverse effects, including nitrogen dioxide (NO_2) production, methaemoglobinaemia, and rebound PH following withdrawal [5]. iNO has also been used to treat PH and RV dysfunction following cardiac surgery and in association with acute massive PE. Overall, studies have failed to demonstrate a significant mortality benefit [6], although these have not focused on cases of life-threatening PH/RV failure.

Prostacyclin and prostacyclin analogues

These potent vasodilators also inhibit platelet activation and cell proliferation. The synthetic prostacyclin, epoprostenol, was the first disease-specific therapy approved for treatment of PAH. A landmark study in patients with NYHA III–IV heart failure due to PAH demonstrated an improvement in survival, symptoms, exercise capacity and pulmonary haemodynamics [7], and transformed the treatment of PAH—and indeed these agents remain the best drug treatment for severe PAH. Clinical effects of epoprostenol are similar to iNO, but it is usually only given intravenously, and has a short plasma half-life (3–6 minutes). Epoprostenol can cause systemic hypotension, as well as non-selective pulmonary vasodilatation, thus abolishing hypoxic pulmonary vasoconstriction and worsening oxygenation in patients with lung disease [8].

Iloprost (synthetic prostaglandin I_2) is licensed for the treatment of PAH in patients with NYHA class III symptoms. Administered by nebulization, it requires administration six to nine times per day due to its short duration of action (60–120 min). Clinical studies

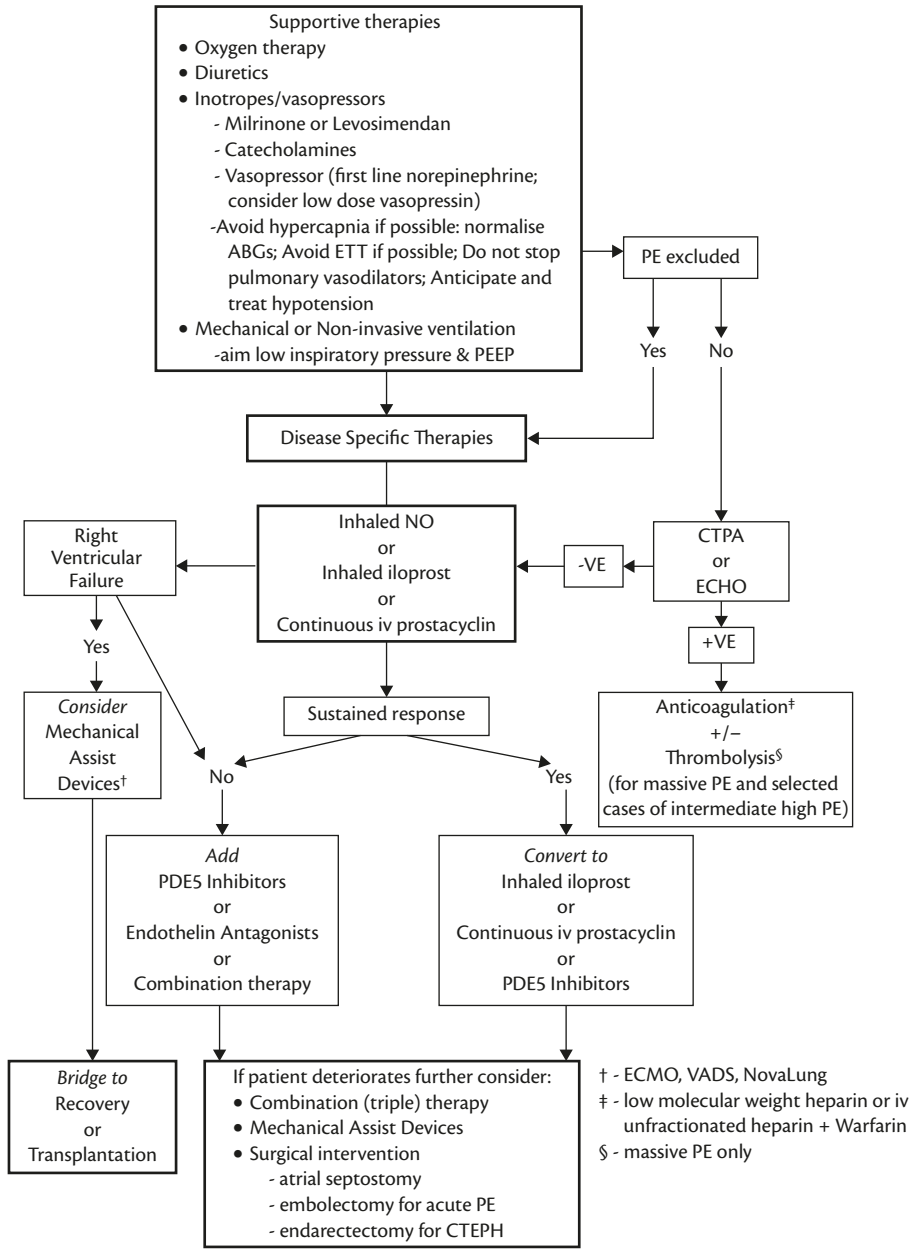

Fig. 169.3 Algorithm for ICU Management of PH and RV failure.

ABGs, arterial blood gases; –VE, negative; +VE, positive; CTEPH, chronic thrombembolic pulmonary hypertension; ETT endotracheal tube, PPV positive-pressure ventilation, PDE phosphodiesterase, PEA pulmonary endarterectomy, PE pulmonary embolism, NO nitric oxide, IV intravenous, ECMO Extracorporeal Membrane Oxygenation, VADs Ventricular Assist Devices, PEEP, positive end-expiratory pressure; CTPA, Computed tomography pulmonary angiogram; ECHO, echocardiography.

demonstrate significant improvement in pulmonary haemodynamics (20% reduction in PVR) without any detrimental effect on gas exchange or systemic blood pressure. The clinical response is at least comparable with that observed with iNO therapy, although iloprost can be used more easily in both ventilated and non-ventilated patients [9]. Despite these potential advantages, the frequency of administration and limited availability has restricted its use.

Phosphodiesterase (PDE) type V inhibitors

PDE5 inhibitors include sildenafil and tadalafil. These agents augment the NO pathway by increasing cGMP levels that are normally rapidly degraded by PDEs, and are common treatments for PAH. Further to promoting pulmonary vasodilation, sildenafil augments biventricular function and attenuates vascular remodelling. A growing literature supports its effectiveness in treating PH in the critically ill. Case series report improved cardiopulmonary haemodynamics, thereby allowing mechanical ventilation and inhaled NO to be withdrawn successfully [10]. Sildenafil is orally active and widely available, allowing it to be used in both general and specialized units. An intravenous preparation is also available for continuous infusion. Sildenafil should be introduced gradually, using low doses (20–25mg orally or 10mg IV (equivalent), 8-hourly), titrated to clinical response and side effects (e.g. systemic hypotension,

gastrointestinal disturbance). It should be used with caution in patients with ischaemic heart disease due to an increased risk of myocardial infarction and ventricular arrhythmias.

Endothelin receptor antagonists

Endothelin-1 (ET-1) is a potent vasoconstrictor and mitogen that stimulates smooth muscle cell proliferation via ET_A and ET_B receptors. Bosentan is an orally active dual ET_A and ET_B antagonist licensed for use in patients with idiopathic PAH, as well as for PAH associated with connective tissue diseases or congenital heart disease [11]. However, no clinical evidence supports its use in treating acute PAH in the critically ill. In addition, it can only be administered enterally, and there are potential concerns over drug-induced hepatic dysfunction (a class effect). Ambrisentan and macitentan are newer endothelin receptor antagonists in use.

Inotropes and vasopressors

These agents can profoundly affect pulmonary haemodynamics. They can improve, but also potentially worsen PH and RV function, depending on the agent and dose administered. Choice should depend upon maintaining a balance between the cardiopulmonary properties of the drug and treating the manifestations of underlying precipitating pathologies, such as severe sepsis.

Catecholamines

The effects of catecholamines on the pulmonary circulation and RV function are variable. Noradrenaline and adrenaline both act on α and β adrenoceptors causing potent systemic vasoconstriction and increased cardiac output, with α effects potentially causing pulmonary arterial vasoconstriction at higher doses. Dopamine induces a similar response, although vasopressor effects are less pronounced, and tachycardia more marked. Dobutamine increases cardiac output through inotropy and chronotropy (β_1 effects), while lowering systemic and pulmonary vascular resistances through vasodilatation (β_2 effect), thus reducing RV afterload. Inotropy must be balanced against increases in heart rate, which may compromise RV filling and RV coronary perfusion, and thereby impairing RV function [12]. In a canine model of acute RV failure, noradrenaline was an effective vasopressor while dobutamine had additional beneficial effects on right ventricular (RV)-pulmonary artery (PA) coupling [13]. Of note, studies in acute PH models show that catecholamines (up to 0.5mcg/kg/min noradrenaline; dopamine or dobutamine up to 10mcg/kg/min) do not increase pulmonary vascular resistance (a theoretical risk due to α effects). In the setting of RV failure in PH patients, dobutamine and then if hypotension persists, a vasopressor (noradrenaline or low dose vasopressin) are often used in combination.

Phosphodiesterase (PDE) type III inhibitors

Milrinone and enoximone are inodilators, acting as competitive inhibitors of PDE isoenzyme 3, raising cyclic adenosine-3,5-monophosphate (cAMP) within cardiomyocytes. This improves myocardial contractility and promotes calcium re-sequestration by the sarcoplasmic reticulum, aiding diastolic relaxation, and thereby improving ventricular compliance and diastolic filling. Milrinone is a potent pulmonary vasodilator, reducing pre- and afterload to both ventricles and, importantly, lowering both PVR and PAP [11]. As a consequence, milrinone is often used in patients with PH and RV failure, including in a nebulised form. It can induce ventricular and atrial arrhythmias, so should be used with caution in patients with prior tachyarrhythmias. It may also cause significant systemic vasodilatation and hypotension requiring pre-emptive vasopressor use.

Calcium channel sensitizers

Levosimendan increases the sensitivity of cardiac myofilaments to calcium ions, thereby improving contractility without increasing myocardial oxygen demand. Levosimendan also causes systemic and pulmonary vasodilatation due to stimulation of ATP-sensitive potassium channels, and PDE III inhibition. These effects may be beneficial in patients with PH and RV failure. A single, randomized control study demonstrated a significant improvement in cardiac output and pulmonary haemodynamics in patients who develop PH and RV failure following ARDS due to severe sepsis [14]. Like milrinone, levosimendan can be associated with atrial arrhythmias (up to 20% of cases) and systemic hypotension so should be used with caution.

Vasopressin analogues

Low-dose vasopressin (0.04 μ/min) and its analogues (e.g. terlipressin) may provide an alternative to catecholamines, causing systemic vasoconstriction (V1 receptor effect) but, paradoxically, promoting vasodilatation, via nitric oxide release, in the pulmonary circulation [15]. This latter effect may be particularly advantageous when patients with PH develop systemic hypotension with certain inotropes (e.g. milrinone, levosimendan) and require a systemic vasopressor. Of note, however, RV-PA coupling experiments are missing for vasopressin and its analogues in models of PH. In addition, vasopressin at higher doses may cause coronary vasoconstriction.

Anticoagulation and thrombolysis

Anticoagulation therapy

Formal anticoagulation is advised in patients with PAH and chronic thromboembolic PH (CTEPH). By contrast, the potential benefit in critically- ill patients with PH has yet to be determined, though routine thromboembolic prophylaxis is advocated in all patients [3].

Thrombolytic agents

Acute PE is the commonest cause of acute PAH in the critically-ill patient with an associated mortality of 6–8%, rising to 30% in massive PE, i.e. in the presence of systemic hypotension, metabolic acidosis or cardiac arrest [16]. Thrombolysis is recommended for treating massive PE with haemodynamic compromise or cardiac arrest [17].

Surgical interventions

Surgery may be considered in patients with severe PH and RV failure despite receiving maximal medical therapy. Such procedures are complex and undertaken only at specialist cardiothoracic centres.

Atrial septostomy

An artificial shunt is created between the atria, with the resulting right-to-left shunt decompressing the right heart and aiding left atrial filling, thereby improving biventricular function and cardiac output, despite the fall in systemic arterial oxygen saturation [18]. This was first used as a palliative measure in 1983 in patients with refractory PH and RV failure. It was subsequent shown to offer significant clinical and haemodynamic improvement in patients with advanced PH. This has not yet been examined in ICU patients who develop acute severe PH and RV failure. Indeed, indicators of very severe RV failure including RAP >20 mmHg are indicative

of procedure-related mortality [18]. In practice it is rarely used in most centres and only as a bridging measure to definitive ongoing treatment (i.e. transplantation).

Pulmonary embolectomy and pulmonary endarterectomy surgery

Surgical pulmonary embolectomy may be considered in patients with massive PE and haemodynamic compromise, where thrombolysis is absolutely contraindicated or in whom thrombolysis has failed. The procedure has been associated with significant perioperative mortality (25–50%), although more recent studies report 15% mortality and an 80% 1-year survival [19]. Pulmonary endarterectomy surgery involves dissection of the organised fibrous tissue from the vessel wall under cardiopulmonary bypass and deep hypothermic arrest, and is highly effective in treating patients with PAH due to proximal CTEPH with low mortality in experiences centres (Papworth data suggests less than 3% mortality). Notable postoperative ICU complications include persistent PH and RV failure, reperfusion pulmonary oedema and pulmonary haemorrhage.

Extracorporeal devices

Extracorporeal membrane oxygenation (ECMO), ventricular assist devices (VADs) and interventional lung assists (iLAs, e.g NovaLung) are being increasingly used to support the RV and reduce afterload in patients with end-stage PAH and RV failure requiring lung transplantation [20]. In most cases, these interventions are used as a bridge to transplantation, but successful recovery of RV function has been described in some case reports. Further evaluation of these techniques is required in the critically ill.

Conclusion

PH with or without RV dysfunction is a poor prognostic indicator when complicating diseases that afflict the critically ill. This suggests that early diagnosis and treatment is important, however there is a paucity of trial data concerning the application of interventions in the critically ill. Indeed, the acute changes in physiology faced by these patients in the ICU setting make large trials difficult to perform. Therefore, understanding of the pathophysiology of PAH and the ICU context (including the effects of mechanical ventilation, high/low pO_2, systemic and pulmonary vasoactive agents, RV and LV physiology) are essential in understanding how to manage these patients. The development of new, disease-specific pulmonary vasodilators, inotropes, and extracorporeal support systems should in theory improve outcomes, but further studies, however difficult to implement, are needed. The impact of advancing and awake extracorporeal life support techniques although exciting bring new challenges to patients and caregivers, where all members of the ICU team including clinical psychologists play an important role.

PART 5.15

Pulmonary embolus

CHAPTER 170

Pathophysiology and causes of pulmonary embolism

Mervyn Singer

Key points

- Pulmonary emboli are predominantly related to thrombi arising from heart or deep veins.
- Non-thrombotic causes include air, fat, foreign body, septic, tumour and amniotic fluid (although the latter does not cause flow obstruction).
- Outcome largely depends on the degree of right ventricular dysfunction.
- There are multiple risk factors including surgery, arrhythmias, prolonged immobility, venous stasis, pregnancy, and an underlying pro-thrombotic tendency, either congenital or acquired, e.g. during pro-inflammatory states such as sepsis.
- Numerous risk stratification scores have been developed derived from clinical features, imaging findings, and biochemical markers of right ventricular strain and myocardial damage.

Causes

Thrombus predominantly form within deep leg veins, pelvic or abdominal veins, within the right atrium or ventricle (especially in patients with long-standing arrhythmias) or, occasionally, within the pulmonary artery itself. The thrombi break off and lodge within the pulmonary vasculature, either as single or multiple emboli.

A small number of cases may be related to non-thrombotic causes, including air, fat or gas, foreign body, septic or tumour emboli, and amniotic fluid embolus. Air embolism occurs following vascular instrumentation or surgical mishaps, or lung trauma with air sucked into disrupted blood vessels. It may also occur following diving accidents or rapid decompression. Fat emboli follows physical trauma (accidental or orthopaedic), usually to long bones or the pelvis. Foreign body emboli are usually related to iatrogenic complications during a vascular procedure, while septic emboli follow infections of veins (usually from in-dwelling cannulae), heart valves, or infected mural thrombi. Features relating to amniotic fluid embolism are related to an acute inflammatory/anaphylactoid reaction following entry of amniotic fluid, fetal cells and other debris into the mother's blood stream via the placental bed, than to physical blockage of the pulmonary vasculature.

The remainder of this chapter focuses on risk factors, risk stratification, and cardiopulmonary consequences of thrombotic pulmonary emboli. Many of the cardiopulmonary consequences are, however, also common to non-thrombotic emboli.

Risk factors

The annual incidence of acute pulmonary embolism (APE) of a thrombotic aetiology ranges between 23 and 69 cases per 100,000 population with a 2-week fatality rate estimated at 11% [1]. From US hospital discharge data, the reported incidence of PE is 0.4% of hospitalized admissions [2]. Risk factors include surgery, arrhythmias, prolonged immobility, venous stasis, pregnancy, and an underlying thrombotic tendency [3]. This heightened procoagulant status may either be congenital, e.g. Factor V Leiden deficiency, related to a pathology such as antiphospholipid syndrome, or in severe pro-inflammatory conditions such as sepsis or major surgery (Table 170.1). Cook et al. [4] identified four independent risk factors for intensive care unit-acquired deep venous thrombosis, namely a personal or family history of venous thromboembolism (hazard ratio 4.0, 95% confidence interval 1.5–10.3), end-stage renal failure (HR 3.7, 95% CI 1.2–11.1), platelet transfusion (HR 3.2, 95% CI 1.2–8.4), and vasopressor use (HR 2.8, 95% CI 1.1–7.2).

However, notwithstanding all these risk factors, the incidence of clinically relevant APE is low in critical care patients treated with a prophylactic heparin. A recent multicentre study of 3764 patients in which two heparin regimens were compared reported an approximate 2% incidence of pulmonary embolism, and a 5.5% incidence of proximal leg deep vein thrombosis diagnosed by compression ultrasonography [5]. Notably, the prevalence of proximal deep vein thrombosis on initial baseline screening was 3.5%.

Classification

Different nomenclatures have been developed due to a profusion of guidelines developed independently by North American and European cardiology and respiratory bodies [3,6–8]. These classifications are based on an assessment of the individual risk of early mortality, and are essentially similar as the presence or absence of right ventricular dysfunction is the critical factor determining outcome following APE. In essence, they can be divided into massive/high-risk (symptomatic RV dysfunction), submassive/intermediate risk (asymptomatic dysfunction and/or RV overload), and small/low-risk (normal RV function)

Risk stratification

A similar problem has arisen with risk stratification with multiple scores reported in the literature, e.g. GRACE, Geneva, Wells,

Table 170.1 Risk factors for thromboembolism

Major risk factors (relative risk 5–20)	Minor risk factors (relative risk 2–4)
Surgery: major abdominal/pelvic surgery, hip/knee joint replacement, post-operative intensive care	**Cardiovascular:** congenital heart disease, heart failure, hypertension, superficial venous thrombosis, central venous catheterization
Obstetrics: late pregnancy, Caesarean section, puerperium	**Oestrogens:** oral contraception, hormone replacement therapy
Lower limb problems: fractures	**Miscellaneous:** obesity, chronic obstructive lung disease, neurological disability, occult malignancy, pro-thrombotic tendency (e.g. Factor V Leiden or protein C deficiency), long-distance sedentary travel
Malignancy: abdominal/pelvic, advanced/metastatic stage	
Reduced mobility: hospitalization, institutional care	
Other: history of previous venous thromboembolism	

Arrhythmias are not noted in these guidelines as a risk factor, although these are clearly recognized as such. Likewise, inflammatory conditions such as sepsis will predispose to a prothrombotic state and an increased risk of embolus.

Simplified Pulmonary Embolism Severity Index, Shock Index, and European Society of Cardiology risk scores [9,10]. These are used both to prognosticate and to define what imaging work-up, and subsequent clinical management should be offered, although none approach very high levels (>90%) of sensitivity and specificity. The scoring systems generally utilize clinical features (e.g. blood pressure (BP), acidosis) with or without markers of myocardial injury or dysfunction (e.g. troponin). In the International Cooperative Pulmonary Embolism Registry [11], haemodynamically unstable patients (based on shock, systolic BP <90 mmHg or a fall in systolic BP >40 mmHg for >15 minutes) had a mortality rate above 50% compared with 15% in haemodynamically stable patients. The Pulmonary Embolism Severity Index is a clinical assessment score derived and validated in >16,000 patients with pulmonary embolism [12].

Table 170.2 lists risk stratification markers proposed by the European Society of Cardiology [6]. Prognostication can also be made in haemodynamically stable patients on the basis of right ventricular dysfunction assessed echocardiographically [13], troponin [14], and plasma B-type natriuretic peptide [15]. A normal B-type natriuretic peptide level had a near 100% negative predictive value for adverse outcomes. While the combination of an increased troponin level and right ventricular dysfunction identified a subgroup at particularly high risk [16], viewed individually the positive predictive value for an adverse outcome ranged from 10 to 20%. Table 170.3 summarizes data on the mortality rates of acute pulmonary embolism.

Table 170.2 Markers used for risk stratification

Clinical markers	Shock Hypotension*
Markers of right ventricular dysfunction	Right ventricular dilatation, hypokinesis, or pressure overload on echocardiography
	Right ventricular dilatation on CT-PA
	Increase in plasma BNP or NT-proBNP levels
	Increase in right heart pressures
Markers of myocardial injury	Raised plasma troponin levels

*Systolic BP <90 mmHg of by >40 mmHg for 15 min.

BNP, Brain natriuretic peptide; NT-proBNP, N-terminal proBNP; CT-PA, computed tomographic—pulmonary angiography.

Cardiovascular consequences

Even though breathlessness or chest pain are the commonest presenting features, the clinical severity of APE is predicated by its impact on the circulatory system, in particular the degree of sudden pulmonary obstruction causing right ventricular overload and failure, and the reduction in cardiac output [17]. An individual patient's baseline cardiovascular reserve is crucial in determining how they cope with the acute obstruction. Various pulmonary and neurohormonal adaptations also aid in providing compensatory responses. Thus, a large embolus in a previously fit and healthy individual may be relatively symptom-free, while patients with long-standing heart or lung problems may decompensate with much smaller emboli.

The acute onset of pulmonary hypertension following APE leads to an increase in right ventricular afterload and strain that may evolve into right ventricular dilation and failure. When severe, the fall in right heart output will reduce cardiac output, even to the point of shock (hypotension and/or organ hypoperfusion), syncope (if brain blood flow is compromised), or an acute cardiovascular collapse with pulseless electrical activity or asystole. APE accounts for 10% of patients admitted with non-traumatic sudden death and 50% of those arriving with electromechanical dissociation or asystole on ECG [18]. In such shock/collapse situations, the right ventricle may not have had sufficient time to dilate so its size on imaging (e.g. computerized tomography, echocardiography) may appear relatively normal, although its functionality may be severely impaired. The reduction in coronary flow secondary to high pressures within the right ventricle may cause subendocardial ischaemia or even infarction of that ventricle. This may further contribute to the degree of right heart failure. Of note, the prognostic value of

Table 170.3 Mortality rates of acute pulmonary embolism

Clinical presentation	Mortality rate
Unselected population	7% at 1 week 13% at 1 month 18% at 3 months
Massive pulmonary embolism	Overall 18–65% (lower with treatment) With cardiogenic shock 25–30% Needing resuscitation 65%
Submassive pulmonary embolism	5–25%
Small pulmonary embolism	Up to 1%

Data from: 'British Thoracic Society guidelines for the management of suspected acute pulmonary embolism', *Thorax*, 2003, **58**, pp. 470–83; PROTECT Investigators for the Canadian Critical Care Trials Group and the Australian and New Zealand Intensive Care Society Clinical Trials Group, et al., 'Dalteparin versus unfractionated heparin in critically ill patients', *New England Journal of Medicine*, 2011, **364**, pp. 1305–14; Torbicki A et al., 'ESC Committee for Practice Guidelines (CPG). syncope as a sign of massive APE has yet to be conclusively demonstrated, particularly where it is not followed by prolonged haemodynamic instability.

When not severe enough to cause shock or collapse, there may still be a fall in cardiac output due to the decrease in left ventricular filling from the obstruction to flow, as well as left ventricular diastolic dysfunction due to right ventricular dilation and bulging of the interventricular septum to the left. This fall in output may be progressive, over hours, days, or even weeks, related to the degree of evolving right heart failure induced by the pulmonary hypertension.

The failing right heart in the post-acute period may thus be a result of maladaptation of compensatory mechanisms. Activation of the sympathetic nervous system with both inotropic and chronotropic stimulation, and the generation of high right ventricular pressures to drive blood through the obstructed pulmonary vasculature are appropriate mechanisms to preserve blood pressure and flow, and thus life, in the short term. However, chronic thromboembolic pulmonary hypertension (CTEPH) may prove harmful later on [19]. There is a reported incidence of 4% of CTEPH after APE. There is still considerable debate in the literature about the long-term risk of right heart failure due to intermediate pulmonary embolism causing ongoing pulmonary hypertension but without initial shock.

Respiratory consequences

Respiratory failure occurs in approximately 10% of APE patients due to several mechanisms. The low cardiac output from a significant APE results in desaturation of mixed venous blood related to increased oxygen extraction by peripheral tissues, which then fails to become fully re-oxygenated on passage through the lungs with resulting arterial hypoxaemia. This will be exacerbated by ventilation-perfusion mismatching due to:

- Atelectasis related to both hypoventilation induced by pain and/or reduced respiratory muscle perfusion.
- Possible areas of pulmonary infarction.
- Development of a right to left shunt (due to inversion of pressures between the right and left atria) through a patent foramen ovale that is anatomically present in varying sizes in 30% of people.
- An excessive systemic inflammatory response related to the acute insult with development of increasing capillary leak and an ARDS-type picture replacing the initial radiographic appearance of clear lung fields.

Pulmonary infarction is caused by small, distally embolizing thrombi usually with no haemodynamic consequences. Alveolar haemorrhage with possible haemoptysis, pleurisy and pleural exudate that often haemorrhagic, are all associated features. Peripheral, often wedge-shaped, infarcts may be seen on X-ray or CT scan.

CHAPTER 171

Diagnosis and management of pulmonary embolism

Mervyn Singer

Key points

- Computed tomographic pulmonary angiography is the current gold standard tool for the diagnosis of pulmonary embolism.
- Mortality risk stratification based on clinical, imaging and biochemical indices dictates the treatment strategy employed in an individual patient, from outpatient anticoagulation to surgical or percutaneous embolectomy for severe, life-threatening cases.
- Anticoagulation is the mainstay of treatment. Fixed dose, subcutaneous heparin is initially commenced (unless contraindicated), with early introduction of oral therapy such as coumadin (warfarin) generally continued for 3–6 months (but may be lifelong).
- Thrombolytic agents should be used in patients with haemodynamic compromise.
- In intermediate-risk, normotensive patients, thrombolysis reduces early mortality or haemodynamic collapse, but this is counterbalanced by an increase in major haemorrhage (including stroke), especially in the elderly.

Diagnosis

Acute pulmonary embolism (APE) should be suspected in patients with new-onset or worsening breathlessness, sharp pleuritic or substernal chest pain, cough, haemoptysis, syncope, hypotension, shock or cardiac arrest with pulseless electrical activity or asystole [1]. Patients may be asymptomatic with the diagnosis made serendipitously during diagnostic imaging for another indication, e.g. cancer staging. Signs include tachypnoea, tachycardia, evidence of deep venous thrombosis (DVT) in 15%, cyanosis in 11%, and pyrexia. Table 171.1 reports clinical presentations in 209 patients with documented APE [2].

Diagnosis is usually made by initial clinical suspicion that prompts more specialized imaging and investigation. Electrocardiographic evidence of right heart strain includes T wave inversion in leads V1–V4, the classic $S_1Q_3T_3$ pattern in leads I–III, peaked P waves, and incomplete or complete right bundle branch block. There may be atrial arrhythmias and evidence of right ventricular (RV) ischaemia or infarction with ST elevation in chest lead V1 plus ST depression in lead V2 being highly specific for RV infarction. Diagnosis is more easily made if a right-sided electrocardiogram (ECG) shows ST elevation in leads V3R–V6R.

The ECG may be normal with smaller pulmonary emboli not causing RV strain/damage, as may the initial chest X-ray, despite concurrent hypoxaemia. X-ray abnormalities include bands of atelectasis, pleural effusions, or hemidiaphragm elevation. Focal, peripheral consolidation may be due to infarction or haemorrhage. Wedge-shaped peripheral infarcts are relatively unusual. Westermark's sign describes focal oligaemia distal to the occluded pulmonary artery that is often enlarged proximal to the clot.

The utility of plasma D-dimer levels, a degradation product of cross-linked fibrin, has been heavily studied [3]. D-dimer levels rise with excessive degrees of coagulation and fibrinolysis, although this can occur due to multiple other reasons, including sepsis, cancer, and trauma. It has reduced specificity in pregnancy, cancer, the elderly, and hospitalized patients [4]. Due to its poor positive predictive value but high negative predictive value, D-dimer testing is frequently used as a 'rule-out' test with a negative value suggesting a low likelihood of pulmonary embolus.

Computed tomographic pulmonary angiography (CT-PA) is the current gold standard diagnostic tool, particularly with the newer high resolution multidetector devices that can even image 5th and 6th order subsegmental vessels [5]. A 97% sensitivity for detecting emboli in the main pulmonary arteries is reported in haemodynamically unstable patients [6]. The PIOPED II study reported 83% sensitivity and 96% specificity for detecting pulmonary emboli by CT-PA [7]. With newer-generation scanners, the yield is likely to be higher still, although the clinical significance of small isolated subsegmental emboli, reported at an incidence of 3–36%, remains open to question [5]. Lower limb CT venography can be performed in tandem to identify DVT, but this increases radiation exposure so is not generally performed.

Isotopic ventilation–perfusion scintigraphy is still used occasionally. This utilizes intravenous injection of technetium (Tc)-99m labelled albumin particles to demonstrate 'cold' abnormalities in lung perfusion due to occlusion of pulmonary arterial branches, but concurrent normal ventilation using tracers such as Tc-99m labelled aerosols or microparticles. The proportion of 'high probability' scans is relatively low as this technique is heavily dependent upon normal lung ventilation, which is frequently not the case, either due to the PE itself or to pre-existing lung morbidity. It has more utility in excluding APE if the perfusion scan is normal [8].

Echocardiography, especially transoesophageal echocardiography, is useful as a bedside tool to assess right ventricular (RV) strain and dysfunction, especially in the emergency department and in patients too haemodynamically unstable to be transferred

Table 171.1 Incidence of individual clinical manifestations of acute pulmonary embolism

Clinical status	Incidence (%)
Cardiac arrest or shock	13
Hypotension without signs of shock	9
Haemodynamic stability, but echocardiographic signs of right ventricular dysfunction	31
Haemodynamic stability, without echocardiographic signs of right ventricular dysfunction	47

Data from Grifoni S et al., 'Short-term clinical outcome of patients with acute pulmonary embolism, normal blood pressure, and echocardiographic right ventricular dysfunction', *Circulation*, 2000, **101**, pp. 2817–22.

for CT-PA [4]. Occasionally, large emboli can be imaged in the main pulmonary arteries. In patients with shock or hypotension, the absence of echocardiographic signs of RV overload or dysfunction strongly excludes APE as the cause of the haemodynamic compromise [9]. This technique is, however, heavily operator-dependent and the more subtle signs of RV dysfunction may be easily missed.

Conventional pulmonary angiography can also be performed to confirm the diagnosis of APE, but this is usually as a prelude to embolectomy that, at the present time, is rarely performed. The PIOPED III trial found that magnetic resonance angiography had insufficient sensitivity and a high rate of technically inadequate images when used to diagnose pulmonary embolism [10].

Biochemical markers of RV dysfunction (e.g. B-type natriuretic peptide) and injury (e.g. troponin) are also measured as markers of prognostication, either alone or in combination with other markers [11,12].

Treatment

The treatment stratagem for acute pulmonary thromboembolism in an individual patient is generally based on the perceived mortality risk for which numerous scoring systems have been developed. Table 171.2 provides one such example with the potential treatment implications listed [1].

The mainstay of treatment is anticoagulation with a rapid-onset agent, such as a subcutaneous low molecular weight heparin (e.g. dalteparin, enoxaparin) or fondaparinux given as a fixed dose regimen (Table 171.3). Unfractionated heparin given by continuous infusion is advised in patients with renal failure (creatinine clearance <30 mL/min) with dosing titrated to achieve a partial thromboplastin time of 1.5–2.5 times above the normal range. The efficacy and safety profile are similar with an in-hospital bleeding risk of 3% [13,14].

Within a day, oral anticoagulation with a vitamin K antagonist (e.g. coumadin (warfarin)) should be commenced in most patients. The two agents should be given in tandem for at least 24 hours after the patient has been fully anticoagulated as adjudged by an international normalized ratio (INR) of 2.0–3.0 (Table 171.3). Vitamin K antagonists are usually given for 3–6 months, although treatment may need to be lifelong in high-risk patients, e.g. those with chronic arrhythmia, active cancer, or recurrent venous thromboembolism [1]. A careful risk-benefit analysis needs to be undertaken in those individuals at risk of bleeding, e.g. those with peptic ulceration or angiodysplasia. Pregnant patients are usually managed on heparin alone, due to the risk of teratogenicity from vitamin K antagonists. Symptomatic patients at low risk (pulmonary embolism severity index risk Classes I and II) could be safely discharged home within 24 hours and managed as an outpatient [14]. Ninety day mortality was 0.6% in both out- and inpatient groups. In recent years new oral Factor Xa inhibitors, such as rivaroxaban, have had equal efficacy and superior safety demonstrated over warfarin [16,17]. Their advantage is administration at fixed doses without the need for routine monitoring of coagulation.

For haemodynamically unstable patients, thrombolysis is advocated on the grounds that clot dispersal is more rapid, right ventricular dysfunction is more actively and effectively treated, short-term mortality is improved, and the risk of long-term pulmonary hypertension and right heart failure reduced. After the thrombolytic has been infused, an infusion of intravenous unfractionated heparin is commenced with a vitamin K antagonist added subsequently (as above).

Mortality can be halved with prompt thrombolysis from the approximate 60% rate reported in patients with massive APE and haemodynamic compromise not treated with thrombolytics [18]. The risk of major bleeding is much higher with thrombolysis compared with anticoagulant therapy alone. Major contraindications

Table 171.2 Mortality risk stratification of acute pulmonary embolism

PE-related early mortality risk	Risk markers			Potential treatment implications
	Clinical (shock or low BP)	RV dysfunction	Myocardial injury	
High (>15%)	+	+	+	Thrombolysis or embolectomy
Intermediate (3–15%)	–	+/–	+/–	Hospital admission
Low <1%	–	–	–	Early discharge or home-based management

Table 171.3 Parenteral anticoagulant agents

Anticoagulant agent	Dose	Monitoring
Unfractionated heparin	80 IU/kg iv bolus, then infusion at 18 IU/kg/hour	Adjust infusion rate to maintain APTT between 1.5–2.5× control Monitor platelet count for heparin-induced thrombocytopenia
Low molecular weight heparins		No monitoring routinely needed. Anti-factor Xa levels may be helpful if at increased risk for bleeding. Avoid (or monitor) if creatinine clearance <30 mL/min
◆ Enoxaparin	1 mg/kg sc every 12 hours or 1.5 mg/kg od	
◆ Tinzaparin	175 U/kg sc od	
◆ Dalteparin	200 U/kg (maximum dose of 18,000 units) od	
Factor Xa inhibitor		
Fondaparinux	od sc injection of: ◆ 5 mg if body weight <50 kg ◆ 7.5 mg if weight 50–100 kg ◆ 10 mg if weight >100 kg	No monitoring routinely needed. Anti-factor Xa levels may be helpful if at increased risk for bleeding. Avoid (or monitor) if creatinine clearance <30 mL/min

include intracranial disease, uncontrolled hypertension and major surgery or trauma within the past 3 weeks. Table 171.4 shows some common thrombolytic regimens. No studies have directly compared thrombolytic regimens, although more rapid infusion (within 2 hours) is generally recommended to achieve faster clot breakdown.

Conclusion

To address the question of thrombolytic use in normotensive intermediate-risk patients, the recently completed PEITHO trial compared anticoagulation with or without tenecteplase in 1006 haemodynamically stable patients with evidence of RV dysfunction and an elevated troponin. While thrombolysis substantially reduced the combined endpoint of early mortality or haemodynamic collapse, this was at the expense of a significant increase in major haemorrhage (including stroke), especially in patients >75 years [19].

No study has clearly demonstrated an advantage of catheter-directed over intravenous thrombolysis. In a recent meta-analysis, catheter-directed therapy had a clinical success rate of 86% and a rate of major complication rate of only 2.4% [19].

Percutaneous mechanical thrombectomy (fragmentation and aspiration of the thrombus under radiographic imaging) or surgical embolectomy under cardiopulmonary bypass is restricted to those high-risk patients in whom thrombolysis is either contraindicated or in those where it has failed to improve a parlous circulatory state.

Inferior vena cava filters can be used in patients in whom anticoagulation is contraindicated and there is a high risk of recurrence of emboli. Retrievable filters can be placed in patients in whom a contraindication to anticoagulation is temporary, or in those where a major surgical procedure is being contemplated. There are no data to support routine use in patients with free-floating proximal DVT. As they carry a significant complication rate including DVT recurrence and post-thrombotic syndrome, their systematic use is not recommended [1].

Table 171.4 Thrombolytic regimens

Thrombolytic agent	Dose
Streptokinase	250 000 U iv bolus followed by 100,000 U/hour infusion for 12–24 hours
Urokinase	4400 U/kg bolus, followed by 4400 U/kg/hour for 12–24 hours
Alteplase	100 mg iv infusion over 2 hours
Reteplase	Two boluses of 10 U given iv 30 minutes apart
Tenecteplase	Weight-adjusted iv bolus given over 5 seconds, ranging from 30 mg (if weight below 60 kg), increasing in 5 mg increments for every 10 kg, to a fixed dose of 50 mg if ≥90 kg

SECTION 6

The gastrointestinal system

PART 6.1

Physiology

CHAPTER 172

Normal physiology of the gastrointestinal system

Annika Reintam Blaser and Adam M. Deane

Key points

- The gastrointestinal (GI) system carries out digestive, endocrine, immune, and barrier functions.
- The GI system protects against antigens using physical, non-immune, and immune-mediated mechanisms.
- GI motor patterns differ according to fasting or post-prandial phases, and assist with storage, mixing, absorption, and eventual evacuation of luminal contents.
- Intestinal blood flow is increased several-fold in the post-prandial phase.
- Although not well clarified, critical illness appears to have profound effects on GI function.

Introduction

Digestion and absorption are the most obvious functions of the gastrointestinal (GI) system, but this region also carries out important endocrine, immune, and barrier activities that are often tightly integrated with other organs. Additionally, the GI system plays an important role in fluid, electrolyte, and acid-base balance [1]. Adequate blood flow to the GI tract is essential for adequate functioning. In this chapter, information relating to the accessory GI organs is limited to endocrine and exocrine secretions.

Structure and organization of the GI tract

The GI system consists of a series of hollow organs (GI tract) into which accessory organs add their secretions. The basic anatomic structure of the GI tract wall includes mucosa, submucosa, muscle, and serosa (or adventitia, if retroperitoneal) [1]. The mucosal layer consists of epithelium (with glands, microvilli, villi, and crypts depending on location) and lamina propria (with capillaries, neurons, immune cells, and a thin layer of smooth muscle—lamina muscularis mucosae) [1]. The submucosal layer contains connective tissue, glands, and larger blood vessels, while the muscle layer consists of inner circular and outer longitudinal layers, with neurones in between.

The enteric nervous system (ENS) consists of the submucosal (Meissner's) plexus located in both small and large bowel, and the myenteric (Auerbach's) plexus located between the circular and longitudinal muscle layers running from oesophagus to rectum [1]. The ENS can operate independently, but extrinsic pathways (usually parasympathetic) regulated by the brainstem are also integrated.

The mouth and oropharynx are essential for chewing and lubrication of food, but also initiate carbohydrate and fat digestion. The oesophagus is a conduit for ingesta to enter the stomach, and limit or clear reflux. The stomach stores ingesta and has substantive motor, secretory, humoral, and digestive functions. The small bowel absorbs nutrient, fluid, and electrolytes, and secretes peptides. Pancreatic secretions and bile enter the duodenal lumen, the former are pivotal for digestion, as well as neutralization of gastric acid entering the small bowel, while the latter assists with excretion of waste products and digestion of lipids. The large bowel absorbs water and electrolytes, as well as carbohydrate that reaches the large bowel unabsorbed, stores luminal contents until evacuation, and secretes fluid and electrolytes.

GI functions

Energy intake

Ingestion requires integration of oro-pharyngeal and oesophageal motility but, in the critically ill, ingestion is commonly bypassed with insertion of nasogastric tubes.

Digestion and absorption are the components of nutrient assimilation [1]. Many dietary foods require digestion before absorption can occur as nutrient needs to be in a component form for transluminal transportation. While enzymes secreted from the pancreas are primarily responsible for luminal digestion, enzymes from the brush border membrane of the small intestinal epithelium are essential for the final part of carbohydrate and protein digestion (membrane digestion) [1]. Absorption mostly takes place at the apical membrane of the small intestine, with active transportation, passive diffusion, facilitated diffusion (requires a carrier, but no energy), or phagocytosis.

Carbohydrates must be broken down into their constituent monosaccharides prior to absorption [1]. Amylase hydrolyses starch into oligo- and disaccharides that are non-absorbable. Enzymes from the brush border membrane, carbohydrases, are necessary to complete digestion to monosaccharides, which are absorbed via the sodium-dependent glucose co-transporter (SGLT1) located in the brush border membrane.

Lipids are disrupted mechanically in the mouth and stomach, with the particles stabilized as an emulsion [1]. Emulsification of fat is assisted by gastric motility. However, lecithin and bile salts are pivotal to this process, facilitating digestion of triglycerides into free fatty acids and monoglycerides by pancreatic lipase. Bile salts also play an important role in forming fatty acids and monoglycerides

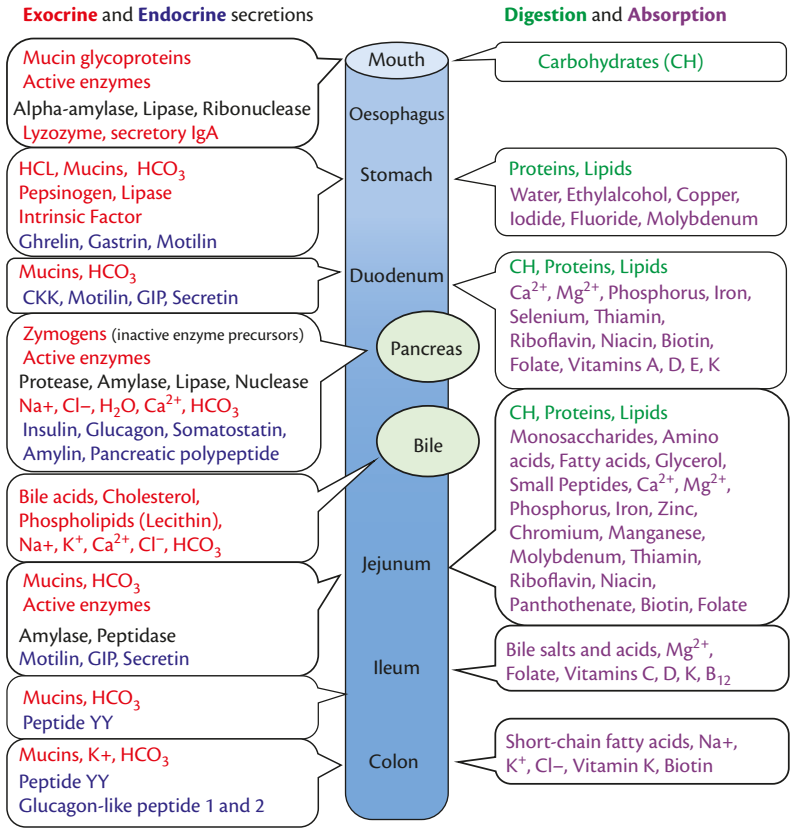

Fig. 172.1 Absorption and digestion of nutrients presented together with secretions of the GI tract.

into micelles that are passively absorbed across the brush border epithelium into the bloodstream.

Protein is partially degraded in the stomach by pepsin. Pancreatic proteolytic enzymes secreted into the proximal small intestine are capable of digesting proteins to oligo-peptides (branches of 2–6 amino acids). Brush border enzymes then digest oligo-, tri-, and di-peptides to amino acids, and the latter are absorbed via several specific co-transporters.

Locations for digestion and absorption of nutrients are presented in Fig. 172.1.

Immunological and barrier functions

The protective mechanisms of the GI system consist of physical, non-immune, and immune elements. Intact gut mucosa provides a physical barrier while gastric acid, intestinal mucin, bile, and peristalsis are part of the non-immunological protective response. The immune-mediated response relies upon gut-associated lymphoid tissue (GALT). GALT consists of aggregates of lymphoid tissue (e.g. Peyer's patches), and diffuse populations of immune cells (lymphocytes and mast cells) mostly located in the small intestine [1,2]. Orally ingested antigens are taken up by GALT where immunocytes are activated [2]. Activated T-lymphocytes secrete IgA in response to prolonged antigen exposure. Transported into the lumen via B-lymphocytes, IgA neutralizes intraluminal antigen/s. The digestive microflora is the major antigenic stimulant for the maturation and migration of precursor lymphoid cells [2]. 'Oral tolerance' describes the immune response to the GI system that allows systemic unresponsiveness to a previously ingested antigen, which is crucial for life [2].

Endocrine function

Peptides released from the stomach, pancreas, and/or intestine modulate motility, secretion, absorption, mucosal growth, and immune function. Many peptides have paracrine and neurotransmitter actions, but only peptides with substantial endocrine action are discussed here.

Hormones secreted from the GI tract

- Ghrelin is secreted primarily by the stomach during fasting, with secretion suppressed by meal ingestion. Ghrelin, the natural secretagogue for growth hormone, is a potent appetite stimulant and accelerates gastric emptying [3].
- Motilin is secreted during fasting and suppressed by nutrient. Exogenous motilin accelerates gastric emptying. In the critically ill the motilin agonist, erythromycin, has a similar effect.
- Gastrin is secreted principally from the gastric antrum in response to nutrients, in particular protein, and is suppressed by acid. Gastrin is the major hormonal regulator of gastric acid secretion.
- Cholecystokinin (CCK) is secreted in response to the presence of nutrient in the duodenum and jejunum. CCK is the major hormonal stimulant of gallbladder emptying, and also suppresses appetite and energy intake. CCK stimulates pancreatic secretion and slows gastric emptying.
- Secretin is principally released in response to acid within the duodenum, but partially digested products of fat and protein as well as bile acid also stimulate its release. Secretin is a potent

stimulant of pancreatic exocrine secretion, but also reduces gastric acid secretion and slows gastric emptying.

- Peptide YY (PYY) is secreted predominantly from the colon and rectum in response to nutrient, with fat as the principal stimulant. PYY slows both gastric emptying and small intestinal transit, and inhibits appetite.
- Glucose-dependent insulinotropic peptide (GIP) is secreted in response to duodenal nutrient and is a potent insulinotropic hormone.
- Glucagon-like peptide-1 (GLP-1) is secreted from the small and large intestine in response to unabsorbed nutrient or bile acids. Together, GLP-1 and GIP are termed the 'incretin' hormones, being pivotal for glycaemic regulation following a meal. In health, GLP-1 stimulates insulin and suppresses glucagon secretion, as well as slows down gastric emptying.
- Glucagon-like peptide-2 (GLP-2) is co-secreted with GLP-1 and has a profound intestinotropic response.

Hormones secreted from the pancreas

- Somatostatin is an inhibitory hormone secreted in response to mechanical and nutrient stimulation. Somatostatin reduces gastric acid, pepsinogen, pancreatic exocrine secretion, and bile flow [4]. Somatostatin analogues (e.g. octreotide) markedly reduce splanchnic blood flow.
- Insulin is secreted from pancreatic β cells, with plasma glucose being the principal stimulant [4]. Insulin lowers blood glucose and promotes storage of carbohydrate and fat.
- Amylin is co-secreted with insulin from pancreatic β cells and slows gastric emptying, insulin and amylin probably act synergistically to attenuate post-prandial glycaemic excursions [4].
- Glucagon is a pivotal counter-regulatory hormone. Glucagon stimulates glycogenolysis and gluconeogenesis in the liver and the kidney [4].
- Pancreatic polypeptide inhibits pancreatic exocrine function and gallbladder contraction.

Requisites to perform GI functions

Motility

The motor activity of the GI tract assists with mixing (non-propulsive movements), propulsion (progressive wave of relaxation, followed by contraction), retropulsion (reflux), and storage. The motor activity of the GI system differs between fasting and fed states, but both appear to be profoundly disturbed during critical illness.

Oro-pharynx and oesophagus

Chewing and swallowing are the main motor functions of the oro-pharynx, with the latter integrated with the oesophagus. Swallowing is a complex process mainly controlled by the swallowing centre in the medulla. The upper oesophageal sphincter opens with swallowing and closes with inspiration. Peristalsis in the oesophageal body is primary when initiated by swallowing, or secondary when initiated by residual bolus or refluxate in the oesophagus. The lower oesophageal sphincter allows coordinated passage of the bolus into the stomach, appropriate venting of gas or liquid from the stomach while limiting noxious gastric content refluxate [5]. Lower oesophageal sphincter relaxation occurs not only because of primary or secondary peristalsis, but also independent of these peristaltic reflexes, which are termed transient lower oesophageal relaxations. In the critically ill, basal lower oesophageal sphincter pressure is profoundly reduced, primary peristalsis appears absent and secondary peristalsis is probably impaired [5]. Accordingly, reflux events are common and poorly cleared.

Stomach

The motor function of the stomach prepares solid digestible nutrient by mixing and grinding chyme, regulates nutrient supply (i.e. gastric emptying), and expels non-nutrient material during fasting.

- Fasting stomach motility is arbitrarily divided into three phases, the so-called 'migrating motor complex' (MMC). MMC phase I is characterized by motor quiescence, phase II by irregular contractile activity, and phase III by periods of regular contractions sometimes referred to as 'activity fronts'. Propulsion of luminal contents occurs mainly during late phase II or phase III.
- Post-prandial stomach motility is initiated by nutrient intake and ends with the recurrence of fasting motility patterns. In contrast to solids, liquid nutrient is initially emptied from the stomach at a more rapid rate and, thereafter, follows an overall linear rate of emptying. Mechanisms underlying this transition likely involve interactions with nutrient receptors in the small intestine (enterogastric feedback). The stomach is separated into two functional regions; proximal (fundal) and distal (antral and pyloric). In the critically ill, delayed gastric emptying occurs commonly. It is usually associated with disordered motility throughout the entire stomach and impaired integration of motor function [5].

Following ingestion of a meal the proximal stomach acts as a reservoir, with inhibition of tonic contraction of the smooth muscle. The resulting 'receptive' relaxation of the proximal stomach allows filling with ingesta, with only minor increases in pressure. This is followed by gastric 'accommodation', which may be prolonged (up to 3 hours) and persists until emptying is almost complete. Fundal contractions then assist with aboral movement of the ingesta.

Post-prandial activity in the distal stomach is characterized by irregular contractions that aid mixing and propagation of nutrient along the gastrointestinal tract. Antral pressure activity assists with mixing and is also a substantial regulator of gastric emptying. However, to retard gastric emptying, limit duodenogastric reflux, and facilitate the mixing of chyme, intermittent pyloric pressure waves (IPPWs) enable prolonged periods of pyloric closure to occur [5].

Small intestine

Fasting MMC patterns propagate from the gastro-duodenal region through the small intestine. In the duodenum the post-prandial motor pattern is characterized by irregular contractions with both antegrade and retrograde pressure wave sequences which usually propagate over short distances only [6]. This pattern causes intermittent and bidirectional flow of chyme to facilitate mixing and grinding. In the critically ill a fasting 'MMC type' of pattern continues during nutrient stimulation, which means that the conversion from a fasting to an inter-digestive motor pattern fails.

Large intestine

The irregular motor activity of the colon includes tonic and phasic contractions. Short duration contractions cause both antegrade and retrograde movement, and assist with mixing and absorption of luminal contents. High-amplitude propagated contractions cause contraction over several segments. They occur more commonly after waking, meals, and may be associated with the urge to defecate [6].

Integrative steering

The GI system is modulated by complex myogenic, neural, and humoral mechanisms. The interstitial cells of Cajal initiate and conduct myogenic activity throughout the gut independent of neural and humoral control. Whether or not the electrical stimulus initiates mechanical contraction is then determined by a number of intraluminal and systemic factors, mediated via neural and/or hormonal pathways.

Neuronal

Neural regulation of the GI system is mediated via extrinsic (**vagus** nerve with both afferent and efferent components) and intrinsic (**enteric** nerves) pathways. The efferent **vagus** nerve provides parasympathetic motor supply to the gut, controlled by a cholinergic excitatory pathway and a non-adrenergic non-cholinergic inhibitory pathway. **Enteric** nerves can convey information in ascending and descending directions via excitatory (acetylcholine and serotonin) and inhibitory (nitric oxide) neurotransmitters.

Hormonal

Hormonal regulation is described in 'Endocrine Function'.

Exocrine secretions

Gastric secretions

The stomach secretes fluid comprising hydrochloric acid, pepsinogen, intrinsic factor, mucous, and bicarbonate, as well as peptides that have paracrine effects. The rate of secretion during the post-prandial phase differs according to whether an individual is aware of food (anticipation), and when nutrient is within the stomach or the duodenum (cephalic, gastric and intestinal phases, respectively). Secretions from the stomach aid sterilization of ingesta (hydrochloric acid), commence digestion (pepsinogen), protect the stomach and duodenum (mucous and bicarbonate), and are essential for the subsequent absorption of vitamin B_{12} (intrinsic factor) [6].

Pancreatic and salivary secretions

The exocrine pancreas secretes >20 proteins, as well as calcium and bicarbonate, and is essential for digestion [1]. Salivary secretions include alpha-amylase and mucins [1].

Intestinal secretions

To facilitate motor and absorptive functions a substantial amount of intestinal fluid is secreted. While nearly all is resorbed in the absence of intestinal disease, net bicarbonate, chloride, and potassium secretion are important.

Perfusion

The coeliac artery is responsible for the main blood flow to stomach, pancreas, and spleen [1]. Small and large intestinal blood supply is from superior and inferior mesenteric arteries, with interconnections between the arcading branches providing multiple collateral pathways [1]. Venous flow from stomach, intestines, pancreas, and spleen is via the portal vein. In health, intestinal blood flow is increased several-fold in the post-prandial phase, but this response may be attenuated in the critically ill. [7]

Fenestrated capillaries in the villi absorb nutrients from the intestinal lumen [1]. The fountain-like arrangement of villi microvessels facilitates counter-current exchange, enabling solutes to move from arteriole to venule without traversing the entire length of the villus [1]. However, this arrangement makes the villus tip susceptible to damage from hypoxia and/or hypotension.

Sympathetic activity directly constricts splanchnic vessels. Parasympathetic activity stimulates intestinal motility and secretion and increases metabolism, thereby indirectly increasing perfusion. The splanchnic circulation serves as a major reservoir of blood; about half the splanchnic blood volume can be rapidly mobilized [1]. A reduction in blood flow leads to production of vasodilatory metabolites. At rest only 20% of O_2 is extracted [1]. This extraction rate can be increased remarkably so temporary reductions in blood flow can be tolerated. Longer durations of such periods may result in irreversible damage as the ischaemic mucosal epithelium at the villi tips sloughs off [1]. This sloughing results in disruption of the barrier allowing entrance of toxic substances and bacteria into the circulation; this is a putative mechanism underlying the development of multi-organ dysfunction.

Conclusion

The GI system plays a crucial role in health. While effects of critical illness on the GI system are incompletely understood, critical illness does appear to have profound effects on this system.

CHAPTER 173

Normal physiology of the hepatic system

William Bernal and Alberto Quaglia

Key points

- Hepatic blood inflow is from two sources; high-pressure, well-oxygenated blood from the hepatic artery and low-pressure, partly deoxygenated blood from the portal vein. Hepatic inflow is maintained by variation in flows in these two systems.
- Although less than a third of total blood flow is delivered via the hepatic artery, it is responsible for the majority of hepatic oxygen supply.
- The liver can be subdivided into eight functionally-independent segments, each with its own vascular inflow, outflow, and biliary drainage.
- The tri-dimensional hepatic microstructure is complex with geographic heterogeneity of hepatocellular function, and resistance to toxic, ischaemic, and metabolic damage.
- The liver is central to a wide variety of synthetic, metabolic, and detoxification functions. The overall balance of activity may be altered rapidly in response to systemic inflammatory stimuli.

The hepatic system

The liver is the largest internal organ, weighing between 1.4 and 1.7 kg in adults. Situated in the right upper quadrant of the abdominal cavity, it is partially subcostal and immediately inferior to the right hemi-diaphragm. It is subdivided into right and left lobes, with the former further divided into caudate and quadrate lobes. The right lobe usually represents three-quarters of the overall liver mass. The liver serves a huge variety of functions and its presence is vital for life. Survival in the anhepatic state is possible only for a few days.

Liver cells may be grossly categorized as parenchymal and non-parenchymal, with the former occupying 80% of liver volume and with the hepatocyte being the predominant cell type. Non-parenchymal cell types include sinusoidal endothelial, hepatic stellate cells and a lymphoid population which represent less than 10% of liver volume, but 40% of cell numbers. The complex macro- and micro-structural arrangement of these cells, and their nutritive blood supply have important functional and pathophysiological consequences.

Hepatic blood supply

The liver receives about 75% of its blood supply through the portal vein (PV) that carries partly deoxygenated blood from the major part of the digestive tract, including spleen, pancreas, and gallbladder. The remaining 25%, yet accounting for 50% of the liver's oxygen supply—arises from the hepatic artery (HA), the second major branch of the celiac axis. The liver may be subdivided into eight functional segments based upon the distribution of vascular supply (Fig. 173.1) [1].

Total hepatic blood flow is equivalent to approximately 100 mL/min per 100 g liver wet weight. Though liver mass constitutes only 2.5% of total body weight, it receives nearly 25% of cardiac output. The liver also accounts for 12% of total blood volume, half may be expelled from the liver through active or passive mechanisms with a potential role as a blood volume reservoir.

Though neural and humoral control mechanisms may play a role, hepatic perfusion is primarily maintained by variation in flows of the hepatic arterial and portal venous systems. While the liver cannot directly control total PV blood flow, the HA can produce reciprocal compensatory flow changes in response to changes in PV flow. This 'hepatic arterial buffer response' (HABR) maintains constancy of total hepatic blood flow. When portal venous flow decreases, hepatic arterial resistance decreases and arterial flow increases, and vice versa through mediators including locally produced adenosine [2].

Increases or decreases in hepatic venous pressure may further influence hepatic blood flow and volume, for example, clinically important effects may be seen in patients when elevated right-sided cardiac pressures result in marked hepatic venous congestion.

Microscopic structure

The tri-dimensional hepatic microstructure is complex and remains to be fully characterized. On conventional bi-dimensional histology preparations, the basic morphological elements are the portal tracts, hepatic sinusoids, hepatocellular plates, and centrilobular venules (Fig. 173.2).

The portal tracts consist of a connective tissue framework incorporating branches of the PV and the HA, bile duct tributaries, nerve twigs and lymphatics (Fig. 173.2) [3].

Portal venous and arterial blood converges into the hepatic sinusoidal vascular network. These sinusoids are delineated by a layer of endothelial cells, with fenestrations allowing the underlying hepatocytes to come into contact with sinusoidal blood. In contact with the internal sinusoidal surface are macrophages (Kupffer cells) and lymphocytes. Blood flows uni-directionally along the sinusoid toward the hepatic venule, with canalicular bile flow in the opposite direction.

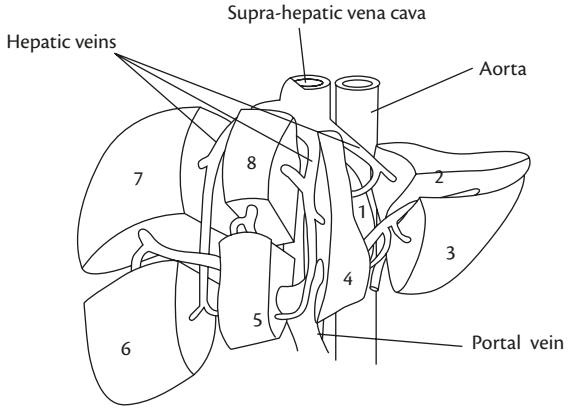

Fig. 173.1 Liver gross and segmental anatomy. Note: Antero-superior view is shown, excluding bile ducts. The Couinaud classification of liver anatomy divides the liver into eight functionally independent segments. Each segment has its own vascular inflow, outflow, and biliary drainage. In the centre of each segment there is a branch of the portal vein, hepatic artery, and bile duct. In the periphery of each segment there is vascular outflow through the hepatic veins.
Segment 1: caudate lobe; 2,3 and 4 left lobe; 5,6,7 and 8 right lobe.

Hepatocytes are separated from the sinusoidal endothelial cells by the space of Disse that is made up of extracellular matrix and contains hepatic stellate cells. Hepatocytes are organized in interlacing 'plates' with their basolateral aspects facing the space of Disse and sinusoidal lumen, and apical aspects coming into reciprocal contact to form canaliculi. Bile constituents are secreted into the canaliculi and eventually drained by the portal bile ducts. The centrilobular venules drain sinusoidal blood into the tributaries of the hepatic veins.

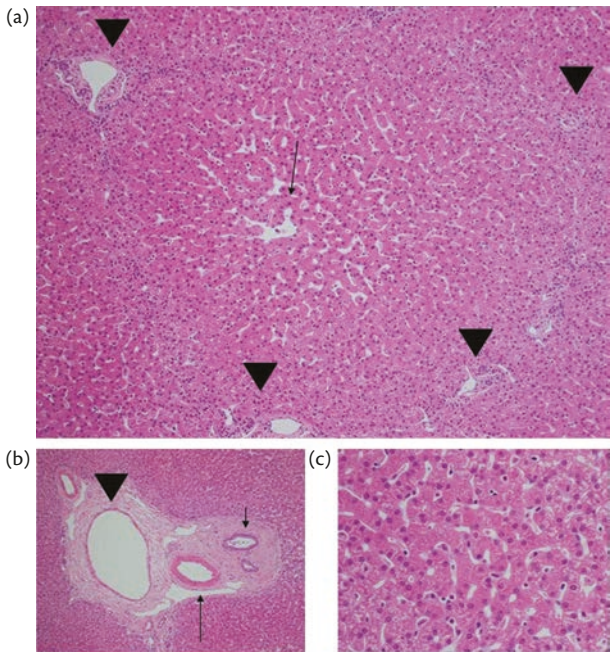

Fig. 173.2 Microscopic anatomy. (a) Arrowheads show portal tracts arranged around a hepatic venules (arrow). (b) A large portal tract include an artery (long arrow), a bile duct (short arrow), and a portal vein branch (arrowhead). (c) Hepatocyte plates and intervening sinusoids.

The orderly histological disposition of portal tracts sinusoids, hepatocellular plates, and centrilobular venules has provided the basis for microscopic structural models such as the Kiernan lobule, Rappaport acinus, and more recently, the Matsumoto primary lobule, the latter based on complex tri-dimensional reconstruction studies. These models have contributed to our interpretation of the various histological patterns of liver injury, inflammation, scarring, and regeneration [4,5].

Anatomic and physiological relationships

Main considerations on the relationship between microscopic anatomy, function, and pathological states include:

- Hepatocellular plates receive a dual arterial and blood supply. In contrast, the biliary tree is largely dependent on the arterial supply, and thus has a poor resistance to ischaemic injury [6].
- Hepatic arterioles and portal branches are regulated by sphincters that can modulate vascular inflow. Hepatic venules are also contractile as are hepatic stellate cells, providing further modulation of vascular in- and outflows. Periportal connections between arterioles and sinusoids and the action of sphincters may provide the basis for functional arterioportal shunts.
- There is a gradient of oxygen tension and distribution of blood constituents between different zones, in particular the periportal and perivenular regions. Blood becomes progressively poorer in oxygen and nutrients from the periportal zone 1 to perivenular zone 3. This is reflected in a geographic heterogeneity of hepatocellular function, and resistance to toxic, ischaemic, and metabolic damage (Figs 173.3, and 173.4) [7].
- Bile secreted into the canaliculi drains into portal bile ducts. The point of contact between the canalicular system and the interlobular bile duct is thought to be the canal of Hering. This is also likely to be the location of progenitor cells that may activate in response to liver injury and contribute to regeneration [8].
- Bile synthesis is heterogeneous with a portal-perivenular gradient. Bile constituents are reabsorbed by biliary epithelial cells

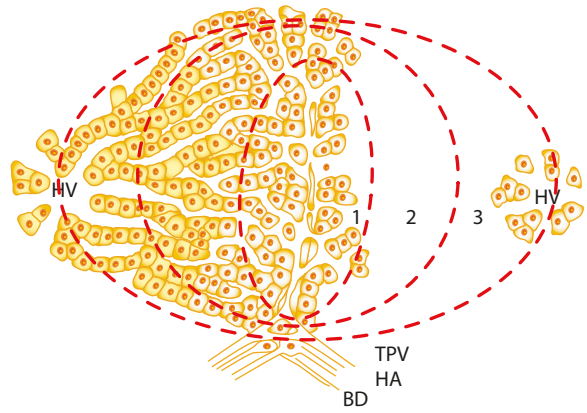

Fig. 173.3 Hepatic acinus. The acinar axis is formed by terminal branches of the portal venule (TPV), hepatic arteriole (HA), and bile ductule (BD). Blood enters the acinar sinusoids and flows sequentially through zone 2 and into zone 3, where it exits via the terminal hepatic venules (HV).

and secreted through their basolateral aspect, followed by reabsorption by the peribiliary vascular plexus in a countercurrent fashion.

- Sinusoidal lymphocytes and Kupffer cells are part of the immunologic defence mechanisms, activating following liver injury and mediating regeneration and fibrosis. Mediator release from Kupffer cells and circulating macrophages homing to an acutely injured liver may modulate the systemic inflammatory response.
- Liver injury induces activation of hepatic stellate cells from a vitamin A storing mode to myofibroblast-like cells, and activation of portal fibroblasts to induce fibrogenesis. The subsequent alteration of the orderly microscopic architecture by fibrous scarring is the basis for the pathophysiology of advanced stage liver disease and its complications.
- The regenerative ability of the liver parenchyma is based on hepatocyte and cholangiocyte re-entry into the cell cycle, and replication. This is observed, for example, after partial hepatectomy. Progenitor cells contribute to regeneration when hepatocyte loss reaches a certain trigger point or when hepatocyte proliferation is impaired. Activation and proliferation of these progenitor cells is followed by their differentiation into hepatocytes or cholangiocytes; the contribution of circulating extra-hepatic stem cells to liver regeneration remains controversial.

Synthetic, metabolic, and detoxification functions

The liver is central to a wide variety of synthetic, metabolic, and detoxification functions [9]. It is the main site of protein synthesis, e.g. exporting up to 12 g albumin daily. Protein synthesis is regulated by various factors, in the case of albumin by changes in osmotic pressure, nutritional state, systemic inflammation, and drugs, particularly corticosteroids.

As the liver serves as the source of most blood coagulation factors, changes in synthetic capacity may also be reflected in altered coagulation status on laboratory testing. However, the functional consequences are complex as a balanced loss of pro- and anti-coagulant proteins may occur [10,11].

Synthesis of coagulation factors II, VII, IX and X is dependent on lipid-soluble Vitamin K. Prolongation of the prothrombin time (PT) may reflect failure of gastrointestinal lipid absorption rather than hepatocellular failure. When the PT is prolonged, intact hepatic function may be inferred by an improvement >30% within 24 hours of parenteral vitamin K administration.

The liver is the primary site of the body's stores of a number of substances including vitamins A, B_{12} and D, and minerals including iron and copper. It also stores most of the body's carbohydrate energy reserves as glycogen, which may represent up to 10% of hepatocyte mass. Synthesis is increased when blood glucose concentrations are high. When blood glucose is low, glycogenolysis is stimulated along with gluconeogenesis from amino acids. The loss of hepatic carbohydrate homeostasis and consequent hypoglycaemia may be an ominous reflection of critically impaired hepatic function. The liver is also key to lipid handling, transport, and metabolism, and is responsible for the synthesis of cholesterol and lipoproteins including high-density lipoprotein. It is also the site of synthesis of hormones and mediators including thrombopoetin, insulin-like growth factor 1, and angiotensinogen, and of the degradation of hormones, e.g. insulin.

The overall balance of hepatic metabolic activity may be shifted rapidly in response to systemic inflammation with an 'acute phase reaction' (APR). Triggered by circulating inflammatory mediators, this results in a series of acute phase phenomena including complex

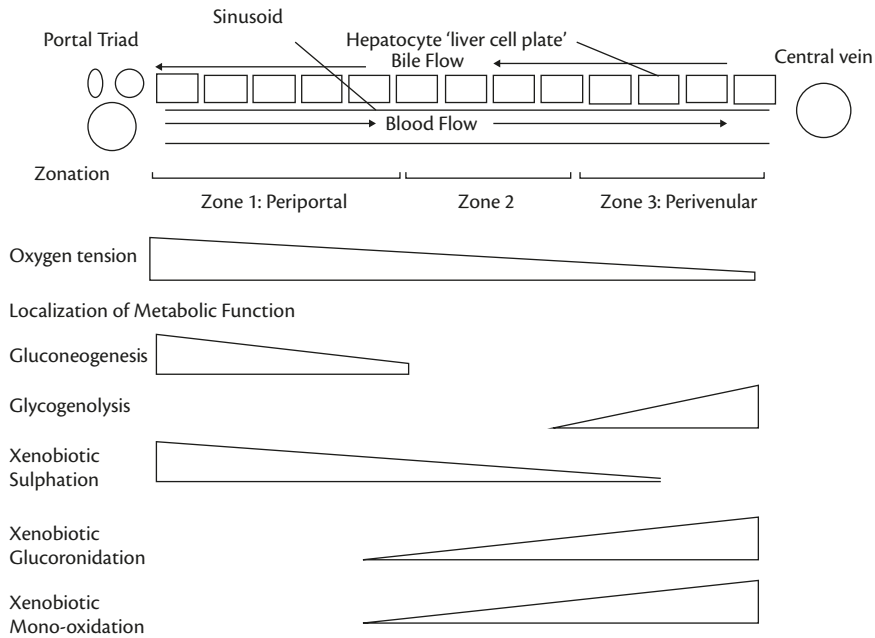

Fig. 173.4 Hepatocyte zonation.
Hepatocytes exhibit marked metabolic heterogeneity or 'zonation' along the liver cell plate, in part reflecting unidirectional perfusion of oxygen and metabolic substrates. Zone I hepatocytes are specialized for oxidative liver functions, while glycolysis, liopgenesis and xenobiotic oxidation is concentrated in perivenular or 'zone 3' hepatocytes. This area is predisposed to toxicity from reactive oxygen intermediates.

Table 173.1 Examples of hepatic acute phase reactants

Name	Function
Positive: increased synthesis	
C-reactive protein	Opsonization, complement activation
Serum amyloid A protein	Immune cell recruitment
Complement proteins	Opsonization, chemotaxis, cell lysis
Mannose binding protein	Complement activation
Alpha-2-macroglobulin	Protease inhibitor: fibrinolysis, coagulation
Hepcidin	Regulation of plasma iron levels
Ferritin	Iron binding
Haptoglobin	Haem-binding
Ceruloplasmin	Copper and iron binding
Alpha-1-antitrypsin	Inflammatory protease inhibitor
Negative: reduced synthesis	
Albumin	Amino acid preservation
Transferrin	Amino acid preservation
Antithrombin	Protease inhibitor; coagulation

changes in circulating and functional levels of immunologic, transport, and coagulation proteins (Table 173.1). APR proteins include anti-infectious agents (such as complement components, C-reactive protein (CRP) and serum amyloid P (SAP)), as well as proteins that promote increased breakdown of lipids and glycogen, fatty acid synthesis, and gluconeogenesis, and coagulation-modulating factors [5,6].

The detoxification functions of the liver are of great clinical relevance in relation to the processing and disposal of endogenous metabolites and toxic compounds of both endogenous and exogenous origin. Intact hepatic urea synthesis is required for the disposal of ammonia, the toxic end-product of nitrogen metabolism. Hyperammonaemia may result in encephalopathy, and is indicative of critically impaired hepatocellular function and/or abnormal portosystemic shunting.

The liver serves as the major site of drug metabolism and excretion; consequently, it is a frequent site of both idiosyncratic and dose-related adverse drug reactions. Alteration in hepatic metabolic function as a consequence of age, gender and hepatic disease may dramatically affect drug clearances with unpredictable therapeutic consequences.

Drug uptake into hepatocytes is followed by metabolism by several families of enzymes. 'Phase 1' reactions of oxidation or reduction may be followed by 'Phase 2' reactions conjugating often reactive intermediates to glucuronic acid, glutathione, sulphate, or acetate. Hepatically bio-transformed drugs may either be transported to sinusoidal blood for eventual urinary excretion, or into bile. Conjugate excretion may be through active molecular transport. Genetic variation in bio-transforming and transporter proteins contributes to the highly complex inter-individual differences in responses to drugs and other xenobiotics.

Bile formation is a highly complex process, resulting in the production of 500 mL of bile each day in adults. Bile serves both excretory and digestive functions. Its constituents reflect the complex transport mechanisms associated with the sinusoidal plasma membranes. It is composed of water, inorganic electrolytes, and organic solutes including bile acids, cholesterol, and phospholipids and bile pigments. Biochemical evidence of cholestasis is a frequent finding in critical illness, and results most commonly from functional changes relating to sepsis and medication including parenteral nutrition rather than overt mechanical biliary obstruction.

PART 6.2

Gastrointestinal monitoring

CHAPTER 174

Imaging the abdomen in the critically ill

Imran Khalid Niazi and Navin Ramachandran

Key points

- Haemodynamic stability remains the single most important deciding factor in the choice for imaging modality used. Initial resuscitation is the priority and should never be delayed for any radiological investigation.
- Each individual scan should be tailored to the patient's clinical history and examination findings.
- Plain film and ultrasound scans are the first-line investigations in most unstable patients.
- CT remains the ideal investigation in haemodynamically stable patients.
- Magnetic resonance imaging has a limited role at present, but may be of value, particularly in children and pregnant patient.

Introduction

Abdominal evaluation of the critically-ill patient is challenging. The patient may have a vague presentation, sometimes with a poor clinical history, few localizing signs, multiple co-morbidities and multi-organ involvement. Often the patient will require resuscitation prior to diagnostic workup, and support devices such as mechanical ventilators and haemofilters may hamper assessment. Indeed in one study, physical examination had a diagnostic specificity of only 45% in blunt abdominal trauma, while clinical signs were helpful in only 43–69% of cases of abdominal abscesses [1].

Such unreliability of clinical indicators and the myriad of abdominal pathologies in a critically-ill patient may lead to diagnostic uncertainty with consequent delays in treatment. These challenges make imaging one of the most critical steps in the management of such patients.

The optimal imaging pathway should be sensitive, specific, and minimize delay in therapy, but should also account for the patient's clinical state and overall radiation dose. The following modalities have a role in abdominal evaluation of the critically ill.

Plain radiographs

Abdominal radiographs have a limited role in evaluation of the critically-ill patient. Supine and erect abdominal films may be useful to look for dilated bowel in intestinal obstruction. However, if the dilated loops contain fluid rather than air they may be missed on plain film. Furthermore, the exact site of obstruction is not usually obvious on plain film. Therefore, most patients will be further assessed with computed tomography (CT) if there is ongoing concern regarding obstruction.

Free intraperitoneal gas may also be evaluated. Erect chest X-rays are still the mainstay of initial investigation for suspected hollow viscus perforation, as small quantities of extra-luminal free gas may be seen beneath the diaphragm (Figs 174.1 and 174.2). To maximize sensitivity, the patient is sat upright for 10 minutes to allow free air to rise to the diaphragm. If the patient is not fit enough to be placed upright, decubitus abdominal films may be of value.

However, a negative plain film does not rule out perforation. Indeed, many surgeons prefer CT for its increased sensitivity, its ability to identify the site of perforation and to rule out occult sealed perforation. The higher radiation burden of CT should be, however, remembered.

In most other scenarios (e.g. abdominal sepsis) plain X-ray findings are non-specific and other modalities are suggested.

Ultrasound

Abdominal ultrasound is particularly useful as it is portable, cheap, and safe. Therefore, it may be used when:

- The patient cannot easily be transferred to the radiology department for more definitive tests such as CT or magnetic resonance imaging (MRI).

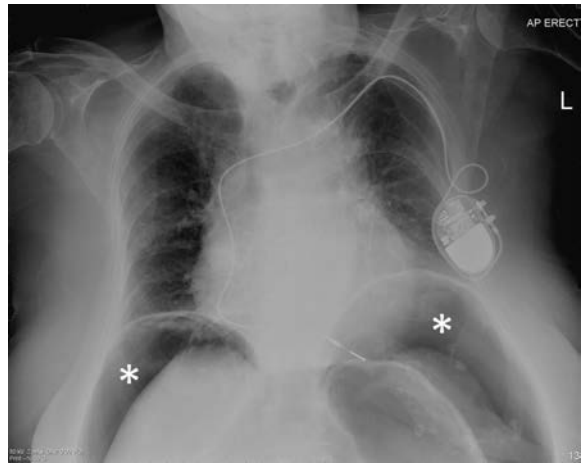

Fig. 174.1 Erect chest X-ray shows extensive free gas beneath the diaphragm (*) in a patient with large bowel perforation.

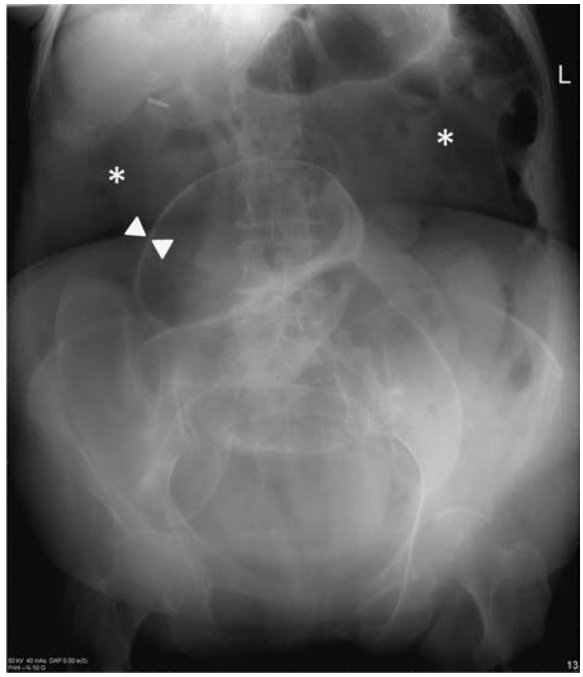

Fig. 174.2 Abdominal X-ray. Extensive pneumoperitoneum with free gas in the upper abdomen (*) and Rigler's sign (arrowheads, pointing out air on both sides of the bowel wall).

- The patient has already had multiple CTs, and ultrasound follow-up (if suitable) effectively reduces overall radiation dose to the patient. This may be particularly important in the younger patient.

Focused Assessment with Sonography for Trauma (FAST) has now become a standard investigation in the trauma patient. FAST is a bedside ultrasound examination focused on evaluation of free fluid in four areas—the 4P's—perihepatic, perisplenic, pelvis, and the pericardium. It is indicated in the unstable critical trauma patient group where detection of any free abdominal fluid will require an urgent laparotomy—any free fluid detected on FAST scan is considered haemorrhage until proven otherwise. Further evaluation with a CT in such a scenario may not be appropriate as it may delay urgently required treatment, unless the patient can be stabilized quickly. In one prospective study, FAST changed trauma patient management in 32.8% of cases, reducing the need for diagnostic peritoneal lavage (DPL) from 9–1 % [2].

Ultrasound is very useful in examining the liver and biliary tract. The commonest scenario is that of the patient with deranged liver function—ultrasound may be used to look for:

- Cholecystitis and its complications. Gall bladder wall thickening with or without adjacent fluid are seen most commonly. Conversely, suspected gall bladder inflammation on CT often requires confirmation with a subsequent ultrasound.
- Biliary tract obstruction with dilatation of the ducts. However, this often requires further evaluation with either CT or MRI to look for the site/cause of obstruction (often obscured by bowel gas on ultrasound) (Fig. 174.3).
- Generalized abnormalities of liver parenchyma such as cirrhosis, or focal lesions such as abscess.
- Occlusion of the portal or hepatic veins. This is not uncommon in the critically ill with abdominal sepsis.

Ultrasound is also used for guidance in abdominal drainage procedures, and for follow-up of fluid collections, e.g. abdominal abscesses, post-surgical collections, and even simple ascites.

Potential pitfalls of ultrasound are:

- **Operator dependence**: the operator should be adequately trained and accredited.
- Inadequate evaluation in the obese.
- **Inappropriate timing of the scan**: e.g. if performed too early in the post-trauma phase, the patient may have minimal intraperitoneal fluid despite widespread injury. Serial exams may help in this situation.
- **Poor localization of the site of injury**: this is the role of CT in the more stable patient where transfer to the scanner is possible.

Fluoroscopy

Fluoroscopy is not commonly used in assessment of critically-ill patients. Its predominant diagnostic role is in upper GI contrast studies to rule out post-operative anastomotic leakages (Fig. 174.4), evaluate bowel stent patency and evaluation of enteral feeding tubes. In many cases, it has now been replaced by CT.

Fluoroscopy is routinely used for guidance in various interventional procedures. Fluoroscopic-guided naso-enteral feeding tube

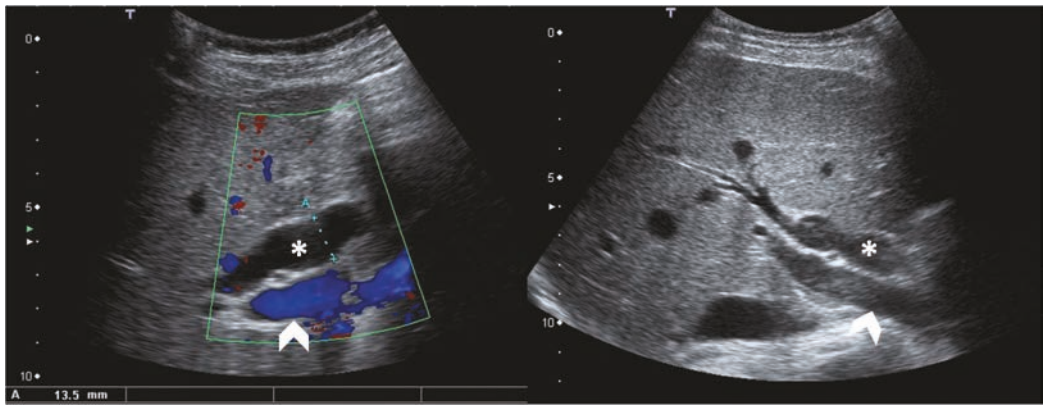

Fig. 174.3 Ultrasound of the biliary system shows common bile duct dilatation (*) with the normal adjacent portal vein (arrowhead).

Fig. 174.4 Spot fluoroscopy image of an upper GI contrast study in a patient post-bariatric gastric sleeve surgery. Contrast flows unimpeded down the oesophagus, through the reconstructed gastric tube and into the duodenal loop (arrows). Note leakage of contrast from the lateral border of the newly constructed gastric tube (arrowheads). Extraluminal contrast pools in the peritoneal cavity (*).

insertion has been proven to be safe, feasible, and accurate with reduced morbidity and higher caloric delivery for the patient [3]. Fluoroscopy also provides guidance in ERCP and other percutaneous biliary procedures, angiography and vascular embolization, and various urological interventions (percutaneous nephrostomies, ureteric stenting).

Computed tomography

CT remains the investigation of choice for most haemodynamically stable patients with suspected abdominal pathology. In the unstable patient it can be a viable option if deemed clinically important. Abdominopelvic CT can be performed under many different scan protocols, each tailored to the clinical question. Use of iodinated IV contrast is recommended in most circumstances and helps to optimize assessment of almost all abdominal pathologies. CT can be performed without IV contrast in patients with renal impairment or a definite history of contrast allergy. This however, significantly reduces the sensitivity and accuracy of disease assessment, often requiring augmentation with other imaging, usually ultrasound.

Scans can be performed at various phases of IV contrast enhancement:

- **Pre-contrast**: ideal for renal calculi or as a 'control' prior to administration of contrast, e.g. to look for subsequent enhancement or leak.
- **Arterial phase**: for arterial assessment in suspected ischaemic bowel or abdominal haemorrhage.
- **Venous phase**: this is the standard phase for CT scanning used in almost all abdominopelvic CTs and is ideal for visualization of solid viscera and most inflammatory conditions. Mesenteric and portal vein assessment is optimal in this phase.
- **Delayed phase**: used for urinary tract evaluation in suspected cases of urinary leakages/trauma, or for assessment of some liver and adrenal lesions.

Bowel-related inflammation such as appendicitis, diverticulitis, and inflammatory disease are usually well-identified on CT, most often with wall-thickening, adjacent fat-stranding and fluid.

Pancreatitis may be identified as thickening and adjacent fat-stranding (Fig. 174.5), as well as its associated complications such as necrosis, fluid collections, and vascular thrombosis/aneurysm formation. In cases of severe pancreatitis, patients may undergo several CTs over a few weeks. The overall radiation burden is thus potentially very high and other modalities such as US or MRI should therefore be considered.

As previously discussed, CT has a high sensitivity for hollow viscus perforation and bowel obstruction. CT is extremely sensitive at delineating intra-abdominal free or contained air (Figs 174.6 and Fig. 174.7)—as low as 0.3 mL of free air can be visible [4]. Furthermore, even smaller amounts of air (invisible on plain film) within the biliary tract, portal vein, or within the bowel wall (*pneumatosis intestinalis*) may be detected.

CT is invaluable in diagnosing abdominal sepsis/abscess. Abscesses are seen as low-density fluid collections with thick enhancing walls. IV contrast demonstrates this enhancement, helping to differentiate collections from free intra-abdominal fluid (Fig. 174.8). Oral contrast administration helps in differentiating these fluid collections from adjacent bowel loops and can also sometimes accurately localize a bowel leak or fistula. Post-operative bowel anastomotic leakages usually present as peri-anastomotic loculated fluid collections with air pockets [5].

CT angiogram has supplanted catheter angiography for assessment of mesenteric ischaemia and GI bleeding. This allows visualization of the mesenteric arteries and veins, and also assessment of bowel enhancement, pneumatosis, and portal venous air (poor prognostic indicators in ischaemia). For intestinal haemorrhage, it should only be used as an adjunct to upper and lower GI endoscopy, which remain the primary investigative tools. Such CTs should only

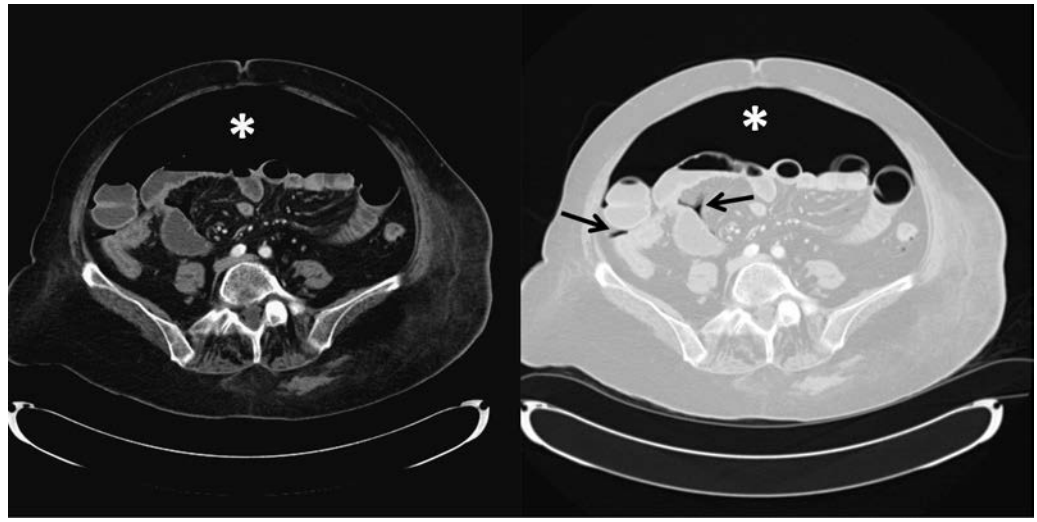

Fig. 174.6 Axial section of CT scan at level of aortic bifurcation in a patient with iatrogenic gastric perforation. Massive pneumoperitoneum with free intraperitoneal air (*) seen between the anterior abdominal wall anteriorly and the bowel loops posteriorly. The free gas is better seen on lung windows (image on the right, *) with locules of inter-bowel loop gas (arrows).

be performed in a clinically stable patient once initial resuscitation has been instituted. A CT angiogram will not be helpful in pinpointing very slow flow bleeding points—these do not usually show up. CT enterographic techniques described by Huprich et al. [6] in 2008 have a 45% active bleeding source detection rate for obscure gastrointestinal bleeding.

Overall, the effectiveness of CT in the management of the critically ill is well documented. Abdominal CT detected an abnormality in 58% of patients, while 69% of critically-injured patients admitted to the ICU with sepsis benefitted from a change in management after an abdominal CT scan [7]. In another prospective study [8], CT changed the management of 81% of critically-ill patients, with management being dependent solely on CT in 37.5% of the patients.

Fig. 174.7 Coronal section of a CT performed a patient with faecal peritonitis. Large amount of free fluid with numerous small air locules (white arrows). Note small air pockets along the inferior edge of the left hepatic lobe (black arrows).

Factors limiting the accuracy of CT include:

- **Patient body habitus**: unlike ultrasound, thinner patients often prove more challenging on CT as adjacent organs are not separated by the usual fat planes.
- **Breathing artefact**: most marked close to the diaphragms, though reduced in the newer, faster generation of CT scanners.
- **Artefact**: from metallic implants/foreign bodies or previous contrast investigations.

Radiation dose incurred by the patient should always be borne in mind when considering a CT scan. For example, multiphase scans should only be performed when needed (e.g. urograms in case of renal tract injuries and CT angiography for haemorrhage and vascular trauma). This is particularly important in paediatric or pregnant patients, where ultrasound is the front-line imaging modality.

Magnetic resonance imaging

MRI has a limited role in evaluation of the abdomen in critically-ill patients. It is often a second-line study when the initial test is inconclusive, e.g. MR cholangiopancreatography (MRCP; Fig. 174.9) or MR small bowel following USS and/or CT. MRI is also used commonly as a second-line investigation in pregnant patients and children after initial ultrasound assessment.

Factors limiting MRI use include:

- Long scan times, which can be a limiting factor in critically-ill patients.
- Increased breathing and movement artefacts compared to CT.
- Limited out-of-hours availability.
- Contraindicated with metallic implants (e.g. pacemakers, foreign bodies, prosthesis), especially if surgery was recent.

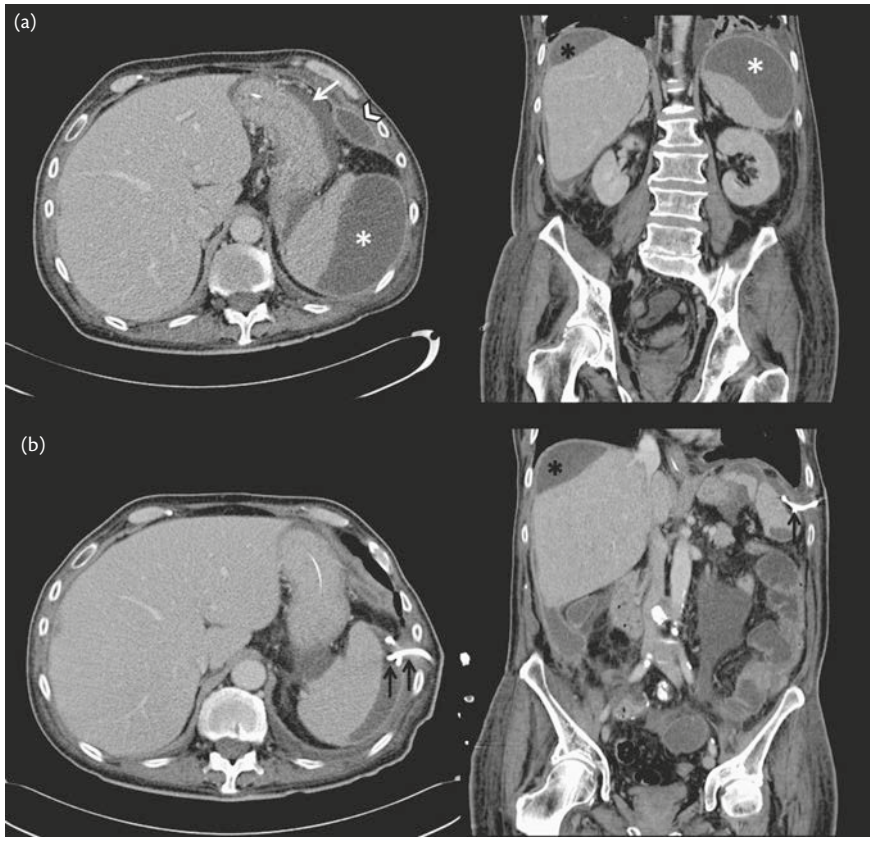

Fig. 174.8 (a) Axial and coronal CT sections of an ICU patient with anastomotic leak after right hemicolectomy. Note the walled-off left subphrenic abscess (*) adjacent to the spleen. Another smaller right subphrenic collection also seen (black *). A small rim of free ascites is seen around the greater curve of the stomach (white arrow). (b) Post-catheter drainage of the left subphrenic abscess—the collection has reduced significantly with a drain *in situ* (black arrows). Note the right subphrenic collection (black *) has slightly increased and subsequently drained.

- Contraindicated in the first trimester of pregnancy (unknown magnetic effect on fetal development), and gadolinium MRI contrast should be avoided if possible throughout pregnancy (again unknown effect on fetus).
- Gadolinium MRI contrast is contraindicated in renal failure (risk of nephrogenic systemic fibrosis).

As scan times are reduced with newer scanners and out-of-hours availability improves, MRI promises to play an increasing role in imaging.

Conclusion

The choice of abdominal imaging in the critically-ill patient is most dependent on the stability of the patient. In unstable patients, initial resuscitation is the priority and only portable radiographs or perhaps portable ultrasound may be possible. As transfer may be extremely hazardous CT scanning is only performed once haemodynamic stability is achieved, or unless management cannot further progress without it [9]. Stable patients may be mobilized for

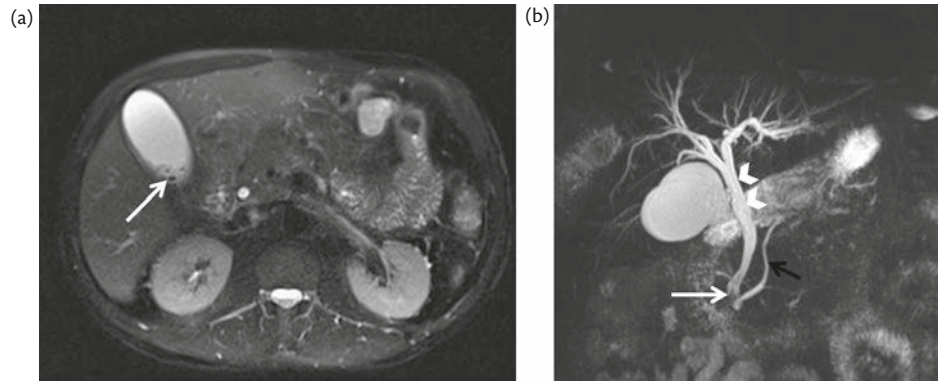

Fig. 174.9 (a) Axial T2 MRI through the gall bladder. Multiple tiny rounded areas of signal loss represent gall bladder calculi (white arrow). (b) MIP Slab MRCP shows the whole biliary tree with mildly dilated common bile duct (arrowheads) and intrahepatic channels, with a calculus in the distal common bile duct (white arrow). Pancreatic duct appears normal (black arrow).

more definitive scans. Apart from biliary pathologies for which ultrasound remains the first choice, CT is the mainstay for imaging in a stable patient. CT allows adequate evaluation for abdominal sepsis, trauma, perforation, inflammatory conditions such as pancreatitis and intestinal haemorrhage.

CHAPTER 175

Hepatic function in the critically ill

Andreas Kortgen and Michael Bauer

Key points

- Hepatic dysfunction is a common problem in the critically ill.
- Inflammatory processes such as sepsis or pancreatitis, ischaemia/reperfusion phenomena, or tissue damage in trauma or surgery may lead to a hepatic stress response.
- Due to the multiple complex functions of the liver, no single test can determine hepatic function as a whole.
- Conventional laboratory measurements, such as enzyme levels, can be useful tools for diagnosis and differential diagnosis of hepatic diseases.
- While conventional markers appear to have advantages in predicting the course of dysfunction in chronic liver disease, especially combined with scoring systems, 'dynamic' quantitative liver function tests are especially useful in assessing hepatic function in the critical care setting.

Introduction

Parenchymal as well as non-parenchymal cells contribute to the manifold hepatic functions of metabolism, synthesis, detoxification, excretion, and the host response, making the liver a crucial organ in the critically ill. The liver is not only a target in multi-organ dysfunction. Liver dysfunction can also lead to further remote organ failure as can be best seen in patients with acute or chronic liver failure, where hepatic encephalopathy, hepatorenal syndrome, and cardiomyopathy are common events. In critical care patients liver dysfunction is an often-underestimated problem in frequency and severity as scoring systems, e.g. the Sequential Organ Failure Assessment (SOFA) score focus on single conventional laboratory parameters, in this case, bilirubin [1]. Using quantitative liver function tests, an incidence of hepatic dysfunction in critical care patients of over 50% is described.

Physiology and pathophysiology of liver blood flow

A quarter of cardiac output is delivered to the liver, making it one of the best-perfused organs. About 70% of liver blood flow is contributed by the portal vein, thus exceeding blood flow via the hepatic artery. Nevertheless, due to partial deoxygenation of portal blood during passage through the splanchnic bed, the contribution of both vessels to hepatic oxygen delivery is almost equal. However, proportions of blood flow via hepatic artery and portal vein may differ substantially, e.g. depending on food intake.

Terminal portal venules and hepatic arterioles are controlled by the autonomic nervous system. In addition, intrinsic factors regulate liver blood flow, changes in portal vein flow lead to contrary changes in hepatic artery flow (hepatic arterial buffer response) while an increase in portal vein pressure leads to an increased vascular resistance of splanchnic vessels (veno-arterial response). All these regulatory mechanisms may be impaired under pathophysiologic conditions. Furthermore, sinusoidal perfusion can be regulated by gradual contraction of sinusoids through perisinusoidal cells. Altogether, failure of these mechanisms may lead to (functional) shunting with impaired regional perfusion and oxygen delivery. This may sometimes occur even when global oxygen delivery to the liver is sufficient. Hepatocellular damage then occurs, most frequently in the pericentral region where oxygen supply is already reduced under physiologic conditions.

Acute phase response and altered gene expression

Inflammatory processes such as sepsis or pancreatitis, ischaemia/reperfusion phenomena, or tissue damage in trauma or surgery may lead to a hepatic stress response. Many key enzymes of metabolic pathways reveal an altered gene expression pattern in such situations. This 'acute phase' response leads to either increased synthesis of, for example, C-reactive protein and fibrinogen (positive acute phase proteins) or, on the other hand, to suppressed protein synthesis, e.g. albumin (negative acute phase protein). Modulation of hepatocellular gene expression and metabolism are influenced by inflammatory mediators released in part by macrophages (Kupffer cells) located within the liver.

Excretory dysfunction

Sepsis-associated cholestasis is a common problem in intensive care unit (ICU) patients, and one of the leading causes of jaundice in hospitalized patients. Hepatocellular excretory dysfunction may be due to altered blood flow and, in particular, to altered transmembrane transport. Many basolateral and canalicular transport proteins are down regulated in the critically ill. In combination with altered gene expression of enzymes of phase I and II metabolism, this may lead to profound changes of endo- and xenobiotic detoxification. In addition to these hepatocellular alterations, ductular

cholestasis may also appear. While hepatocellular impairment is, in principle, fully reversible, ductular damage of epithelium may lead to persistent alterations, up to secondary sclerosing cholangitis [1].

Diagnostic assessment

Due to the multitude of hepatic functions, no single test can provide a sufficient overview of the liver as a whole. If anything, liver assessment comprises a portfolio of different tests. Conventional 'static' laboratory measures include, for example, more or less specific liver enzymes, coagulation factors, albumin, and bilirubin [2,3]. By contrast, quantitative liver function tests assess specific partial liver functions at the time of testing. Such 'dynamic' tests can estimate clearance capacities and metabolic functions of the liver [1].

Conventional laboratory measures

Several laboratory measures are routinely used to evaluate hepatic function and impairment, e.g. plasma concentrations of liver enzymes [3]. These enzymes can be divided into two main groups:

- Those indicating hepatocellular damage such as transaminases.
- Those reflecting cholestasis and damage of bile epithelia, such as alkaline phosphatase or γ-glutamyltransferase (GGT).

They have discrete distributions in different tissues, are measurable in blood under normal physiological conditions, and do not represent measures of liver function.

Aspartate aminotransferase (ASAT) is produced in many different organs including liver, heart, brain, pancreas, kidney, and lung, and in white and red blood cells. Its intracellular location is both cytosolic and mitochondrial. By contrast, alanine aminotransferase (ALAT) is a liver-specific enzyme located almost exclusively within the cytosol. Glutamate dehydrogenase is located within mitochondria, predominately in the pericentral region of the liver lobuli, i.e. the boundary zones of the liver. Although it is a ubiquitous enzyme, measurable increases are solely due to hepatocellular necrosis. GGT is located at the cytosolic membrane. Measurable elevations are usually due to liver or biliary tract injury, e.g. different cholestatic diseases or in alcohol- or drug-induced injury. Elevated values of alkaline phosphatase can be found in hepatobiliary diseases, bone diseases, and malignant tumours.

Measures of synthetic liver function include albumin, cholinesterase, standard coagulation tests, e.g. prothrombin time, international normalized ratio (INR), or individual coagulation factors. While plasma or serum concentrations of these biochemical measures can reflect loss of functional hepatocytes in chronic liver disease, they have major limitations in acute care. This may be related to a long half-life, e.g. for cholinesterase. In addition, the mentioned acute phase response is accompanied by a profound reprogramming of gene expression and thus liver synthesis, leading to hypoalbuminaemia and other protein deficiencies. Blood loss and activation of the coagulation system may impair the corresponding tests. Furthermore, many critical care interventions, such as transfusion of albumin and plasma preparations, or anticoagulation therapy (e.g. with argatroban), can lead to iatrogenic changes in the previously mentioned measures.

Bilirubin is formed during degradation of haem derived predominantly from the haemoglobin within erythrocytes. Bilirubin is transported to the liver bound to albumin, where it is taken up into hepatocytes by membrane transporters and then conjugated with glucuronic acid. Water-soluble glucuronized bilirubin is then excreted into bile in an ATP-dependent process (Fig. 175.1). Elevated serum/plasma bilirubin levels can be due to prehepatic causes such as haemolysis with predominantly unconjugated bilirubin, or intra- and post-hepatic causes with a predominantly conjugated hyperbilirubinaemia. Typically, critically-ill patients with jaundice have a conjugated hyperbilirubinaemia. In an Austrian survey, about 11% had elevated bilirubin levels (>2 mg/dL [34 μmol/L], SOFA liver subscore ≥2) within 48 hours of ICU admission [2]. This was an independent risk factor of mortality. Nevertheless, bilirubin as a marker for liver dysfunction in ICU patients has limitations, for example, turnover of haem and liver function may be altered concurrently.

In summary, conventional ´static´ liver measures can yield valuable diagnostic data. In critically-ill patients, however, these have limitations, especially when rapid changes of liver function and perfusion occur. On the other hand, they are advantageous in assessing the prognosis of chronic liver diseases, especially when used in combination with scoring systems such as the model for end-stage liver disease (MELD) Score or the Child–Turcotte–Pugh (CTP) Score (Table 175.1 and Box 175.1) [4]. However, there is still an ongoing search to improve these scores, e.g. incorporating sodium values in the MELD-Score to generate a MELDNa Score which led to an improved prediction of outcome [1].

Liver function tests

Dynamic quantitative liver function tests assess current liver function with respect to the ability of the liver to eliminate and/or metabolize a specific substance. Values of these tests generally depend upon the specific hepatic function being measured and on functional liver blood flow. Many of these tests have profound limitations in the ICU patient with respect to practicability, i.e. logistic effort, staff expenditure, and duration. Suitable tests for daily clinical practice are the MEGX (monoethylglycinexylidide) test, assessment of indocyanine green elimination and, probably, a recently introduced methacetin breath test [1].

For the MEGX-Test lidocaine 1 mg/kg is administered intravenously. Lidocaine is metabolized in hepatocytes by the cytochrome P450 enzyme CYP3A4 to MEGX (Fig. 175.1). At 15 and/or 30 minutes after injection blood samples are drawn to measure MEGX concentrations by HPLC or GLC. When evaluating the MEGX test result, any confounding influence of drugs that inhibit or induce CYP3A4, or that are simply metabolized by CYP3A4, must be taken into account. Healthy volunteers have gender-specific differences of MEGX production. In addition, lidocaine may cause major side-effects. Nevertheless, the MEGX test result does prognosticate in critical care patients.

Indocyanine green (ICG) is an anionic, infrared absorbing dye. After intravenous application ICG is bound to plasma proteins, most notably albumin and α_1-lipoprotein, and is taken up nearly exclusively into hepatocytes by basolateral transport proteins. Without transformation it is excreted into bile by multidrug resistance protein (MDR)-3, an ATP-dependent transport protein (Fig. 175.1). There is no enterohepatic recirculation. The plasma disappearance rate of ICG (PDR_{ICG}) can be non-invasively assessed at the bedside with a transcutaneous finger probe. For pulse densitometry measurement, a bolus of 0.25–0.5 mg/kg body weight ICG

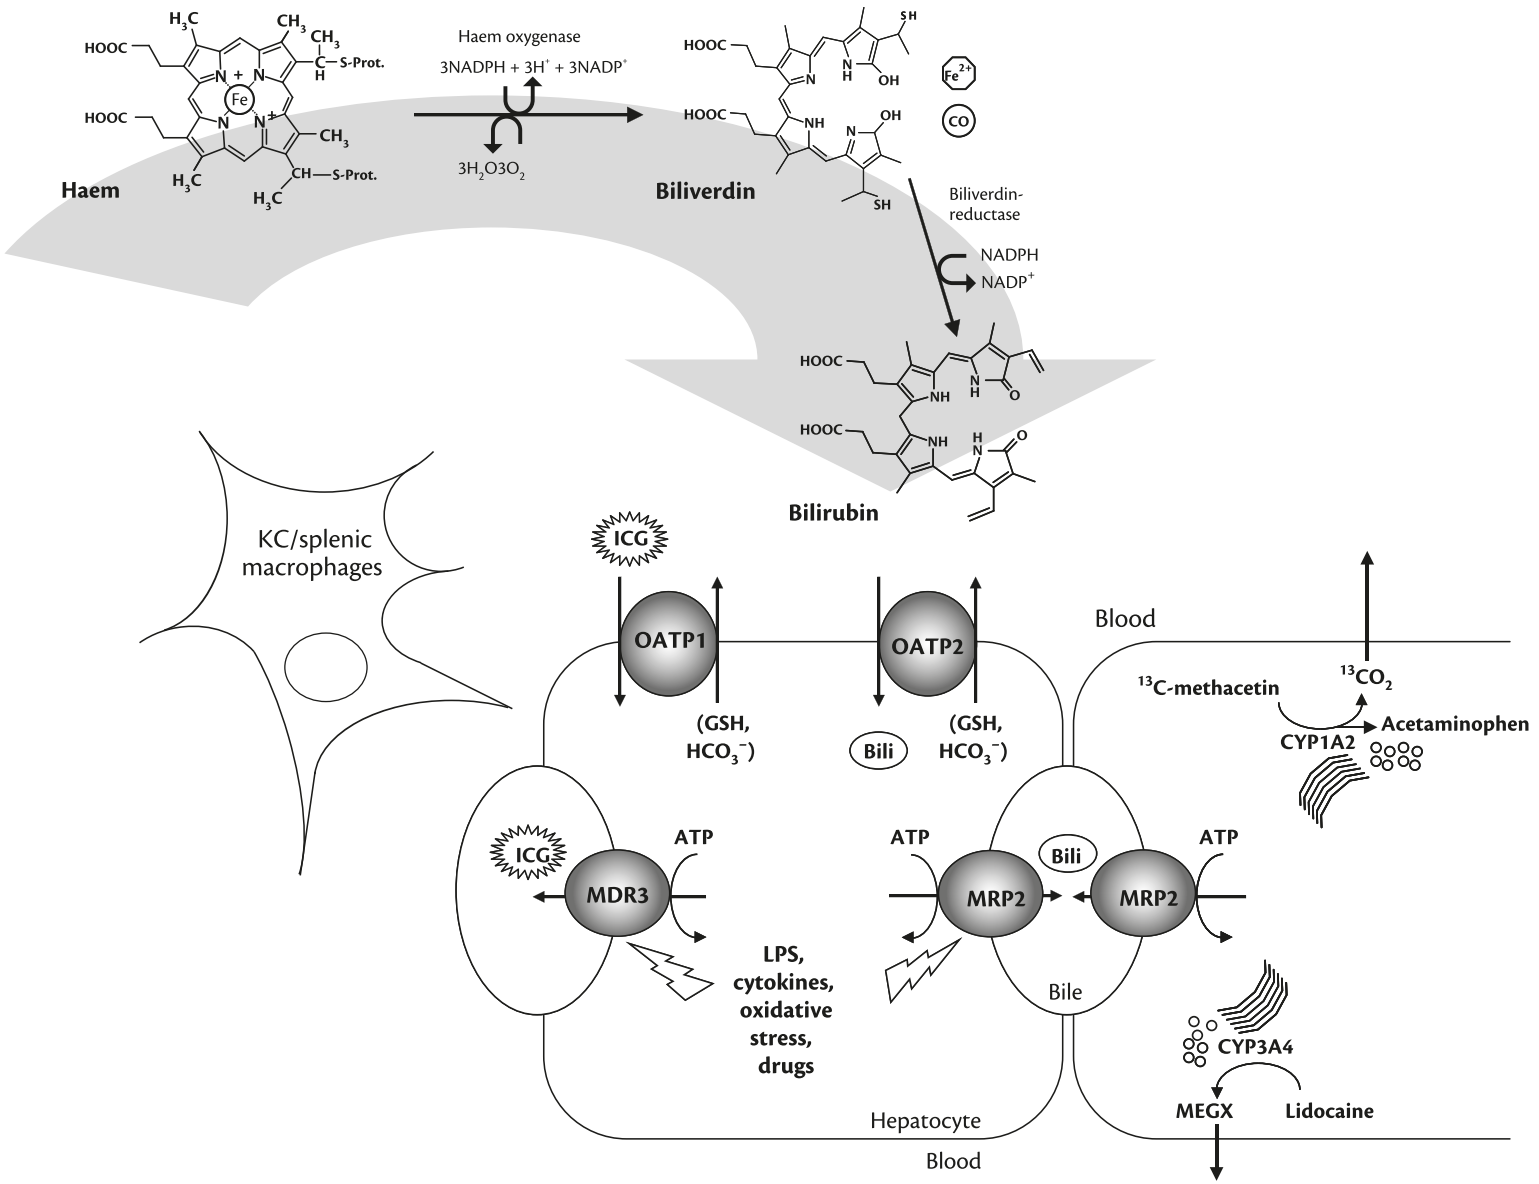

Fig. 175.1 Molecular mechanisms of some examples of hepatic function tests. Haem, for example, derived from breakdown of haemoglobin is degraded to biliverdin and further to bilirubin under the catalytic influence of haem-oxygenase and biliverdin reductase. This degradation primarily takes place in spleen and hepatic macrophages (Kupffer cells) for senescent erythrocytes, and in hepatocytes for free or haptoglobin-bound haem. Due to variable amounts of haem, multiple conversion steps and alterations in hepatocellular function, bilirubin displays an overall slower and less predictable kinetic than the xenobiotic ICG. The MEGX- and ^{13}C-methacetin breath tests measure the function of specific cytochromes involved in xenobiotic metabolism.

GSH, glutathione; ICG, indocyanine green; KC, Kupffer cell; LPS, lipopolysaccharide; MDR, multidrug resistance protein; MRP, multidrug resistance-associated protein; OATP, organic anion transporting polypeptide; CYP, cytochrome P450; MEGX, monoethylglycinexylidide.

Data from various sources (see references).

Table 175.1 Child–Turcotte–Pugh Score

Score	1	2	3
Bilirubin [mg/dL] ([μmol/L])	<2 (<34)	2–3 (34–51)	>3 (>51)
Albumin [g/dl]	>3.5	2.8–3.5	<2.8
INR (prothrombin time [s] prolonged)	<1.7 (<4)	1.7–2.3 (4–6)	>2.3 (>6)
Ascites	Absent	Slight	Moderate
Hepatic encephalopathy	Absent	I–II°	III–IV°

Single score values are summed up and grouped as:

Child class A: 5–6, compensated disease, 1-year survival rate about 100%.

Child class B: 7–9, significant functional impairment, 1-year survival rate about 80%.

Child class C: 10–15, decompensated disease, 1-year survival rate about 45%.

Reproduced from Pugh RNH et al., 'Transection of the oesophagus for bleeding oesophageal varices', *British Journal of Surgery*, **60**(8), pp. 646–9, with permission from John Wiley and Sons. Copyright © 1973 British Journal of Surgery Society Ltd.

Box 175.1 Model for Endstage Liver Disease (MELD) score

$$\text{MELD Score} = 10 \times (0.378 \times \log_e(\text{bilirubin in mg / dL}) + 1.12 \times \log_e(\text{INR}) + 0.957 \log_e(\text{creatinine in mg / dL}) + 0.643) \quad \text{[eqn B1.1]}$$

Calculated values are rounded to integers and range from 6 to 40. Higher calculated values are set to 40. Measured laboratory values <1 are set to 1. Maximum value of creatinine is 4. In patients with a need for intermittent dialysis on two occasions, or for continuous renal replacement therapy for >24 hours during the last week, creatinine values are set to 4. Patients must be at least 12 years old. For younger patients a paediatric score (PELD) is used.

Predicted 3-month-mortality rates:

- **MELD score 6:** 1.9%
- **MELD score 20:** 11%.
- **MELD score 30**: 49%.
- **MELD score 40**: 98%.

Reproduced from Kamath PS and Kim WR, 'The model for end-stage liver disease (MELD)', *Hepatology*, **45**(3), pp. 797–805, with permission from John Wiley and Sons. Copyright © 2007 American Association for the Study of Liver Diseases.

is given intravenously. Normal values of PDR_{ICG} range from 18 to 25%/min. The retention rate of ICG after 15 minutes (R15, normal range 0–10%) is another parameter of ICG elimination reflecting similar information [1].

PDR_{ICG}/R15 measurements have been evaluated in major hepatobiliary surgery including liver transplantation, as well as in non-hepatic surgery (e.g. cardiac surgery) and in the critical care setting [4]. In liver transplant recipients, perfusion disorders or episodes of rejection are reflected by an impaired PDR_{ICG}. In both liver resection and after cardiac surgery, a reduced ICG elimination was associated with higher morbidity and a prolonged length of ICU stay. Its prognostic value was also demonstrated in septic patients and a mixed cohort of ICU patients. PDR_{ICG} may be reversibly reduced in obstructive jaundice. While a reduced PDR_{ICG} still leaves uncertainties regarding sinusoidal hypoperfusion and true hepatocellular dysfunction, normal values make such disturbances unlikely. Rapid changes within a few hours are likely to reflect changes in perfusion. However, measured values may still underestimate the true impairment of canalicular excretory function.

Another recently introduced bedside test is the ^{13}C-methacetin breath test. ^{13}C-methacetin is metabolized in hepatocytes by the cytochrome P450 isoform 1A2 (CYP1A2) to paracetamol and ^{13}C-labeled carbon dioxide (Fig. 175.1) that can be measured in the exhaled breath. ^{13}C-methacetin 2 mg/kg is given intravenously and the $^{12}C/^{13}C$ ratio is measured by an isotope-selective monitor in expired air from 10 minutes pre-injection until 1 hour post-injection to assess the maximum values of exhaled $^{13}CO_2$. Carbon dioxide production is assumed to be 300 mmol/hour/m^2. Results represent the maximum capacity of methacetin metabolism if turnover is saturated. Normal values are >315 μg metabolized methacetin/hour/kg body weight. Results can be influenced by increased overall metabolism and food intake. Several drugs can also inhibit/induce production or are also metabolized by CYP1A2, potentially influencing test values. The test is being evaluated in patients after hepatic resection or liver transplantation as well as septic patients, and seems to reflect liver dysfunction in both the early post-operative course and in sepsis.

Conclusion

Hepatic dysfunction is an underestimated problem in critical care patients. Manifold partial functions require a portfolio of different liver tests to get an overview of hepatic function. Quantitative 'dynamic' liver functions test add substantial information and may help to guide therapy especially in the dynamic course of critically-ill patients [1].

PART 6.3

Gastrointestinal haemorrhage

CHAPTER 176

Pathophysiology and causes of upper gastrointestinal haemorrhage

Tasneem Pirani and Tony Rahman

Key points

- Thorough history and examination is key for accurate diagnosis pre-endoscopy.
- Upper gastrointestinal haemorrhage may be oesophageal or gastroduodenal in origin.
- Peptic ulcer disease (PUD) is the most common cause of upper gastrointestinal haemorrhage.
- Gastric protection should be considered in high risk patients using non-steroidal anti-inflammatory agents.
- *Helicobacter pylori* testing and treatment is recommended for anyone with PUD.

Introduction

Causes of upper gastrointestinal haemorrhage (UGIH) can be described according to the underlying pathophysiology. Older studies reported an incidence of peptic ulcer disease (PUD) at endoscopy as high as 50%. More recent studies show that it remains the most common diagnosis, accounting for approximately a third of cases, with gastric ulcers being more common than duodenal ulcers [1].

Detailed history and clinical examination at the time of presentation with UGIH is invaluable in providing clues as to the cause of the bleeding and appropriate management. Table 176.1 summarizes some of the diagnoses that should be suspected on the basis of clinical history and examination.

Causes classified anatomically

Oesophageal

Inflammation and ulceration of the oesophagus is caused by exposure to gastric acid. This may be exacerbated by increased production of acid, stress, drugs, and Zollinger–Ellison syndrome. Incompetence of the lower oesophageal sphincter due to the presence of a hiatus hernia, medication that cause relaxation of the physiological sphincter, delayed gastric emptying and nasogastric tubes all lead to increased acid exposure. Bleeding from this region is usually diffuse. Oesophageal varices in patients with portal hypertension can cause massive haemorrhage. Portal hypertension leads to development of collateral vessels that divert blood to the systemic circulation. These collateral vessels form by opening and dilating existing vascular channels. Oesophageal varices are such portosystemic collaterals and should be suspected in patients with cirrhosis.

Oesophagitis from other causes such as candidiasis or herpes simplex infection may cause pain, dysphagia, and bleeding. These causes should be suspected in immunocompromised individuals and require appropriate antifungal, antiviral, and acid suppression therapies.

A history of protracted or violent retching and, subsequently, haematemesis suggests a possible Mallory–Weiss tear at the oesophagogastric junction. This linear tear is thought to arise from a rapidly occurring and transient transmural pressure gradient.

Gastro-intestinal malignancy may lead to haemorrhage from the ulcerating lesion itself, or following invasion of submucosal vessels causing either or both haematemesis and melena. These may halt spontaneously or require therapies such as argon plasma coagulation (APC), laser coagulation, or even surgery.

Gastroduodenal

A clinical history of abdominal pain, antacid use, weight loss, regular use of non-steroidal anti-inflammatory agents (NSAIDs) or aspirin may point towards gastric or PUD.

NSAID-induced injury results from both local effects and systemic prostaglandin inhibition. Symptomatic PUD caused by exposure to NSAIDs is mainly a consequence of systemic (post-absorptive) inhibition of gastrointestinal mucosal cyclo-oxygenase (COX) activity. Healthy gastric and duodenal mucosa use COX-1 to produce mucosal-protective prostaglandins [2]. These prostaglandins not only reduce acid secretion, but also stimulate bicarbonate secretion in addition to other cytoprotective mechanisms. Gastrointestinal toxicity from NSAIDs is higher in older patients, particularly if there is a prior history of ulcer disease, use of dual antiplatelet therapy, or when NSAIDs are used with concomitant anticoagulant therapy [3]. In such cases, gastroprotection with a proton pump inhibitor (PPI) is often used.

Selective serotonin reuptake inhibitor (SSRI) use also increases the risk of UGIH, whether used alone or in combination with NSAIDs [4]. This is likely related to inhibition of platelet aggregation.

Helicobacter pylori is implicated in duodenal ulceration and is a recognized carcinogen for gastric carcinoma [5]. The risk of

Table 176.1 Likely sources of bleeding based on history and examination findings

Clues from history and examination	Cause of bleeding
Stigmata of chronic liver disease: spider naevi, clubbing, palmar erythema, jaundice, encephalopathy, ascites, cachexia, cirrhosis alcoholism, chronic viral hepatitis, and all causes of non-cirrhotic portal hypertension	Portal hypertensive gastropathy, varices, and coagulopathy
Protracted retching, alcoholic binge, a period of emesis preceding haematemesis	Mallory–Weiss tear
Weight loss, anorexia, dysphagia, early satiety, and abdominal mass	Malignancy
Abdominal pain, regular use of NSAIDs or aspirin, heart burn, smoking, and *Helicobacter pylori*	Peptic ulcer disease
Prescribed immunosuppressant, diabetes, HIV, heartburn, regurgitation, and odynophagia	Oesophagitis, oesophageal candidiasis, oesophageal ulceration
Hereditary haemorrhagic telangiectasia, aortic valve replacement, and chronic renal failure	Angiodysplasia
Previous aortic aneurysm repair, infected aortic graft, palpable pulsatile abdominal mass, and fistulating disease (e.g. Crohn's Disease)	Aorto-enteric fistula
Known pancreatic or hepatic malignancy, and coagulopathy	Local invasion of duodenum, haemobilia
ICU admission, multi-organ failure and inotrope requirements	Stress ulceration

uncomplicated PUD is significantly higher among NSAID users who are also positive to *H. pylori* [6]. Diagnosis of duodenal ulceration should be followed by empirical *H. pylori* eradication with 'triple or quadruple therapy'. This consists of a PPI and 2 or 3 antibiotics given over 1–2 weeks. The choice of antibiotics should take into account local antibiotic resistance patterns and any history of antibiotic allergy. PPI therapy may lead to false negative results with Helicobacter stool antigen tests and rapid urease tests on gastric biopsy samples.

Stress ulceration commonly occurs in critically unwell patients and those in multi-organ failure. Transient ischaemic insults to the gastric mucosa lead to inflammation, erosions, and ulceration. Classically, this affects the antrum and may appear as gastritis with erosions or ulcers. Endoscopic treatment may be required if a specific source of bleeding has been identified. In the case of more generalized gastritis or duodenitis, acid suppression therapy is required. Nasogastric feeding is protective. These lesions resolve as the patient recovers.

Risk factors in intensive care patients include mechanical ventilation, renal replacement therapy, thrombocytopenia or other coagulopathy, and administration of aspirin, clopidogrel or other anticoagulant therapies [7]. Prophylaxis in the form of H_2 receptor antagonists, or PPIs are routinely used. Prophylaxis may however, increase the risk of ventilator-associated pneumonia and *Clostridium difficile* diarrhoea, and may even affect iron absorption.

Gastric and ectopic varices as a consequence of cirrhosis and portal hypertension, or as a result of splenic vein thrombosis following pancreatitis, can lead to life-threatening haemorrhage. Clinical suspicion should be high when faced with a patient with an appropriate history and clinical examination. Diffuse gastric ooze secondary to portal hypertensive gastropathy may also present with UGIH. Management is focused on correcting coagulopathy and blood transfusion.

Angiodysplasia is the acquired degenerative dilatation of normal blood vessels that can be found anywhere throughout the gastrointestinal tract. They are seen as isolated, tortuous, thin-walled vessels that either cause occult bleeding and present with anaemia, or cause overt UGIH. Gastric antral vascular ectasia (GAVE), also known as watermelon stomach, is a condition where prominent erythematous streaks traverse the antrum and converge on the pylorus. These usually present with recurrent anaemia. Conditions associated with GAVE include connective tissue disorders, particularly scleroderma, portal hypertension, chronic renal failure, and bone marrow transplantation.

Aorto-enteric fistulae may occur in the presence of previous aortic aneurysm repair, aortic stent insertion, the use of aortic balloon pumps, and other fistulating diseases such as Crohn's disease. This can cause catastrophic bleeding requiring surgical intervention. Zollinger Ellison syndrome (hypergastrinaemia) is another rare cause of UGIH, presenting with weight loss, abdominal pain, and diarrhoea. It should be suspected in cases where multiple ulcers are seen, or when ulcers fail to heal despite optimal therapy.

Dieulafoy lesions are dilated aberrant submucosal vessels that erode the overlying epithelium in the absence of an ulcer. They are approximately 10 times the normal calibre of mucosal capillaries, and are typically located within 5 cm of the oesophagogastric junction. Bleeding is often self-limiting, but can be significant. The bleeding site is often difficult to locate in the absence of active bleeding.

Knowledge of the possible causes of UGIH and the associated risk factors allows the clinician to manage their patients holistically to reduce further risk.

CHAPTER 177

Diagnosis and management of upper gastrointestinal haemorrhage in the critically ill

Tasneem Pirani and Tony Rahman

Key points

- Detailed history and examination may indicate the cause of bleeding and direct management.
- The patient should be resuscitated and stabilized prior to endoscopy.
- Scoring systems can be used to guide the urgency for endoscopic therapy.
- Initiation of pre-endoscopy proton pump inhibitors (PPI) is not routinely recommended.
- Routine re-scoping at 24 hours is reserved for cases where initial endoscopy is considered suboptimal, or in cases where rebleeding is considered life-threatening.

Introduction

Upper gastrointestinal haemorrhage (UGIH) usually presents with melaena or haematemesis. Occasionally, a brisk UGIH presents with haematochezia.

Melaena is a 'tarry' black stool with a characteristic offensive odour resulting from digestion of blood within the small intestine. Brisk UGIH can also present with passage of bright red blood or haematochezia per rectum, for example in the case of an aorto-enteric fistula.

Haematemesis is vomiting of blood from the upper gastrointestinal (GI) tract and may occur after swallowing blood following a nasopharyngeal haemorrhage. Patients presenting with haematemesis have a higher mortality than those presenting with melaena alone [1]. 'Coffee ground vomiting', often taken as an indicator of UGIH, is a poor clinical sign.

Haematochezia is the passage of fresh blood per rectum. This is usually from a colonic source, but a brisk UGIH can occasionally be responsible.

Diagnosis

A thorough medical history focusing on past medical history, particularly of gastrointestinal bleed and co-morbidities such as clotting disorders, malignancy, or liver disease should be sought. Direct questions pertaining to risk factors for gastrointestinal bleeding should be asked, and a history of medication such as aspirin, clopidogrel, warfarin, non-steroidal anti-inflammatory drugs, selective serotonin re-uptake inhibitors, and other novel antiplatelet agents or anti-coagulants ascertained.

Symptom assessment followed by clinical examination to identify signs of hypovolemia, chronic illness, or cirrhosis is useful. It is important to identify the likely source of the bleed, and determine subsequent management. The information gathered also guides decisions regarding resuscitation, empirical medical therapy, and subsequent diagnostic tests required. Several factors associated with poor outcome in terms of the severity of the bleed and need for intervention have been recognized; these can be used to obtain a severity score.

Laboratory investigations such as full blood count (FBC), biochemistry, and coagulation studies should be performed urgently, and cross-matching of blood (+/– blood products) requested. The results may provide useful information about the chronicity of the haemorrhage (mean corpuscular volume, platelet count, renal dysfunction, and coagulopathy), or indicate factors that may be associated with increased risk of severity and/or mortality such as concomitant anti-coagulation therapy, liver, and renal dysfunction.

Initial management

Regardless of the exact cause of the haemorrhage, the priority is prompt initial assessment (Airway, Breathing, Circulation, and Disability) and resuscitation, avoiding complications of haemodynamic compromise. Resuscitation should take priority over endoscopic and radiological investigations. Admission to a GI bleed or Specialist Unit results in improved outcomes [2]. In the absence of such Units, patients should be managed in an environment where vital signs such as heart rate, blood pressure, respiratory rate, conscious level, and urine output are monitored at least hourly. Resuscitation should be guided by clinical and physiological variables, while taking into consideration the patient's age and co-morbidities. Definitive airway protection is recommended in patients with haematemesis and a reduced level of consciousness.

Traditional resuscitation techniques using large amounts of crystalloid and packed red blood cells without other blood products can exacerbate the dilutional and consumptive coagulopathy of a

large haemorrhage [3]. Over-resuscitation may also theoretically increase the risk of rebleeding as a result of increased venous and arterial flow. Recent published reports support conservative transfusion policies over generous policies (i.e. transfuse when haemoglobin <7 g/dL versus <9 g/dL) [4]. However, it should be stressed that individual patients require individualized transfusion regimens based on their clinical condition. Crystalloids and/or volume expanders should be used initially to restore tissue oxygenation and perfusion [5]. Placement of a central venous catheter may be useful in elderly patients and those with cardiac co-morbidities. Large bore peripheral venous cannulation is sufficient in most cases.

Initiation of a pre-endoscopy PPI does not alter important clinical outcomes of mortality, rebleeding or the need for surgery. Its routine use pre-endoscopy is thus not recommended and should not delay or replace endoscopic therapy. In patients awaiting endoscopy, pre-emptive high-dose intravenous PPI may be used [6].

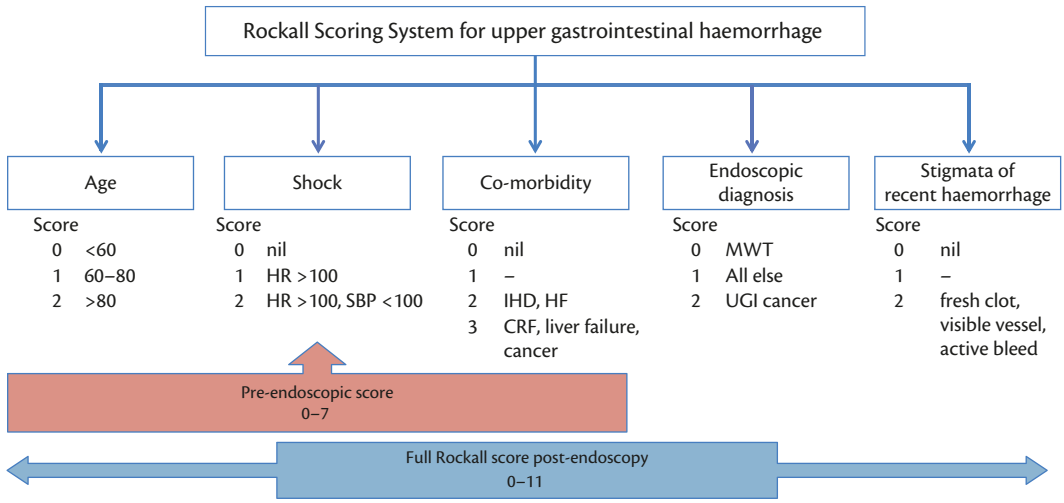
The risk of discontinuing antiplatelet and anti-coagulant agents needs to be assessed for individual patients by weighing up risks and benefits. Early discussion with relevant experts such as cardiologists and haematologists is advised. This ensures that the patient receives the correct composition and quantity of products in order to control the situation, and to permit diagnostic and therapeutic endoscopic assessment to take place safely. This is particularly suggested in complex clinical scenarios, e.g. mechanical heart valve replacement, post-coronary artery bypass surgery, disseminated coagulopathy, severe sepsis, recent coronary stent insertion, and massive haemorrhage.

Prothrombin concentrates should be considered in patients on warfarin who are actively bleeding. Platelet transfusions, fresh frozen plasma and cryoprecipitate should also be given as needed in situations of active bleeding when clotting parameters are impaired (i.e. INR >1.5, platelet count $<50 \times 10^9$/L, fibrinogen <1g/L). Platelet transfusion should be given to patients with life-threatening bleeds who have received antiplatelet drugs such as aspirin or clopidogrel [7]. Thromboelastography (TEG®) or thromboelastometry (TEM®) can provide a global assessment of haemostatic function from initial clot formation to clot dissolution [8]. These assessment techniques can be used in parallel with conventional coagulation screen to guide treatment. The anti-fibrinolytic agent, tranexamic acid has not yet been shown to have a beneficial effect in UGIH and is therefore not recommended for routine use.

Administration of intravenous erythromycin prior to endoscopy improves gastric motility and thereby mucosal views for the endoscopist. Prokinetics may be administered 30–90 minutes prior to endoscopy.

Scoring systems

Scoring systems have been developed and validated to risk stratify patients into low, medium, and high risk of rebleed and mortality. They can help to predict the need for hospital admission and endoscopic treatment. The Rockall score (Fig. 177.1) provides information on rebleed and mortality risk [9]. Its main disadvantage is that a complete score requires results of an upper GI endoscopy. The Glasgow Blatchford score (GBS) (Table 177.1) [10] is based on simple clinical and laboratory variables and is extremely useful in predicting the need for treatment. The lack of subjective variables or the need for endoscopy to complete the score makes



Rockall score	% Pre-OGD Mortality	% Post-OGD Mortality
0	0	0
1	2.4	0
2	5.6	0.2
3	11	2.9
4	24.6	5.3
5	39.6	10.8
6	48	17.3
7	50	27
8	>80	41.1

Fig. 177.1 Rockall numerical risk scoring system.

the GBS easier to use. A score of zero carries a minimal risk for requirement of interventions such as transfusion, endoscopy, or surgery. These patients can therefore be considered for early discharge and outpatient management. Scores ≥6 are associated with a >50% risk of needing an intervention. However, scoring systems are not designed to be used in isolation and do not replace clinical history and diagnostic skills in informing decisions about further care.

Endoscopy

Confirmation of the diagnosis of UGIH may be achieved by oesophagogastroduodenoscopy (OGD). This is the diagnostic modality of choice as it also provides the opportunity for therapeutic intervention. If unsuccessful, computed tomography (CT) angiography and/or mesenteric angiography may be required. Video capsule endoscopy also offers a diagnostic option, particularly in cases of bleeding from the small bowel, but it does not provide a therapeutic option.

Endoscopy should be offered to unstable patients with severe acute upper gastrointestinal bleeding immediately after resuscitation. All other patients should receive endoscopy within 24 hours of admission [11]. This should only be performed by trained staff, ideally in the surroundings of a dedicated and well-equipped endoscopy unit. Early endoscopy is associated with reduced transfusion requirements and reduced length of stay in hospital. However, in unstable patients it is also associated with a reduction in rebleeding rates and the need for surgery when compared with patients undergoing later endoscopy [12]. If the patient requires airway protection and ventilation, endoscopy should be performed in the operating room or the intensive care unit. Appropriate consent should be obtained from the patient or their next of kin/legal representative. Thorough documentation is mandatory.

Urgent OGD requires the patient to be kept nil by mouth for at least six hours prior to the procedure. Such preparation is not possible in emergency cases. Awake patients with a patent airway are likely to require either local anaesthetic to the oropharynx or low dose intravenous sedation for procedure tolerance. Sedated patients require blood pressure and pulse oximetry monitoring as a minimum.

Pharmacological and endoscopic therapies

Ulceration involving a visible or actively bleeding blood vessel or stigmata of recent bleed may require injection of 1:10,000 adrenaline in four quadrants around the vessel to provide local vasoconstriction and tamponade. It is recommended that epinephrine is not used as monotherapy and should be followed by a second intervention, e.g. thermo-coagulation involving application of compressive pressure to the vessel with the probe, while coagulation is being performed, or endoscopic clips applied to achieve haemostasis in a manner similar to surgical ligation. Endoscopic injection of fibrin or thrombin may also be used to achieve haemostasis. The oesophagus is thin-walled so caution must be exercised when injecting epinephrine or when applying thermo-coagulation as perforation may occur.

Haemospray is a nanopowder that has shown encouraging success in achieving acute haemostasis in pilot studies. It becomes cohesive and adhesive when in contact with moisture, forming a stable mechanical barrier at the site of bleeding. It is easy to apply and does not require direct tissue contact.

Endoscopic therapy should only be delivered to actively bleeding lesions, non-bleeding visible vessels, and to ulcers with an adherent blood clot [13]. A combination of endoscopic therapies is superior to a single modality alone [14].

Other therapies such as argon plasma coagulation (APC), where a jet of ionized argon gas is directed towards a bleeding lesion, and laser coagulation are frequently used to halt bleeding from angiodysplastic lesions and malignancies. Failure to control haemorrhage from these lesions may necessitate surgery.

Patients with active bleeding or other high-risk stigmata (such as a visible vessel or adherent clot) should receive a combination of endoscopic therapy and a PPI infusion to prevent recurrent bleeding [15], mortality and the need for surgical intervention. An intravenous bolus of PPI (e.g. omeprazole, pantoprazole) followed by continuous infusion is commenced. This helps to stabilize the clot by maintaining gastric pH >6, thus optimizing platelet aggregation and clot formation [16].

In bleeding from peptic ulcer disease (PUD) a biopsy should be taken for histological examination or for rapid urease testing (if not already on a PPI), to test for *Helicobacter pylori*. Eradication therapy should be instituted if confirmed positive. There is no evidence

to suggest that *H. pylori* eradication influences the rate of rebleeding in the acute phase of peptic ulcer bleeding [17].

Endoscopy should only be repeated within 24 hours if the initial procedure is considered sub-optimal, or in patients in whom rebleeding is likely to be life-threatening [18].

Detailed management of variceal bleeding is covered in a separate chapter. Endoscopic band ligation (EBL) is the treatment of choice for bleeding oesophageal varices. Sclerotherapy using agents such as ethanolamine oleate injection above and below the rupture point of the varix is another possibility. No differences are found in rebleed rates, complication or mortality when endoscopic sclerotherapy is compared with EBL. Injection of the tissue glue, cyanoacrylate is predominantly used for gastric or ectopic varices. The use of self-expandable metal stents (SEMs) in cases of refractory oesophageal variceal haemorrhage has been successful in small case series. More commonly, however, balloon tamponade using a Sengstaken–Blakemore tube is used in such cases with elective deflation at time of re-endoscopy within 24 hours. Occasionally, referral for transjugular intrahepatic portosystemic stent shunting (TIPSS) may become necessary.

Interventional radiology, video capsule endoscopy, and balloon enteroscopy

Occasionally, despite ongoing bleeding, the OGD is non-diagnostic. In other cases bleeding continues despite optimal attempts at endoscopic therapy. Computerized tomographic angiography (CTA) can be used to show extravasation of contrast at the site of the bleed. Arterial bleeding rates as low as 7.0 mL/min can potentially be detected [19]. Once the bleeding site is located, digital subtraction angiography and super-selective embolization of the arterial supply to the bleeding lesion is performed. Embolic agents such as coils, glue, or polyvinyl alcohol may be administered. This is a very successful method of controlling mesenteric bleeding. Bowel infarction and ischaemia account for the majority of complications. Super-selective catheter deployment may reduce this risk. Other potential complications include contrast allergy and contrast nephropathy, particularly in situations of concurrent dehydration, use of nephrotoxic drugs, chronic kidney disease, and prior use of intravenous contrast for CTA. Bleeding from the arterial puncture site and pseudo-aneurysm formation are other recognized complications. Clinical success and cessation of bleeding with embolization is quoted between 67–89%, however, rebleeding is evident in up to 30% of cases [20].

Radionuclide scanning with Technetium 99m-labelled red cells detects bleeding at rates as low as 0.1 ml/min. This can be useful to detect subtle bleeding not seen on endoscopy or CT angiography. It is most useful in slow bleeding and, as the labelled red cells circulate for 48 hours, it allows for repeat scanning. It is most commonly used in non-emergency situations, following which appropriate targeted therapy is chosen.

Video capsule endoscopy (VCE) is a frequently used modality for detecting bleeding beyond the reach of a standard endoscope. The advantages are relative non-invasiveness, a higher magnification than conventional endoscopes and, since the capsule moves passively, it does not inflate the bowel and thus images the mucosa in the collapsed state. This enables a more physiological examination of the small bowel. The obvious disadvantage is that once a bleeding point or pathology is identified, balloon enteroscopy, radiological embolization, or surgery is required to treat the area as VCE is only a diagnostic technology.

Enteroscopy

Visualization of the small bowel beyond the distal duodenum can be challenging. However, if bleeding is suspected from the small bowel, which averages 4–6 m in length in an adult, other diagnostic and therapeutic modalities may become necessary. Push enteroscopy, using longer paediatric colonoscopes or an enteroscope, requires the scope to be manoeuvred into the small bowel as far as possible, usually up to the jejunum. Though this procedure is readily available, it still carries the disadvantage of not being able to cover the entire length of the small bowel. Single or double balloon enteroscopy technique, advances the endoscope through the small bowel by alternately inflating and deflating balloons, and pleating the small bowel over an 'over' tube. In effect this shortens the length of the bowel and allows for more distal visualization of the small bowel as well as treatment to bleeding lesions. These procedures are usually lengthy, and require deep sedation or general anaesthesia. The other disadvantage of these techniques is the lack of universal expertise and availability in emergency situations.

If significant haemorrhage continues despite non-surgical therapeutic attempts, the patient should be reviewed for consideration of surgery to control the haemorrhage. A second attempt at endoscopic therapy is generally recommended in most cases.

CHAPTER 178

Diagnosis and management of variceal bleeding in the critically ill

Deanna Blisard and Ali Al-Khafaji

Key points

- The normal hepatic venous pressure gradient (HVPG) is 3–5 mmHg, and an HVPG of at least 10–12 mmHg defines clinically significant portal hypertension and predicts the clinical course.
- Primary prophylaxis of variceal bleeding is primarily achieved with non-selective β-blockers.
- Secondary prophylaxis is best achieved by a combination of non-selective β-blockers and endoscopic band ligation.
- The combination of endoscopic intervention and pharmacological treatment (vasoactive drugs and antibiotics) is the best management of an acute variceal bleed.
- Early referral of high-risk patients for transjugular intrahepatic portosystemic shunt (TIPS) is important.

Introduction

Portal hypertension is the increase in portosystemic pressure gradient in any portion of the portal venous system. It can result from pre-hepatic abnormalities (e.g. portal vein (PV) thrombosis), intrahepatic non-cirrhotic causes (e.g. schistosomiasis), or post-hepatic abnormalities (e.g. Budd–Chiari syndrome). Cirrhosis is the most common cause. Portal pressure increases initially due to increased resistance to flow, mostly due to architectural distortion of the liver from fibrous tissue and regenerative nodules, as well as increased PV inflow. There is also active intra-hepatic vasoconstriction, mainly related to decreases in nitric oxide bioavailability [1].

Varices are collateral venous channels through which portal blood reaches the systemic venous system. The portal-mesenteric venous system drains the entire GI tract, from oesophagus to rectum, with the most clinically significant of these channels being around the cardia of the stomach. Varices also occur around the umbilicus ('caput medusae'), around the spleen, and in the rectum.

Evaluation

Measurement of portal pressure by the hepatic venous pressure gradient (HVPG) is the best method to stratify risk [1–3]. The HVPG in cirrhotics is best assessed by measuring the gradient between the wedged hepatic venous pressure (WHVP, a measure of sinusoidal hepatic pressure) and the free hepatic venous pressure (FHVP, systemic pressure) [1–3]. The WVHP is obtained by placing a catheter in the hepatic vein under fluoroscopy and wedging it into a small branch. It is corrected for increases in intra-abdominal pressure or ascites by subtracting the FHVP [1].

The normal HVPG range is 3–5 mmHg; values >5 mmHg define portal hypertension, while a HVPG of at least 10–12 mmHg defines clinically significant portal hypertension and predicts the clinical course in cirrhotics. Both the absolute value of HVPG and temporal changes have predictive value for the development of oesophagogastric varices [1], risk of variceal haemorrhage [3], development of non-variceal complications of portal hypertension (e.g. ascites, encephalopathy) [1], Hepatocellular carcinoma (HCC) [1], and death [1,3].

Natural history of varices

Varices and variceal haemorrhage are the complications that result most directly from portal hypertension. Gastroesophageal varices (GEV) are present in approximately 50% of cirrhotic patients [1]. The presence of varices correlates with the severity of liver disease, ranging from 40% in Child A patients to 85% in Child C patients [1,2].

Cirrhotic patients without varices develop them at a rate of 5–10% per year, higher in decompensated cirrhosis [1,4]. The strongest predictor for development of varices is a baseline HVPG >10 mmHg [1]. Variceal haemorrhage occurs at a yearly rate of 5–15%, with the most important predictor being the size of the varices [1]. Other predictors are decompensated cirrhosis and endoscopic evidence of red wale sign [1,5]. Bleeding can stop spontaneously in up to 40% of patients, but is still associated with a mortality of at least 20% at 6 weeks [1].

The main factor determining variceal rupture is likely to be variceal wall tension, with vessel diameter being one of the major determinants. Another determinant of wall tension is the pressure in the varix, which is directly related to the HVPG. Therefore, patients whose HVPG decreases to <12 mmHg or at least 20% from baseline levels ('HVPG responders') have a lower probability of developing recurrent variceal haemorrhage [1] and a lower risk of developing ascites, spontaneous bacterial peritonitis (SBP), and death [1].

Diagnosis

The gold standard for diagnosing GEV is oesophagogastroduodenoscopy (OGD). GEV are generally classified by size—small, medium, and large. Recommendations for medium-sized varices are the same as for large [1]. Cirrhotic patients with GEV have a higher rate of death and risk of decompensation than those without. The frequency of surveillance endoscopies in patients with no or small varices depends on their natural history. Initial screening should be done when the diagnosis of cirrhosis is established [5]. In compensated cirrhosis with no varices on screening endoscopy, the OGD should be repeated in 2–3 years [5,6]. In those with small varices, the OGD should be repeated in 1–2 years while, in decompensated cirrhosis, it should be repeated yearly [5,6].

OGD also remains the main method for diagnosing variceal haemorrhage. This diagnosis is made when endoscopy shows one of the following: active bleeding from a varix, a 'nipple' over the varix, clots overlying the varix, or varices with no other source of bleeding [1]. Less invasive methods such as capsule endoscopy are currently being evaluated. However, the accuracy of evaluating the presence and size of varices and red wale marks is suboptimal, and has moderate sensitivity for diagnosing portal hypertensive gastropathy (PHG) and not suitable to diagnose GV [1].

Management

Management of varices is divided into three main areas: primary prophylaxis, acute haemorrhage treatment and management, and secondary prophylaxis. Pharmacological therapy currently consists of splanchnic vasoconstrictors (e.g. vasopressin, somatostatin), non-selective β-blockers (NSBB)) and venodilators (nitrates). Vasoconstrictors act by reducing portal venous inflow via splanchnic vasoconstriction. NSBB affect portal flow via both β-1 blockade, which decreases cardiac output, and β-2 blockade, producing splanchnic vasoconstriction [1]. Venodilators decrease intrahepatic and/or portocollateral resistance. However, the decrease in portal pressure appears more related to systemic hypotensive effects (i.e. a decrease in flow). Endoscopic therapies have no effect on either portal flow or resistance. Endoscopic procedures include banding (variceal ligation), sclerosing agents (variceal sclerotherapy), or tissue adhesives (variceal obturation). Shunting (either radiological or surgical) markedly reduces portal pressure by bypassing the increased resistance.

Primary prophylaxis

In patients with cirrhosis and no varices, expert consensus panels do not support the universal use of NSBB, but agree that surveillance endoscopies should be performed every 2–3 years, and annually with decompensation [6]. A large multicenter trial failed to show benefit from NSBB in patients with HVPG >5 mmHg at baseline, but no varices [7]. NSBB also did not prevent the development of varices [7].

For patients with small varices that have not bled, NSBB prophylaxis should be used in high-risk patients, such as advanced liver disease and the presence of red wale sign on the varices [8]. Non-high-risk patients can receive NSBB to delay variceal growth, although long-term benefits are not well established [9]. For those not taking NSBB, expert panels suggest surveillance OGD every 2 years, and annually with decompensation [1,6]. Two placebo-controlled studies assessing the efficacy of NSBB in preventing growth of small varices had conflicting results [9,10]. As with other such studies, a high percentage of patients on β-blockers had to be withdrawn due to side effects (11% versus 1% in the placebo group).

Both NSBB and endoscopic variceal ligation (EVL) are effective in preventing the first variceal bleed in patients with medium/large varices that have not bled. A meta-analysis comparing NSBB to no treatment or placebo showed a reduction of risk of first variceal bleed (14% in the NSBB group versus 30% for placebo) [1]. Mortality was also reduced in the NSBB group [1].

A decrease in HVPG <12 mmHg eliminates the risk of haemorrhage and improves survival [1], while decreases >20% from baseline (or even 10%) significantly decreased the risk of first variceal haemorrhage [1,7]. Therapy is titrated to maximal tolerated doses (propranolol 20 mg bd, nadolol 40 mg od). A reduction in heart rate does not correlate with a reduction in HVPG. Prophylactic therapy needs to be continued indefinitely, as risk of bleeding recurs with NSBB cessation [11].

Meta-analyses [12] have shown that EVL had a small, but significant lower incidence of first variceal bleeding when compared to NSBB. However, there was no mortality benefit. Although the EVL group had fewer adverse events (4% versus 13%), these events were more severe. The choice should be based on patient characteristics, preferences, and local resources and expertise.

Acute variceal haemorrhage

Improved management over the last two decades has led to decreasing mortality rates [1]. Initial resuscitation efforts involve basic measures, including evaluating the 'ABC's' to achieve haemodynamic stability. In patients with a low or intermediate risk (Child class A or B, HVPG <20 mmHg), standard therapy should be started. This includes the combination of a vasoconstrictor (e.g. octreotide, terlipressin) started on admission and maintained for 2–5 days, plus endoscopic therapy [1,8] together with prophylactic antibiotics. The goals of blood volume resuscitation should be maintaining haemodynamic stability and haemoglobin levels of 7–8 g/dL [1,8]. More aggressive resuscitation can lead to increases in portal pressures, and to more bleeding and mortality.

Despite the lack of evidence supporting correction of coagulopathy and thrombocytopenia, many endoscopists (including our own) target a platelet count >50,000/μL and an International Normalized Ratio (INR) <2. A multicentre placebo-controlled trial of recombinant factor VIIa (rFVIIa) in actively bleeding cirrhotic patients failed to show benefit over conventional management [13]. However, a **post hoc analysis** suggested that rFVIIa reduced the failure rate in controlling bleeding in Child–Pugh B and C patients; further studies are needed.

There is a high risk of developing SBP and other infections in variceal haemorrhage, leading to an early recurrence of bleeding and greater mortality [14]. Bacterial infections may initiate the bleeding episode via impaired haemostasis and increased portal pressures [1,2,14]. Short-term prophylaxis with antibiotics in variceal haemorrhage (and all types of GI bleeding in cirrhotics) decreases the rate of bacterial infections and increases survival. Therefore, prophylaxis should be considered standard practice in all acute variceal haemorrhage [1,8]. Antibiotics should be chosen based on the institution's antibiotic resistance patterns, and continued for seven days.

Pharmacological therapy should be considered first-line treatment for variceal bleeding based on a recent meta-analysis of 15 trials comparing sclerotherapy and pharmacological treatment (vasopressin +/– glyceryl trinitrate, somatostatin or octreotide) [15]. NSBB should not be used acutely as they may cause worsening hypotension and blunt the tachycardia response.

Vasopressin is the most potent splanchnic vasoconstrictor which, in turn, leads to decreases in portal flow and pressure. However, its clinical usefulness is limited by side-effects including cardiac and peripheral ischaemia, arrhythmias, hypertension, and bowel ischaemia [1]. Terlipressin is a synthetic analogue of vasopressin with a longer biological activity and less side-effects. It is effective in controlling acute variceal haemorrhage and is associated with decreased mortality [1]. At present, it is not available in the United States.

Somatostatin and analogues such as octreotide also cause splanchnic vasoconstriction. Advantages include safety and that they can be used continuously for five days or longer; however, meta-analysis are controversial [1]. Octreotide may be a useful adjunct to endoscopic therapy [8,16] and is continued for 5 days in our institution.

After patient stabilization, OGD should be performed as soon as possible, enabling endoscopic therapy if the source is confirmed (Fig. 178.1) [8]. A meta-analysis of 10 randomized controlled trials shows an almost significant benefit of EVL in initial control of bleeding when compared to sclerotherapy [12]. One study involved in the meta-analysis showed that HVPG increased after both EVL and sclerotherapy, but decreased in the EVL group after 48 hours. EVL is therefore the preferred from endoscopic treatment for acute bleeding [1,8].

Despite all measures, variceal bleeding may not be controlled or recurs early in about 10–20% of patients. An HVPG >20 mmHg is predictive of treatment failure [1]. Shunts, most commonly TIPS, are clinically effective as rescue therapy for those patients who fail to respond to endoscopic or pharmacological therapy [1]. Early TIPS (within 24–48 hours of admission) offers significant survival benefits among high-risk patients in two randomized controlled trials [1]. TIPS within 72 hours of variceal bleeding, in addition to EBL, has been recently shown to be highly effective in preventing recurrent bleeding and improved short- and long-term survival in patients with Child's C or Child's B cirrhosis with active bleeding during endoscopy [17]. Notably, there was no increase in encephalopathy, heart failure nor any other complications in the TIPS-treated patients compared to EBL alone. Balloon tamponade is effective in temporarily controlling haemorrhage in over 80% of patients [1]. Its use should be restricted to patients with uncontrollable bleeding where more definitive therapy (e.g. TIPS) is planned within 24 hours, as potentially lethal complications can occur. Complications include aspiration, migration, and necrosis/perforation of the oesophagus with mortality rates as high as 20% (Fig. 178.2).

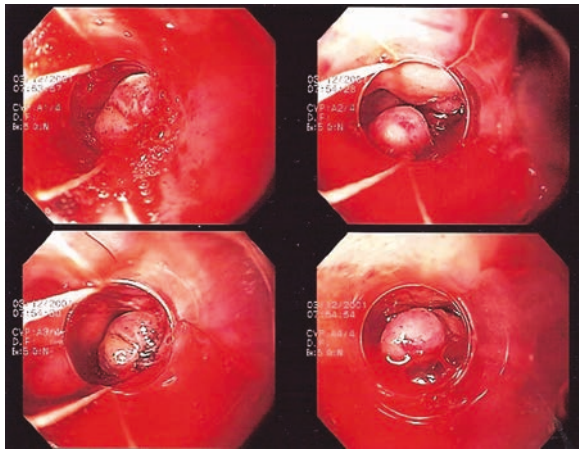

Fig. 178.1 Bleeding oesophageal varix being banded.

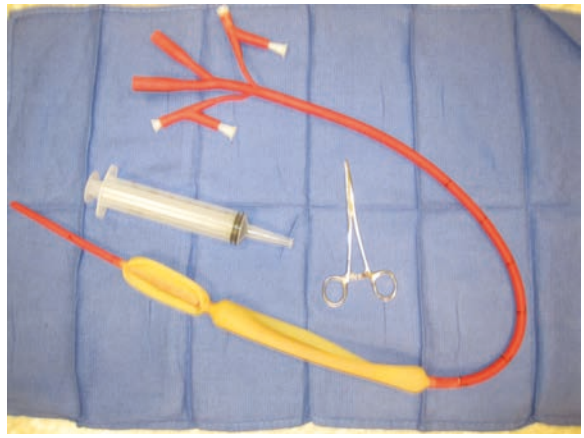

Fig. 178.2 Minnesota tube.

Gastric varices

The approach to gastric varices depends on the type of varices. Gastric varices are classified into four categories: GOV1, GOV2, IGV1, and IGV2 [18] (see Fig. 178.3). GOV1 and GOV2 are gastric varices that extend from oesophageal varices across the gastroesophageal

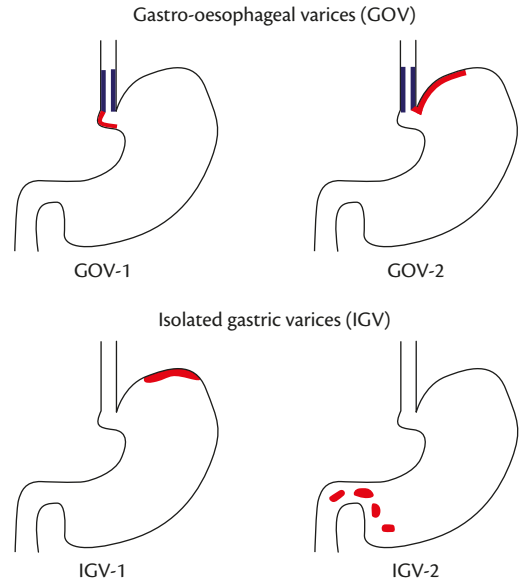

Fig. 178.3 The Sarin classification of gastric varices.
Reproduced from Sarin SK et al., 'Prevalence, classification and natural history of gastric varices: a long-term follow-up study in 568 portal hypertensive patients', *Hepatology*, **16**, pp. 1343–9, Copyright © 1992 American Association for the Study of Liver Diseases, with permission from John Wiley and Sons..

junction. In GOV1, they only extend 5 cm or less, while in the GOV2 group, the varices extend into the fundus. IGV refers to isolated gastric varices. IGV1 are varices found only in the fundus and IGV2 are isolated non-fundic varices. Type 1 gastric varices (GOV1) are the most common, accounting for 74% [16]). They are an extension of EV along the lesser curve of the stomach, and their management should be the same. GOV are present in 20% of cirrhotic patients, either isolated or combined. Bleeding is more severe and carries a higher rate of death [16] (Fig. 178.4). Limited data exist for the management of bleeding from fundal varices. Acute fundal gastric variceal bleeding is more effectively controlled with tissue adhesives (e.g. N-butyl-cyanoacrylate, isobutyl-2-cyanoacrylate, or thrombin) [1,16] than EVL. A large randomized trial compared gastric variceal obturation (GVO) with N-butyl-cyanoacrylate versus EVL in patients with acute gastric variceal haemorrhage. It demonstrated that control of active bleeding was similar in both groups, but rebleeding was less frequent with GVO [1]. The use of these agents is preferred in endoscopic therapy of fundal varices; if unavailable, TIPS should be considered first-line therapy. TIPS is also more effective in preventing recurrent bleeding [1] versus endoscopic therapy. Several studies have shown bleeding control rates of over 90% with TIPS for gastric varices. A prospective study showed equal efficacy in controlling gastric fundal and oesophageal variceal bleeding [1] with salvage TIPS. Treatment should be based on local expertise.

Secondary prophylaxis

The median rebleeding rate in untreated individuals is approximately 60% within 1–2 years of the index haemorrhage, with a mortality of 33% [1]. Prevention of recurrent VH is key in managing these patients, and secondary prophylaxis should be initiated as soon as possible after the initial episode. Those patients who required shunt surgery or TIPS would not require further preventative measures. NSBB or sclerotherapy decreases the rebleeding rate to around 42–43% [1], although sclerotherapy has a higher incidence of side-effects.

The combination of NSBB and nitrates has a synergistic effect on reducing portal pressure, and is theoretically more effective than BB alone [1,19]. However, clinical trials have shown the combination is no different from NSBB alone when looking at rebleeding rates and mortality. Only one study directly compared a combination versus propranolol alone in prior variceal haemorrhage [1], showing. A non-statistically significant benefit from combination therapy. Data from other randomized clinical trials show that the median rebleeding rate in those treated with combination therapy is approximately 35% [1], lower than BB alone. However, combination therapy has more side-effects and is poorly tolerated.

EVL is the endoscopic method of choice for preventing variceal rebleeding, and is superior to sclerotherapy. A median rebleeding rate in patients treated with EVL in different randomized clinical trials is around 32% [1]. EVL sessions are repeated at 7–14-day intervals. Once gone, OGD is usually repeated every 3–6 months. Complications of EVL occur in about 14% of cases and are minor.

The most rational approach would appear to be a combination endoscopy plus pharmacological therapy since NSBB protects against rebleeding prior to EVL. Two randomized trials demonstrate the benefit of combined treatment versus EVL alone, with rebleeding rates of 23 and 14% in EVL + BB versus 47 + 38% in EVL alone [20]. These results support combination therapy, even though consensus conferences recommend EVL or BB + nitrate as first line therapy [8].

The lowest rate of rebleeding (~10%) is in HVPG responders [1,3]. These are patients in whom pharmacological therapy (NSBB alone or BB + nitrate) leads to a decrease in HVPG <12 mmHg or a reduction >20% from baseline [1,3]. Shunt surgery effectively prevents rebleeding. However, this option carries a marked increase in the risk of hepatic encephalopathy with no effect on survival [1].

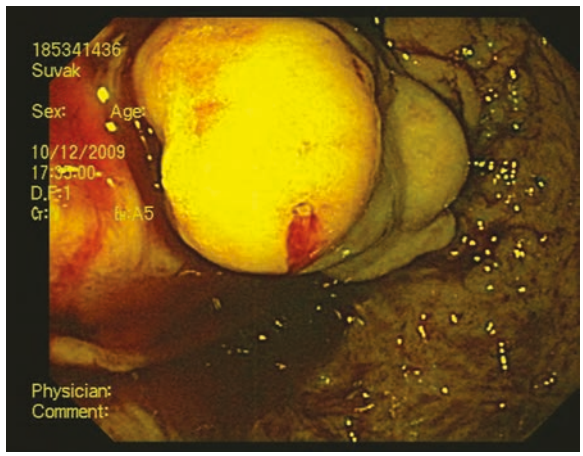

Fig. 178.4 Bleeding gastric varix.

CHAPTER 179

Pathophysiology and causes of lower gastrointestinal haemorrhage

Leslie M. Kobayashi and Raul Coimbra

Key points

- Lower gastrointestinal bleeding is less common than upper gastrointestinal bleeding, but is increasing in frequency, is a common cause of hospitalizations and results in significant utilization of health care resources.
- Acute lower gastrointestinal bleeding primarily presents with haematochezia or bright red blood per rectum, and melena; upper gastrointestinal bleeding may present with similar symptoms/signs in up to 9% of cases and must be ruled out in all patients.
- Diverticulosis is the most common cause of lower gastrointestinal bleeding in Western populations, and is increasing in frequency, likely due to the increasing numbers of elderly patients.
- Haemorrhoids are one of the most common causes of lower gastrointestinal bleeding in the younger patient. However, more proximal concomitant source of bleeding and malignancy should be ruled out in all symptomatic patients.
- Neoplastic lesions including polyps and carcinomas account for a significant minority of lower gastrointestinal bleeding cases, and are of particular concern among patients ≥50 years of age; with a family history of malignancy; or associated symptoms such as weight loss, pain, and change in bowel habits.

Presentation

Lower gastrointestinal bleeding (LGIB) can be defined as any gastrointestinal (GI) haemorrhage whose origin exists beyond the ligament of Treitz, although more modern classification systems differentiate LGIB due to colorectal sources from mid gut bleeding due to sources in the small bowel [1]. LGIB occurs when mucosal irritation/inflammation, friable masses, arteriovenous malformations (AVMs), or trauma to the colon or rectum causes intraluminal shedding of blood. Peristalsis then propels this blood along the faecal stream where it may result in haematochezia or melena. Haematochezia is the passage of bright red blood from the rectum and is the most common presenting symptom of LGIB [1]. Haematochezia primarily occurs if bleeding sources are located in the distal portions of the GI tract. However, bleeding may occasionally arise from more proximal sources and remain bright red due to the cathartic effects of large amounts of intra-luminal blood. Melena, the passage of dark, black, or tarry stools occurs if sources of bleeding are higher in the GI tract, allowing the oxidation of haematin.

Bleeding, presenting as either haematochezia or melena can range from low volume intermittent losses to massive haemorrhage with haemodynamic instability. Alternatively, LGIB may be detected in asymptomatic patients by faecal occult blood testing for work-up of anaemia or during routine screening. As upper GI bleeding (UGIB) may present in a similar fashion to LGIB in up to 9% of cases, UGIB should be ruled out as a cause of presenting symptoms [2]. This can be done simply in the acute setting by nasogastric lavage and return of bilious non-bloody fluid. If no bile is noted, more thorough examination with upper GI endoscopy is required to reliably rule out UGIB as a cause of symptoms.

Incidence

LGIB is quite common, with an annual incidence of 20–45 cases per 100,000 population [3,4]. It is a frequent cause of emergency department visits, hospitalizations, and healthcare expenditure. LGIB accounts for 0.5% of hospitalizations, or 120/100,000 cases in the United States; diverticular bleeding alone cost one billion dollars in 2001 [4]. LGIB is responsible for 23–33% of all GIB (3-4). In contrast to UGIB which has been decreasing in frequency over time with the introduction of acid-suppressing medications and *Helicobacter pylori* treatment, LGIB is increasing in incidence/frequency [3]. LGIB is even more frequent among the elderly, occurring in 181/100,000 among persons aged 45–64, and as high as 1,871/100,000 for those aged ≥85 [3]. Age is the main risk factor associated with LGIB, with the elderly accounting for 65% of hospitalizations [3-5]. There are multiple reasons for an increased risk of LGIB among the elderly, including increased incidences of diverticulosis, AVM, and neoplasia, as well as the frequent usage of medications that increase bleeding risk such as antiplatelet agents, anticoagulants, and non-steroidal anti-inflammatories (NSAIDs) [5,6]. The number of patients on such medications who present with LGIB is increasing significantly, affecting up to 54% [1,7]. These agents are associated with

more severe bleeding episodes, longer hospital stays, more frequent need for blood transfusion and in-hospital complications [6,8]. Approximately 28.4% of patients with LGIB present with some haemodynamic instability [7].

Aetiologies

The three commonest causes of LGIB in the US include diverticulosis, haemorrhoids, and masses such as (benign) polyps and (malignant) tumours [1,9]. Inflammation and infection can cause generalized friability of the colonic mucosa resulting in LGIB, e.g. ischaemic and inflammatory bowel disease (IBD) and haemorrhagic diarrhoea. Other less common causes include AVMs, solitary rectal ulcers, and radiation proctitis. As the majority of LGIB resolves spontaneously, the source may not be identified in 2.5–30.3% of cases [1,10,11]. Multiple sources may be present in up to 40% of cases [11].

Diverticulosis

Colonic diverticulae are outpouchings of the intestinal mucosa through the muscular wall of the intestine (Fig. 179.1). They occur near the origin of nutrient vessels where the bowel wall is relatively weak. Diverticulosis is found commonly among Western populations with a prevalence ranging from 17–45%, and increases in frequency with age, being present in over half of those aged ≥50 years [5]. Approximately 17% of patients with diverticulosis will experience an episode of bleeding, and it accounts for 30–57% of LGIB [1,2,4]. While diverticulae are more commonly found in the left colon, right-sided lesions have a higher tendency to bleed and account for 50–60% of diverticular bleeds [2,4,12]. The incidence of diverticular LGIB is increasing over recent years, and may be due in part to our aging population [1]. Bleeding due to diverticular disease may result in severe or massive haemorrhage in up to a quarter of patients with risk factors including hypotension, anaemia, coagulopathy, (INR ≥1.5) and use of antihypertensive medications [13].

Haemorrhoids

Haemorrhoids are the commonest cause of LGIB in non-elderly patients. Its prevalence ranges from 4–10% in the general population [5,14]. They account for 20–24% of LGIB cases; and this incidence appears to be stable over time [1,9], but can increase to as high as 54–96% in low-risk patients (age <55, no family history of malignancy or inflammatory bowel disease, no other abdominal

Fig. 179.1 Coronal CT image showing sigmoid diverticulosis.

or bowel symptoms) [15,16]. While haemorrhoids and other benign anal disorders such as fissures and fistula-in-ano are common causes of LGIB, and haematochezia in particular, patients may also harbour more proximal concomitant bleeding lesions or malignancies.

Masses

Spontaneous bleeding from neoplastic colorectal lesions (Fig. 179.2) accounts for 2–33% of LGIB cases; the frequency of a malignant source increases with patient age. Benign polyps account for 5–13% of cases and biopsy or polypectomy for 1–6% [2,9]. The rate of post-procedural bleeding decreases as endoscopic technology improves, and if patients are kept off anticoagulant, antiplatelet, and NSAID medications following their procedure [2].

Arteriovenous malformations

These include vascular ectasias, angiomas, and angiodysplasias. AVMs can be found throughout the GI tract, but are most often seen in the right colon and small bowel. AVMs can be classified based on angiographic characteristics, location, patient age, and history [17]. Type 1 lesions are solitary right-sided colonic lesions, primarily occurring in the elderly. These are likely acquired lesions forming as a result of chronic obstruction of submucosal veins and eventually resulting in arteriovenous communication. In contrast Type 2 AVMs are congenital, are larger than Type 1 lesions, and occur primarily in the small bowel. Type 3 lesions are punctate angiomas [17]. AVMs occur with a wide range of frequencies depending on the patient population, but are rare in the overall population accounting for only 2–5% of LGIB cases [1,2]. They are more frequent among the elderly, occurring in 2–37% of cases [4,5].

Fig. 179.2 (a) Axial and (b) coronal CT images of a near obstructing sigmoid colon cancer.

Inflammation

Colitis due to inflammatory, ischaemic, or infectious causes are responsible for 9–21% of cases of LGIB. Crohn's disease and ulcerative colitis are most common among younger male patients and cause 2–8% of cases of LGIB [2,10]. Ischaemic colitis is relatively rare in the general population, but is one of the commonest causes (up to 30% of cases) among the critically ill [2]. These patients often present with severe cramping abdominal pain out of proportion to examination findings; among the critically ill they may present with severe haemorrhage. The most common infectious organisms associated with haemorrhagic diarrhoea include *Salmonella, Histoplasma, Shigella, Campylobacter, Yersinia*, and enterohaemorrhagic *Escherichia coli* strains, as well as cytomegalovirus.

Radiation proctitis is a relatively rare cause of LGIB, accounting for 1–5% of cases, but occurs in up to 20% of patients undergoing radiation therapy [18]. It is likely to become increasingly important as the use of radiation therapy to treat pelvic malignancies continues to rise. Radiation causes endothelial cell swelling, vacuolization, and thrombosis as well as mucosal telangiectasias resulting in haematochezia, tenesmus and diarrhoea. LGIB due to radiation proctitis can be severe and recurrent [2].

Unusual causes

Solitary rectal ulcer syndrome (SRUS) occurs when chronically prolapsing mucosa causes local trauma and transient ischaemia resulting in formation of a benign ulcerative lesion in the mid-rectum. In addition to haematochezia, patients often complain of constipation, difficulty with defecation, and tenesmus. While an uncommon cause of LGIB in the ambulatory population, SRUS is more common among ICU patients, accounting for 21–31% of cases occurring after ICU admission [19].

Small bowel pathology is responsible for 1–9% of LGIB [1,5]. The commonest cause of small bowel LGIB is Meckel's diverticulum [11]. Other small bowel causes include IBD, intussusception, vascular ectasia, AVMs, tumours and polyps, and celiac disease.

In discussing the aetiology of LGIB it is important to distinguish between non-elderly and elderly populations, as well as the hospitalized patient. Benign anorectal disorders and IBD are more frequent among younger patients [20], while diverticulosis of both the right and left colon, angiodysplasia, and malignancy are much more common among the elderly [4]. In patients hospitalized for other causes prior to demonstrating signs or symptoms of LGIB, intestinal ischaemia, and SRUS, rarely encountered entities among ambulatory patients, are among the commonest causes of LGIB. The aetiology of LGIB slightly differs among non-Western civilizations where malignancy is more common and diverticular disease much less common. A meta-analysis of over 53,000 Chinese patients found colorectal cancer, polyps, and colitis to be the commonest aetiologies of LGIB, while diverticulosis accounted for only 1.1% of cases [10].

CHAPTER 180

Diagnosis and management of lower gastrointestinal haemorrhage in the critically ill

Leslie M. Kobayashi and Raul Coimbra

Key points

- Initial management of all lower gastrointestinal bleeding should begin with establishment of adequate intravenous access, fluid resuscitation with balanced crystalloid solution, and judicious use of transfusion of blood and blood products to ensure haemodynamic stability.
- Early urgent colonoscopy following rapid bowel preparation with polyethylene glycol solution is safe and well tolerated in most patients, and results in accurate diagnosis.
- In patients unable to tolerate endoscopy or bowel preparation, in those with inadequate or non-diagnostic endoscopy, and those with very fast or very slow haemorrhage, alternative diagnostic techniques include angiography, computed tomography (CT) scanning, and tagged red blood cell (RBC) scanning.
- A small proportion of patients with lower gastrointestinal bleeding have a small bowel source; in these patients capsule endoscopy, single- and double-balloon enteroscopy, and CT scanning are the most effective diagnostic modalities.
- Most cases of lower gastrointestinal bleeding stop spontaneously and do not recur. In patients requiring therapeutic intervention, endoscopy is the preferred modality as it is effective and associated with a low rate of recurrent bleeding and complications.

Resuscitation

The first step in the management of lower gastrointestinal bleeding (LGIB) is resuscitation. Haemodynamically unstable patients should be treated immediately with placement of large bore intravenous (iv) access, either two large peripheral cannulae or a central line. Isotonic fluids and transfusion of blood and blood products should be utilized for intravascular volume repletion. A Foley catheter should be placed to monitor urine output. Consideration should be given to placing an arterial line for continuous invasive haemodynamic monitoring and repeat blood sampling. Routine lab tests should include blood group type and screen, complete blood count, arterial blood gas, coagulation parameters, and thromboelastography, if available. For stable patients, it is still important to measure baseline lab values, establish good peripheral iv access, and consider placing a Foley catheter for strict monitoring of fluid balance. After stabilizing the patient, a careful history should be taken, with special emphasis on use of anticoagulant, antiplatelet, and non-steroidal anti-inflammatory drugs (NSAIDs); symptoms of anaemia or hypovolaemia; personal or family history of malignancy or inflammatory bowel disease (IBD), and change in bowel habit. In patients on anticoagulants with evidence of haemodynamic instability, active or ongoing bleeding, reversal of the agent should be undertaken immediately as part of their general resuscitation. Reversal may include transfusion of fresh frozen plasma or platelets; agents such as desmopressin, activated factor VIIa or prothrombin complex concentrates; and haemodialysis. Patients should have a complete abdominal examination, seeking any stigmata of liver disease such as caput medusae, hepatosplenomegaly and ascites; and digital rectal exam for haemorrhoids, fissures, masses, strictures, and gross blood.

Diagnosis

LGIB stops spontaneously in the majority of cases so an exact source for bleeding may not be found in patients whose symptoms do not recur. Patients who present with haemodynamic instability, have continued evidence of bleeding, persistent or worsening anaemia, or associated abdominal symptoms should undergo further work-up to determine the etiology and possibly undergo treatment once stabilized [1]. As upper GI bleeding (UGIB) may present in a similar fashion as LGIB in ~9% of cases, diagnostic manoeuvers to exclude an UGIB source must be undertaken prior to diagnosis or treatment of LGIB [2]. Nasogastric lavage should be performed as a first-line diagnostic modality. If bilious non-bloody fluid returns, UGIB can be confidently excluded. If not, or if blood is noted, upper GI endoscopy is required.

Once UGIB has been ruled out, colonoscopy should be the initial diagnostic study of choice, and performed as quickly as possible. Timing should ideally be performed within the first 12–24 hours, as earlier examination results in a higher diagnostic yield, is associated with decreased hospital length of stay, and may contribute to decreased cost of care [3–7]. The diagnostic accuracy ranges widely from 48–100% depending on timing, indication, patient demographics, and type/use of bowel preparation [1,3–8]. Bowel preparation in

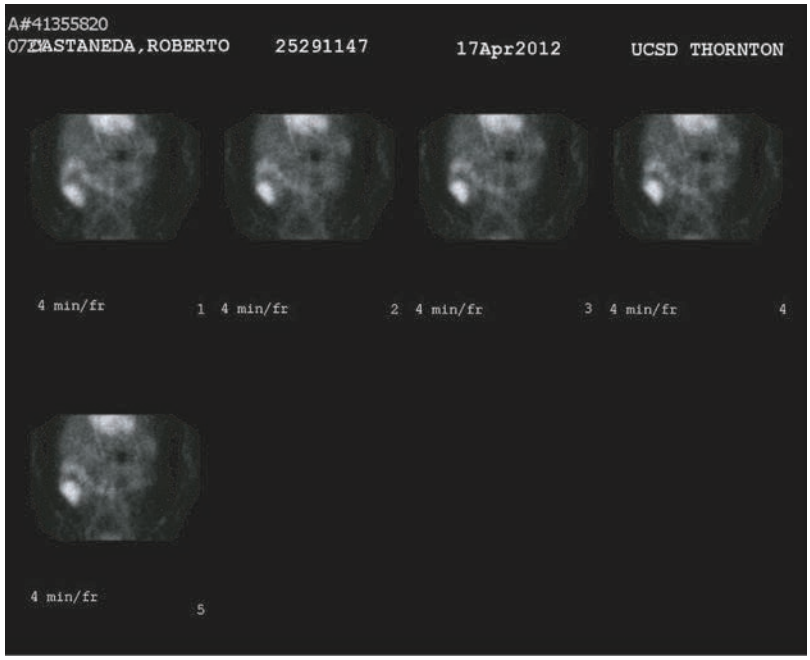

Fig. 180.1 Tagged red blood cell scan revealing abnormal uptake in the right hemi-abdomen suggestive of right colonic source of haemorrhage.

the setting of acute onset LGIB was felt to be dangerous and technically difficult. However, a growing body of evidence suggests that, if performed appropriately, it is safe, feasible, and improves diagnostic yield [4]. Most current protocols utilize a polyethylene glycol solution delivered via nasogastric tube followed rapidly by colonoscopy within the first 12 hours of presentation. This protocol accurately diagnoses LGIB in 74–100% of cases, a pooled analysis of six recent studies found an overall diagnostic yield of 91% [4,7].

If a bleeding source cannot be identified on colonoscopy, or endoscopy is not possible due to lack of availability, patient intolerance or instability, or is non-diagnostic due to poor bowel preparation or massive bleeding, other diagnostic methods include angiography, computed tomography (CT), and tagged red blood cell (RBC) scan. Angiography requires blood loss of at least 0.5–1 mL/min to be detectable, but has the benefit of being both diagnostic and therapeutic [6]. Its diagnostic yield ranges widely (25–87%), increasing in haemodynamically unstable patients and those with ongoing blood loss [4,6]. CT is another diagnostic option, with recent technological improvements resulting in improved detection rates. In one small prospective study CT angiography outperformed even colonoscopy in its ability to localize bleeding (100% versus 52.9%), and diagnose the etiology (88.2% versus 52.9%) [9]. Overall, CT has a sensitivity ranging from 79–100% [4,6,9,10]. CT angiography has higher yields in patients with evidence of active bleeding, but animal models suggest it can detect bleeding as slow as 0.3–0.5 mL/min; unlike other diagnostic modalities it can identify extra-luminal sources of haemorrhage [11,12]. Tagged RBC scan is most useful in detecting blood loss as low as 0.1–0.5 mL/min [6,13]. Unfortunately, the diagnostic yield ranges from 23–88%. Sensitivity does appear to be higher for LGIB (Fig. 180.1) as compared with UGIB, but can still result in false localization in 22% of cases [1,13]. Direct comparisons of endoscopy to radiographic studies are few, but suggest that overall endoscopy has a higher diagnostic yield than angiography or scintigraphy [3,4,14].

Small bowel lesions are the source of LGIB in a minority of cases. These lesions are mainly vascular in nature, followed in frequency by neoplasms and inflammatory lesions [6]. The commonest methods to investigate the small bowel include push enteroscopy, single- or double-balloon enteroscopy, and capsule endoscopy. Small bowel lesions may also be visualized on CT scan, tagged RBC scan, and angiography. The highest diagnostic yields are found with capsule or balloon enteroscopy, and CT scan in patients with active haemorrhage.

Treatment

Once a source for LGIB has been identified, treatment options include endoscopic or angiographic intervention and surgery. If a bleeding source cannot be identified and the patient is unstable, requiring ongoing transfusion, or has massive blood loss, emergent surgery is the only option.

Endoscopic therapies for LGIB include band ligation; injection of epinephrine, sclerosants, or ethanol; thermal contact, argon plasma coagulation, and placement of haemoclips. Which technique is used depends on the location, type, and characteristics of the lesion and operator experience with the different devices. Injection techniques affect haemostasis by causing chemical vasoconstriction and volume tamponade. Coagulation haemostasis can be achieved with contact devices such as heater probes and bipolar cautery, or non-contact devices such as the argon plasma coagulator. This is particularly useful for diffuse or multifocal sources of haemorrhage. Clips and band ligation use physical tamponade of the bleeding source to create haemostasis. They are particularly effective with diverticular and haemorrhoidal causes. Endoscopic therapies are generally successful with effective haemorrhage control in 80–96% of patients [4,15]. Re-bleeding rates range from 23–30% [3,4]. Complication rates are generally low, ranging from 0–2% and include perforation, sepsis, aspiration, and cardiac complications [1,4].

Angiographic therapies include embolization with microcoils (Fig. 180.2), polyvinyl alcohol particles, or gelfoam; and continuous infusion of vasopressin. Embolization can control haemorrhage successfully in 76–100% of patients [4,16,17]. Efficacy of intra-arterial vasopressin ranges from 62–100%, and may be slightly higher for colonic as compared to small bowel lesions [2]. The highest rates of haemorrhage control following angiographic intervention are found with caecal, ileal, and jejunal lesions, and bleeding of diverticular origin. Re-bleeding rates following angio-embolization range from 8–24%, while recurrence rates following vasopressin infusion are higher (40–50%) [2,4,16–18]. Risk factors for recurrent bleeding include post-procedural, post-operative or post-traumatic bleeding, non-diverticular source, multisystem organ failure, co-morbidities, transfusion requirements ≥6 units, shock, and coagulopathy or anticoagulant use. Complications following coil embolization are generally low, ranging from 5–17%, compared to 9–21% with vasopressin (2,4,6,15). Complications following angio-intervention include arrhythmias, myocardial ischaemia, pulmonary oedema, abdominal pain, fevers, access site complications such as pseudo-aneurysm, dissection or haematoma, contrast-induced nephropathy, and allergy. The most feared complication is bowel ischaemia. Fortunately, this is quite rare in most modern series, particularly if using microcoil embolization with super-selective catheterization. Minor and major ischaemic complications occur in 4.5–7% and 0–1.4% of cases, respectively [17,18]. As technology has improved, ischaemic complication rates have decreased, while the popularity of embolization over vasopressin infusion has increased [2]. In patients failing endoscopic management, angiographic

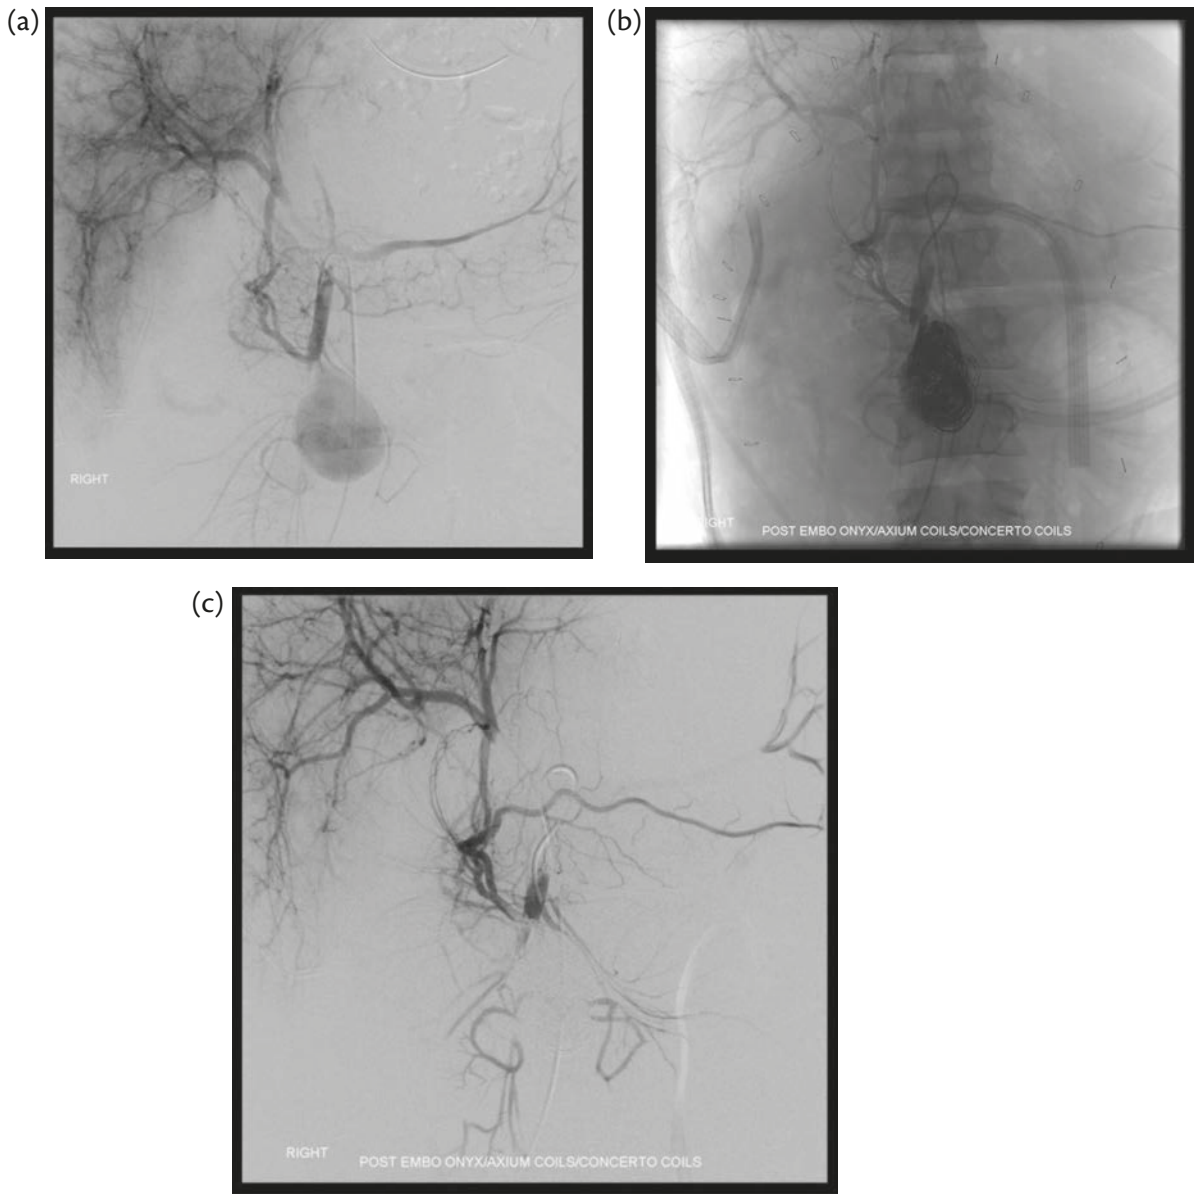

Fig. 180.2 Angiography revealing large proximal superior mesenteric artery pseudo-aneurysm. (a) Before coiling. (b) During coil placement. (c) Post-coiling angiogram with cessation of flow into aneurysm.

treatment appears to be similar to surgery in efficacy and complication rates. It should be considered an adjunct, or alternative to surgical treatment, particularly among high risk patients.

Outcomes following endoscopic and angiographic intervention vary with regard to efficacy and re-bleeding rates. Few trials have directly compared the two diagnostic and therapeutic modalities, though there is some suggestion that endoscopy results in better diagnostic yields, higher percentages of patients amenable to intervention, fewer complications, and shorter lengths of stay [3,4]. These comparisons primarily utilized older angiographic techniques; direct comparison of modern endoscopic interventions to super-selective coil embolization are lacking.

Surgery

The need for operative control of bleeding is decreasing as endoscopic and angiographic intervention improves, dropping from 20–25% to 8–16% [5,15,17]. Indications for surgery include excessive blood transfusion (≥4–10 units), haemodynamic instability, poor response to resuscitation, and failure to control bleeding by other means. Prior to surgery, localization of bleeding is key to success and minimization of risk of recurrence. The rate of re-bleeding is understandably higher with blind resection, up to 42%, compared with 14% following resection with accurate localization with endoscopy or radiographic imaging [2]. Accurate pre-operative localization also allows safer resection, improves rates of haemostasis, and is associated with significant decreases in post-operative morbidity and mortality [2]. If a source of bleeding cannot be localized pre-operatively the bowel can be serially clamped intra-operatively to localize bleeding if successful segmental resection is an option. If not, blind subtotal colectomy is the only therapeutic option. Blind segmental resection should not be performed as its morbidity and mortality is as great or greater than that following blind subtotal colectomy, with higher re-bleeding rates [2]. Excluding recurrent bleeding, the morbidity associated with surgical treatment of LGIB is high, with complications occurring in up to 23% of patients [15]. Overall surgical mortality ranges from 2.9–20% [8,19], but can be significantly increased following blind resection [2].

Outcomes

Morbidity and mortality are particularly high among the elderly who may have additional co-morbidities, poor physiological reserve, and are frequently on medications that worsen or prolong bleeding such as aspirin, NSAIDs, and anticoagulant and antiplatelet agents. LGIB has historically been associated with a lower mortality than UGIB, but results in longer hospitalizations and more resource utilization [20].

Overall morbidity for LGIB ranges from 6.4 to 21%; a recent review of 20 studies found a 26% rate of minor complications and 17% for major complications [4,5,17]. These complications include cardiac (e.g. myocardial infarction, exacerbation of heart failure), pulmonary (e.g. pneumonia, aspiration), abdominal pain, bowel ischaemia, access site (pseudo-aneurysm, dissection, haematoma, thrombosis or embolism), and allergic reaction. Risk factors for morbidity include associated co-morbidities, advanced age, and need for surgical treatment [5].

Mortality rates range from 3.6–25% with most large studies reporting mortality of 3–5% [5,6,8,20,12]. Patients presenting with active bleeding or haemodynamic instability, and those requiring urgent or emergent surgery have the highest risk of dying. Other risk factors include advanced age, intestinal ischaemia, coagulopathy, requirement for blood transfusion, severe co-morbidities, and male gender [5,12].

PART 6.4

Disordered gastric motility

CHAPTER 181

Vomiting and large nasogastric aspirates in the critically ill

Tong J. Gan and John T. Lemm

Key points

- A wide range of conditions can cause nausea and vomiting, making it a common occurrence in the critically ill.
- A deeper understanding of the pathophysiology of vomiting has led to the emergence of effective anti-emetics, each targeting a specific neurotransmitter in the emetic pathway.
- Serotonin antagonists are the first line anti-emetic of choice for most cases of nausea and vomiting due to their efficacy and favourable side effect profile.
- Large nasogastric aspirates must be managed aggressively in order to prevent delays in enteral nutrition.
- Management of large gastric aspirates involves gastric drainage, prokinetic agents, and if necessary, post-pyloric feeding.

Introduction

A common manifestation of critical illness is alteration in normal gastric function, ranging from delayed gastric emptying to severe episodes of nausea and vomiting. While seemingly benign, perturbations in gastric function can have severe consequences, including electrolyte disturbances, aspiration, and even vomiting-induced mechanical injury. Furthermore, as the beneficial role of early enteral feeding in the critically ill has become firmly established, effective means of managing altered gastric function are paramount.

Nausea and vomiting

A vast number of conditions are associated with nausea and vomiting, and not surprisingly, these symptoms are common among the critically ill (Table 181.1). Nausea is an unpleasant sensation, perceived prior to the active phases of retching and vomiting. This contrasts with the passive regurgitation of gastric contents that may occur silently, typically has no prodromal symptoms, and can be relieved with a head-up posture. Differentiating between these two processes is crucial, as their pathophysiology and treatments are markedly different.

Pathophysiology

While the act of vomiting is regulated by the brainstem, the pathophysiology of nausea is much less clear. The cerebral cortex appears to process various afferent inputs from lower centres, such as the chemoreceptor trigger zone and the vestibular system, as well as higher centres supplying emotional states, pain, and olfaction into the sensation of nausea. Importantly, nausea is a distinct process that may not always precede vomiting, although it can be as or more distressing than vomiting. The conscious experience of nausea is typically accompanied by autonomically-mediated vasomotor activity.

Recent research demonstrates not one, but several, medullary structures that work in concert to produce the vomiting reflex, defined as the 'central pattern generator for vomiting' [1]. One main afferent limb of this system involves serotonin-releasing enterochromaffin cells of the gastrointestinal tract. The serotonin binds 5-HT_3 receptors activating vagal afferent from the gastrointestinal tract that terminate across the medulla. Another critical afferent input involves the area postrema, a blood–brain barrier free structure that acts as a chemoreceptor zone, sensing stimuli such as drugs or toxins. Additional inputs supplying the medulla include consciously perceived noxious stimuli from the cerebral cortex, the vestibular system, and the cranial nerve-mediated gag reflex. Research into these afferent pathways has elucidated the neurotransmitters responsible for emetic effects and has facilitated the development of anti-emetic agents. Histaminergic H_1 and cholinergic muscarinic M_1 receptors are principally responsible for the vestibular vomiting pathway, while gastrointestinal vagal pathways are predominantly mediated by serotonin 5-HT3 receptors. Other neurotransmitter systems involved include dopaminergic D_2 receptors and neurokinin (NK_1) receptors.

Once a critical threshold of afferent input is reached, the efferent limb of the vomiting reflex is mediated via several brainstem nuclei. Simultaneous contraction of the abdominal wall, diaphragm, and intercostal muscles against a closed glottis result in the act of retching. Vomiting then occurs when the upper oesophageal sphincter relaxes and the pressure gradient from these muscular contractions promotes oral ejection of gastric contents. Post-dromal symptoms include pain, diaphoresis, shivering, and generalized weakness.

Vomiting in the critically-ill patient

Nausea and vomiting are manifestations of a wide range of disease states, and are exceedingly common in the critically ill. Intensivists should not discount emesis as innocuous, as even short periods of vomiting can result in catastrophic injury. Mild complications include emotional distress, increased post-surgical pain and mild dehydration. More severe harm may occur in the form of wound dehiscence, esophageal rupture, severe dehydration, electrolyte

Table 181.1 Conditions associated with nausea and vomiting

Gastrointestinal illness	Non-gastrointestinal illness	Metabolic disorders	Drugs/toxins
Gastroenteritis	Vestibular disorders	Pregnancy	Post-operative nausea and vomiting
GI obstruction	Elevated ICP	Diabetic ketoacidosis	Opiates
Pseudo-obstruction	Intracranial haemorrhage	Uraemia	Antibiotics
Gastroparesis	Migraine headache	Hypercalcaemia	Chemotherapy agents
Intestinal ischaemia	Psychogenic vomiting	Hyponatraemia	Radiation therapy
Peptic ulcer disease	Bulimia	Thyroid disorders	Dopamine agonists
Biliary colic/cholecystitis	Myocardial infarction	Parathyroid disorders	Hypoglycaemics
Appendicitis	Cardiomyopathy	Liver failure	Anti-arrhythmics
Hepatitis	Severe pain	Adrenal insufficiency	Ethanol
Pancreatitis	Cough	Porphyria	Envenomations
Cyclic vomiting syndrome		Acute mountain sickness	Food poisoning
Functional vomiting syndrome			

disturbances and metabolic alkalosis. Perhaps the most devastating of all vomiting complications in the ICU setting is pulmonary aspiration of gastric contents. While any ICU patient may suffer from nausea and vomiting, two patient subsets are at highest risk: the acute post-operative patient, and those with neurological disease.

Post-operative nausea and vomiting

Post-operative nausea and vomiting (PONV) are among the commonest complications following anaesthesia, with an overall incidence estimated at 30%, and up to 80% in high-risk patients. Patient-related risk factors include female gender, non-smokers, and a history of motion sickness or previous PONV. Anaesthesia-related predictors include duration of anaesthesia and administration of nitrous oxide, opiates, and volatile anaesthetics. Surgical procedures such as strabismus correction, ear, nose, and throat, major abdominal, breast, and neurosurgery are all associated with higher rates of PONV. In addition to the risk of physical harm imposed by PONV, its associated emotional distress should not be discounted. Post-surgical patients have stated that they would spend up to $100 USD to avoid PONV [2].

Management of PONV begins with pre-operative risk-stratification and associated levels of escalating anti-emetic prophylaxis. The intensivist should have a thorough understanding of this strategy and identify the exact anti-emetics administered intra-operatively. Repeating an anti-emetic from the same class within 6 hours is a common, expensive, and ineffective method of PONV treatment in the ICU setting; other classes of anti-emetics should be supplemented instead. Finally, heightened awareness of pulmonary aspiration is necessary due to impaired levels of consciousness commonly found in post-operative patients.

Vomiting in neurological disease

Neurological disease represents another common aetiology of nausea and vomiting in the ICU setting. Subarachnoid haemorrhage, migraine headache, vestibular disease, and conditions that raise intracranial pressure (ICP) are associated with an incidence of vomiting as high as 80%. Prompt treatment is paramount in this setting, as protracted vomiting can further raise ICP and exacerbate the pathology. Furthermore, vomiting in this setting is another risk factor for pulmonary aspiration, as such patients commonly have impaired levels of consciousness [3].

Management of nausea and vomiting

Proper management of nausea and vomiting should begin, if possible, with preventative measures. Nausea can be a harbinger of vomiting and should be aggressively treated with anti-emetics to prevent the complications of vomiting. A differential diagnosis as to the aetiology of vomiting is necessary; surgically correctable causes must be identified and dealt with early.

Clinicians now have an array of anti-emetic choices at their disposal. While many patients readily respond to one drug class, a more effective strategy will require multi-modal techniques. The astute intensivist requires knowledge of each anti-emetic class type, as well as their benefits and drawbacks. The patient may still require management of dehydration and electrolyte disturbances. Basic chemistry panels will guide electrolyte supplementation, while dehydration is typically managed with balanced crystalloid infusions.

Serotonin antagonists

With availability of generic ondansetron, the 5-HT_3 receptor antagonists have become a mainstay in anti-emetic therapy due to their effectiveness and favourable side-effect profile. Exerting their effects at both serotonin receptors in the gastrointestinal tract and brain they are particularly effective treatments for chemotherapy-induced nausea and vomiting (CINV) and PONV. While ondansetron is the most widely available, dolasetron, granisetron, and palonosetron all have similar efficacy. Palonosetron, with a half-life of nearly 40 hours is of particular use in preventing delayed nausea and vomiting seen after chemotherapy. Contrary to common belief, 5-HT_3 antagonists have very similar efficacy compared with dexamethasone and droperidol. The widespread use of serotonin antagonists as a first-line anti-emetic stems from their relatively positive side-effect profile compared with these other agents [4,5].

Dopamine-D_2 antagonists

Dopamine antagonists have established anti-emetic efficacy and are readily available in most settings. The three main classes of dopamine

antagonists include prokinetics such as metoclopramide, phenothiazines, and the butyrophenone droperidol, all of which are believed to act on the chemoreceptor trigger zone. Regardless of class, all dopamine antagonists can cause anti-serotonergic and extrapyramidal side-effects at high doses. Metoclopramide mediates its anti-emetic effect through prokinetic activity in addition to dopamine receptor antagonism. A 10-mg intravenous dose is typically used for management of vomiting, however, while this dose is effective in emptying the stomach, it has weak anti-emetic properties. Higher doses may possess greater anti-emetic properties, but at the expense of extrapyramidal side-effects. Alternative D_2 antagonists that also act on histamine and cholinergic receptors include phenothiazines, e.g. promethazine and prochlorperazine. Lower doses have adequate anti-emetic properties (promethazine 6.25 mg; prochlorperazine 10 mg), while higher doses increase the risk of sedation.

Droperidol is a highly effective anti-emetic that has fallen out of favour due to a somewhat controversial FDA black box warning regarding its QTc prolongation effects. Droperidol increases QTc, in a dose-dependent manner. Doses from 0.625 to 1.25 mg possess anti-emetic effects. At this low dose, QTc rose on average only 15-msec, smaller than the 20-msec rise associated with 4 mg of ondansetron [4]. All controversy aside, the ICU setting provides a suitable environment for the 2–3 hours of continuous ECG monitoring recommended by the FDA after droperidol administration, although it should be avoided in patients with a history of QTc prolongation or torsade de pointes.

Antihistamines

Histamine antagonists mediate their anti-emetic effect primarily via blocking the vestibular vomiting pathways, making them particularly suited for motion sickness or patients with vestibular dysfunction. Diphenhydramine and dimenhydrinate are effective anti-emetics, but commonly lead to drowsiness. The sedative side-effects of the antihistamine class must be considered before administration to patients with already altered levels of consciousness.

Anticholinergics

Hyoscine is an effective anti-emetic typically administered via a transdermal patch to prolong its duration of action. Like the antihistamine class, it mediates its effects primarily through the vestibular pathways. Commonly used to prevent PONV, the patch is applied pre-operatively and provides up to 72 hours of anti-emetic coverage. Side-effects include sedation, blurred vision, and dry mouth, and elderly patients are at higher risk of anti-cholinergic mediated agitation. A recent meta-analysis did not show an increased risk of the various anticholinergic side effects when used in the peri-operative setting, other than visual disturbances [6].

Dexamethasone

Dexamethasone is another effective anti-emetic. However, given its slower onset of action, it is much better when administered as a prophylactic agent. While many providers use anti-emetic doses upwards of 10 mg, doses as low as 4 mg are as effective, with a duration of 24 hours [7]. Caution must be applied when administering dexamethasone to diabetics or patients with head injury as it may precipitate a rise in serum glucose levels [8]. Another potential complication includes immunosuppression, although this has not been reported with a single anti-emetic dose.

Neurokinin antagonists

While other classes of anti-emetics have targeted the afferent vomiting pathways, the neurokinin antagonists represent a breakthrough in targeting efferent pathways. Neurokinin-1 (NK1) has long been known to elicit emetic activity, but only recently have selective NK1 receptor antagonists come to fruition. Aprepitant and its intravenous form, fosaprepitant, are currently the only available drugs in this class, with several others under development. Their relatively long half-life makes them excellent preventative agents for CINV and PONV. When 4 mg ondansetron was compared with 40 and 125 mg of aprepitant for PONV prevention, the incidences of vomiting were 26, 10, and 5%, respectively [9].

Large nasogastric aspirates

Critical illness commonly impairs gastric motility and leads to intolerances or delays in enteral feeding. Gastric aspirates, otherwise known as gastric residual volumes (GRV), have become the default measurement in which to assess tolerance to enteral feeding, yet practice varies widely. As a consequence, GRV cut-offs ranging from 150 to 500 mL are commonly used to define tolerance of enteral nutrition [10]. While numerous complications stemming from large gastric residual volumes have been postulated, the greatest threat to the patient is interruption in enteral feeding. A recent meta-analysis demonstrates reduced mortality when enteral nutrition is provided within the first 24 hours of ICU admission, while another study found an association with increased ventilator-free ICU days [11,12]. A thorough appreciation of excessive GRV and its management are therefore critical to prevent delayed enteral nutrition in the critically ill [13].

Pathophysiology

Gastrointestinal motility is the result of orchestration between the enteric nervous system, enteric endocrine cells, and gastrointestinal smooth muscle. The central nervous and systemic endocrine systems then provide additional modulation, and as in nausea and vomiting, wide arrays of neurotransmitter systems are responsible for coordination of this activity [14]. The final result is a co-ordinated process by which gastrointestinal smooth muscle relaxes in order to accept food, then contracts to propel it further along the tract. The stomach relies on this complex pattern of relaxation and contraction, not only to propel food, but also to grind solids before they pass into the small intestine. Stomach motility is exquisitely sensitive to perturbations induced during critical illness, and drugs such as opioids, sedatives, and vasopressors may amplify these disturbances. Traumatic brain injury is another common cause of gastric retention and has proven especially resistant to conservative management with prokinetic agents. Fortunately, post-pyloric feeding is generally tolerated by the critically ill, and represents a simple means of managing gastric dysmotility.

Complications

Intensivists have long known that large gastric residual volumes are not innocuous, yet until recently, aspiration pneumonia was

believed to be the most severe side-effect of gastrointestinal dysmotility. Recent studies do not support this belief and, indeed, show no difference in pneumonia rates between liberal and conservative GRV thresholds [15]. Interruptions in enteral feeding represent a much greater threat. Minor complications from large GRV include gastric dilatation, nausea and vomiting, and electrolyte disturbances. Acute gastric dilatation is a manifestation of large GRV and is associated with patient discomfort. Acid-base status and electrolyte panels should be monitored as hypochloraemic alkalosis commonly occurs with chronic loss of large nasogastric aspirates.

Management

Reversible causes of dysmotility should be sought and corrected. Medications with known anti-motility side-effects, such as opioids and anticholinergics, should be avoided. Inadequate pain control can be effectively managed with non-opioid analgesics, while suspected gastrointestinal obstruction warrants a surgical consult. When reversible causes have been addressed, gastric dysmotility should be managed with a combination of drainage, prokinetic agents, and post-pyloric feeding.

Gastric drainage

Symptomatic gastric dilatation requires drainage, either intermittent or continuous in severe cases. More protracted episodes require crystalloid solutions and electrolyte supplementation to replace the volumes drained.

Prokinetic agents

Metoclopramide is a dopamine antagonist that has prokinetic properties primarily in the upper gastrointestinal tract. An intravenous regimen of 10 mg every 6 hours improves antropyloroduodenal co-ordination, although demonstrating benefit in critically-ill patients has been modest at best [16]. High-dose erythromycin (100–200 mg tid) is another agent that augments gastric motility and has a synergistic effect when prescribed alongside metoclopramide. Recent concerns over bacterial resistance and cardiac arrhythmias have limited its widespread use.

Post-pyloric feeding

Patients that fail conservative management strategies, or those perceived to be at high risk for gastric dysmotility, require post-pyloric feeding, either via nasogastric tube or jejunostomy. Fine-bore, 8 Fr soft nasogastric tubes with wire stylets are the most commonly used for this purpose. For post-pyloric placement, a tube length of at least 100 cm is optimal. Successful placement is most readily achieved using fluoroscopy, either at the bedside or in interventional radiology suites. Magnetically-guided systems (e.g. Cortrak) are gaining popularity as they show promise to speed placement and minimize radiation exposure. Blind placement should be avoided if fluoroscopy or magnetically-guided placement is available, as success rates are low. Prokinetic agents, such as metoclopramide may assist blind passage across the pylorus, but radiographic confirmation should always precede commencement of feeding if blind techniques are used. For patients that fail nasogastric feeding tube placement, or who require chronic, post-pyloric feeding, a surgically-placed jejunostomy is required.

CHAPTER 182

Ileus and obstruction in the critically ill

Philip Stevens and Paul Dark

Key points

- Obstruction is the commonest cause of acute intestinal failure in critical care.
- Management is dependent upon whether the obstruction is adynamic (paralytic) or mechanical in origin.
- Mechanical obstruction is more likely to require surgery and must be presumed present until actively excluded.
- Seventy per cent of post-operative small bowel mechanical obstruction is adhesional and likely to settle within 7 days of conservative management.
- Nutritional support should be considered when acute intestinal failure lasts >5 days.

Introduction

Intestinal obstruction results either from physical blockage (mechanical obstruction) or failure of propulsive motor activity (adynamic obstruction), the latter being synonymous with 'ileus' in common usage. Together, these represent the most frequent cause of acute intestinal failure in critical care that, in turn, may be either a consequence of, or a driver for, multiple organ dysfunction. Levels of evidence are graded according to definitions of the Oxford Centre for Evidence-based Medicine [1].

Physiology of gastrointestinal motility

Gut activity is controlled by the enteric nervous system and co-ordinated by autonomic innervation, hormonal, and chemical mediators. Specialized smooth muscle cells generate slow-wave electrical rhythmicity with decreasing frequency from duodenum to ileum. In the fasted state, mechanical activity is characterized by periods of phasic contractions known as Phase 3 of the migrating motor complex (MMC). This housekeeping activity clears debris from the small intestine. Loss of Phase 3 contractions is associated with the development of bacterial overgrowth and feed intolerance.

In the fed state, contractile activity results in segmentation that enhances mixing. Short segments of peristalsis allow aboral movement of food, the rate of which is regulated by humoral feedback mechanisms such that, within 1–2 hours, meals are cleared from the small intestine. Less is known about colonic contraction, which largely produces segmentation with mass movements up to three times a day resulting in transport of waste material [2].

Ileus

Epidemiology and aetiology

Clinically significant loss of small bowel motility is often a transient event secondary to abdominal surgery. It occurs in up to 15% of intestinal resections [3]. Other causes of paralytic ileus or pseudo-obstruction are less common (Table 182.1).

Pathogenesis

Sympathetic tone and inflammatory mediators (TNF-α, IL-1ß, IL-6, prostaglandins, nitric oxide) have an enterostatic effect. This is exacerbated by pharmacological effects, such as stimulation of peripheral μ-opioid receptors (PAMORs). Clinical features depend on the region of bowel affected. Gastroparesis or pyloric dysfunction results in vomiting or failure to tolerate nasogastric feed. Small bowel ileus is associated with varying degrees of feed intolerance or abdominal distension. Colonic pseudo-obstruction results in cessation of bowel movements or flatus. Consequences of ileus include acute intestinal failure, resulting in failure of substrate supply during the increased demand of catabolism, and intestinal ischaemia with evidence suggestive of bacterial translocation or perforation.

Management of ileus

Adynamic obstruction is managed conservatively with correction of any electrolyte disturbance, nutritional support, and minimization of enterostatic drug use. Rarely, surgical decompression may be necessary if ileus arises in the context of abdominal compartment syndrome. The pattern of recovery depends upon the segment of bowel involved, with small bowel recovering more quickly than stomach or colon. Return of colonic motility, however, seems to be a key factor in the clinical resolution of ileus [4].

Pharmacological management of ileus has largely focused on stimulation of motility by reduction of sympathetic tone. Prokinetic agents (e.g. metoclopramide, tegaserod, erythromycin, atilmotin) have not been shown to reduce ileus in clinical trials. Anti-inflammatory effects of cyclo-oxygenase-2 inhibitors have shown promise in the prevention of post-operative ileus, although their use in critical illness may be limited by microcirculatory disturbances and renal dysfunction. Anticholinesterase inhibitors (e.g. edrophonium, bethanechol) have been reported to be effective, but trials are lacking and clinical application is limited by cholinergic side effects [5]. Endoscopic pacing has only been described to date in animal models.

Table 182.1 Causes of acute intestinal failure

Cause	Mechanism	Examples
Adynamic (Ileus)	Acquired	Post-abdominal surgery
	Neurogenic	Spinal or head injury/hip fracture
	Inflammatory/infective:	Chagas' disease
	◆ Intestinal	Post-operative scleroderma
	◆ Intraperitoneal	Abscess/peritonitis
	◆ Retroperitoneal	Pancreatitis/malignant infiltration (Ogilvie's)
	◆ Systemic	SIRS/MODS/shock/myocardial infarction/stroke
	Infiltrative	Amyloidosis
	Pharmacological	Anticholinergics
	Metabolic	Opiates
	Over distension	Calcium channel blockers
	Congenital	Ganglion blockers
	Myopathic or neuropathic	Hypokalaemia/hypomagnesaemia
		Hypoxia/uraemia/diabetes/myxoedema
		Advanced mechanical obstruction
		Chronic intestinal pseudo-obstruction
		MELAS, MMIHS, MNGIE
Mechanical (obstruction)	Intraluminal	Gallstone ileus, foreign body
	Intramural	Tumour/intussuscepting polyp
	Extramural	Adhesions/hernia/extrinsic compression
Mucosal disease	Primary defects of absorption	Infective enteritis
		Inflammatory bowel disease
		Radiotherapy/chemotherapy

MELAS, mitochondrial myopathy, encephalopathy, lactic acidosis and stroke-like episodes; MMIHS, megacystis microcolon intestinal hypoperistalsis syndrome; MNGIE, mitochondrial neurogastrointestinal encephalomyopathy; MODS, multiple organ dysfunction syndrome.

Cisapride, a 5-HT4 receptor antagonist, promotes post-ganglionic acetylcholine release in the myenteric plexus, increasing the number and amplitude of duodenal contractions post-prandially. However, widespread clinical application has been limited by concerns regarding cardiovascular toxicity. Consequently, its application is largely restricted to post-operative ileus and feed intolerance in children with short bowel syndrome (**level 4**) [6].

Opioid effects on gastrointestinal motility are well documented. The balance between analgesic suppression of sympathetic activity and direct inhibition of gastrointestinal motility has been the focus of much interest in enhanced recovery programmes. Regional infiltration of local anaesthetics reduces demand for systemic opioids and PAMOR antagonists mitigate opioid-induced enterostasis. However, evidence to date for these agents has been from trials in chronic degenerative illnesses (methylnaltrexone) [7], or post-operative ileus (alvimopan) [8] (**level 1b**). Data on their utility in critical illness are lacking.

Neostigmine is an anticholinesterase inhibitor that promotes parasympathetic tone in the gut wall. Cholinergic side effects, including bradycardia, vomiting, excessive salivation and abdominal cramps, may be mitigated by glycopyrronium bromide or atropine. Epidural neostigmine has reduced time to restoration of bowel function in elective abdominal aortic surgery (**level 1b**) [9], and is moderately effective in relieving acute colonic pseudo-obstruction in critical illness (**level 1b**) [10]. However, its usefulness in small bowel ileus is less clear. Pyridostigmine is a similar drug that may prevent recurrent pseudo-obstruction (**level 4**) [11], although its efficacy in critically-ill patients is unknown.

Colonoscopic decompression may be required when conservative management fails. However, repeated procedures may be necessary with a 2% risk of perforation each time (**level 4**) [12]. Recurrence may be less likely with the osmotic laxative, polyethylene glycol, although data are limited (**level 1b**) [13]. As a stimulant laxative, bisacodyl has potential for maintenance use but, again, clinical evidence is lacking.

Obstruction

Definition

Mechanical obstruction indicates occlusion of the lumen in a normally motile segment of bowel. It may be complete or incomplete (i.e. allowing passage of minimal volume with proximal distension; also known as **subacute** obstruction), and simple or strangulated (depending on whether the obstructed segment has compromised perfusion). A closed-loop obstruction occurs when the obstructed loop has no proximal means of decompression, such as an obstructed hernia or colon with a competent ileocaecal valve. Closed-loops are more likely to progress to perforation if untreated.

Epidemiology

Up to 10% of patients undergoing abdominal surgery will develop significant post-operative mechanical obstruction [14]. Post-operative small bowel obstruction is most likely to occur following open abdominal surgery in the infracolic compartment, especially colectomy or ileo-anal pouch surgery, or emergency surgery, particularly following perforated appendicitis [15]. In contrast, small bowel obstruction is less common following laparoscopic surgery [16]. Nevertheless, mechanical obstruction is more likely than ileus following laparoscopic surgery, in which a low threshold for re-operation should be maintained [17].

Aetiology

Eighty per cent of mechanical obstruction occurs in the small bowel, most commonly by adhesions, hernias or intra-abdominal neoplasia (in descending order). Large bowel obstruction is more commonly due to tumours, diverticular stricture or volvulus (in the case of the caecum and sigmoid colon). Causes of mechanical obstruction can be classified according to their origin in relation to the bowel wall as intra-luminal, intra-mural, or extra-mural.

Pathogenesis

Stretch receptors stimulate the intestine-intestinal reflex, via extrinsic nerves, such that distension results in reflex relaxation of distal bowel and stimulation of increased contractions proximally. In the presence of static mechanical obstruction, this increases peristalsis resulting in colicky abdominal pain. As intraluminal pressure increases the bowel distends, increasing transmural tension and compressing the vasculature. If the obstruction is not overcome, the proximal bowel is eventually overridden by inhibition of

motor activity. Strangulation occurs if reflex relaxation occurs after ischaemic injury is established, or if mesenteric blood flow is interrupted by direct vascular occlusion as with volvulus, intussusception or hernia sac entrapment. Uncorrected, ischaemia leads to loss of mucosal barrier function and the potential for bacterial translocation or necrosis with perforation, resulting in sepsis.

Symptoms

These vary from predominant vomiting to painful distension depending on whether the level of obstruction is high or low (i.e. proximal or distal bowel). Initially, vomiting is typical of gastric or upper small bowel involvement. Stagnation and bacterial overgrowth occur later in obstruction, resulting in effortless feculent vomiting. Failure to pass flatus or faeces is a hallmark of complete obstruction and occurs earlier with more distal obstruction.

The hallmark of obstruction is colicky pain, characterized by an inability to settle in a position of minimal pain, in contrast to the peritonitic patient, who lies still to minimize pain. Signs of peritonitis in the presence of obstruction indicate late presentation with possible perforation or necrosis of the underlying bowel. However, these features may be absent in sedated patients so clinical suspicion should remain high in critically-ill patients intolerant of enteral feeding.

Management

Urgent operative resolution is important if there are signs of peritonitis, severe sepsis, strangulation, or a closed-loop obstruction. Complete large bowel obstruction with caecal tenderness or volvulus also requires prompt operative correction due to the risk of imminent perforation. However, 70% of post-operative small bowel obstruction is due to adhesions and will usually settle with nasogastric drainage and nutritional support, usually via a peripheral cannula or percutaneously inserted central catheter (PICC line). Obstruction after laparoscopic surgery, on the other hand, is much more commonly the result of port-site herniation (**level 4**) [16]; early laparotomy should be considered in order to avoid strangulated obstruction.

Patients who settle with conservative management tend to do so within seven days (**level 4**) [14]. The risk of strangulation within this time is negligible in the absence of closed-loop obstruction and severe sepsis (**level 3a**) [15]. Re-operation for those who do not settle becomes particularly hazardous as, within 10–14 days of surgery, obliterative peritonitis may convert the peritoneal cavity into an impenetrable fused block, precluding safe dissection. Early surgical involvement is therefore essential. When indicated, re-operation for obstruction should be performed by a senior, experienced surgeon. Great care is necessary to avoid inadvertent intestinal injury and creation of gastrointestinal fistulae (**level 2b**) [18].

Differentiating a dynamic from mechanical obstruction

In comparison with mechanical obstruction, pain is not a significant feature of adynamic obstruction. However, it can be difficult to differentiate between them in the sedated, post-operative or spinally-injured critically-ill patient. Deep sedation, neuromuscular blockade, and steroid therapy can all contribute to masking clinical signs. Hyper-echoic bowel sounds may be absent in long-standing mechanical obstruction. More subtle clinical features, such as intolerance of tube feeding, or alteration of bowel or stoma output, may be the first signals of impending serious intra-abdominal pathology.

Plain abdominal radiography may be helpful with identifying sigmoid or caecal volvulus, hernial obstruction, foreign body ingestion, or gallstone ileus. However, sensitivity is limited by the possible failure to identify fluid-filled, distended loops. Urgent surgical opinion is recommended where clinical suspicion remains. Erect abdominal radiography has been superseded by contrast-enhanced studies. Water-soluble contrast may be both diagnostic and therapeutic as hyperosmolar gastrografin stimulates peristalsis. Plain films demonstrating passage of contrast into the large bowel within 2 hours effectively excludes small bowel ileus. Contrast enemas can also rule out distal obstruction in colonic pseudo-obstruction. Double contrast CT scans will identify 95% of obstructions, delineate the level and cause of obstruction, and provide information regarding bowel viability. Critically-ill patients must be stable for transfer. When doubt remains despite imaging, an exploratory laparotomy may be necessary.

Nutritional support

A pragmatic definition of acute intestinal failure applicable to the bedside is an inability to tolerate 80% of estimated nutritional requirements delivered enterally for a minimum of 48 hours [19]. Intolerance of enteral feeding expected to last ≥5 days is generally seen as an indication for parenteral nutrition, although controversy exists over the ideal timing of its introduction in critically-ill patients [20].

Conclusion

In general, if a patient has obstructive symptoms, a surgical opinion is essential to assist in consideration of the underlying cause and the realistic chances of resolution. Decide early if further investigation is required—look for and treat correctable systemic factors. Regardless of cause, consider whether nutritional support is required until resolution of acute intestinal failure is achieved.

CHAPTER 183

Diarrhoea and constipation in the critically ill

Geoffrey J. Dobb

Key points

- All except short-term intensive care unit patients should have a bowel management plan.
- Severe diarrhoea can rapidly induce dehydration and electrolyte imbalance with significant mortality, especially in infants, debilitated or malnourished children and adults, and in developing countries.
- *Clostridium difficile* is now the most cause of infectious diarrhoea in hospitals in Europe and North America.
- Constipation is very common in patients needing intensive care.
- Faecal impaction can complicate any form of constipation and must be excluded by rectal examination.

Introduction

Disordered gastrointestinal function is common in the critically ill. Diarrhoea and constipation both have major adverse effects on patient comfort and dignity. Both also have secondary effects that may impact on outcomes. Normal stool consistency can be defined as type 3 or 4 on the Bristol stool form scale [1]. All except short-term intensive care unit (ICU) patients should have a bowel management plan though, in practice, these are used less often than other ICU process of care plans [2]. When used, they appear to reduce the frequency of diarrhoea and constipation [3].

Diarrhoea

Diarrhoea is an increase in the frequency, quantity, and liquidity of faeces. The circumstances of intensive care make quantitative definitions based on weight or volume of stool hard to implement, and the process of measurement has implications for infection control when the cause is unknown. More pragmatically, diarrhoea is often defined as passage of ≥3 liquid stools in a day.

Diarrhoea can be the predominant symptom of severe systemic illness, especially in infants, but is also a common complication of hospital-acquired infection or drug treatments. Depending on definition used and setting, the reported frequency is 40–90% [4]. While most diarrhoea episodes do not have an infectious cause, the potential severity and infection control implications of infectious diarrhoea are increasingly recognized as important issues for the critically ill.

Pathophysiology

Approximately 1500 mL of liquid intestinal content reach the caecum each day, but only 100–200 mL water is normally lost in faeces. The colon can absorb up to 4500 mL water a day. Increased water loss with diarrhoea occurs if the fluid volume entering the caecum exceeds the maximum absorption capacity of the colon, if colonic absorption is impaired, or there is net loss of water into the colon.

Absorption of water in the colon is closely linked to electrolyte absorption. Energy-dependent active transport of electrolytes across the colonic mucosa draws water into the extracellular space. The colon can transport water against an osmolar gradient of up to 50 mOsmol/L, unlike the ileum where absorbed electrolytes are accompanied by iso-osmolar amounts of water. Water absorption is greater in the ascending colon than descending colon or rectum.

Rapid colonic transit times through the proximal colon, associated for example with some neuro-endocrine tumours or carcinoid, limit the potential for water absorption and cause diarrhoea.

Normal intestinal secretion, absorption and motility are maintained by highly complex interactions of >30 hormones and hormone-like peptides, plus sympathetic and parasympathetic nervous systems. Secretion and activity are altered during critical illness; in addition, many inflammatory mediators released during sepsis and other inflammatory syndromes affect gut function. In animal studies, pro-inflammatory cytokines are secreted into the gut lumen during endotoxaemia [5].

Other non-infectious factors contributing to diarrhoea include splanchnic vasoconstriction as a physiological response to hypotension or exogenous vasoconstriction (e.g. noradrenaline, vasopressin) with reduced supply of energy substrates needed for reabsorption of salt and water, reduced enteral feeding (the colonic mucosa normally receives 60–70% of energy needs from the gut lumen), altered gut flora as a result of proton pump inhibitors or H_2 antagonists allowing colonization of the upper gastrointestinal tract or antibiotic use, and reduced bile acid re-absorption, increasing the amount reaching the colon and causing water and electrolyte secretion. Hypoalbuminaemia is common in the critically ill and has been associated with an increased frequency of diarrhoea, but studies are inconclusive.

Infectious diarrhoea

In many developing countries 25–50% of childhood mortality is associated with diarrhoea l disease. Malnutrition is a risk factor for mortality. In adults dehydration, electrolyte imbalance and

weight loss tend to be proportionately less severe but can still be life-threatening, especially in the severely malnourished, debilitated and those with severe end-stage disease, e.g. AIDS. Pneumonia and septicaemia are common concurrent infections in those who die.

Causes

Bacteria causing diarrhoea in developed countries include *Salmonella, Shigella, Yersinia, Campylobacter, Clostridium perfringens, Clostridium difficile*, and *Staphylococcus aureus*. These are commonly transmitted by food, but in hospital and intensive care, the potential for faecal transmission requires strict infection control procedures, including care with disposal of liquid faeces, soiled linen, and cleaning materials. *Salmonella, Shigella, Yersinia*, and *Campylobacter* are invasive, causing an inflammatory diarrhoea that can be associated with fever and abdominal pain. Stools are usually watery, but can contain blood or mucus.

Enterotoxins are the cause of diarrhoea associated with *Staphylococcus aureus, Bacillus* spp., some *Escherichia coli* and *Clostridium perfringens*. Enterotoxin-induced diarrhoea usually lasts about 24 hours. Enterotoxins act in varying ways, but the diarrhoea is non-inflammatory and mediated by reduced water and electrolyte absorption. *Clostridium perfringens* type C, mainly found in South East Asia, causes enteritis necroticans.

Escherichia coli form part of the normal intestinal flora, but six pathogenic strains are associated with diarrhoea:

- Shiga toxin-producing *E.coli*, also referred to as enterohaemorrhagic *E. coli*. This is the strain most commonly associated with *E. coli* food-borne diarrhoeal illness. The strain causing the 2011 European outbreak was O104:H4, and the commonest in the USA is O157:H7.
- Enterotoxingenic *E.coli.*
- Enteropathogenic *E.coli.*
- Enteroaggregative *E. coli.*
- Entero-invasive *E .coli.*
- Diffusely adherent *E. coli.*

The *Shigella* toxin-producing *E. coli* causes a variable illness mimicking *Shigella* infection with abdominal pain, diarrhoea (sometimes bloody), and vomiting. Illness duration is usually 5–7 days. Approximately 5–10% of patients, mainly children, develop the life-threatening complication of haemolytic uraemic syndrome with renal failure, micro-angiopathic anaemia and thrombocytopenia.

Cholera is an acute diarrhoeal illness caused by *Vibrio cholera.* It is estimated to cause over 100,000 deaths a year worldwide out of 3–5 million cases. Perhaps 75% of those infected are symptom-free. Of those who develop symptoms, 80% have mild-to-moderate illness and 20% develop acute watery diarrhoea causing dehydration. It can kill within hours of onset. Two serogroups, O1 and O139, cause outbreaks. It is a disease of poor sanitation and a risk after natural disasters in endemic areas.

Clostridium difficile is the commonest cause of infectious diarrhoea in North American and European hospitals, and is increasing in both frequency and severity [6]. The virulent BI/NAP1/027 strain has been associated with some hospital outbreaks. It produces considerably more A and B toxins that cause intestinal mucosal inflammation. While its presence in the colon can be asymptomatic or associated with only mild diarrhoea, it is the major cause of antibiotic-associated colitis and pseudomembranous colitis. Toxic megacolon is an uncommon, but severe complication of pseudomembranous colitis. It should be suspected when a patient who is on, or has recently received, antibiotics develops increasing abdominal pain, distention, and fever. Approximately half the patients with toxic megacolon present with shock, and need intensive care and surgical review. Failure to respond to medical treatment—fluids, vasopressor support, vancomycin 125–500 mg (depending on severity) enterally 6-hourly plus metronidazole 500 mg intravenously 8-hourly, with increasing abdominal pain and colonic distention is an indication for subtotal colectomy.

Norovirus and rotavirus are well-recognized forms of hospital- or ICU-acquired diarrhoea. Rotavirus predominantly affects young children and is endemic worldwide. It causes both watery diarrhoea and vomiting that lasts 3–8 days, so dehydration and electrolyte loss can be severe and cause death, especially in malnourished and debilitated infants and young children. Norovirus is one of the commonest causes of diarrhoea worldwide. It causes outbreaks in nursing homes and hospitals. Importantly, it is easily transmitted to health care workers with a very short incubation time, in part because it survives well in faeces and vomitus.

Giardia lamblia, Cryptosporidiosis, and *Entamoeba histolytica* are important causes of severe diarrhoea in developing countries. Reactivation of *Strongyloides stercoralis* can be precipitated by critical illness and cause diarrhoea.

Management

Infectious diarrhoea is generally highly transmissable from patient-to-patient, or via health care workers. Many are notifiable diseases and managing outbreaks is an important public health function. ICU patients with diarrhoea should be isolated, and extreme care taken with disposal of faeces and vomitus. Strict adherence to hand hygiene is extremely important; patient-to-patient transmission of pathogens often indicates that this has failed. Any outbreak of diarrhoea in an ICU requires involvement of infection control staff, microbiology expertise to determine the cause, patient isolation or cohorting, and environmental cleaning.

Health care workers assigned to international aid agencies and those travelling to endemic areas can be immunized against cholera, but this is less than 100% effective. Careful ICU design including use of single rooms can limit the risk of patient-to-patient transmission. Innovative approaches, such as using copper on ICU surfaces may also have a role.

A good history is important to determine if there are chronic diseases present that are associated with diarrhoea. Other important questions relate to recent and past travel, drug history, family health, and exposure to others with diarrhoeal illness.

Physical examination should assess signs of dehydration, body temperature, pulse and blood pressure, and abdominal examination for signs of distention, tenderness, guarding, and bowel sounds. Rectal examination is important to exclude constipation with overflow of liquid faeces. Signs are non-specific, but can give an indication of severity. The nature of the stool including liquidity, and the presence of blood or mucus are also non-specific.

Stool samples should be sent for culture and sensitivity testing. The scope can be guided by the clinical setting and information obtained from history and examination. During outbreaks, individual pathogens should be sought, e.g. *Escherichia coli* O157-H7, norovirus. ICU patients should always have their stool checked for

the presence of *Clostridium difficile* toxins. Abdominal X-rays have a low yield except to detect severe colonic distention in toxic megacolon associated with, for example, *C. difficile* or ulcerative colitis.

Sigmoidoscopy has a limited role, but can provide diagnostic information if there is a flare-up of chronic colitis, an invasive colitis, or if the typical pseudomembranes of pseudomembranous colitis are present.

Laboratory investigation should include plasma electrolytes, magnesium, urea, creatinine, and phosphate. A high haematocrit suggests dehydration. A stool osmotic gap >100 mosmol/kg (2 × stool $[Na^+ + K^+]$ minus plasma osmolality) demonstrates osmotic diarrhoea or malabsorption.

Treatment should be directed at any known and treatable underlying cause. Many drugs have diarrhoea as a side-effect; review and cessation of all non-essential medications may stop the diarrhoea. Many ICU patients are given laxatives and the cumulative effects of these should not be overlooked. Medication given as elixirs through feeding tubes can contain large amounts of sorbitol and be responsible for osmotic diarrhoea.

Enteral feeds are often blamed for diarrhoea, although evidence is limited. Implicated predisposing factors, include high feed osmolality, lactose intolerance, bacterial contamination, bolus (as opposed to continuous) feeding, lack of dietary fibre, and re-feeding syndrome. Most modern commercially available feeds are lactose-free, contain a source of fibre, and are given through closed systems that limit the risk of bacterial contamination.

Avoidance and correction of dehydration and electrolyte imbalance are the mainstays of treatment. Except for severe dehydration, oral rehydration therapy (ORT) is sufficient, either orally or through a nasogastric tube. The WHO recommends glucose or rice water-based fluids with an osmolarity of 200–310 mOsmol/L and sodium 60–90 mmol/L [7]. WHO oral rehydration salts contain (in mmol/L) sodium 75, chloride 60, potassium 20, citrate 10, and glucose 75; total osmolarity is 245mosmol/L. The addition of zinc has been recommended in developing countries. Carbonated drinks, diluted cordial, and fruit juices are not suitable. Commercial ORT solutions are readily available in developed countries. Mild-to-moderate dehydration is corrected by 50–100 mL/kg body weight of ORT over 4 hours with ongoing replacement of losses at approximately 120 mL ORT for every watery stool or vomit. Severe dehydration may need intravenous balanced salt solution until peripheral perfusion and urine output return to normal, followed by ongoing ORT for replacement of losses.

Antibiotics have a limited role in treating infectious diarrhoea. Most are viral or self-limiting. Some options for antibiotic treatment are shown in Table 183.1, using the cheapest available.

Anti-motility agents (e.g. loperamide 4 mg initially followed by 2 mg after each loose stool to a maximum of 16 mg in 24 hours for adults, or codeine phosphate) are relatively contraindicated in infectious diarrhoea and may prolong shedding of infectious organisms, but are often used for symptomatic relief or prolonged diarrhoea.

Probiotics are advocated to reduce the frequency of antibiotic-associated diarrhoea, including that caused by *Clostridium difficile*. A meta-analysis of trials assessing *Saccharomyces boulardii* suggested a 50% risk reduction; *Lactobacillus GG* also appears effective [8]. There is insufficient evidence to recommend probiotics for prevention/treatment of *C. difficile*-induced diarrhoea [8]. While there is no clear increase in adverse events associated with probiotics, the evidence is insufficient to be certain.

Constipation

Constipation is the most common disorder of intestinal motility. In the general community its prevalence is estimated at 3–17%

Table 183.1 Antibiotic options for bacterial infectious diarrhoea

Organism	Antibiotic	Comment
Bacillus spp.	Not indicated	
Campylobacter spp.	Erythromycin	Reduces duration of diarrhoea and shedding of organism
Clostridium difficile	Metronidazole, vancomycin	See text
Clostridium perfringens	Not indicated	
Escherichia coli	Trimethoprim-sulphmethoxazole	
	3rd generation cephalosporin	For systemic complications
Salmonella spp.	Not indicated unless high risk	Prolong carrier state, risk of relapse
	Trimethoprim-sulphmethoxazole	For high risk patients, severe diarrhoea
	3rd generation cephalosporin	Invasive disease, typhoid
Shigella spp.	Trimethoprim-sulphmethoxazole	
	3rd generation cephalosporin	For bacterial resistance, invasive disease
Staphylococcus aureus	Not indicated	Enterotoxin
Vibrio cholerae	Doxycycline	
	Erythromycin	2nd line
Yersinia spp.	Trimethoprim-sulphmethoxazole	Only for high risk, complicated disease
	3rd generation cephalosporin	

depending on definition and population studied. A period of constipation is very common in critically-ill patients. Contributing factors include immobility, drug side effects, reduced food intake, abdominal surgery, and neurohumoral changes.

Chronic constipation is generally defined as less than two bowel movements a week, persisting in the absence of obstruction, and despite medical treatment and a high fibre diet. Constipation has three forms:

- **Slow transit**: reduced colonic motility slows stool transit through the colon resulting in hard faeces and infrequent bowel actions.
- **Normal transit**: normal colonic motility, but small bulk results in hard faeces and straining.
- **Pelvic floor dysfunction**: incomplete evacuation and obstruction.

Faecal impaction can complicate any form of constipation. The patient cannot pass faeces spontaneously. Faeces are hard and abdominal discomfort common. It is an important cause of faecal incontinence.

The frequency of constipation in ICU patients depends on the definition and the population studied; most studies report between 20 and 58% [9,10] but 83% has been reported [11]. A PaO_2/FIO_2 ratio <150 and hypotension increase the risk of constipation. Having constipation is associated with adverse outcomes and a prolonged ICU stay.

Constipation must be differentiated from mechanical obstruction, pseudo-obstruction and ileus.

Pathophysiology

Defecation is usually under a high level of voluntary control to prevent incontinence. During normal rectal emptying, rectal pressure, and intra-abdominal pressure increase accompanied by inhibition of the smooth and striated muscle of the rectal sphincter. During rectal emptying the pelvic floor descends, followed by increased pelvic floor muscle activity as it returns to the resting position at the end of defecation.

Colonic motor activity is mainly localized to short segments and occurs in an uncoordinated way at irregular intervals through the day. Several times a day, most commonly after wakening or in the late post-prandial period, high-pressure contractions propagate as a peristaltic wave over a long length of colon (mass movements), and transport colonic content distally. These contractions are accompanied by an urge to defaecate or precede defaecation during consciousness. Sleep, sedation, and abdominal incisions inhibit colonic motor activity. Peristaltic contractions are less frequent in constipated patients.

Colonic muscle is innervated by the myenteric plexus, which includes cholinergic and peptidergic neurons sensitive to vasoactive intestinal peptide, substance P, encephalin, somatostatin, and other mediators. It is also innervated by the autonomic nervous system and influenced by gastrointestinal hormones. The parasympathetic supply to the proximal and distal colon are from the vagus nerve and pelvic nerves, respectively. The sympathetic supply to the proximal and distal colon comes from splanchnic or lumbar nerves arising from the superior and inferior mesenteric ganglia, respectively. Catecholamines inhibit colonic muscle contraction. Loss of the pelvic parasympathetic nerve supply interferes with reflex control of defecation.

Disordered motility and bowel distention cause abdominal discomfort and pain in conscious patients. More severe distention contributes to raised intra-abdominal pressure with its associated adverse effects [12].

Causes

Main causes of constipation are summarized in Box 183.1. Constipation is also almost invariable in patients with circulatory shock as a consequence of splanchnic hypoperfusion. Most patients given narcotic analgesics and sedatives become constipated. The role of altered food intake and dietary fibre remain unclear despite multiple investigations.

Constipation is more common in the elderly. Women are also more prone to constipation, particularly during pregnancy.

Management

Clinical history and examination may provide evidence of any reversible cause. A detailed drug history should be taken, and a rectal examination performed to exclude faecal impaction and to inform the patient's bowel management plan.

If the rectum is full, a suggested management pathway is shown in Fig. 183.1. Suppositories are dissolved into a liquid at body temperature. Glycerine suppositories draw water into the faeces by osmosis, while stimulant suppositories (e.g. bisacodyl) stimulate colonic peristalsis and secretion of fluid into the lumen. Small volume (5 mL) sodium citrate enemas or larger volume sodium phosphate enemas (133 mL) contain poorly absorbed ions including magnesium, phosphate, sulphate, and citrate that draw water into faeces by osmosis. Retention of larger volume enemas may contribute to fluid overload and electrolyte imbalance. These are also risks associated with colonic lavage. Manual evacuation is generally a last resort and needs to be performed with care to avoid anal or rectal trauma. It can cause parasympathetic stimulation with extreme bradycardia, especially in patients with spinal injury. Once the rectum is empty, patients can revert to the standard care pathway outlined in Fig. 183.1.

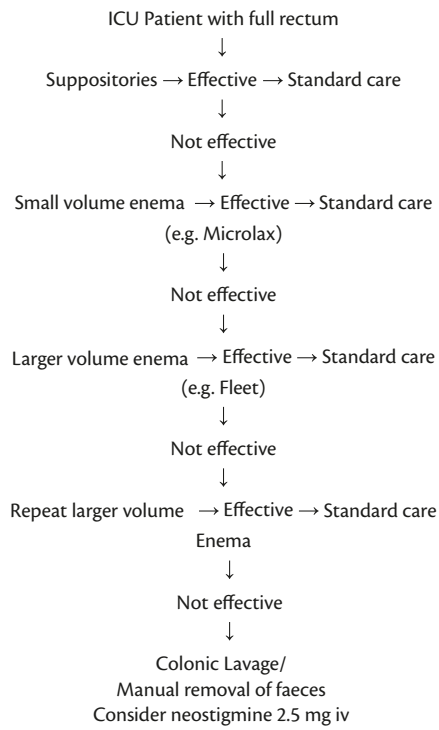

Fig. 183.1 Management plan for constipated ICU patients with a full rectum.

Box 183.1 Causes of constipation

- **Environmental**: need for bedpans, commode, lack of privacy, noise, unfamiliar toileting environment.
- **Neurological**: head injury, spinal injury with quadriplegia or paraplegia, multiple sclerosis, autonomic neuropathy, pelvic surgery.
- **Psychiatric**: depression, dementia, anorexia nervosa.
- **Drug-induced**: opiates, sedatives, catecholamines, antidepressants, antipsychotics, anticholinergics, aluminium-containing antacids, antihypertensives, diuretics, oral iron supplements, laxative abuse.
- **Endocrine**: hypothyroidism, pregnancy, hypercalcaemia, diabetic neuropathy.
- **Metabolic**: hypercalcaemia, lead poisoning, acute porphyria, dehydration.
- **Nutritional**: reduced food intake, altered diet, reduced dietary fibre.
- **Abdominal surgery.**

If the rectum is empty, a staged response is recommended. In patients who are eating or on enteral feeds, ensure that sufficient dietary fibre is being given. If deficient, it can be supplemented by bulking agents, e.g. ispaghula husk, guar gum. If constipation persists, stimulant laxatives can be added, e.g. senna, bisacodyl. These are not recommended for long-term use. Persisting constipation with an empty rectum after 2 days can be treated by adding an osmotic laxative, e.g. sorbitol, lactulose, magnesium salts. These can cause diarrhoea when constipation resolves. Macrogol 3350 is an alternative. Constipated patients should have a rectal examination at least every 2 days and be treated as per Fig. 183.1 if the rectum is full.

Conclusion

Emulsified paraffin is no longer recommended for treating constipation in ICU patients. Methylnaltrexone has been investigated as a specific treatment for opioid-induced constipation and appeared effective [13]. Neostigmine has been used for refractory constipation in both adults and children with success in anecdotal reports.

PART 6.5

The acute abdomen in the ICU

CHAPTER 184

Pathophysiology and management of raised intra-abdominal pressure in the critically ill

Inneke E. De laet and Manu L. N. G. Malbrain

Key points

- The diagnosis of intra-abdominal hypertension/abdominal compartment syndrome (IAH/ACS) relies on accurate intra-abdominal pressure (IAP) measurement. The current gold standard for measurement is intermittently every 4–6 hours via the bladder, using ≤25 mL of instillation volume, in a completely supine position, using the mid-axillary line as a zero reference point.
- IAP monitoring should be performed in all critically ill or injured patients exhibiting ≥1 risk factors for the development of IAH, and continued until risk factors are resolved and IAP has remained normal for 24–48 hours.
- IAH and ACS cause organ dysfunction through direct compression of the heart, compression of both arterial and venous perfusion of the abdominal organs, and abdominothoracic pressure transmission. All organ systems are affected by IAH-induced injury.
- The WSACS medical management algorithm contains several minimally invasive techniques aimed at decreasing IAP and sustaining adequate systemic and regional perfusion. These can be applied in a stepwise fashion until IAP is decreased. Current evidence to support these techniques is rather low, but since there are no reports on adverse effects and there is a possible therapeutic benefit, some of them were retained as weak recommendations in the guidelines.
- Standard surgical treatment of established ACS not responding to non-invasive management consists of decompressive laparotomy via midline or transverse incision. Promising alternative surgical strategies like subcutaneous linea alba fasciotomy (SLAF) are being developed to avoid the complications of the open abdomen. Prophylactic open abdomen (OA) treatment is currently only recommended for trauma damage control surgery. Critically ill patients with an OA are preferentially treated with NPT.

Introduction

The negative effects of increased intra-abdominal pressure (IAP) on organ function were known to the pioneers of physiology centuries ago. However, Kron, et al. coined the term 'abdominal compartment syndrome' (ACS) in the 1980s and launched the modern revival of interest in this phenomenon. Initially, researchers and clinicians were mainly focused on overt ACS, a dramatic complication seen mostly in emergency surgical or trauma patients that almost invariably leads to death when untreated, and which carries a guarded prognosis even when treated (by decompressive laparotomy). Gradually, interest has shifted to more moderate forms of raised IAP termed intra-abdominal hypertension (IAH), which has proved to be more amenable to prevention and treatment. IAH was also more frequently seen in non-trauma surgical patients and medical patients, mainly in those requiring massive fluid resuscitation. This led to increased awareness among both the surgical and critical care communities, and the birth of the World Society of the Abdominal Compartment Syndrome (WSACS, www.wsacs.org) in 2004. From 2006, WSACS has published guidelines for definition, diagnosis and management of IAH/ACS [1,2]. In 2012, the guidelines were updated based on the Grading of Recommendations, Assessment, Development, and Evaluation (GRADE) system in order to provide better consistency in identifying and rating the quality of available evidence and strength of management suggestions and recommendations [3]. This chapter briefly summarizes basic concepts relating to IAH/ACS and reflects the essentials of the current 2013 WSACS guidelines.

Definitions

Table 184.1 summarizes the current WSACS consensus definitions regarding IAH and ACS [3]. Since the standard treatment for ACS is still decompressive laparotomy (DL), which leaves the patient with an open abdomen (OA), a new classification for OA was also proposed.

Although the physiopathology of raised IAP in children is quite similar to adults, cut-off values for definitions and IAP measurement technique differ somewhat [4]. Definitions amended for

Table 184.1 Definitions regarding IAP according to the 2013 WSACS guidelines update

Intra-abdominal pressure (IAP)	Steady-state pressure concealed within the abdominal cavity
Abdominal perfusion pressure (APP)	APP = MAP – IAP
'Normal' IAP	Approximately 5–7 mmHg in critically ill adults
Intra-abdominal hypertension (IAH)	Sustained or repeated pathological elevation in IAP ≥12 mmHg
IAH grading	IAH is graded as follows: ◆ Grade I, IAP 12–15 mmHg ◆ Grade II, IAP 16–20 mmHg ◆ Grade III, IAP 21–25 mmHg ◆ Grade IV, IAP > 25mmHg
Abdominal compartment syndrome (ACS)	Sustained IAP > 20 mmHg (± APP < 0 mmHg) that is associated with new organ dysfunction/failure
Primary IAH/ACS	Condition associated with injury or disease in the abdominopelvic region that frequently requires early surgical or interventional radiological intervention
Secondary IAH/ACS	Conditions that do not originate from the abdominopelvic region
Recurrent IAH/ACS	When IAH/ACS redevelops following previous surgical or medical treatment of primary or secondary IAH/ACS
IAP measurement	The reference standard for intermittent IAP measurements is via the bladder with a maximal instillation volume of 25 mL of sterile saline. IAP should be expressed in mmHg and measured at end-expiration in the completely supine position after ensuring abdominal muscle contractions are absent and with the transducer zeroed at the level of the mid-axillary line
Polycompartment syndrome	Condition where two or more anatomical compartments have elevated compartmental pressures
Abdominal compliance	Abdominal compliance quantifies the ease of abdominal expansion, is determined by elasticity of the abdominal wall and diaphragm, and expressed as the change in intra-abdominal volume per change in intra-abdominal pressure in L/mmHg
Open abdomen (OA)	Any abdomen requiring temporary abdominal closure due to skin and fascia not being closed after laparotomy. The technique of temporary abdominal closure should be explicitly described
OA classification	Classified by the following grading system: **1 – No fixation** 1A: clean, no fixation. 1B: contaminated, no fixation. 1C: enteric leak, no fixation. **2 – Developing fixation** 2A: clean, developing fixation. 2B: contaminated, developing fixation. 2C: entero-atmospheric/cutaneous fistula, developing fixation. **3 and 4 – Frozen abdomen** 3: frozen abdomen, no fistula. 4: frozen abdomen with entero-atmospheric/cutaneous fistula.
Lateralization of the abdominal wall	Phenomenon whereby musculature and fascia of the abdominal wall, most well seen in rectus abdominis muscles and their enveloping fascia, move laterally away from the midline with time

MAP, mean arterial pressure.

Adapted with permission from Kirkpatrick AW et al., 'Intra-abdominal hypertension and the abdominal compartment syndrome: updated consensus definitions and clinical practice guidelines from the World Society of the Abdominal Compartment Syndrome', *Intensive Care Medicine*, 39, 7, pp. 1990–1206, Copyright © 2013 Kirkpatrick et al., with permission.

paediatric use are listed in Table 184.2 otherwise non-listed definitions given in Table 184.1 also apply to children.

Pathophysiology and epidemiology

Since the abdominal compartment is surrounded by a combination of rigid (spine, rib cage, and bony pelvis) and semi-rigid borders (the muscular abdominal wall, diaphragm, and pelvic muscles), it is vulnerable to the development of raised compartmental pressure. When intra-abdominal volume (IAV) increases, the compliant abdominal wall initially expands, keeping IAP constant over a relatively wide range of IAV [5]. However, when abdominal wall expansion reaches its maximum, or when abdominal compliance is impaired by internal (e.g. oedema) or external (e.g. restrictive bandages or sutures) causes, any increase in IAV leads to a rapid increase in IAP. Therefore, any condition associated with increased IAV and/or decreased abdominal compliance can lead to IAH and/or ACS. The WSACS has published a list of risk factors that

Table 184.2 Definitions regarding IAP for paediatric use according to the 2013 WSACS guidelines update [13]

IAP measurement	Reference standard for intermittent IAP measurement in children is via the bladder using 1 mL/kg as an instillation volume, a minimal instillation volume of 3 mL and a maximum installation volume of 25 mL of sterile saline.
'Normal' IAP	In critically ill children is approximately 4–10 mmHg.
IAH	In children defined by a sustained or repeated pathological elevation in IAP >10 mmHg.
ACS	In children defined as a sustained elevation in IAP of >10 mmHg associated with new or worsening organ dysfunction that can be attributed to elevated IAP.

Definitions', Malbrain ML et al., copyright 2006, European Society of Intensive Care Medicine and the European Society of Paediatric and Neonatal Intensive Care, with kind permission of Springer Science and Business Media.

are partly supported by literature data and partly based on physiopathological common sense [2]. A modified version is presented in Table 184.3.

Due to increased awareness, primarily in surgeons, the incidence of overt ACS (specifically primary ACS) is decreasing as concepts such as damage-control surgery and prophylactic use of the OA have found their way into the routine surgical management of critical abdominal trauma or injury. At the same time, aggressive fluid resuscitation for sepsis, burns, and trauma have led to an increased incidence of IAH, especially secondary IAH. The incidence for IAH in the critically ill varies across populations, but ranges from 25% in the general ICU population [6] to 75% in patients with septic shock. This is a worrying development since the mortality of secondary IAH is even higher than that of primary IAH [5]. A critical factor in the development of secondary IAH appears to be the iatrogenic effect of massive fluid resuscitation [7]. In some populations, e.g. postoperative patients after major abdominal surgery, a direct correlation between fluid balance and IAP was found. Better targeting of fluid resuscitation and fluid balance control currently offer the best hope for lowering the incidence of IAH in the critically ill [8].

The effect of IAH on organ function

The impact of IAH on the cardiovascular system is multifactorial. Cephalad displacement of the diaphragm leads to direct compression of the heart and decreased contractility. Compression of the systemic arterial circulation increases afterload, while reduced venous return from the lower half of the body due to inferior vena cava compression decreases preload. All these changes usually lead to a decreased cardiac output, which can temporarily be corrected by fluid loading although this, in turn, can lead to further increases in IAP [9]. Cephalad displacement of the diaphragm is also associated with abdominothoracic pressure transmission. This leads to a 'cosmetic' (i.e. not reflecting a true physiologic change) increase in all pressures measured intrathoracically (such as central venous pressure (CVP) and pulmonary artery occlusion pressure (PAOP)), but also to clinically relevant physiological phenomena [10]. The increased thoracic pressure leads to increases in CVP and intrajugular pressure, impaired venous outflow from the brain, and increased intracranial pressure (ICP). This association between IAP and ICP is important to consider when treating patients with IAH at risk of brain injury [5].

Increased IAP leads to dysfunction of all abdominal organs due to compromise of arterial blood flow, venous outflow obstruction, and impaired microcirculatory flow. Kidney failure is the most

often and consistently described organ failure associated with IAH though hepatic, adrenal, and gastrointestinal dysfunction have also been repeatedly reported [5,11]. Notably, IAH can lead to increased bacterial translocation, lending truth to the adage 'the gut is the motor of sepsis' [1].

IAP monitoring

Since clinical examination is unreliable for detecting raised IAP in critically ill patients, the diagnosis of IAH and ACS hinges on accurate measurement of IAP [5]. Theoretically, IAP can be measured intermittently or continuously, directly in the peritoneal cavity or indirectly through hollow viscera, most frequently bladder or stomach [12]. The WSACS recommends routine measurement of IAP through the bladder in critically ill or injured patients when any known risk factor for IAH/ACS is present [2,3].

Currently, the most adopted form of IAP monitoring involves intermittent IAP measurement through the bladder every 4–6 hours using no more than 25 mL of instillation volume, starting when at least one risk factor (Table 184.3) for IAH is present. This is continued until the risk factor(s) have resolved and IAP has remained normal for 24–48 hours [13]. Gastric IAP measurement techniques are mainly used when the bladder is not available for catheterization, a localized increase in pelvic pressure is suspected (e.g. due to a pelvic haematoma), or monitoring of the upper abdominal compartment is deemed useful (e.g. in severe acute pancreatitis).

Management of intra-abdominal hypertension and abdominal compartment syndrome

Since the modern revival of ACS as a real concern in critically ill or injured patients, surgery (DL) has been considered the ultimate treatment. Initially, when overt primary ACS was the only clinical entity considered, DL was even considered the only treatment option, even though outcomes were poor in terms of mortality [14]. Over the years, as focus shifted towards earlier and more moderate stages of increased IAP (mostly secondary IAH), more attention was diverted towards non-invasive techniques to decrease IAP [15]. A medical management algorithm has been produced by the WSACS [16], see Fig. 184.1.

Medical management

Bearing in mind the mechanisms through which IAH develops, it is evident that IAP can be lowered by decreasing IAV, increasing abdominal compliance or combining both. The WSACS medical management algorithm is essentially a collection of non-invasive techniques that were proposed to reach these goals, either after small clinical studies or based on a pathophysiological rationale. They are organized into five major categories (evacuating intraluminal contents, evacuating extraluminal intra-abdominal contents, improving abdominal wall compliance, managing fluid balance, and optimizing systemic and regional perfusion) [15]. In each of these categories, techniques are arranged into steps of increasing invasiveness (and presumed efficacy). The algorithm is designed to be used by experienced clinicians with a certain degree of flexibility, ascertaining which is the most likely mechanism of IAH in an individual patient, carefully selecting the physiological category most likely to benefit that patient, and applying the corresponding measures in a stepwise fashion until IAP decreases. Flexibility, allowing the clinician to tailor the treatment to the patient, is one of the algorithm's most defining features. This also means that its efficacy is largely dependent on user knowledge and experience.

Another downside to the algorithm is that evidence supporting many of the techniques is low at best. The last revision (2013) of the WSACS guidelines using the GRADE methodology made weak recommendations for using a protocol to avoid sustained IAH, using sedation and analgesia for pain and anxiety relief, for brief trials of neuromuscular blockers for patients with IAH, consideration of body position in patients with IAH, gastric or colonic decompression using tubes for patients with gastric or colonic dilatation and IAH, and the use of neostigmine for established refractory colonic ileus [13]. A weak recommendation was made to avoid a positive cumulative fluid balance in critically-ill patients with, or at risk of, IAH, after the acute resuscitation phase has been completed and the inciting issues/source control have been addressed [13]. The WSACS also suggested that an enhanced ratio of plasma/packed red blood cells should be used for resuscitation of massive haemorrhage versus low or no attention to plasma/packed red blood cell ratios. Paracentesis or percutaneous catheter drainage (PCD) is another minimally invasive procedure frequently advocated for treating IAH [17]. The WSACS eventually made a weak recommendation to use PCD to remove fluid (in the setting of obvious intra-peritoneal fluid) in those with IAH/ACS when technically possible, compared to doing nothing [13]. It also recommended that PCD be used to remove fluid (in the setting of obvious intra-peritoneal fluid) in those with IAH/ACS when technically possible compared to immediate DL, as this may remove the need for DL. Both recommendations were again based on low quality evidence [13]. Due to lack of evidence, the WSACS consensus conference could not make any recommendations on using APP as a resuscitation target, the use of diuretics to mobilize fluids, the use of renal replacement therapy or administration of albumin to mobilize fluids, [13].

The fifth column of the medical management algorithm ('optimize systemic/regional perfusion') deserves extra attention. The measures described here are not designed to decrease IAP, but to optimize the general ICU management of patients with IAH/ACS [18]. In particular, haemodynamic management should be adapted to the increased IAP in patients with IAH. Due to abdomino-thoracic pressure transmission, cardiac filling pressures (mainly CVP and PAOP) are 'falsely' increased, i.e. poorly reflect cardiac preload [10]. Abdomino-thoracic pressure transmission depends on abdominal wall compliance and can be estimated by obtaining a simultaneous CVP and IAP pressure tracing, inducing IAH by putting a small weight on the abdomen and measuring the resulting CVP increase. This allows for correction of CVP (transmural CVP) to better reflect cardiac preload. An alternative strategy is to use volumetric monitoring, using parameters such as left ventricular end-diastolic volume index) or global end-diastolic volume index that are less affected by IAH [9]. Due to decreased venous return from the inferior vena cava, IAH can mimic a state of increased fluid responsiveness [19]. Although, if necessary, fluid loading can be used temporarily to correct this state, this can also exacerbate IAH. In most patients, increasing efforts to decrease IAP is probably a better strategy in terms of long-term improvement.

Abdominothoracic pressure transmission also causes decreased compliance of the thoracic wall, while lung compliance remains mostly constant. Therefore, in order to achieve similar tidal

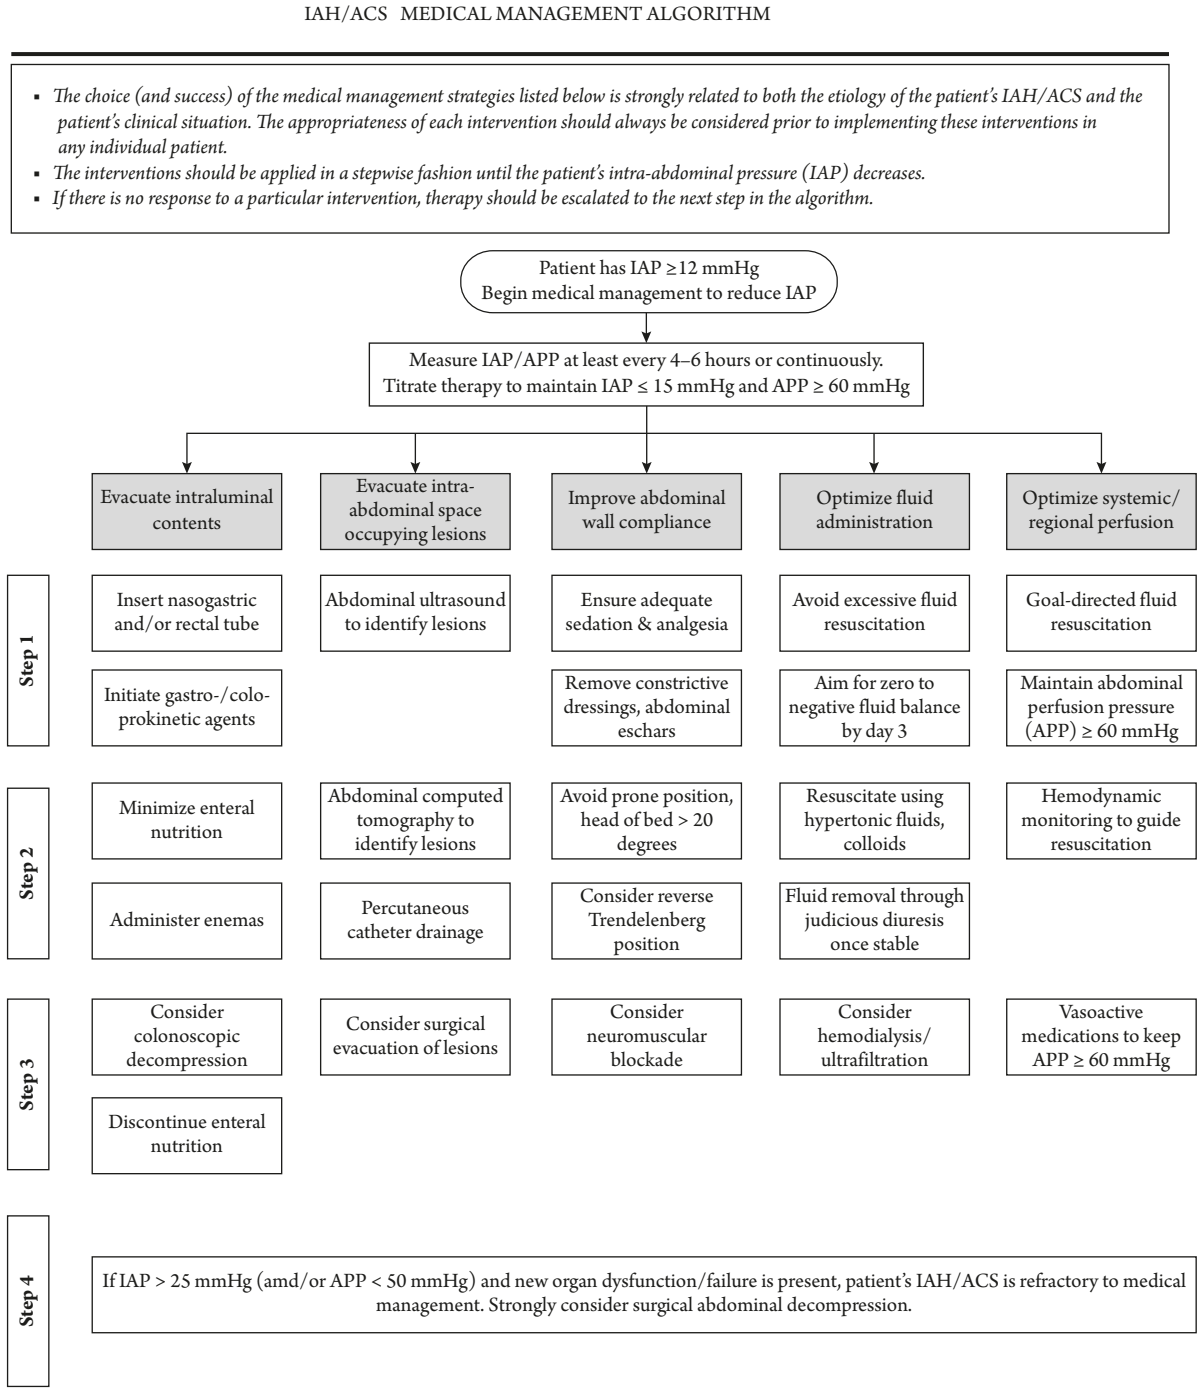

Fig 184.1 Medical management of IAH/ACS.

volumes, higher ventilation pressures are needed in the presence of IAH. Higher than normal positive end-expiratory pressure (PEEP) is recommended to preserve alveolar recruitment since IAH causes increased atelectasis and decreased functional residual capacity [18].

Surgical management

When the different options contained in the medical management algorithm have been exhausted and the IAP is still critically elevated, surgery becomes unavoidable. DL through a midline incision is still the most standard approach to abdominal decompression. Dramatic improvements in organ function and immediate decreases in IAP have been reported consistently after DL. However, DL is associated with a high risk of complications and mortality remains high afterwards [14]. To address these issues some less invasive surgical techniques were developed, most notably subcutaneous linea alba fasciotomy (SLAF). SLAF appears to be a promising alternative with a sustained effect on IAP and

decreased morbidity when compared with full DL, but these findings need further confirmation.

Standard DL leaves the patient with an open abdomen, needing temporary abdominal closure (TAC). Several techniques for TAC have been developed in the past (e.g. Bogota bag, Wittmann patch, zipper closure, non-absorbable mesh), but all are associated with a high complication rate (particularly enterocutaneous fistula and large ventral hernia) and significantly longer ICU and hospital stays [5]. Recently, negative pressure therapy (NPT) has significantly changed OA management [15]. Treatment with NPT dressings specifically designed for use in the abdominal cavity appears to reduce the typical complications associated with TAC. Additionally, NPT may successfully remove inflammatory mediators along with peritoneal fluid from the peritoneal space, leading to lower cytokine levels, both in peritoneal fluid and plasma [20], possibly leading to improved organ function. The WSACS 2013 recommendations made a strong recommendation to use NPT in critically ill patients with an OA, albeit based on low grade evidence [13]. It is important to note that no outcome comparisons have yet been made on the various types of NPT (commercially available vs home-made, different types of commercially available NPT dressings).

Instead of closing the abdomen after a primary surgical procedure and monitoring IAP, many authors suggested using the OA prophylactically to avoid the development of IAH/ACS and its complications. Naturally, it is important to consider that some patients, who would not have developed ACS had their abdomen been closed, are needlessly exposed to the complications associated with OA. The 2013 recommendations advocate prophylactic OA only for trauma patients with 'physiological exhaustion' [13].

Even though the evidence base for both surgical and medical management of IAH/ACS is currently weak, Cheatham, et al, have shown that a global approach, including prophylactic use of the open abdomen, early abdominal decompression, negative pressure therapy and the medical management algorithm can achieve, in the hands of experienced clinicians, better outcomes in terms of primary closure rates, time to closure, and even survival [15].

CHAPTER 185

Perforated viscus in the critically ill

Ori D. Rotstein

Key points

- The patient with an 'acute abdomen' requires timely and accurate investigation to direct appropriate management; among imaging modalities CT scanning has assumed a dominant position.
- Various pathological processes can lead to loss of gastrointestinal (GI) wall integrity including inflammation, neoplasm, infarction due to compromised blood supply, and mechanical causes including trauma and obstruction.
- The commonest causes of abdominal visceral perforation are appendicitis, diverticulitis, and perforated peptic ulcer.
- The major principles of management comprise stabilization of patient physiology, timely administration of appropriate antimicrobial therapy, and adequate source control.
- Antibiotic selection should take into account patient physiology, severity of the pathological process, and an increased likelihood of multi-resistance following hospital-acquired perforation.

Introduction

An 'acute abdomen' is defined as the rapid onset of severe abdominal pain that comes to medical attention, usually in an Emergency Department setting, and requires timely and accurate investigation to direct appropriate management. Approximately 4% of patients presenting to US Emergency Departments have a primary diagnosis of abdominal pain, making it the 4th commonest presenting complaint [1]. Most patients presenting with an acute abdomen have symptoms related to an intra-abdominal process, although pulmonary or cardiac events can sometimes manifest with acute abdominal symptoms. Within the abdomen, diseases of the gastrointestinal (GI) tract, genitourinary tract, and vascular system can all present acutely and be labelled as an 'acute abdomen'. This chapter will focus on gastrointestinal tract diseases, in particular those leading to a perforated viscus as the underlying pathological entity.

Aetiology of perforated viscus

By definition, perforation of a hollow viscus requires transmural disruption of the GI tract wall. Several pathological processes can lead to loss of GI wall integrity including inflammation, neoplasm, infarction due to compromised blood supply, and mechanical causes including trauma and obstruction. Table 185.1 lists common aetiological entities by GI tract level and was compiled by review of operative reports where visceral perforation was found [2]. Appendicitis was the most frequent diagnosis, followed by diverticulitis and perforated peptic ulcer. Transmural disruption due to malignant ulceration/necrosis is relatively rare, although malignancy causing proximal obstruction and perforation is well described. Similarly, intestinal obstruction can cause perforation when there is vascular compromise, e.g. closed loop obstruction. Intestinal ischaemia followed by gangrene also leads to loss of bowel wall integrity.

Diagnosis of perforated viscus

This is based on clinical examination supported by laboratory investigation and diagnostic imaging. Most patients look unwell, are in acute distress and may be febrile. Pathological processes leading to the perforation and the local peritoneal response dictate both the clinical symptom complex and imaging results. Under ideal circumstances, local host defences contain the spread of GI content though the peritoneal cavity by physically walling off the perforation with bowel and omentum. Presumably, this localization occurs more frequently when the intestinal disruption is small and insidious, e.g. diverticulitis, perforated Crohn's disease, appendicitis. Here, pain and tenderness are localized and occasionally associated with an abdominal mass. The abdomen distant from the site of maximum tenderness may be soft and non-tender, and bowel sounds are usually present. By contrast, free spillage of gastrointestinal content without localization leads to diffuse peritoneal irritation. This is manifest by pain that is steady, severe, and aggravated by movement. Physical examination reveals diffuse tenderness, abdominal wall rigidity and guarding, with accompanying anorexia and nausea. Intra-abdominal infection from a perforated viscus may also exhibit signs of septic shock, characterized by hypo- or hyperthermia, tachycardia, and hypotension. Haemodynamically, these patients may have an increased cardiac output and reduced peripheral vascular resistance.

Abnormal laboratory data, particularly leukocytosis >11,000 cells/mm^3 or profound leukopenia, may be observed. Blood chemistry is generally undisturbed, but may reveal evidence of dehydration with elevated blood urea nitrogen levels and a metabolic acidosis. Urinalysis is essential to rule out urinary tract causes such as pyelonephritis and renal colic.

Table 185.1 Aetiology of perforated viscus and probability of free air on CT scan/plain radiographs

Cause	Total (*n*)	Percentage of all perforation
Appendicitis	38	34
Diverticulitis	12	12
Peptic ulcer	11	10
Bowel ischaemia	10	9
Trauma	10	9
Malignancy	9	8
Post-surgical	4	4
Endoscopic injury	4	4
Biliary source	3	2
Other	11	10
Total	**114**	**100**

Reproduced from Kumar et al., 'The etiology of pneumoperitoneam in the 21st century', *Journal of Trauma and Acute Care Surgery*, **73**(3), pp. 542–8, copyright 2012, with permission from Wolters Kluwer Health.

Medical imaging will hopefully confirm the diagnosis and potentially point to the underlying pathology. Plain abdominal X-rays are invariably performed, but do not always show free air in the peritoneal cavity nor do they frequently help to elucidate the aetiology. The presumed *sine qua non* for visceral perforation is the presence of free air. This is only observed when a large amount of free air is present, such as might occur with perforated peptic ulcer disease (~70%) [2]. Furthermore, plain radiographs do not reveal locules of air that might be observed with localized visceral perforations, e.g. locally-perforated appendicitis or diverticulitis. Other imaging modalities are routinely used to aid diagnosis and management, ultrasonography and CT scanning being the most frequent. Ultrasonography is mainly useful in equivocal cases of right lower quadrant pain, with a view to diagnosing acute appendicitis. Perforated appendicitis may also manifest as a localized abscess in the peri-appendiceal region. For the purpose of managing the patient with an 'acute abdomen', CT scanning has assumed a dominant position. In diagnosing acute appendicitis, the sensitivity and specificity of CT scanning was superior to ultrasonography [3]. However, the ability to specifically diagnose locally-perforated appendicitis is not consistent. The presence of peri-appendiceal air locules is uncommon, and localized fluid collections may represent inflammatory fluid/phlegmon collections rather than discrete abscesses indicative of perforation.

CT scanning is useful in defining other pathological abnormalities including focal defects in the bowel wall, bowel wall thickening, perivisceral fat stranding, free abdominal fluid, the transition point of an obstruction, and the presence of metastatic disease in the peritoneum and/or distant organs. Together, these help to direct the treating physician to both the location and nature of the pathological process. Multi-detector CT scanning predicted the site of perforation in 85% of patients, with the presence of extraluminal air bubbles, segmental bowel wall thickening, and focal defects in the bowel wall being most predictive [4]. A recent meta-analysis of the use of multi-detector CT in the diagnosis of acute mesenteric ischaemia also showed a high degree of sensitivity and specificity for detecting and excluding this entity. This is highly relevant in the ICU patient where mesenteric ischaemia as a cause of an abdominal catastrophe is relatively common [5]. Here, the diagnosis of peritonitis may be challenging because of underlying patient factors which preclude accurate clinical examination. This cause of 'acute abdomen' is particularly lethal because delayed diagnosis may permit progression to infarction and perforation. In addition to CT scanning, several adjunctive diagnostic modalities including peritoneal lavage and bedside laparoscopy have been suggested.

Management

The major principles underlying management related to perforated viscus are:

- Stabilization of patient physiology.
- Timely administration of appropriate antimicrobial therapy.
- Initiation of source control manoeuvres, i.e. addressing the underlying pathological process.

Stabilization

Spillage of gastrointestinal content into the abdominal cavity induces an inflammatory response, with peritoneal fluid sequestration. The magnitude of response usually correlates with peritonitis severity, ranging from minor haemodynamic perturbations after local perforation to profound haemodynamic instability following free perforation of the GI tract with diffuse peritoneal infection. Specifics of managing resuscitation in the latter setting are addressed elsewhere.

Antimicrobial therapy

Timely and appropriate antimicrobial therapy is essential to optimize outcome. Empiric selection of antimicrobial therapy is based on the likely pathogens found in the infection. For GI tract disruption causing intra-abdominal infection, the recovered flora are polymicrobial, consisting of a mixture of Gram-positive aerobic bacteria, Gram-negative facultative anaerobic bacteria and anaerobes. The commonest microbes recovered include *Escherichia coli, Bacteroides fragilis,* and *Enterococcus faecalis*. Antimicrobial therapy should include agents with activity against Gram-negative facultative anaerobic bacteria (e.g. *E.coli)* and anaerobes (e.g. *B. fragilis*) [6]. In straightforward cases of intra-abdominal infection, antimicrobial coverage of *Enterococcus* is unnecessary [6]. Using this general principle, a number of antimicrobial regimens have been compared and shown to be effective, although the need for patient stratification was cited as a flaw in many trials [7].
